2. Locally high Nusselt number regions were observed between the neighboring jets and show streaky distributions due to the collisions of wall jets. As the cross flow rate increases, the wall-jet interacting regions begin to be drifted downstream and finally vanish away, because the strong cross flow weakens the wall jets and finally washes out them.

3. When the cross-flow/jet-velocity ratio increases from 0.25 to 0.35 in one-row jets (and 0.3 to 0.4 in three-row jets), the maximum Nusselt number decreases dramatically. This is because the strong cross flow bends the impinging jets in the cross flow direction and the potential core region of the jet cannot reach the target plate.

ABSTRACT. CFD (Computational Fluid Dynamics) can be used to calculate air flows in and around buildings. By linking CFD with a HAM-model (Heat, Air and Moisture), heat and mass transfer between air and porous materials is incorporated into the calculations. This paper presents experimental data for the validation of these newly developed CFD-HAM models.
To conduct the experiments, a climate chamber representing a small room of 1.8 meter high, 1.8 meter wide and 1.89 meter long was built. Air enters the room as a jet of which the temperature and relative humidity are closely controlled. A sample of calcium silicate was placed in one of the walls of the chamber. During the experiment the relative humidity of the jet was altered from 50% during 16 hours to 70% during 8 hours. This cycle was repeated several times. Meanwhile temperature and relative humidity in the chamber and in the calcium silicate sample were monitored.

Keywords: *experiment, hygroscopic material, moist air, heat and mass transfer*

INTRODUCTION

Temperature and relative humidity are two very important parameters in the building interior. First of all they determine to a great extent the comfort level of a building. For example temperature inside an office or a house is kept between certain levels, not to cold and not to hot. Once the temperature deviates from these levels, occupants experience discomfort. The same counts for the relative humidity in a room. Both too dry and too humid air is unpleasant for building occupants and studies have shown that relative humidity has a severe impact on the perceived indoor air quality [1].
Next, temperature and relative humidity also play an important role in the durability of a building. A lot of damage mechanisms in buildings are triggered by temperature or relative humidity or a combination of both. For example too high relative humidity can cause mould growth or even condensation. An other example is damage caused by temperature and humidity fluctuations. Materials shrink and expand as temperature drops and rises alternately. Hygroscopic materials adsorb or desorb water vapour when relative humidity changes, causing again expansion or shrinkage. This expanding or shrinking resolves into stresses in the material which lead to cracks and damage [2].

Often large, expansive and energy consuming equipment is needed to keep temperature and relative humidity at an acceptable level. For many decades researchers have looked for ways to improve the energy efficiency of buildings without reducing the comfort level. Simonson et al. [3] found that using hygroscopic building materials can reduce relative humidity and temperature fluctuations and increase the perceived indoor air quality and occupant comfort level. An other study showed that using hygroscopic materials in a building can reduce the energy use of that building [4].

Due to rapid development in computer memory and speed, it has become popular to perform computer simulations to evaluate the hygrothermal behaviour of a building. These simulations also help in improving the design of buildings. Chen [5] gives a short overview of some of the current modelling techniques. Here a distinction is made between zonal models and CFD models to calculate air distributions in buildings. In zonal or lumped models a building is divided into zones, mostly one zone for every room. The parameters of interest (temperature, ventilation rate, relative humidity) are considered constant for every zone. These strong simplifications limit the computational time to minutes or even seconds. In reality however air in a room is not well mixed and research has shown that local temperature and relative humidity in a room can differ a lot [6, 7]. By using CFD models (Computational Fluid Dynamics) local effects can be studied. CFD can calculate air distributions in rooms in detail. Often a model for heat and species transport is added so temperature and relative humidity distributions are calculated as well.

However, to incorporate vapour transport in building materials an extra model has to be added. Two approaches can be found in literature namely the directly coupled models and the indirectly coupled models. Directly coupled models solve both the fluid domain and the porous material domain with one solver. Examples of such models can be found in [6] where steady state calculations are performed and [8] for transient simulations. Indirectly coupled models solve the fluid and porous domain in different solvers and exchange the information. An example of this approach can be found in [9].

Because these computer models have different levels of approximations, the results will also have different levels of uncertainty. Consequently, CFD results can not be trusted without proper validation. However, finding the necessary validation data in literature is not so evident.
Belardi et al. [10] developed a model for evaluating the non-isothermal moisture migration in porous building materials. To evaluate this model, one- and two-dimensional experiments were performed using lime-cement mortar and Gotland sandstone. However, these experiments were designed to create a constant temperature and relative humidity at the boundaries of the material. So they are not useful to validate coupled CFD-HAM models where air movement is simulated as well.
Talukdar et al. [11] discus the design of an experimental facility, the transient moisture transfer (TMT) facility. This facility is designed to measure 1-D heat and moisture transfer between a flowing air stream and a porous material. The experimental data generated with this facility is excellent to validate CFD-HAM model. Nevertheless the question still remains whether or not the model performs well for full scale environments with more complex airflow. Therefore a new test setup has been designed and built for more complex flows.

CLIMATE CHAMBER DESIGN

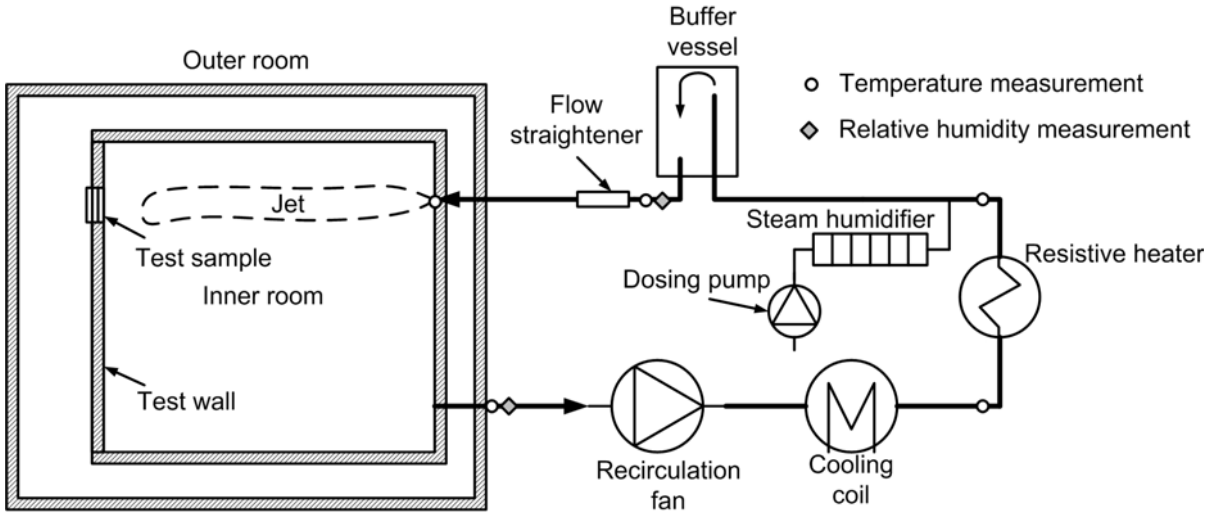

Figure 1. Schematic representation of the test facility.

The purpose of the experimental setup is to measure temperature and relative humidity distributions in a porous material sample together with the air flow patterns around the material. Contrary to the TMT-facility of Talukdar et al. [11], the new setup is used to generate more realistic flow patterns typical for buildings. A schematic representation of the new test facility is shown in Figure 1.

The test facility can be divided into two parts namely the climate chamber shown on the left of Figure 1 and the climate control group shown on the right of Figure 1.
The climate chamber is made up of an inner and an outer room. The inner room measures 1.8m wide, 1.8m high and 1.89m deep. Here an air jet enters and hits a test sample of calcium silicate installed in the opposite wall. The outer room is merely there to reduce the influences of the outside temperature fluctuations. The wall panels of the inner and outer room consist of 6 cm rigid high density polyurethane foam (λ=0.0223W/mK) sprayed in between two skins of white polyester lacquered, galvanized steel plate, 0.63mm in thickness. The floor panels consist of multiplex panels with phenol anti-slip surface reinforced with glass fibre.
Temperature, relative humidity and velocity of the entering air jet are closely controlled with a dedicated air conditioning system. This system draws air from the inner room with a recirculation fan. This air is than cooled below the dewpoint by a cooling coil and thus dehumidified. The dehumidified air is then reheated to the desired temperature and a specially designed steam humidifier humidifies the air to the desired relative humidity. The air then passes through a buffer vessel to dampen out some fluctuations. Finally a flow straightener ensures a fully developed flow pattern when the air enters the climate chamber.

TEST SAMPLE

A test sample of calcium silicate is placed in a test wall as shown on Figure 1. This samples measures 200mm by 200mm and has a thickness of 100mm. The sample is sliced in four layers of various depths. Figure 2 shows the details of the test sample. The first layer of calcium silicate has a thickness of 10mm, the second a thickness of 15mm, the third measures 25mm and the last 50mm.

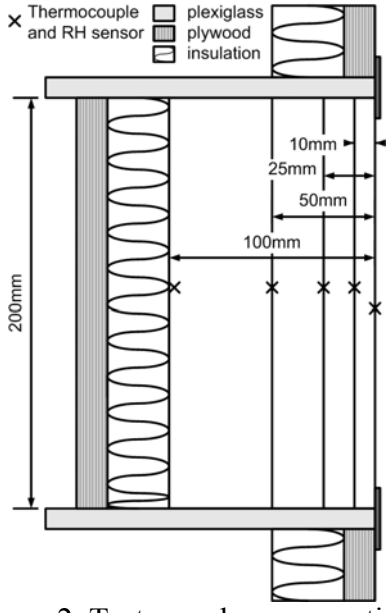

Figure 2. Test sample cross section.

In between the different layers, thermocouples and relative humidity sensors are placed. These sensors measure the temperature and relative humidity distribution in the sample. Thermocouples type K are used for this setup and calibrated with a dry block calibrator. This results in an accuracy of ±0.1°C.

Small capacitance relative humidity sensors made by Honeywell are used for the relative humidity measurements in the sample. These sensors relate the electrical capacitance of the sensor material with the relative humidity of the surrounding air. A chilled mirror with an uncertainty 0.2°C for the dew point is used as a transfer standard for calibrating the relative humidity sensors. This results in a total uncertainty on the relative humidity sensors of 1.4%.
The test sample is placed in a box of Plexiglas. The sample side walls and back wall are sealed with paraffin to avoid moisture penetration. At the same time insulation around the sample should avoid heat losses to the surroundings.

For validation purposes it is very important to have a good knowledge of the material properties. The properties of the calcium silicate used here were measured during the HAMSTAD-project (Heat, Air and Moisture Standards Development). More details on this project funded by the European Commission can be found in [12]. An overview of the material properties is shown in Table 1. The governing equation for moisture transport using a permeability approach is given by

$$-\frac{\partial w}{\partial t} = C\frac{\partial p_c}{\partial t} = \Delta\cdot(K\nabla p_c)$$
$$C = \left|\frac{\partial w}{\partial p_c}\right| \tag{1}$$

To properly describe the capillary pressure curve in the hygroscopic as well as the overhygroscopic range, a multimodal function of the "van Genuchten" type is used.

$$w(p_c) = w(p_{c,0})\sum_{i=1}^{3}\gamma_i(1+(c_i p_c)^{n_i})^{-[1-1/n_i]} \tag{2}$$

Here $w(p_{c,0})$ stands for the water content at zero capillary pressure, γ_i are the weighting factors ($0<\gamma_i\le 1, \Sigma\gamma_i = 1$), c_i and n_i are model parameters. The appropriate values of these parameters are also tabulated in Table 1.

Table 1
Material properties of calcium silicate

Property	**Value**	**Unit**	
Bulk density ρ	270	kg/m³	
Thermal capacity c_p	1000	J/kgK	
Thermal conductivity λ	$0.06+5.6.10^{-4}w$	W/mK	
Capillary moisture content w_{sat}	894	kg/m³	
Moisture content w			
Index i	1	2	3
Weight factor γ_i	0.05	0.1	0.85
Parameter c_i	$-2.46x10^{-6}$	$-2x10^{-6}$	$-2.47x10^{-6}$
Exponent n_i	3	1.85	2.44

The moisture permeability K is given by

$$K = \frac{2.61\times10^{-5}}{5.6R_vT}\left(1-\frac{w}{w_{sat}}\right)\Bigg/\left(0.8\left(1-\frac{w}{w_{sat}}\right)^2+0.2\right) \tag{3}$$

CLIMATE CONTROL

During the experiment the boundary conditions have to be well known. Therefore the climate chamber is well insulated and made air tight. To increase the insulation effect an outer room is built around the inner room which reduces the effect of outdoor temperature fluctuations. All these measures should result in adiabatic and moisture impermeable boundary conditions.
Not only the boundary conditions but also the inlet conditions have to be closely controlled. The inlet velocity is kept constant by setting the fan at a constant rotation speed. Temperature and relative humidity are controlled by a dedicated air conditioning unit. The control strategy for temperature and relative humidity is shown on Figure 3. Two approaches can be used. Figure 3a shows the first approach. In this control strategy two control loops can be distinguished namely one for temperature and one for relative humidity. Temperature and relative humidity are measured at the chamber inlet. These values are then compared with the corresponding setpoints. The difference between setpoint and measured value then serves as an input for the PID controller which steers the resistive heater for temperature control and the humidifier for humidity control. G11, G12 and G22 on Figure 3a represent the transfer functions of the system. The two control loops are not entirely separated. Changes in temperature change the relative humidity when the absolute humidity stays the same. This is represented by G12.
To avoid this effect a second approach based on the humidity ratio ω can be implemented as shown on Figure 3b. At a constant temperature a change in the humidity ratio will alter the relative humidity in accordance with equation 4. On the other hand, a change in temperature will not alter the humidity ratio as long as the water vapour pressure is lower than the saturation pressure. This means that the two control loops on Figure 3b no longer interact with each other which allows a smoother control.

$$\varphi = \frac{\omega p}{\omega p_{sat} + 0.622\, p_{sat}} \tag{4}$$

The relative humidity is measured with capacitive sensors. These sensors are used not only for humidity measurements in the test sample as mentioned earlier, but also for humidity control. However, therefore a fast response of the sensors is essential. To check the response time of the sensors two small tests were conducted. During the first test the humidity ratio is kept constant while the temperature alters. In the second test, temperature is kept constant while the humidity ratio is altered. The response of the humidity sensor is then measured. Results of these measurements showed that when temperature stays constant, the response of the sensors is in the order of seconds or even less. However the response time grows tremendously when temperature changes. A response time up to ten minutes is measured. This is in correspondence with Dooley et al.[13] who came to the same conclusions.

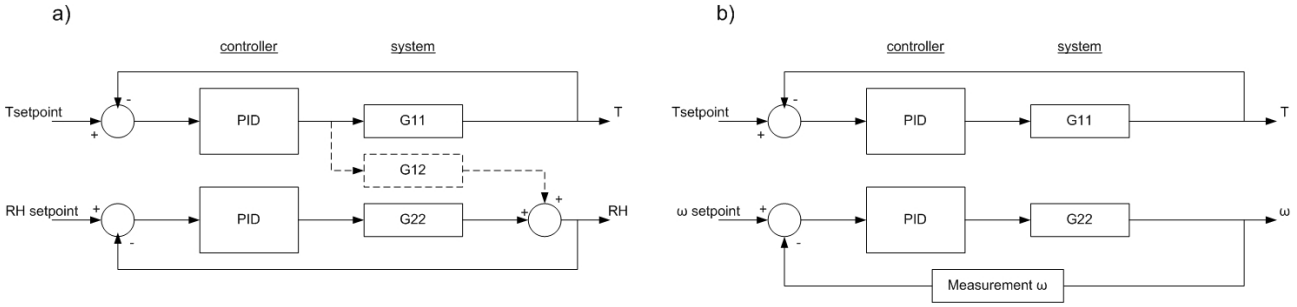

Figure 3. Control algorithms, (a) controlling relative humidity RH[%],
(b) controlling humidity ratio ω[kg/m³]

TEST PROCEDURE

The test sample is first preconditioned in the climate chamber. Therefore the chamber inlet temperature is set at 25°C and the inlet relative humidity to 50%. The jet blows with a mass flow rate of 68 ± 2 kg/hr on the test sample. The sample is preconditioned until fluctuations in temperature and relative humidity in the sample over one day are smaller than the measurement error. For the temperature this error is 0.1°C, for the relative humidity 1.4%.
Once the test sample and climate chamber can be considered at steady state, step changes in relative humidity are performed while temperature at the chamber inlet is kept constant. First the relative humidity is augmented from 50% to 70% during 8 hours and then it is lowered again to 50% during 16 hours thus covering a whole day. This cycle is repeated for several times and the response of the temperature and relative humidity in the test sample is measured. The results of these measurements are discussed in the next paragraph.

MEASUREMENT RESULTS

Moist air at constant temperature hits the test sample. At first the test sample is preconditioned so that the temperature and humidity inside the sample can be considered constant. Figure 4 and Figure 5 show the temperature and relative humidity inside the test sample at various depths. At the start of the measurements, temperature and relative humidity are almost the same for all three measurement depths. Temperature at 50mm is slightly lower than at the other depths probably because of a bad insulation of the back wall of the sample. A cycle of eight hours high relative humidity (70%) and 16 hours of low relative humidity (50%) is then performed. When the air relative humidity changes from 50% to 70% the porous test sample start to take up moisture and the relative humidity in the test sample starts to rise. Part of the water vapour entering the porous material condenses and releases latent heat. This latent heat results in a temperature increase in the test sample even if the supply air temperature is kept constant. The farther away from the surface of the sample, the less pronounced the temperature and relative humidity changes are. The opposite effects are seen when the relative humidity of the air changes from 70% back to 50%. The relative humidity in the sample drops as well as the temperature because moisture in liquid form evaporates from the sample using latent heat for the phase change. These measurements seem to correspond well with the expectations and can now be used for validation purposes.

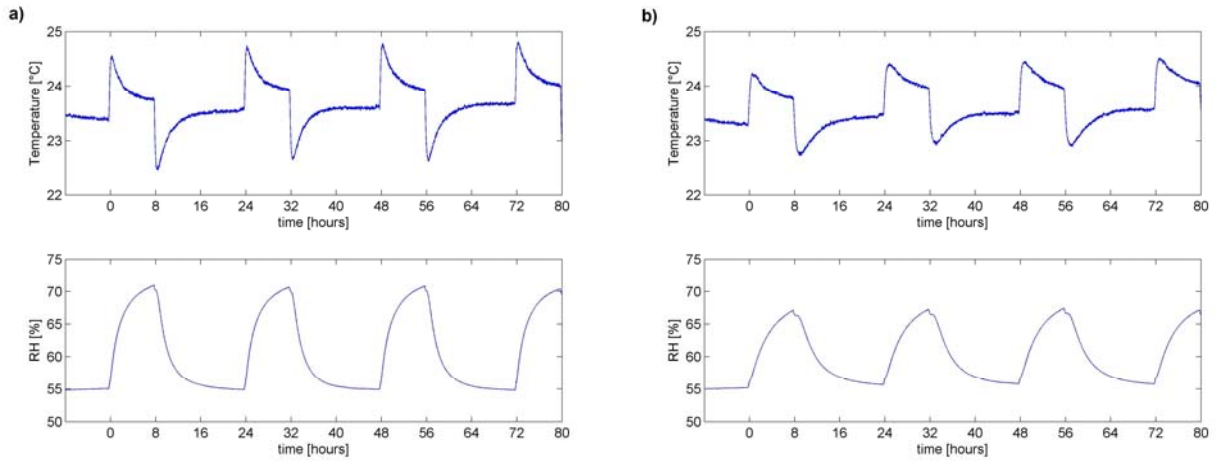

Figure 4. Temperature and relative humidity inside the test sample at 10mm depth (a) and 25mm (b)

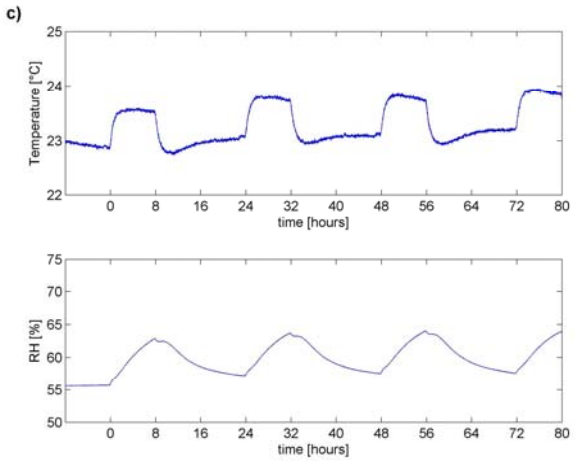

Figure 5. Temperature and relative humidity inside the test sample at 50mm depth (c)

CONCLUSIONS

CFD is becoming increasingly popular to investigate local heat, air and moisture transfer problems in buildings. New models are being developed but there is still a lack of well documented experimental data for validation. In this paper the design of a climate chamber is discussed together with some measurement results.
Inside the climate chamber a sample of calcium silicate was placed. The material properties of this sample were measured during an earlier research project. Temperature and relative humidity were measured inside the sample at 10mm, 25mm and 50mm depth. The sample was first preconditioned at 50% RH and 25°C and then exposed to cycles of 8 hours high humidity and 16 hours low humidity. The resulting measurements of temperature and relative humidity are presented in this paper. The measurements correspond well with the expectations. These measurements can now be used to validate new CFD-HAM models.

NOMENCLATURE

Quantity	Symbol	SI unit
Moisture capacity	C	m^2/s^2
Moisture permeability	K	s
Capillary pressure	p_c	Pa
Ideal gas constant water vapour	R_v	J/kgK
Moisture content	w	kg/m^3
Saturation moisture content	w_{sat}	kg/m^3

ACKNOWLEDGEMENT

The results presented in this paper have been obtained within the frame of the FWO project B/05836/02 funded by the FWO-Flanders (Research Fund Flanders) and the IWT SBO-050451 project heat, air and moisture performance engineering a whole building approach funded by the IWT (Institute for Science and Technology in Flanders). There financial support is gratefully acknowledged.

COMPARISON OF DIFFERENT TOOLS TO STUDY GAS-LIQUID FLOW

ABSTRACT. In an effort to obtain a comprehensive knowledge of gas-liquid flows, in this paper the use of different tools available at the University of Nottingham to study gas-liquid flow in pipes is presented, followed by a comparison of the instrumentation performance. Air-silicone oil is used as the working mixture. The tools are capacitance wire mesh sensor (WMS), electrical capacitance tomography (ECT), capacitance probes and computational fluid dynamics (CFD) modelling. This is supplemented by illustrations of the sort of information that have been obtained. In general the agreement in the comparison is fairly good. However, it is observed that the WMS provides a better spatial resolution than ECT (with a first order reconstruction method) and is excellent for measurement of bubbly flow parameters.

Keywords: *Wire-mesh, ECT, capacitance, CFD*

INTRODUCTION

The flow of gas-liquid mixtures is of paramount importance to a number of operations in industry. A recent example is the flows of oil and natural gas from sea bed completions to the floating production/storage facilities. The flows are made complex by the very flexible nature of the interface between gases and liquid. Not surprisingly, considerable efforts have been put into measuring the distribution of the phases about the pipe and on methods from predicting that. This includes a wide range of tomographic sensors that are able to produce a graphical representation of the cross sectional flow inside the pipe, such as, x-ray tomography, gamma-densitometry tomography, positron emission tomography, magnetic resonance imaging, ultrasonic system, infrared tomography and electrical based tomography. The requirement in most work is to supply a relatively low cost imaging of industrial processes for control purposes, which is known as process tomography, while maintaining at the same time a fast time resolution with the consequence of much lower, but sufficient, image resolution. Consequently it is expected that only two systems can be considered to fall within this criterion, namely, ultrasound and electrical tomography, which have eventually developed into powerful experimental instruments capable of flow pattern identification due to the improvement of digital technology.

The field of electrical tomography can be separated into two distinct regions based on the method by which the electrical field is produced, either resistance or capacitance. Each individual measurement technique will have unique advantages and disadvantages in relation to the accuracy, frequency and resolution of the measured images produced. The choice will be based primarily on the electrical properties of the fluids, whether they conduct or not. Electrical capacitance

tomography (ECT) is a truly non-invasive technique since the sensing electrodes are usually not in contact with the medium under consideration but are positioned peripherally around the pipe exterior. Most of the work reported in the literature which involves ECT has been carried out with gas-solid flows such as fluidised beds and pneumatic conveying, for example Azzopardi et al. [2]. However, recently the range of applications is growing fast.

A tomography technique based on electrical resistance measurement is the conductivity wire mesh sensor, which although intrusive, allows the study of two-phase flows with high spatial and temporal resolution. As a result recently an increasing number of applications of this technique have been reported, for gas-liquid flow in different flow regimes, for instance, Azzopardi et al. [1]. However this sensor is not able to detect flows where no conductive phase is present. In order to tackle the study of nonconductive flows, more recently this sensor has been improved by Da Silva et al. [3] at Forschungszentrum Dresden-Rossendorf, resulting in what is known as capacitance wire mesh sensor, whose main structure is similar to the conductivity wire mesh sensor. Early results obtained with this instrument at Nottingham were introduced by Thiele et al. [4].

On the other hand, attempts have also been made to achieve the prediction of multiphase flow behaviour in terms of the phase distribution, interface location and velocity field using the approach of computational fluid dynamics. Several multiphase flow models for computational fluid dynamics are being implemented in commercial packages, making it possible to study the flow behaviour. It is important however to compare this predictions with experimental data in order to increase confidence in its applicability and overcome shortcomings.

In an effort to extract as much information as possible on the complex behaviour of two-phase flows, in this paper a comparison of the performance of different tools available at the University of Nottingham to study gas-liquid flow in pipes is done. The comparison is made based on several two-phase flow parameters such as phase distribution and structures frequency. This is supplemented by illustrations of the sort of information that have been obtained. The tools are capacitance wire mesh sensor (WMS), electrical capacitance tomography (ECT), capacitance probes and computational fluid dynamics (CFD) modelling.

DESCRIPTION OF TOOLS

All the work hereby reported is based on the flows that were created on an inclinable facility, which has been kept vertical for this particular task. This facility has a test pipe of 6 m length and of 67 mm internal diameter with the two-phase flow being fed at the bottom. More details can be found in Hernández Pérez et al. [8]. Conditions studied were superficial velocities: air - from 0.05 to 4.7 m/s and for liquid - from 0.0 m/s to 0.7 m/s. The two-phase mixture under investigation is air-silicone oil, where silicone oil is an excellent insulator and has a viscosity ~5cp. The measurements were carried out simultaneously with the instruments located along the pipe as shown in Table 1.

Table 1
Location of instrumentation on the test section of the rig

	Cap probe 1	ECT Plane 1	ECT Plane 2	Cap probe 2	Wire mesh
Location from the mixing section (m)	4.15	4.40	4.49	4.75	4.92

The first capacitance probe was located at 4.15 m from the inlet, followed shortly by the ECT; this gives a flow development length of approximately 62 pipe diameters to the first capacitance sensor and a total of approximately 67 pipe diameters to the ECT. The two capacitance sensors are

separated by a distance of 0.35 m and placed directly on the outside wall of the pipe. The wire mesh sensor was located at 4.92 m from the mixing or inlet section, i.e. at the top, in order to avoid any possible intrusive effects to impinge on the measurements from the other probes. A brief description of the instrumentation is provided below. This was supplemented with high speed footage to capture the flow behaviour after the wire mesh sensor.

Capacitance probes

The capacitance probes were used earlier by Hernandez-Perez and Azzopardi [5]. It consists of a pair of electrodes mounted around the pipe. This arrangement provides values of the cross section averaged liquid holdup (or void fraction).

Capacitance wire mesh sensor

The capacitance wire mesh sensor consists of two planes of 24 stainless steel wires with 0.12 mm diameter, 2.8 mm wire separation within each plane and 2 mm axial plane distance. The sensor is built into an acrylic resin frame supports which allows it to be mounted in the test pipe. Figure 1 shows a photograph of the sensor. A detailed description of this instrument can be found in Da Silva et al. [3].

Electrical Capacitance Tomography (ECT)

Electrical Capacitance Tomography is a non-intrusive measurement technique that exploits the difference in relative permittivity of the two phases present in the pipe. The ECT system (Tomoflow R100) utilised consists of a capacitance sensor, measurement circuitry and a data acquisition computer; it has been described and used previously by Hassan and Azzopardi [6] for liquid-liquid flow and also been applied successfully to gas-solid flows by Azzopardi et al. [1]. The capacitance sensor comprises a set of equal sized electrodes. They are made using flexible Printed Circuit Board (PCB) technology. It is easy to adapt the instrument to pipes of different diameter. Here, an 8 electrode capacitance sensor has been mounted externally around the pipe, as the pipe wall material is non-conducting. The measurement electrodes are 35 mm long and 26.43 mm wide each. The distance between centres of two measuring planes is 89 mm. Guard electrodes are placed on either side of the measurement electrodes. The probes were calibrated by taking readings with the pipe empty (gas only) and full of silicone oil.

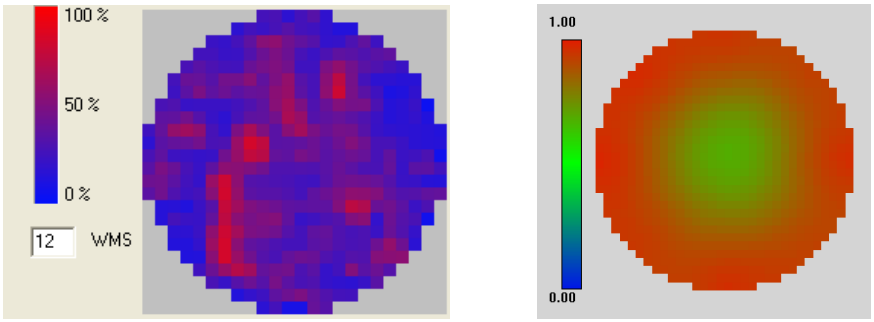
Figure 1. Instrumentation employed in this work

Computational Fluid Dynamics (CFD)

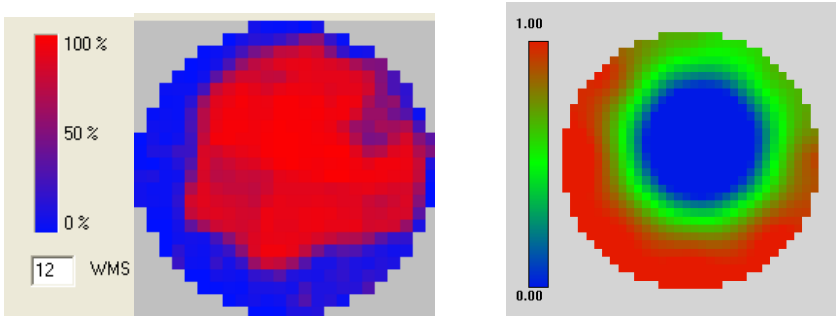
In addition to the measurement instruments above, CFD modelling is being used to predict the flow behaviour, particularly the velocity field. The velocity field is important because it determines the interaction among bubbles. In this case a particular condition has been chosen to suit the applicability of the Volume Of Fluid (VOF) approach of Hirt and Nichols [7] as employed in earlier work, Hernández Pérez et al. [8], on a vertical pipe of 67 mm diameter. As in the experimental work, the air and silicone oil flow is supplied at the inlet section of the computational flow domain (pipe), then the two-phase mixture flows along the pipe and is finally discharged through the outlet at atmospheric pressure. Here a different commercial CFD package is has been employed from the earlier work [8]. This implies a few differences, mainly in the solution algorithm utilised; the Semi-Implicit Method for Pressure-Linked Equations (SIMPLE) has been used in Star-CD. A mesh with 300,000 cells has been used, meaning a similar spatial resolution to that of the WMS.

RESULTS AND DISCUSSION

Example results are shown in Figure 2. The images on the left side display the wire mesh sensor output of the instantaneous cross sectional phase distribution. This particular version has 24x24 wires and so a spatial resolution of 2.75 mm. It can sample entire the plain at frequencies of up to 5000 Hz. However, most of the results obtained were taken at 1000 Hz. The measurements are confined to a single plain. In contrast, ECT output, also illustrated in Figure 2 (on the right), shows the cross-sectional distribution of the two-phase mixture averaged over the length of the sensor electrodes, which must be sufficiently large to give a measureable change in capacitance. Furthermore due to the so called soft-field nature of this tomographic modality, it has a lower cross sectional resolution. It was also taken at a lower sampling frequency (200 Hz); however, ECT has capabilities for higher sampling frequencies at the cost of a spatial resolution. It can be appreciated that he Taylor bubble observed at the lower part of Figure 2 is off-centre, due to flow instabilities.



Liquid slug body above; Taylor bubble below



Wire mesh sensor **Electrical Capacitance tomography**

Figure 2. Comparison between contours of phase distribution taken simultaneously with both wire-mesh sensor and electrical capacitance tomography. Screenshots taken at a liquid superficial velocity of 0 m/s and a gas superficial velocity of 1.4 m/s

An advantage of ECT is that measurements are made simultaneously at two plains and therefore information can be obtained on structure velocities.

If the representation of the gas-liquid interface is considered, it can be observed that the wire mesh sensor produces a sharper interface together with a better spatial resolution than ECT as shown in Figure 2. These differences are more noticeable in the bubbly flow region. In fact the WMS has been widely used as a tool for the measurement of bubble size, which is a very important parameter to describe dispersed bubble flows, Prasser et al. [9], as well as the liquid slug body in slug flow regime. Visual observations in the transparent section of the pipe show that the gas entrainment consists of a considerable amount of bubbles smaller than the resolution of the wire mesh sensor, which might not be captured. It is noted that the ECT images presented here have been obtained utilising a first level reconstruction algorithm. Data is also being examined using the methodology of Warsito and Fan [10], which is known to give sharper, more detailed images.

It is important to note that the relevance of this work is that, the combination of the high resolution of the WMS with measurements at two positions of the ECT provides a more detailed understanding of the flow structure over a wide range of flow conditions. In addition, the measurements at five axial positions allow structures to be tracked as they progress downstream. Particular attention has been paid to the detection of structures such as liquid slugs and Taylor bubbles by means of the time series of void fraction, as in Figure 3, where the time series for WMS, ECT and capacitance probe are presented. The time series are similar with small differences that show the structure development when moving along the pipe.

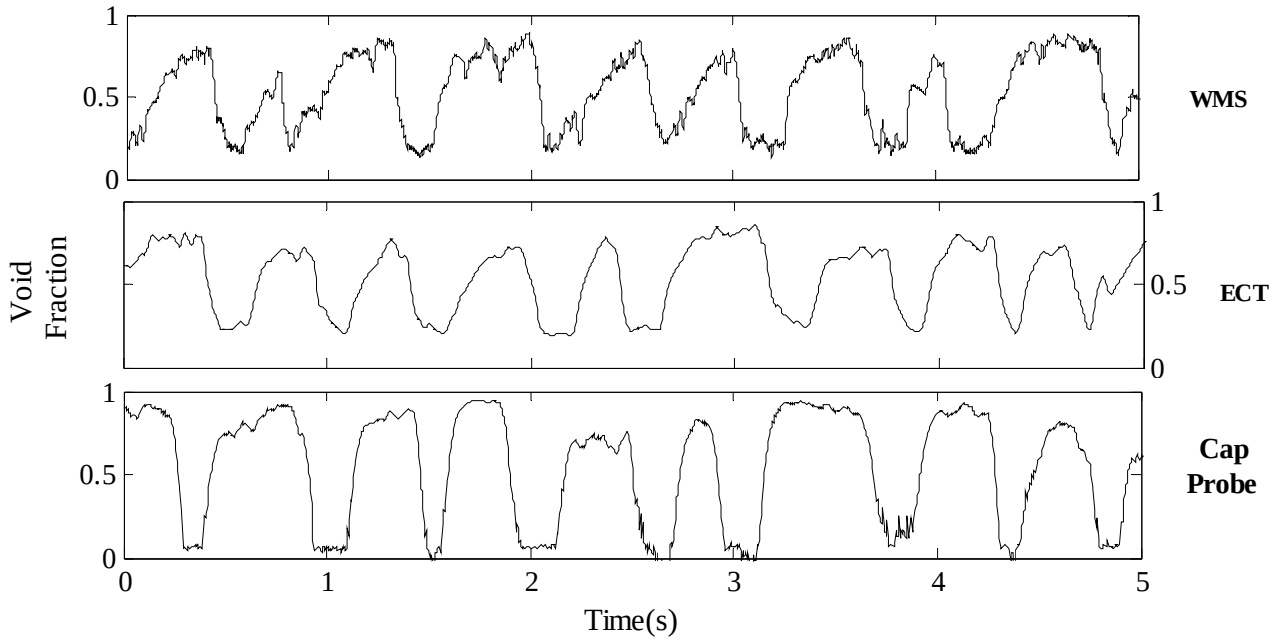


Figure 3. Comparison of time series of cross sectional average void fraction. Superficial velocities are 0 m/s and 0.56 m/s for gas and liquid respectively

Most studies of two-phase flow using ECT or wire mesh sensor are focused on the phase distribution, however, more information can be obtained. In many situations it is necessary to know the mean value of the gas or liquid volume fraction. Average void fraction has been calculated for several runs at different flow conditions. A typical example of the average void faction comparison is presented in Figure 4. The results of all of these instruments are shown to agree on the overall (averaged over time and cross-section) void fraction. However some differences are found which are under investigation, as they could be due to the instruments positions and flow development or calibration problem.

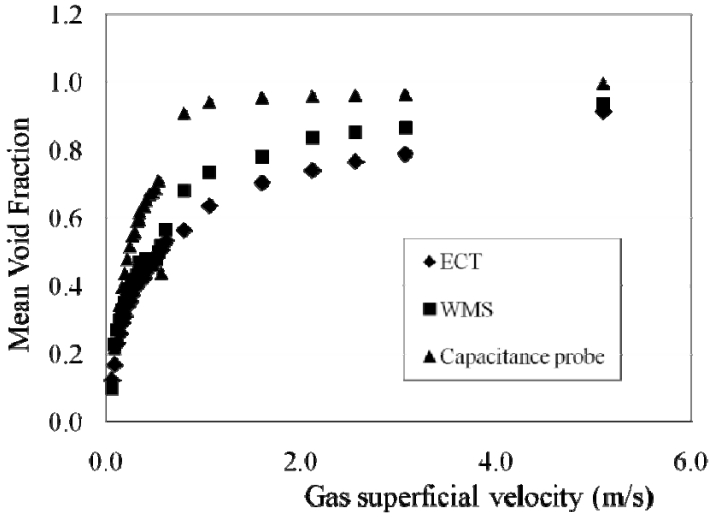

Figure 4. Comparison of mean void fraction: liquid superficial velocity = 0 m/s

Flow pattern identification shown by means of the Probability Density Function (PDF) of the cross-sectional averaged data of WMS and ECT along with capacitance probe readings has been carried out. A typical example is presented in Figure 5. All three instruments predict slug flow, as demonstrated by the double peak shape of the plots.

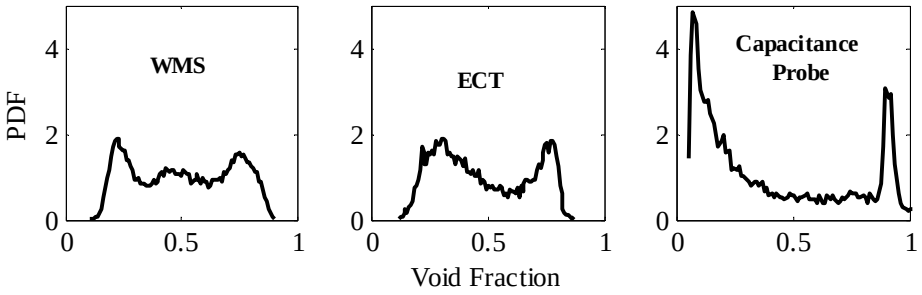

Figure 5. Comparison flow pattern prediction by Probability Density Function. The PDFs correspond to the time series presented in Figure 3

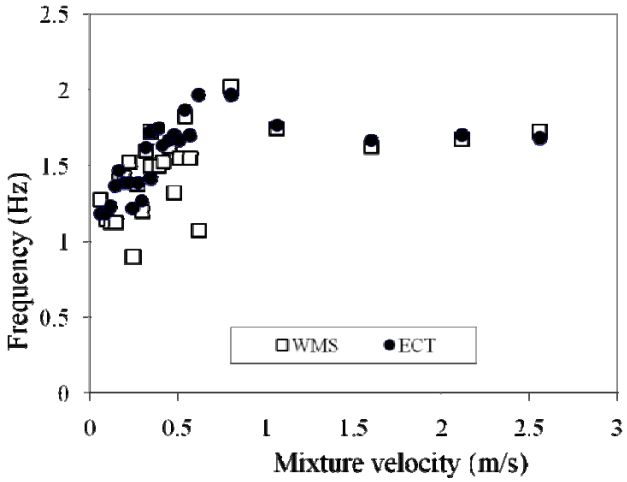

Figure 6. Comparison of structure frequency: liquid superficial velocity: 0 m/s

Structure frequency has been obtained applying Power Spectral Density (PSD) method and the results are presented in Figure 6 for the case of liquid superficial velocity of 0 m/s. The agreement is fairly good, particularly for the conditions of mixture velocity above 1 m/s. As expected, scatter

in the frequencies at mixture velocity lower than 1 m/s is observed and could be associated with bubbly flow where the structures such as small bubbles and void waves are not so easily identified. In addition, structure velocity has been obtained by applying cross correlation corresponding to two signals at two measurement stations. As expected, a fairly linear relation is obtained with the mixture velocity, Figure 7, which is in agreement with the correlation of Nicklin et al. [11].

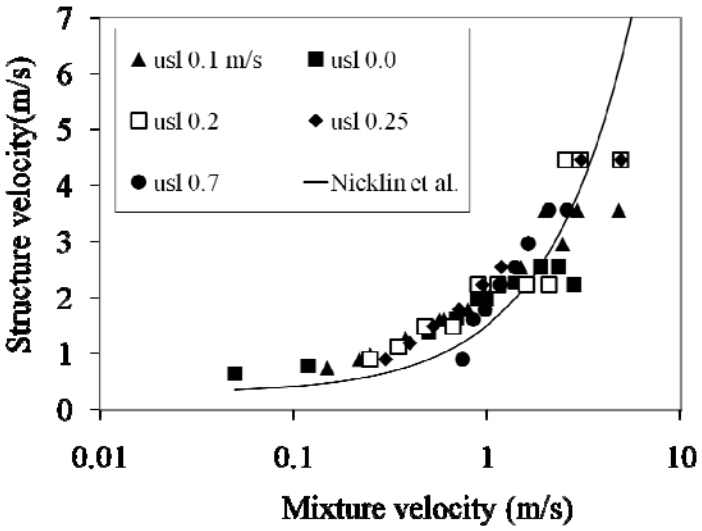

Figure 7. Structure velocity obtained using ECT

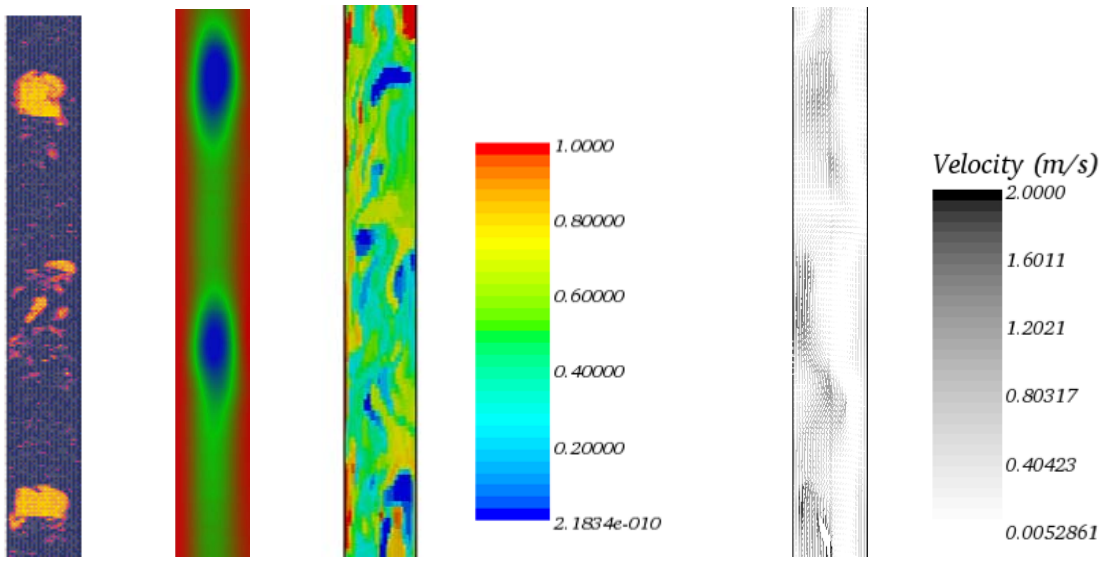
The CFD output shows characteristics similar to those observed visually and from the instrumentation. The flow is rather complicated, as can be seen in Figure 8, heterogeneous gas hold-up distribution within the pipe induces density fluctuations that originate circulation currents influencing strongly phase mixing. A cluster of small bubbles is observed by both ECT and CFD as a single bigger bubble. Hernández Pérez et al. [8], observed that the agreement is both qualitative but also quantitative, i.e., in the Probability Density Function plots and in the Power Spectral Densities obtained from experiment and computational results. Those parameters will be extracted from the present computations.



WMS ECT CFD contours of liquid and velocity field

Figure 8. Comparison of phase distribution obtained with WMS, ECT and CFD respectively, CFD velocity field is also included. Superficial velocities: liquid 0m/s and gas 0.15 m/s.

CONCLUSIONS

Different tools have been used to study gas-liquid flows and a comparison has carried out of the outputs. The combination has resulted in a comprehensive characterisation of the flow by gathering several flow parameters, which include flow pattern identification, structure frequency and velocity, void fraction and velocity field. By placing different sensors along the pipe flow structures have been tracked. In general the agreement in the comparison is fairly good. However, it is observed that the WMS currently provides a better spatial resolution than ECT and is excellent for measurement of bubbly flow parameters. Some differences have been found in the measured average void fraction values.

ACKNOWLEDGEMENTS

This work has been undertaken within the Joint Project on Transient Multiphase Flows and Flow Assurance. WAVY STRUCTURE OF LIQUID FILMS IN ANNULAR GAS-LIQUID FLOW

ABSTRACT. High-speed modification of LIF technique was used to study spatio-temporal evolution of waves on liquid film in annular gas-liquid flow with and without entrainment. It was shown that in both flow regimes wavy structure is represented by two types of waves: primary and secondary waves; all the secondary waves are generated at the back fronts of primary ones. In entrainment regimes primary waves are known as disturbance waves, and secondary waves are known as ripples, although regularities of ripples generation were not clarified in earlier works. Separation of waves in regimes without entrainment into primary and secondary ones, and, consequently, similarity of liquid film wavy structure in regimes with and without entrainment, is shown for the first time.
Keywords: *annular flow, disturbance wave, ripple wave*

INTRODUCTION

The joint flow of liquid film along channel wall and high-velocity gas stream along the center of the channel is called annular two-phase flow. The case of high gas and liquid flowrates when liquid droplets are entrained from film surface into the core of gas stream is called annular-dispersed flow. Heat and mass transfer of annular-dispersed flow are essentially influenced by the liquid entrainment, and physically based modeling of this process is very important but still unsolved problem. According to the commonly accepted opinion, two types of waves exist on film surface in presence of entrainment: disturbance waves with high (several times higher than average thickness of the film) amplitude and short-length ripple waves. Woodmansee & Hanratty [1] observed that ripples travelling on disturbance waves crests are ruptured by the gas flow and considered this phenomenon as the main source of entrainment.

The quantitative information on appearance and evolution of these two types of waves and on their interrelations is necessary for creating the physically based models of entrainment phenomenon. In the most part of experimental works where wavy structure in annular flow is studied, investigators separate all the waves into disturbance waves and ripples (normally the amplitude-based criteria are used for this purpose) and then study these two types separately as if they are totally independent on each other [2-4]. The disturbance waves seem to be the most interesting type of waves for the investigators, and huge amount of works is devoted to measuring their characteristics like frequency, velocity, spacing, amplitude, etc. (see, e.g., review [5]). The disturbance waves properties usually keep constant values along large (several meters) downstream distances [6], whereas ripples have short lifetime [2, 7-9].

The characteristic feature of entrainment phenomenon which must be taken into account in all entrainment models is the existence of so-called critical Reynolds number. When liquid Reynolds number is lesser than this critical value, there is no entrainment at any gas stream velocity. The commonly accepted explanation of this feature is that the disturbance waves do not appear in regimes without entrainment. Thereby, film surface in no-entrainment regimes is considered to be covered by

E-mail address: aleks@itp.nsc.ru

the ripples only; the transition to entrainment is considered to occur when disturbance waves appear due to increasing of liquid flowrate [5, 10-11].
Ripples that present on liquid film surface in regimes without entrainment are considered to belong to the same type as the ripples that present in regimes with entrainment. Properties of ripples in regimes without entrainment were studied in works [3, 12-13]. The amplitudes, velocities and wavelengths were shown not to change with downstream distance and slightly depend on gas and liquid flowrates. Asali and Hanratty [14] have shown that experimentally measured spatial wavelength of ripples exceeds theoretically predicted wavelength of maximum growth nearly twice.
Some works, devoted to studying the wavy structure of annular flow, were based on different approaches. Thus, Sekoguchi and coauthors [15-17] used a multiple-electrode conductivity system to resolute the spatio-temporal evolution of liquid film thickness. In particular, they found "ephemeral waves", which sometimes appear on back fronts of disturbance waves and move slower than the latter. Another type of waves was observed by Ohba and Nagae [18] in upward flow near the transition to entrainment. These waves, that were named "ring waves" were found to be shorter than disturbance waves and wider than ripples; this difference was observed in longitudinal as well in transverse direction.
Nevertheless, the literature lacks systematic information on the regularities of waves appearance and evolution in annular and annular-dispersed flows. The aim of our work is to obtain the detailed and systematic information on waves appearance and interrelation in annular flows in regimes with and without entrainment.

EXPERIMENTAL SETUP AND MEASUREMENTS TECHNIQUE

The downward annular flow was organized in vertical Plexiglas cylindrical tube with inner diameter d=15 mm and 1 meter length. Measurements were performed 8-20 cm downstream the inlet. The ring slot distributor with the gap width of 0.5 mm was used to introduce the liquid film into the tube; the gas flow entered the channel through a smaller diameter tube, co-axial to the channel.
Liquid Reynolds numbers Re=142, 220 and 350 were chosen for regimes with entrainment, and Re=40 and 60 – for regimes without entrainment. Re was defined as $q/\pi d\nu$, where q is volumetric liquid flowrate and ν is kinematic viscosity of liquid. The range of average gas velocities Vg was 22-58 m/s (gas Reynolds numbers 22000-58000, respectively). Distilled water was used as the liquid, air was used as the gas.
Laser induced fluorescence technique was used to recover the instantaneous distribution of film thickness along the longitudinal section of the channel. To ensure high sampling rate, the CCD-camera with linear (one-pixel width) sensor was used for registration the local brightness of the re-emitted light. This camera allowed working frequency of 2 kHz. The investigated section was enlightened by the continuous green (532 nm) laser; the beam was optically transformed into vertical sheet with width about 1 mm. The fluorescent dye was Rhodamin-6G (concentration was 30 mg/l).
Spatial resolution was 0.1 mm per pixel. Exposition time of the measuring system was 250 μs and registration frame rate was 2000 fps. The dependency of local intensity of re-emitted light on local film thickness was obtained by organizing a set of gaps of certain thickness. The detailed description of registration system can be found in [19].
The most convenient form of presentation of experimentally obtained data on film thickness evolution in space and time are the spatio-temporal fields of film thickness (see Figs. 1, 2, 4). The waves move across this surface along characteristic lines, and velocity of a wave is characterized by the slope of this line.

EXPERIMENTAL RESULTS

Regimes with entrainment

An example of spatio-temporal evolution of film thickness for flow with entrainment is shown in Figure 1. The disturbance waves move along high-slope characteristic lines. Flow direction is from lower values of x to higher values. Disturbance waves are separated by thin substrate of approximately constant thickness. It can be seen that surface of substrate is covered by ripples, and that all the ripples traveling on substrate appear at the back slopes of disturbance waves.

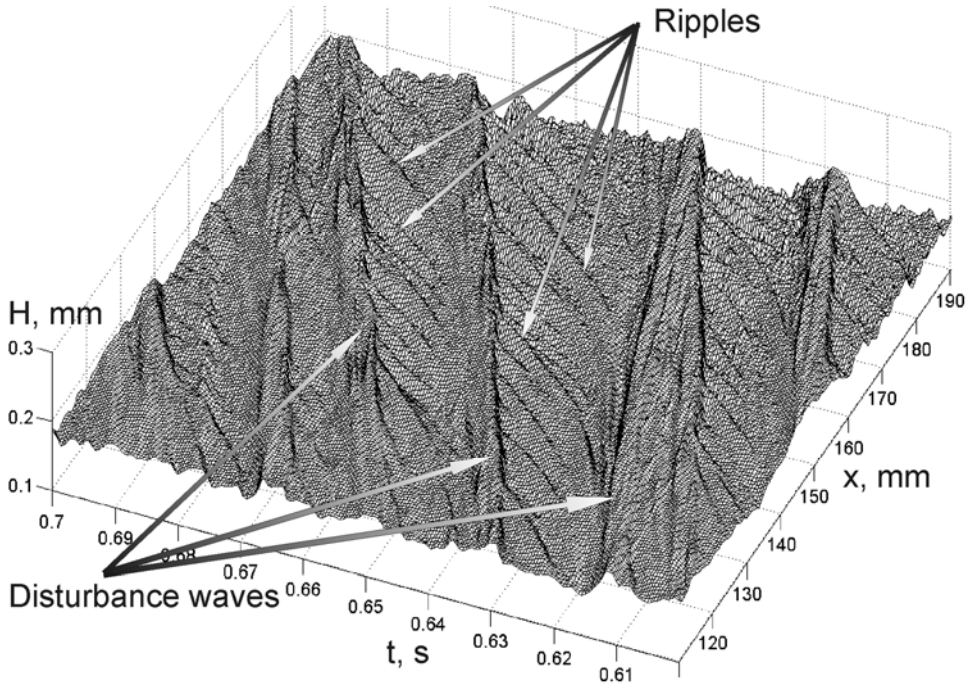

Figure 1. Disturbance waves and ripples on substrate in entrainment regime. Heights of disturbance waves are decreased to make ripples on substrate more distinguishable. Re=350, Vg=27 m/s.

The velocity of a ripple right after inception is close to that of disturbance wave, but afterwards it slowly decelerates and finally reaches some constant value of velocity. When the following disturbance wave overtakes the ripple on substrate, the latter is being absorbed by the former without essential influence on the disturbance wave's characteristics. The described picture explains short lifetime of such ripples, that was revealed in earlier works (e.g., [2]) using cross-correlation analysis.
Figure 2 shows a higher-scale picture of spatio-temporal evolution of disturbance wave. It can be seen that crest of disturbance wave is also covered by ripples. Similar to ripples on substrate, these ripples do also appear at the back slope of disturbance wave, but the inception point in this case is located closer to front of disturbance wave. Ripples on disturbance waves crests move faster than parent disturbance waves, and, after reaching the disturbance wave's front, they gradually disappear. This disappearance corresponds to mentioned above description of entrainment, made in [1] – the disappearing ripples are evidently disrupted by the gas flow and the resulting droplets are entrained into the core of gas stream.

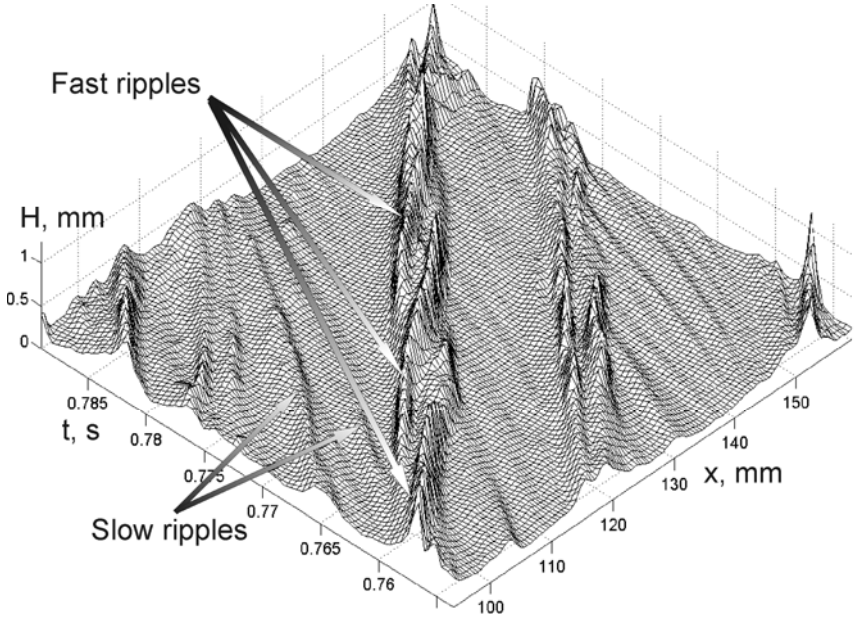

Figure 2. Ripples on disturbance wave. Re=350, Vg=27 m/s.

Figure 3 shows the average velocity of disturbance waves and ripples depending on gas stream velocity. Solid circles correspond to the average velocity of "fast" ripples travelling on disturbance waves crests, squares mark the average velocity of disturbance waves, crosses mark the velocity of "slow" ripples travelling on substrate, and the empty circles indicate the difference between velocity of the "fast" ripples and velocity of disturbance waves. It can be seen that this relative velocity is rather close to the velocity of "slow" ripples on substrate. All the velocities linearly depend on gas stream velocity.

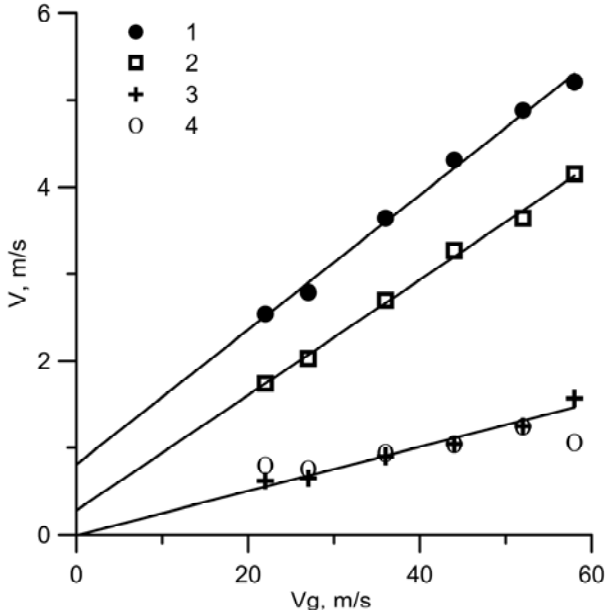

Figure 3. Average velocities of "fast" ripples (1), disturbance waves (2) and "slow" ripples (3). The velocity of "fast" ripples relatively to disturbance waves is also shown (4.)

Regimes without entrainment

Below certain value of liquid Reynolds number (Re~70 for downward air-water flow [5]), called critical Reynolds number, no entrainment was observed even for very high gas velocities. This is usually explained by absence of disturbance waves in regimes without entrainment. Thus, on liquid film surface in such regimes one could expect to observe only one type of waves - the ripples.

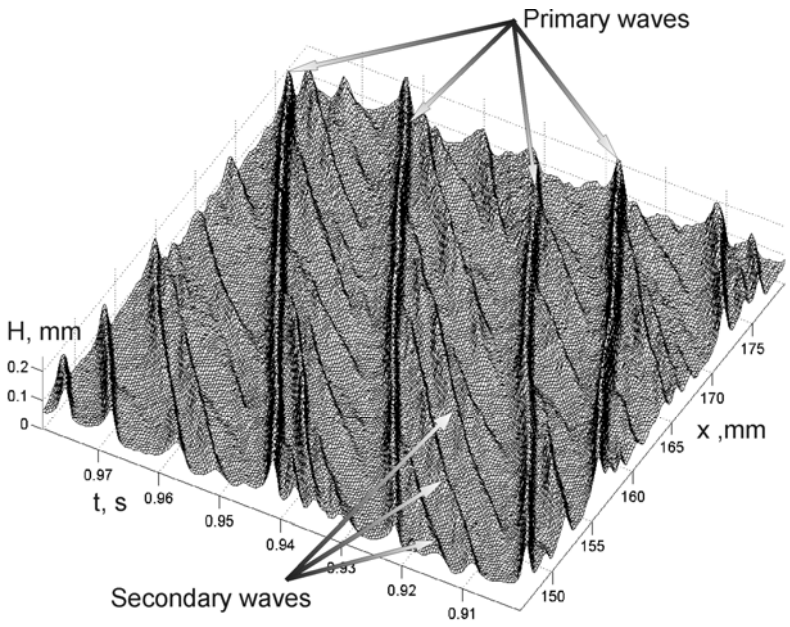

Figure 4. Primary and secondary waves in regimes without entrainment. Re=40, Vg=27 m/s.

Our experiments unexpectedly showed that in regimes without entrainment wavy structure also consists of two types of waves (see Figure 4). Waves, belonging to one of these types, are generated at the back fronts of waves of the other type, that's why we have called these two types "primary waves" and "secondary waves". The primary waves are characterized by high velocity and long life. The secondary waves appear at the back fronts of primary ones; they move essentially slower and are thus short-living, since any of them is promptly absorbed by the following primary wave. The described picture is very similar to that of regimes with entrainment: primary waves resemble disturbance waves, and secondary waves are similar to "slow" ripples, traveling on substrate.

The two main differences are observed between wavy structure in regimes with and without entrainment. First one consists in fact that in regimes without entrainment the secondary waves can move only slower than primary ones, while in regimes with entrainment secondary waves (usually called "ripples") may move either slower or faster than primary waves (usually called "disturbance waves"), as it was shown in Figures 1 and 2.

The second difference, that possibly explains the first one, is the fact that disturbance waves in regimes with entrainment are much higher than primary waves in regimes without entrainment; the sharp change in amplitude of primary waves occurs near the critical Reynolds number. The amplitudes of primary and secondary waves in regimes without entrainment are rather close to each other. That is the reason why the two types of waves in such regimes were not identified in earlier works where standard methods of waves separation with amplitude-based criteria were used.

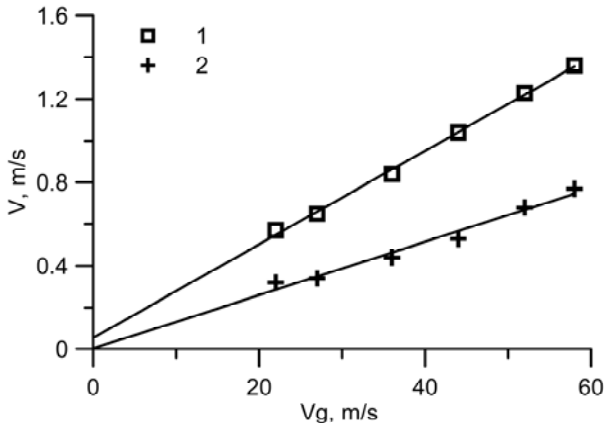

Fig. 5. Average velocities of primary (1) and secondary (2) waves in regime without entrainment. Re=40.

Figure 5 shows the average velocities of primary and secondary waves in regime without entrainment. Squares mark the average velocity of primary waves, crosses mark the velocity of secondary waves. The velocities of both types linearly grow with gas stream velocity and velocity of primary waves is about twice higher than that of secondary waves. The separation criterion, based on velocities of individual waves, allows effective separation the two types of waves in regimes without entrainment.

CONCLUSIONS

Experimental observations revealed that wavy structure in regimes with and without entrainment consists of two types of waves: long-living and short-living waves. Short-living waves are always generated at the back fronts of long-living waves, that's why we prefer to refer long-living waves as "primary waves" and the short-living waves as "secondary waves". The short life of secondary waves is explained by the scenario of their evolution: in a short time after appearance they are either being absorbed by the following primary wave (case of "slow" secondary waves) or being disrupted by the gas shear at the crest of primary wave (case of "fast" secondary waves). "Fast" secondary waves are observed only in regimes with entrainment that is possibly explained by the high amplitude of primary waves in such regimes. Primary waves and "slow" secondary waves exist in both regimes (with and without entrainment). In regimes with entrainment the primary waves are known as "disturbance waves", the secondary waves are known as "ripples". In regimes without entrainment the existence of primary and secondary waves was found for the first time.

The described similarity gives essentially different understanding of the transition to entrainment. It was commonly accepted that with increasing of liquid flowrate the transition to entrainment occurs due to appearance of the new type of waves – disturbance waves. Our observations allow the supposition that the primary waves in regimes without entrainment belong to the same type of waves as the disturbance waves in regimes with entrainment do. In other words, the wavy structure in regimes with and without entrainment is represented by the same two types of waves. The transition to entrainment, in our opinion, occurs due to abrupt growth of primary waves amplitude, and this growth leads to appearance of "fast" primary waves. The disruption of the latter by the gas shear is the reason of entrainment. Thus, these experimental observations allow development of the fundamentally new theoretical approaches to modeling of entrainment phenomenon.

INFRARED THERMOGRAPHY OF FLUIDIC MUSCLES

E. Ravina[1] *

[1] University of Genoa, Dept. of Mechanics and Machine Design, Genoa, Italy

ABSTRACT. The paper describes the results of a research activity, still under development, oriented to the characterization of pneumatic muscles and based on infrared thermography monitoring. Fluidic muscles are innovative pneumatic components able to mimic human muscular contractions and extensions. On the contrary of many other pneumatic and fluidic devices, the working conditions of muscles are characterized by significant fluid temperature variations: this suggest an interdisciplinary approach, researching correlations between mechanical and thermal variables.

Keywords: *fluidics, muscles, thermography*

INTRODUCTION

The concept of fluidic muscle has been patented in fifties. It is related to the contraction/extension of animal muscles and often it is realized through cylindrical elastomers operating under internal pressure variation (Fig. 1).
The muscle uses membrane expansion to achieve its stroke length. The proprietary membrane consists of a collection of woven fibres; the weave is a three-dimensional rhomboidal form, which helps give the tube its flexibility and the ability to expand. Two woven layers of the high-tensile supporting material enclose the muscle's polymer core.
Applying either pneumatic or hydraulic pressure to the muscle causes radial expansion. This action produces tensile force in the axial direction, which shortens the muscle and generates an initial pulling force that is more than ten times that of a pneumatic cylinder at the same pressure and diameter. Acting much like a spring, the force exerted by the pneumatic muscle varies as a function of its elongation. Maximum force is produced at the neutral position.

Figure 1. Fluidic muscle (by FESTO)

E-mail address: enrico.ravina@unige.it

Although fluidic muscles are used as a substitute for pneumatic cylinders, they cannot be used as a one-to-one replacement in a given application. That's because they are typically twice as long as conventional cylinders for a given stroke length. Various couplings and attachments facilitate use of the fluidic muscle in a wide range of applications, including assembly tables, presses, lifting equipment, and medical equipment. This device used as actuator or spring is characterized by:

- low cost;
- high power/weigh ratio;
- good efficiency;
- no relative motions;
- no lubrication;
- use of cheap and ecological fluids (air, water,..);
- possibility of application in extreme environments (vacuum, high gradients of temperature, magnetic fields, radioactivity,..).

The muscle assemblies three main components:

- deformable body realized in elastomer, with high axial deformability;
- external undeformable fibres;
- metallic terminals.

Attractive features of this type of pneumatic actuator concern arising generated forces (up to 10 times higher than a conventional cylinder of the same diameter), good mechanical responses (velocities from 0.001 mm/s up to 3 m/s, accelerations up to 100 m/s^2, forces up to 6 kN), zero leakage (any mechanical parts in relative motion), simple control technology both for high (up to 100 Hz) and very low actuation frequencies. In addition, its lightness and compactness allow versatile and innovative applications.

However dynamic behaviour, optimal performances and life cycle are strongly influenced by environmental parameters, by mechanical and thermal stresses related to the operating conditions and by air fluid dynamics. Phenomena of interest concern hysteresis cycles under different pressure loads, repeatability position errors, reproducibility conditions, and relationships between contraction phases or frequency and air temperature distribution.

In particular the actual temperature distribution along the muscle strongly influences its mechanical response: it depends on the techniques of air supply and drain, on the muscle length, and on the inside pressure levels. The versatility of use of this fluidic component in very different applications and working conditions suggests the development of not invasive monitoring procedures, in order to identify the role of the temperature distribution on its mechanical performances.

TEST BENCH

The experimental investigation is developed through an original test bench (Fig. 2), expressly designed and realized by the author for monitoring and diagnosis of fluidic muscles.

Different sizes of muscles can be tested, simulating variable external loads by means an antagonist pneumatic actuator. The muscle can be actuated with timed on-off pneumatic valve or by a proportional flow control valve. The test bench is equipped with a load cell located between muscle and antagonist cylinder, while pressure transducers detect the inside pneumatic conditions. Muscle terminals can be misaligned in different way, simulating actual operating conditions.

The variable geometry of the muscle surface, continuously submitted to contractions and stretching, doesn't allow the temperature measurement by means contact conventional sensors (thermocouples or thermometers): infrared thermography is successfully applied. The heat produced within the muscle is conducted, through the composite layers forming the muscle, on the outside surface, where can be detected by a thermo camera: in this experience an IR Flex Cam T camera (by Infrared Solution, inc.) is used.

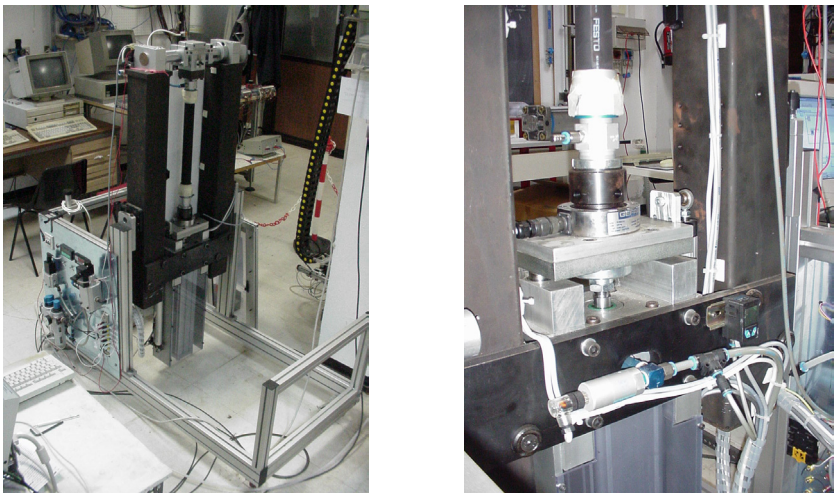

Figure 2. Overall view and details of the experimental test bench

The basic theoretical reference (Stephan – Boltzmann law) correlates the emitted power to the absolute temperature of the surface through the emissivity; the general relationship relating the effective radiance to the surface temperature is:

$$L = \tau\,\varepsilon\,L^0(T) + \tau\,(1-\varepsilon)\,L^0(T_a) + (1-\tau)\,L^0(T_{atm})$$

where L is the radiance, L^0 the total radiance of a reference black body, τ the effective atmospheric transmissivity, ε the emissivity, T the absolute temperature the body under test, T_{atm} the temperature of the non-scattering isothermal atmosphere and T_a the temperature of the isothermal surroundings.
The correct evaluation of the muscle surface temperature detected by thermo-cameras must takes into account of the shape of the emitting body: the pneumatic muscle is assumed as a body having a cylindrical symmetry and the detected temperature is corrected taking into account the shot angle Φ between muscle and camera: compensation functions proposed in literature are applied.
Finally the environment temperature must be considered: in the present research activity the muscle surroundings temperature is monitored in real time and used as parameter for the correct evaluation of the muscle temperature distribution.
All the test bench mechanical and thermal variables are managed to an acquisition and control unit operating with virtual instrumentation software (Labview, by National Instruments inc.), originally implemented on PC. Mechanical actions and programmed thermo- pictures are automatically integrated.

SOME EXPERIMENTAL TESTS

The aim of the study is to find all possible correlations between cinematic and dynamic performances of fluidic muscles and their temperature distributions: in particular correspondences between actual position errors and temperature may be a significant monitoring reference on correct working conditions.
An original set of experimental tests, fully automatic, are implemented on different sizes of muscles; key parameters are:

- input air pressures at the muscle and at the antagonist cylinder;
- maximum contraction factor (up to 25% of the muscle length);
- excitation frequency;
- digital t_{ON}/t_{OFF} sequences;
- programmed opening laws to flow control proportional valves;

- fluid dynamic air conditions inside the muscle;
- thermal environmental conditions.

Reasons of space force to select the aspects analysed in this paper. In particular, results concerning the effects on the temperature distribution along the muscle in correlation with muscle length, working frequency and supply pressure are focussed and discussed.
Standard tests are organized programming sets of 500 continuous contraction/extension cycles on muscles having different size: here muscles having 40 mm of diameter and length from 120 to 360 mm are compared. The pressure supply is variable from 1 to 6 bars: the same metallic terminal of the muscle is involved in inlet and outlet fluid flow. Tests aren't implemented in thermostatic chamber, but the environmental temperature variation is in the range 25.5 ÷ 26.5 °C, acceptable for compared experiments oriented to detect different thermal distributions.
The emissivity is chosen equal to 0.95, approximating the composite material of the muscle surface to rubber. Particular care has been kept to effects of reflection generated by the metallic terminals: screens of special adhesive paper are successfully used.
Significant gradients of temperature and inverted distributions are surprising results of this integrated analysis.

Effect of the muscle length

Muscles of different length (from 120 mm, named hereafter "short" muscle, up to 360 mm, named "long" muscle) are compared all things being equal: diameter (40 mm), working frequency (0.5 Hz), contraction factor (20% of the nominal length) and inlet pressure (4 bar).
Figs. 3 and 4 refers on temperature distribution at the end of the working cycle: an overview shows that the temperature is more uniformly distributed in the "short" than in the "long" muscle.

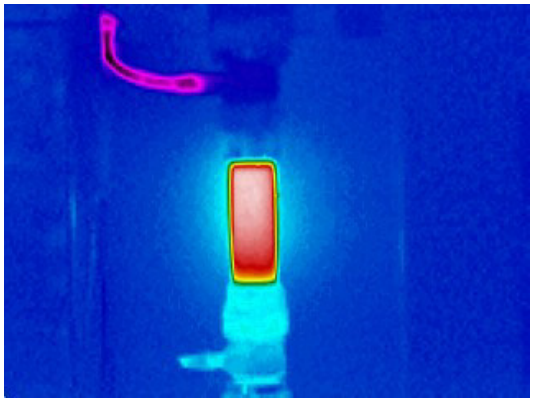

Figure 3. "Short" muscle infrared view

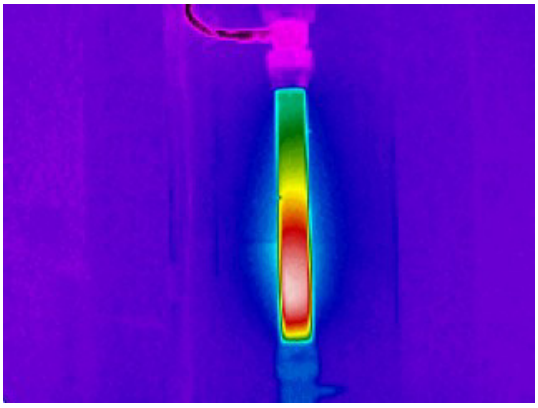

Figure 4. "Long" muscle infrared view

Figs. 5 and 6 report the longitudinal (axial) temperature distribution: minimum and maximum values are very similar, while average values and functions of axial distribution are very different. Short muscle shows a more uniform temperature, while into long muscle the heat is concentrated at the opposite side with respect to the pneumatic connection.

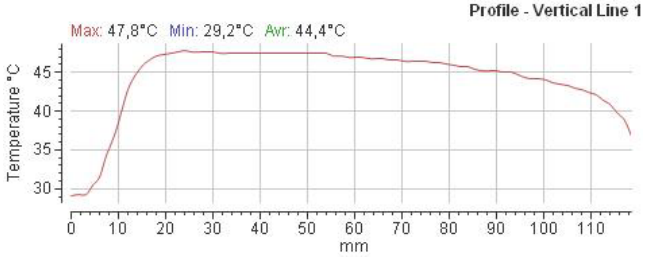

Figure 5. Axial distribution ("short" muscle)

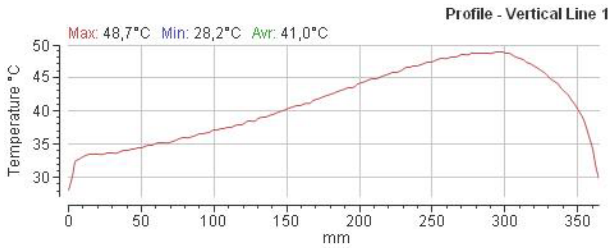

Figure 6. Axial distribution ("long" muscle)

This phenomenon increases reducing the contraction factor and the internal air pressure: for instance Figs. 7 and 8 show the corresponding results at 15% of contraction factor and air pressure at 3 bar.

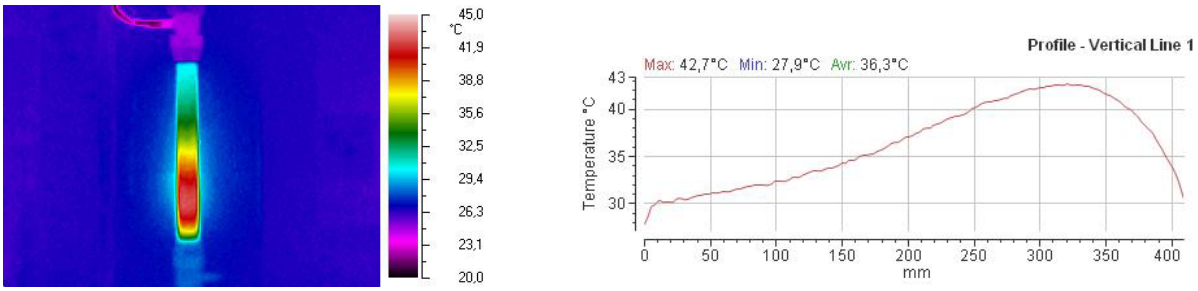

Figure 7. “Long” muscle at 3 bar and 15% of contraction factor

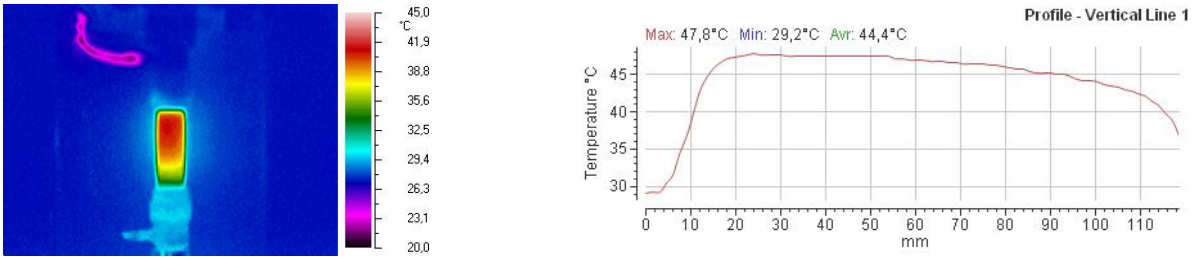

Figure 8. “Short” muscle at 3 bar and 15% of contraction factor

Minimum and maximum temperatures of 120 and 360 length muscles are reported in Figs. 9 and 10. Contraction factor is selected at 10%, 15% and 20% (codes c10, c12 and c20) and the air pressure is changed from 2 to 6 bar (codes from p20 to p60); an identification contraction-pressure code is used. For example, c10p50 code concerns a test with contraction factor of 10% and pressure of 5 bars. All the pneumatic parts of the muscle are monitored, including metallic terminal, fittings and hoses.

Figure 9. Minimum and maximum temperatures on a “short muscle”

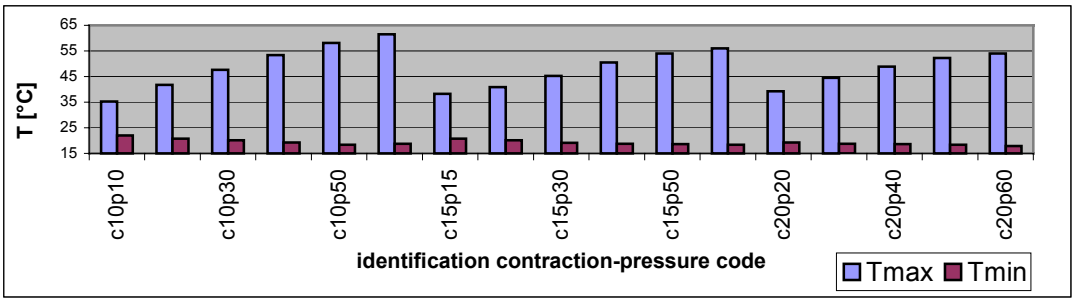

Figure 10. Minimum and maximum temperature on a “long” muscle

An overall comparison on hot and cold spots shows differences of temperature up to 45 °C: coldest points are typically located on the air hose.

Effect of the working frequency

Fluidic muscles are able to cover a wide range of working frequency, satisfying both very slow and very fast motion conditions. Frequency variation influences the local temperature of the muscle, in different way with the length. An example of results is reported in Fig. 11. Temperatures of "long" and "short" muscles (length codes L360 and L120) are compared on four frequency values: 0.25, 0.50, 0.75 and 1 Hz (frequency codes from F025 to F100). Contraction factor is fixed to 10% and the air pressure to 6 bars. Long muscle reaches higher temperatures: this trend is also confirmed to higher frequencies, but maximum and minimum temperatures trend to a stabilization.

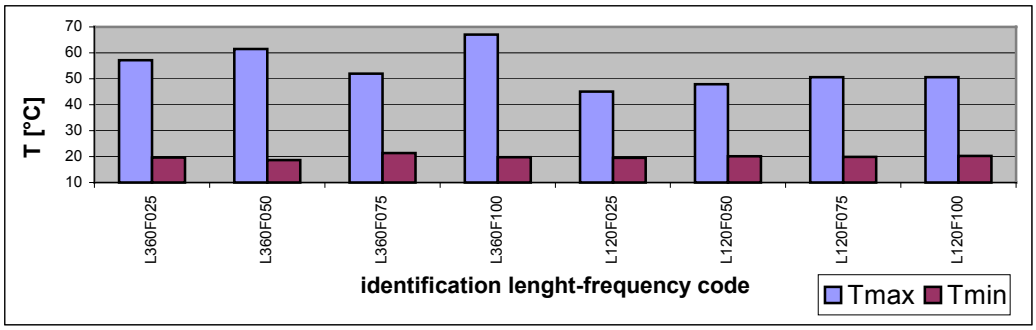

Figure 11. Effects of the working frequency

The effect of the frequency on the thermal distribution is shown in Figs. 12 and 13 (a and b), respectively at frequencies of 0.25 Hz and 1 Hz. Fig. 12 concerns a "short" muscle and compares, practically at the same number of pixels, the density vs. temperature on a rectangular area selecting hot and cold points of its flexible surface. Peaks of density are detected to high temperatures and this effect is enhanced at higher frequencies.

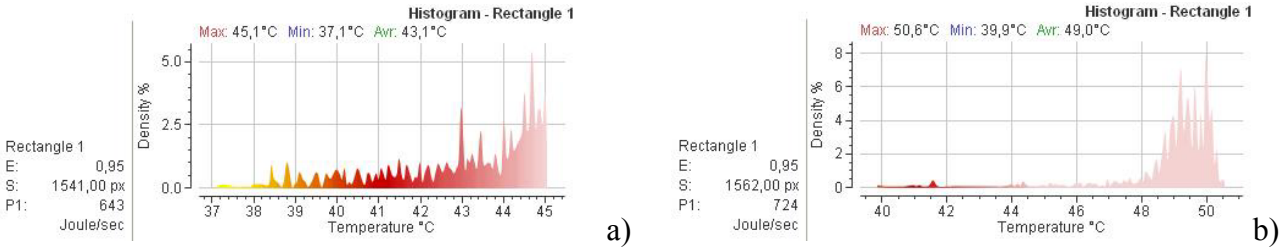

Figure 12 (a and b). Density vs. temperature for "short" muscle working at different frequencies

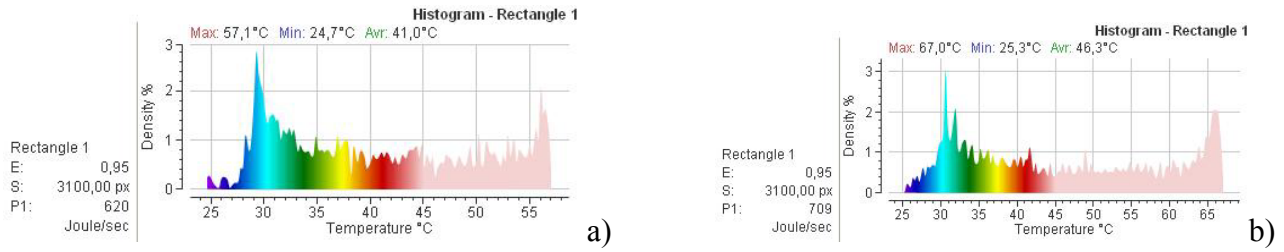

Figure 13 (a and b). Density vs. temperature for "long" muscle working at different frequencies

The detected density distribution for "long" muscles is very different. Relevant concentrations are detected to low temperatures (Fig. 13) and the dependence to the frequency values seems to be less significant. The maximum temperatures are higher (58 ÷ 68 °C against 45 ÷ 52 °C); P_1 represents the corresponding absolute radiation power.
In all the different case studies the absolute radiation power $[P_1 = \sigma \varepsilon T^4]$, the radiation energy $[P_2 = \sigma \varepsilon (T^4 - T_0^4)]$ and the radiation energy + the energy loss by convention $[P_3 = \sigma \varepsilon (T^4 - T_0^4) + h_m (T-T_0)^{3/4}]$ can be evaluated and compared.

Effect of the supply pressure
Inside pressure level plays a role of position stabilization of the muscle, especially when it is used as actuator. For example in Fig. 14 temperature distributions on the same "short" muscle supplied at 2 and 6 bar, are compared: maximum temperature increases with pressure, while the density distributions are very similar.

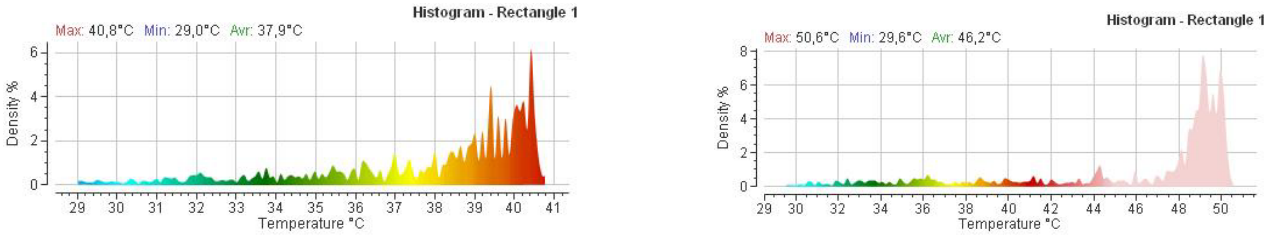

Figure 14. Density distribution for a "short" muscle supplied at 2 and 6 bar

MECHANICAL FALLOUT

Thermal phenomena are interlaced to muscles cinematic and dynamic performances: on this aspect the research activity is still under development. In particular it is oriented to monitoring the position errors generated by muscles applied in automatic sequences, under different working conditions and to the definition of relationships between the corresponding variables. Hereafter some example of results deduced from the experimentation on the cited test bench are reported.
Fig. 15 compares the error position of a "long" muscle under three different contraction factors (10, 15 and 20%), powered on 20 automatic cycles at pressure of 2 and 6 bar. Increasing pressure the error decreases. Finally, Fig. 16 synthesizes analogous trends for a "short" muscle, powered at pressure of 4 and 6 bar. The error distribution is very different with respect to the previous case, while the effect of the contraction factor on the position accuracy seems to be not particularly significant. These tests have been initially implemented on 200 automatic cycles: moreover, the observed characteristic distribution of the position error is stabilized within the initial 20 cycles.

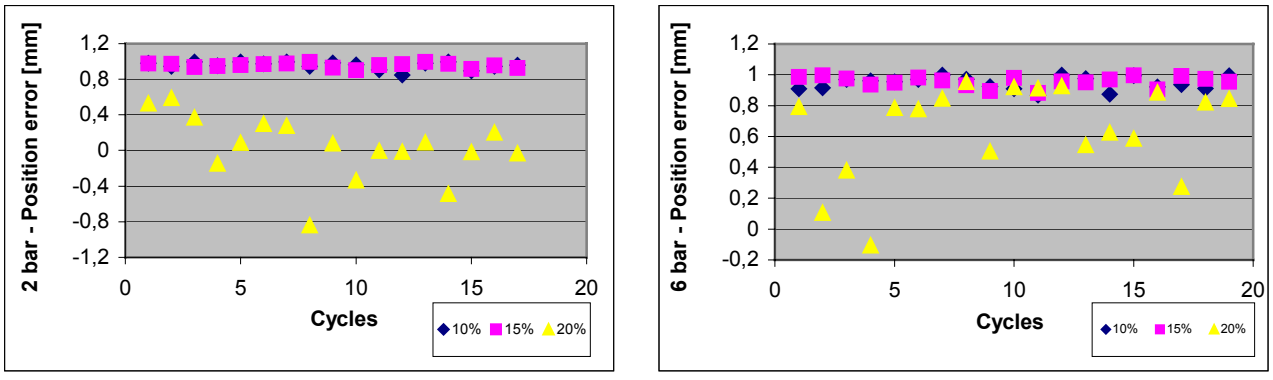

Figure 15. Position error of a "long" muscle, actuated at 2 and 6 bar

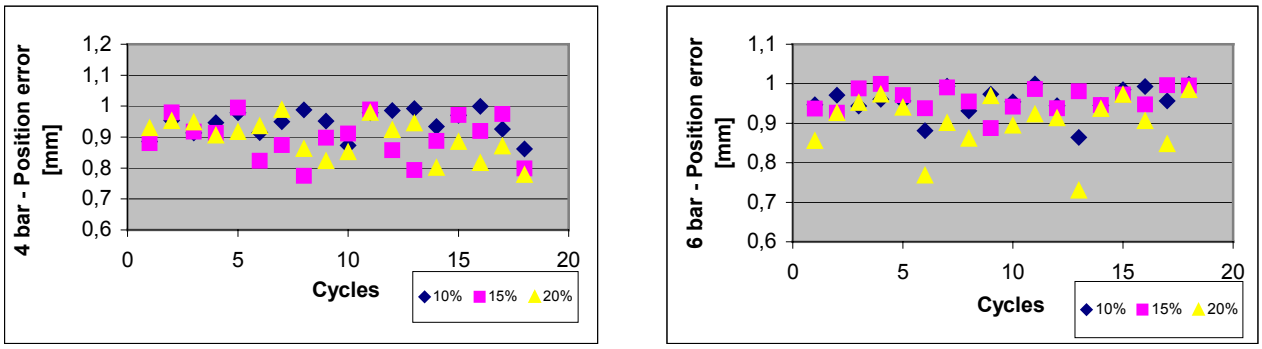

Figure 16. Position error of a "short" muscle, actuated at 4 and 6 bar

CONCLUDING REMARKS

The fluidic muscle is a mechanical device working under variable temperature: that is one of its peculiar operating aspects, very different with respect to other pneumatic components, usually working in quasi-isothermal conditions. A methodical analysis of the thermal behaviour of fluidic muscles has been implemented: monitoring based on not intrusive temperature detection is proposed. Under asymmetrical supply and exhaust "short" and "long" muscles are compared.
The final goal of the present research is the correlation between thermodynamic phenomena and mechanical performances: in this paper only some problems related to the thermodynamics of fluidic muscles have been focussed and described. Comparisons between standard and anomalous thermal distributions seem to be also significant in order to predict equipment troubleshooting and anomalous or failure conditions.

ABSTRACT. Experimental data obtained in a free piston rapid compression machine is presented in this article. The goal of the experiments was to find a relation between the compression pressure in the device and the heat flux out of the compressed gas in order to ultimately provide insight in the energy efficiency of the Pulsed Compression Reactor. A sophisticated surface thermocouple was used to measure the temperature of the cover of a single shot experimental setup. Calculating the heat flux and coupling this result to the measured pressure, a linear, reproducible relation between the pressure and heat flux was found.
From the measurements it could be concluded that as far as the measurement technique is concerned, the data shows that the experimental sensor as well as the analysis method used gives insightful information about the device under investigation. The formation of a cold boundary layer during compression could be observed.

INTRODUCTION

Background

To cope with the tremendous world wide energy losses in the chemical industry, the Pulsed Compression Reactor (PCR) is under development. The principals of this reactor were developed over fifty years ago as can be seen from patents by Brutzkus [1] and the book by Kolbanovskii [2]. Further developments have been achieved by Glushenkov [3]. It promises to be a very compact, economical and energy efficient alternative to conventional chemical reactors used for the most energy consuming high temperature processes. Though it is expected that the PCR is much more efficient than conventional reactors, no real research has been done to ascertain the energy efficiency qualitatively. Two main energy losses from the PCR can be identified: heat losses to the surrounding and pressure losses through the gap along the reactor wall. This article focuses on obtaining a relationship between the heat flux from the hot compressed zone and pressure in the reactor, thus giving some insight into the quantitative heat losses from the reactor.
The PCR is a free piston impulse compression device. It rapidly compresses the reactants by a free piston. Due to the compression the reactants are heated and spontaneously react, similar to a homogeneous charge compression ignition engine. The expansion of the compressed gasses release energy to the piston, which is immediately used to compress the next batch of reactants in a continuous process. The experiments under discussion in this article mimic a single pulse of

compression, investigating the heat transfer effects during this single stroke of compression, without chemical reactions.

Goal of the experiments

Research in the past on heat losses from internal combustion engines has yielded many different empirical relations, relating various parameters, such as temperature, pressure and compression ratio to heat transfer rate [4-11]. This experiment attempts to find such a relation for a free piston compressor, capable of attaining compression ratios well beyond those reached in internal combustion engines. Specifically the relation between the pressure of the compressed gas and the heat flux to the wall is sought after. This relation gives an indication of the deviation of the process from ideal-, adiabatic assumptions. It is also a start to find the quantitative energy efficiency of the pulsed compression reactor. Previous research on the Pulsed Compression Reactor performed by Roestenberg et al. [12], focussed on finding the heat flux from a similar but continuous reactor. The results found here were averaged results over a large series of cycles. This research attempts to find the instantaneous heat transfer during one pulse.

EXPERIMENTAL SETUP

The experimental setup is comprised of a stainless steel cylinder, containing a free-, graphite piston. The cylinder and piston is machined to have a very tight clearance. The motion of the piston is initiated by injecting compressed air into the cylinder below the piston. This is done through an especially designed fast acting valve. This valve, as well as the cylinder with piston is shown schematically in Figure 1. The figure shows the three valve chambers: the lower-, trigger- and launch chamber, the valve shoe, the cylinder, the piston, the upper chamber and the top cover. The lower chamber of the valve is pre-charged with a counter pressure, to push the valve shoe up and hold the valve closed. The launch chamber is then charged with the launch gas. To initiate the process, compressed air is injected into the trigger chamber. The combined pressure of the launch gas and the trigger gas forces the valve down, enabling the launch gas to escape into the cylinder. Immediately as the launch gas escapes, the piston starts to move up, and the valve closes again. As the piston moves up, the gas above the piston is compressed and the temperature and pressure in the upper chamber rise. As the piston passes the outlet ports, the remaining launch gas escapes. During the descent of the piston, the pressure reached below the piston is limited by the presence of a small hole, to dampen the reciprocation of the piston. During the cycle, which lasts in the order of 10ms (depending of the pressures used), the pressures in the different valve chambers as well as in the top chamber are recorded. Also a fast thermocouple integrated in the surface of the upper cover measures and records the temperature of the surface of the top cover.

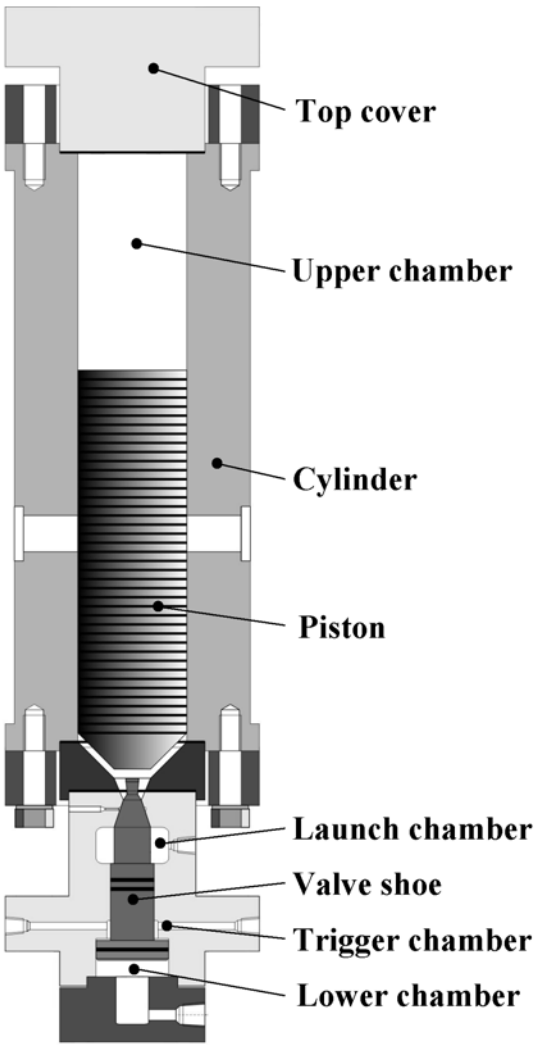

Figure 1. Schematic drawing of the single shot reactor

Measurement techniques

The parameters of interest to be measured are the pressure of the gas and the temperature of the surface of the top cover. The pressure is measured using a fibre optic high temperature dynamic pressure sensor. This sensor, produced by Optrand Inc., measures the pressure by optically monitoring the deflection of a flexing metal diaphragm. The type used was a 20kHz AutoPSI sensor.

To measure the temperature of the surface of the reactor cover, no readily available sensor was found. Instead a thermocouple, designed especially for this purpose, was manufactured. The technique was used before by Oude Nijeweme [13] and Gatowski et al. [14]. The thermocouple consisted of a chromel and a constantane ribbon, each 25µm thick. These were sandwiched between two sheets of mica and separated by a third sheet, each 5µm thick. This sandwich, 1mm wide, was embedded in the material of the reactor cover, running vertically through the cover and protruding on both sides. This is schematically shown in Figure 2. Before use, the inner surface of the thermocouple was grinded with fine sanding paper. This formed micro junctions across the mica between the chromel and constantane sheets, completing the thermocouple circuit. The temperature of the micro junctions could now be measured by measuring the potential difference between the two protruding sheets on the outside of the reactor.

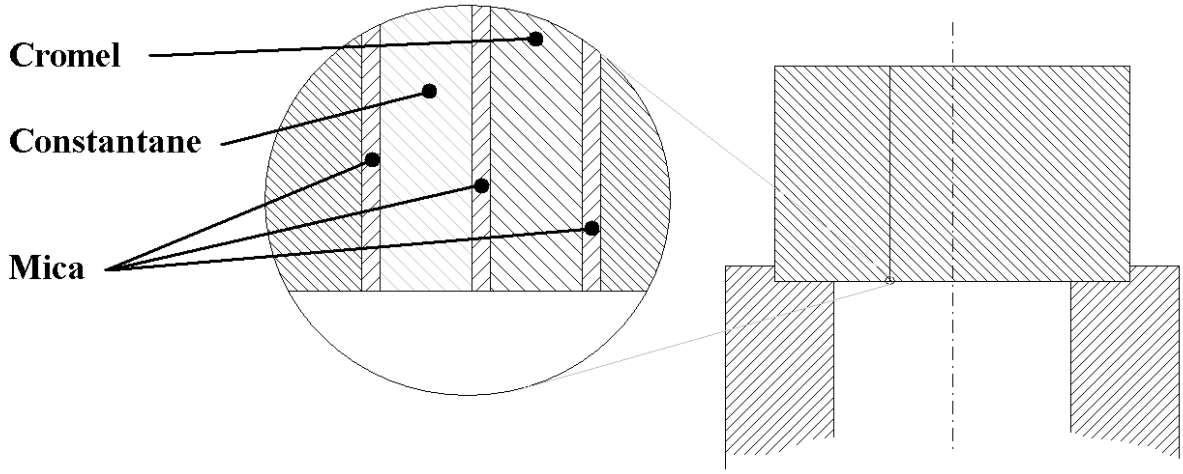

Figure 2. Schematic view of the temperature sensor

DATA ANALYSIS METHOD

The data obtained by the experiment contains some degree of electronic noise. In order to make the data more suitable for data analysis, the data is filtered by means of a fifth order Butterworth low-pass filter, with a cut off frequency equal to one tenth of the sample frequency (for most experiments the sample frequency was 150kHz). This reduced the amplitude of the noise in the measurements significantly enough to make further analysis of the results possible and meaningful.

To analyse the data obtained, and find the heat flux from the compressed gas into the reactor cover, the analytical solution was the solution to the penetration problem into a semi infinite domain with a non constant surface temperature, taken from Hoogendoorn et al. [15], was applied. This solution is shown in equation (1).

$$T(x,t) = \int_0^t \frac{dT_0}{dt'} erfc\left(\frac{x}{\sqrt{4\alpha(t-t')}}\right) dt' \tag{1}$$

The solution is a function of the wall surface temperature T_0. The heat flux into the wall is a function of the gradient of the temperature at the surface.

$$q(t) = -k\frac{\partial T}{\partial x}\bigg|_{x=0} = -\frac{k}{\sqrt{\alpha}}\int_0^t \frac{dT_0}{dt'}\frac{\partial}{\partial x} erfc\left(\frac{x}{\sqrt{4\alpha(t-t')}}\right)\bigg|_{x=0} dt' \tag{2}$$

The derivative of the surface temperature with respect to time that occurs in the equation should somehow be extracted from the measurement data. To apply this equation to the measurement data obtained, the integral in equation (2) is written as a summation of discrete integrals, each over the length of one measurement time step. In this equation, N is the number of samples taken in the measurement, up to time t.

$$q(t) = -\frac{k}{\sqrt{\pi\alpha}}\sum_{i=1}^{N-1}\int_{t_i}^{t_{i+1}} \frac{dT_0}{dt'}\frac{1}{\sqrt{t-t'}}dt' \tag{3}$$

The smaller integrals are chosen such that, from t_i to t_{i+1}, the temperature at the wall is known at the bounds of the integral from the measurement. The gradient of this temperature with respect to time can therefore be estimated for the period within the integral, by linear approximation. This can be solved exact for any time in the measurement, by evaluating all the separate integrals, and carrying out the summation.

$$q(t) = -\frac{k}{\sqrt{\pi\alpha}}\sum_{i=1}^{N-1}\int_{t_i}^{t_{i+1}} \frac{T_{i+1}-T_i}{\Delta t}\frac{1}{\sqrt{t-t'}}dt' \tag{4}$$

By evaluating equation (4) for all measurement times, the heat flux, as a function of time, is calculated for the whole measurement.

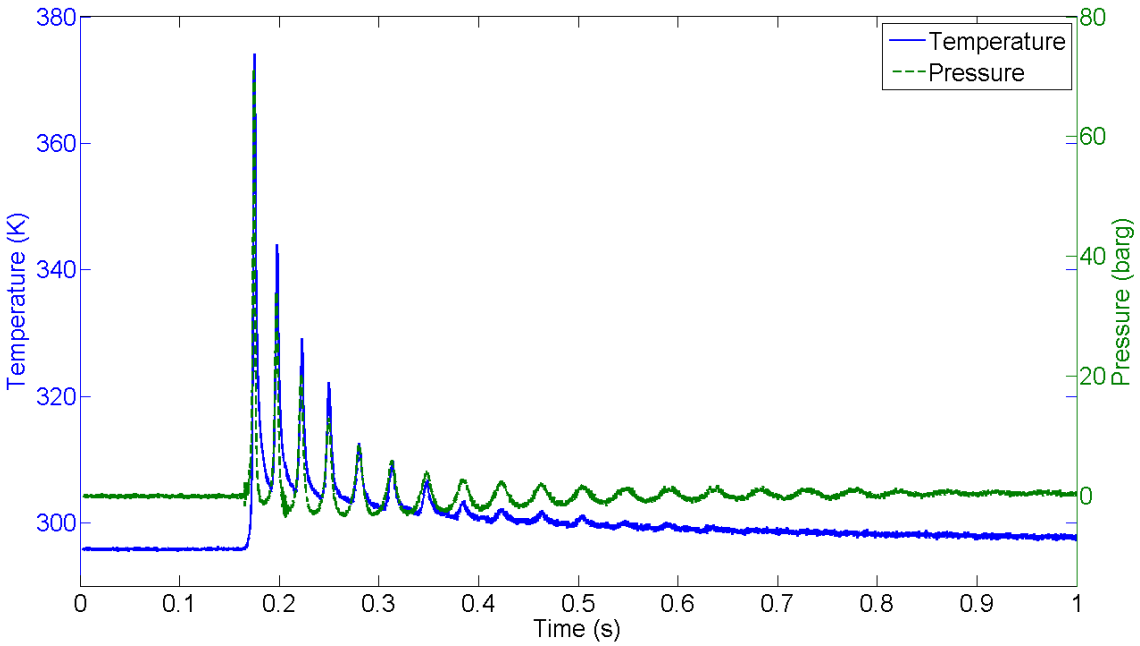

Figure 3. Example of measured pressure and temperature

RESULTS

Data obtained

A series of experiments was performed, at various launch pressures. Experiments were carried out several times for each launch pressure. In Table 1 the different launch pressures used, their respective average peak pressure and temperature are indicated. Additionally the maximum deviation from the measured average is shown. The result of the measured pressure and the measured surface temperature of one of the experiments is shown in Figure 3. It is clear that though real "single shot" behaviour is not attained, the reciprocations of the piston are heavily dampened. In Figure 4 the first peak of the experiment is zoomed in upon. There is a small phase shift between the pressure peak, and the temperature peak. Because of the walls thermal inertia, the surface temperature does not follow the gas temperature directly. When the gas is already cooling down, it's temperature is still higher than that of the wall, and heat is still flowing to the wall. Thus the peak wall temperature is reached as the gas is already cooling.

Table 1
Experimental results

Launch pressure (barg)	Average peak pressure (barg)	Max. deviation from average (bar)	Peak wall temperature (K)	Max. deviation from average (K)
40	71	1.0	373	1.4
60	144	2.0	417	7.1
80	230	6.5	471	9.1

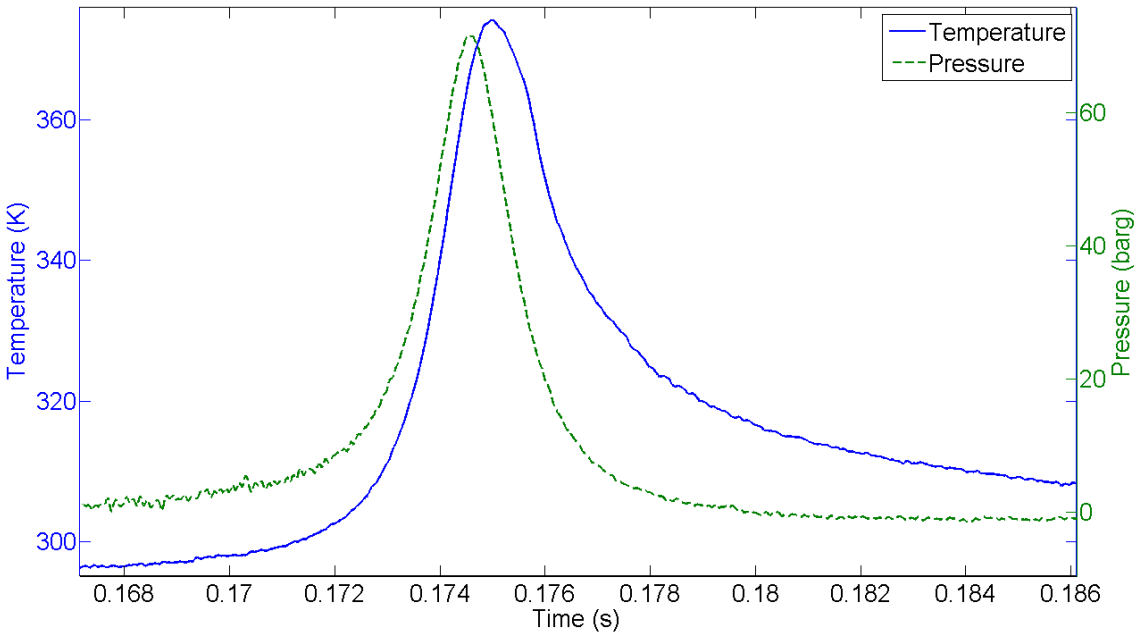

Figure 4. Example zoomed in on first peak

Results by post-processing

When the analysis method described earlier is applied to the data obtained, the heat flux can be calculated. In Figure 5 the calculated heat flux is plotted against the measured pressure, for the same experiment as in Figure 3 and Figure 4. From this plot a linear relation between the pressure and the

heat flux becomes visible. The heat flux during the compression of the gas is somewhat higher than the heat flux during expansion. The fluctuations that are visible in the result can be made to disappear by using a filter with a lower pass frequency. The downside is that the height of the peaks of the experiment, which are quite sharp, is reduced significantly, influencing the results.
The results of one entire series are shown in Figure 6. It is visible that the same gradient of the P-Q line is found, irrespective of the pressure reached. From this figure, also another interesting feature appears. During the down stroke, all measurements show a sudden dip in the heat flux, to the negative side, around 30 barg. While when looking at a single measurement one might think that this is caused by noise or calculation error, it becomes clear looking at Figure 6, that it does in fact occur every experiment, and for experiments with the same peak pressure, also around the same point during expansion.

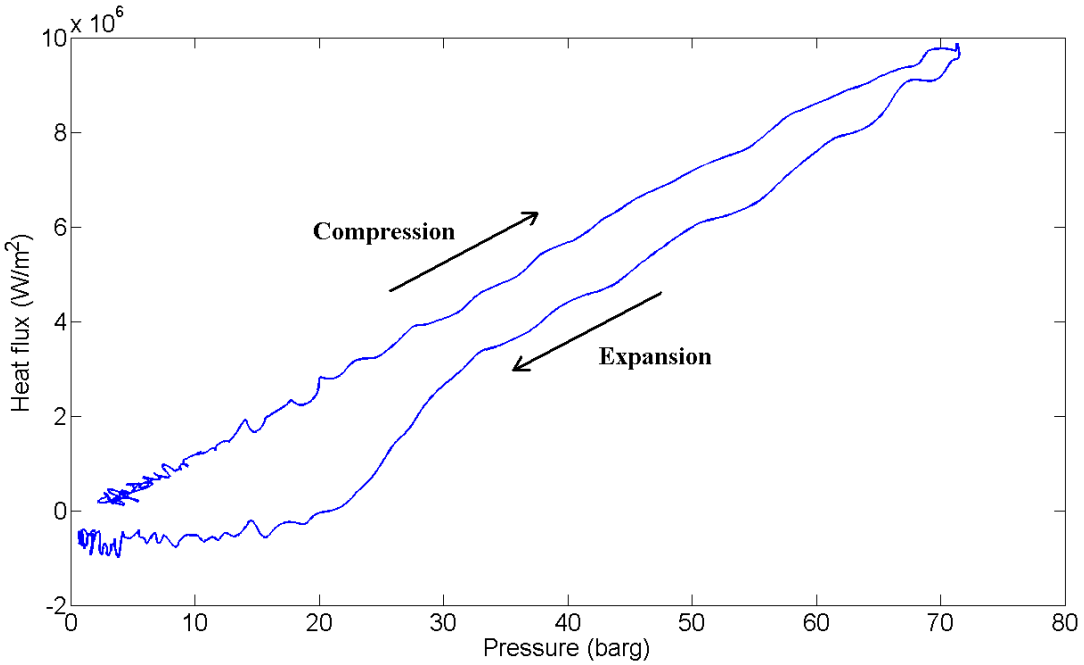

Figure 5. Plot of calculated heat flux against measured pressure

CONCLUSIONS AND DISCUSSION

From the data obtained several conclusions can be drawn. Firstly, as far as the measurement technique is concerned, the data shows that the experimental sensor as well as the analysis method used gives insightful information about the device under investigation. Though one question one might ask is whether the sensor does indeed measure the temperature of the surface fast enough to justify the analysis technique. Though this question remains partially unanswered, the following can be reported. During one series of experiments the data produced by the sensor after one test to very high pressure (360 barg, sensor surface temperature over 600 K), the shape of the temperature curves recorded was different than previous experiments. Also subsequent experiments to lower pressures, gave different results than expected and obtained before (measured temperatures were lower, with a larger phase shift, and less of a determined spike). This was attributed to oxidation of the sensor surface during the brief high temperatures, and indeed regrinding of the sensor solved the problem. This might lead one to conclude that, if a minute layer of oxidation does already influence the results so gravely, the sensor does indeed, when in good condition, measure the surface temperature.
Perhaps the most striking feature of the results found is the linearity of the heat flux-pressure relation during the compression stroke. Though the linearity diminishes somewhat for higher launch pressures,

the similarity in results for different pressures is still striking. Since the goal of the experiments was to find a relation between pressure and heat flux, one could argue that the results could hardly have been better. Future research will have to determine the nature of this relation.
The formation and progression of a boundary layer is visible in that the heat flux is slightly lower for the expansion stroke than the compression stroke. This effect becomes more pronounced as higher pressures and, as a result, higher temperatures are reached. This seems logical, since for a bigger temperature difference between the core gas and the wall, the formed boundary layer is more likely to have a more pronounced effect on the heat flux.

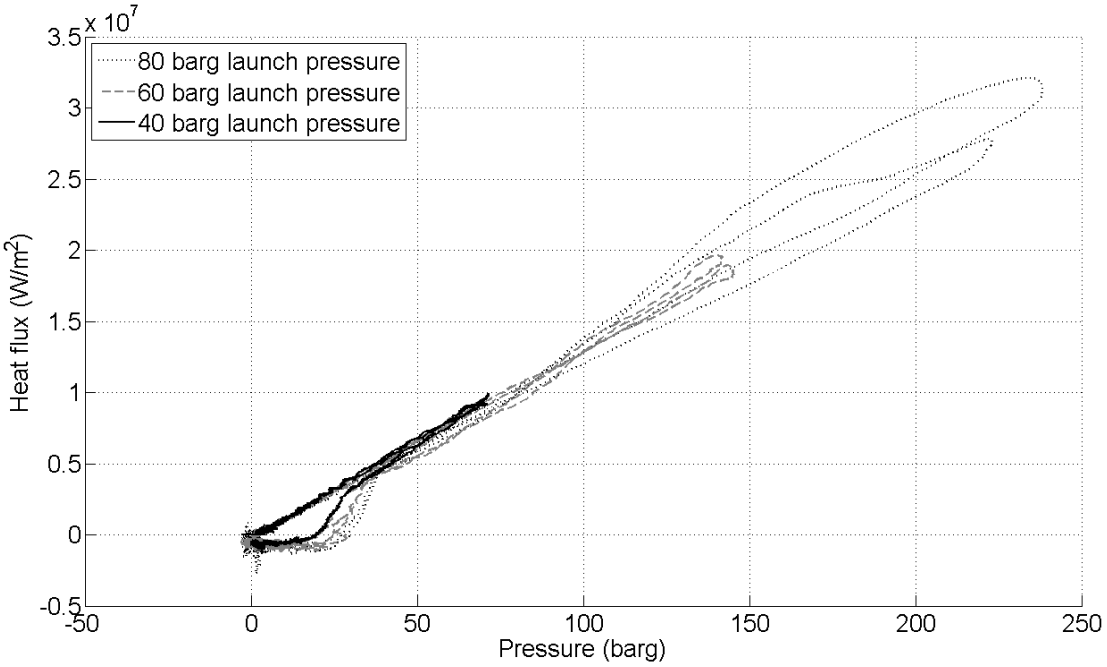

Figure 6. Plot of the results of one series of experiments

The observed sudden dip is also an interesting result for discussions. One possible explanation may be offered (among others) by the work of Annand et al. [5]. In their experiments, which were similar to these, but with a lower pressure, also a rapid drop of the heat flux to below zero was found during the expansion, at a moment where the temperature difference was still positive. This was explained by the following thought experiment. If one considers a compressed gas at 800 K, surrounded by a wall at 400 K, a relatively cool boundary layer, with a temperature between that of the gas and the wall, will rapidly be established. As the gas is then expanded to ambient pressure, the core of the gas will cool to a temperature close to the temperature it had before compression (assuming no chemical reactions took place, and not too much heat was lost). However, the boundary layer will cool to a temperature much lower than that, even lower than that of the wall. This super-cooled boundary layer will introduce negative heat flux towards the wall, well before the core gas temperature is lower, or even equal, to the wall temperature. Since the likelihood of the presence of a boundary layer was already discussed, there is also a very clear possibility of this boundary layer to become super-cooled. Of course, a super-cooled boundary layer occurs only when a high rate of cooling (due to expansion) is present. The occurrence of the sudden dip in heat flux is reasonably near the end of expansion, a moment when cooling rate is highest. Whether this explains the sudden dip in the heat flux remains to be proven.

YIELD STRESS DROPS: CREATION, FREE-FALL AND IMPACT ON A SOLID SURFACE

G. German, V. Bertola*
University of Edinburgh, Edinburgh, United Kingdom

ABSTRACT. The process of drop formation from a capillary needle and its subsequent impact on a solid surface is studied experimentally by high-speed imaging, with focus on drops of viscoplastic or yield stress fluids (i.e., those materials which exhibit a fluid behaviour only when the applied stress exceeds a certain threshold value, called yield stress), and compared to the behaviour observed in Newtonian drops. The yield stress of the fluid is shown to alter significantly the detachment process, the drop shape during free-fall, and the impact morphology. The results can be interpreted in terms of a dimensionless number comparing the yield stress magnitude and the capillary pressure.

Keywords: *Drops, Yield stress, Bingham fluid, Capillary break-up, Drop impact*

INTRODUCTION

The creation of a liquid drop falling by gravity, and the subsequent impact on a solid surface, are common phenomena in Nature as well as in several industrial applications, and extensive literature can be found about them [1,2]. Examples of applications are spray painting and cleaning, inkjet printing, pesticide distribution, spray cooling and firefighting devices, fuel atomisation in internal combustion engines, fabrication of micro-lenses, and many others [3].

As it is well known, the behaviour of a drop after collision with the surface is complex, and depends both on the characteristics of the drop and on those of the surface. In all cases, during the first few milliseconds after making contact with the surface, the drop spreads creating a disc-shaped liquid layer called lamella. Subsequently, the lamella retracts, and its behaviour is essentially determined by the competition between inertial forces (depending on the drop kinetic energy) and capillary forces (depending on the surface tension). The relevant dimensionless numbers during the impact and the expansion phase are the Weber number, defined as $We = \rho D_0 u^2 / \sigma$, and the Reynolds number, $Re = \rho D_0 u / \eta$, where ρ is the fluid density, D_0 the drop equilibrium diameter, u the impact velocity, η the fluid viscosity, and σ its surface tension. These numbers express the ratios between inertia and capillarity and between inertia and viscous dissipation, respectively. Sometimes, viscous dissipation is taken into account using the Ohnesorge number, $Oh = \sqrt{We} / Re$. During the retraction phase there is a competition between viscous dissipation and capillarity, expressed by the capillary number, $Ca = u_R \eta / \sigma$, where the impact velocity is replaced by the retraction velocity of the lamella, u_R.

Although most applications involve Newtonian fluids, in the past decade the study of non-Newtonian drops has been attracting a growing interest [4-7]. While these works focus on the effect of viscoelasticity on impacting drops, obtained by dissolving small amounts (of the order of 100 ppm) of flexible polymers into a Newtonian solvent, the study of the so-called viscoplastic or yield stress fluids has received a comparatively little attention [8]. Such fluids respond like elastic solids for applied

stresses lower than a certain threshold value, which is called the yield stress, and flow only when the yield stress is overcome. A well-known constitutive equation for yield stress fluids is provided by the Herschel-Bulkley model [9], which can be written in the form:

$$\tau = \tau_0 + C\dot{\gamma}^n \tag{1}$$

where $\dot{\gamma}$ is the shear rate, τ_0 is the yield stress, and C and n are constants. For $n = 1$ equation (1) reduces to the Bingham model [10]. A more accurate description of the yield stress fluid phenomenology can be achieved through advanced rheophysical models [11].

The aim of this work is to investigate the morphology of drops of a model yield stress fluid detaching by gravity from a capillary needle and impacting onto a solid surface. A previous study on vaseline drops impacting on a plexiglass surface [8] shows that the fluid yield stress can prevent the formation of spherical drops, and relates the maximum spreading diameter of the lamella to the yield stress magnitude through the Bingham number, $Bm = \tau_0 D_0 / \eta u$. However, this analysis remains somewhat qualitative, and completely neglects capillarity. Here, the whole process of drop formation by capillary instability, free fall, and impact on surfaces of different wettability is studied, attempting at isolating the effects of the yield stress from those of viscosity and shear-thinning. The results can be interpreted by introducing a dimensionless number that compares the yield stress and the capillary pressure, which was previously introduced to characterise the flow of a gel in capillary tubes [12].

EXPERIMENTS

Fluid characterisation

Model yield stress fluids were prepared using a water-based polymer gel (commercial hairdressing gel). The typical composition of these gels includes a blend of water, alcohol, silicones, glycerine, surfactants, and other polymers. In order to change the value of the yield stress in a continuous fashion, the gel was diluted into de-ionized water at different concentrations (five solutions with mass fractions of 0.2, 0.25, 0.3, 0.35 and 0.4). The solutions were mixed slowly in a container to avoid the formation of bubbles, left to settle for 24 hours and then thoroughly mixed to ensure homogeneity using a magnetic stirrer.

The yield stress of these model fluids was measured by means of a Haake MARS rotational rheometer, equipped with a plate–plate sensor having a diameter of 35 mm and a gap of 1 mm. Sandpaper was glued on both the rotating an the fixed surface in order to avoid wall slip effects. The yield point of each solution was determined by imposing a stress ramp (100 points in 300 s) on the fluid sample, and measuring the angular displacement of the rotating plate.

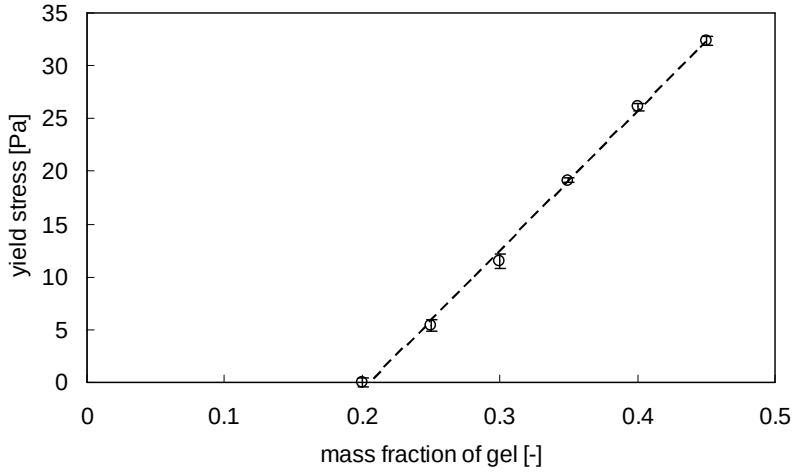

Figure 1. Measured yield stress of the model fluid as a function of the gel concentration.

For small values of the stress, the sample behaves like a solid and has a little deformation; when the stress grows beyond a critical value, the sample starts flowing and therefore the angular displacement of the disk grows indefinitely at a faster rate. The crossover of the two straight lines interpolating the deformation-stress curve in a log–log scale before and after its bending point defined the yield point. The results are reported in figure 1, which shows that the yield stress is a linear function of the hair-gel mass fraction. Apparent viscosity measurements obtained by controlled shear rate tests in the shear rate range $0 < \dot{\gamma} < 100$ s^{-1} reveal a shear-thinning behaviour, which was fitted using the Herschel-Bulkley model (equation 1).

The equilibrium surface tension of the fluids was measured with a Kruss EasyDyne tensiometer equipped with a De Nouy ring. Since the sensor displacement is imposed, this method is not affected by the yield stress of the fluid: in fact, the measured surface tension was 34 ± 2 mJ/m^2 for all solutions, in good agreement with the value measured for aqueous solutions of polysorbate 20 surfactant (which is a component of the gel) above the critical micellar concentration (c.m.c. = 36 mJ/m^2) [13]. Dynamic surface tension effects, which may be important due to the short timescale of drop impacts (typically ~5 ms), were not considered because at concentrations above the c.m.c. several surfactant molecules are available in the bulk fluid, so that the migration time for the surfactant molecules to reach the newly created surface during the lamella spreading can be neglected.

Experimental setup and procedure

The experimental setup is schematically shown in figure 2. Drops were created at the tip of a 0.838 mm i.d. (gauge 18) hypodermic needle with flattened bevel by a screw-driven syringe dispenser, and detached under their own weight. In order to change the impact velocity, the dropping height was adjusted using a Vernier height gauge with a precision of ±0.01 mm. The needle was centered over an aluminium square block (40 mm x 40 mm) upon which different substrates could be placed. In particular, impacts on a hydrophilic clean glass surface were compared to impacts on a hydrophobic Parafilm-M surface (equilibrium contact angle with water $\theta_e = 95^o \pm 2^o$).

A high-frame rate CMOS camera (Mikrotron MC1311) equipped with a 18-108/2.5 macro zoom lens (Navitar Zoom 7000) and horizontally aligned with the surface recorded the impacts of single drops. Back-to-front illumination was provided by a fluorescent lamp equipped with light diffuser, which ensured a uniform illumination intensity, and images with a resolution of 720×512 pixels were captured at 1000 frames per second. Magnification was kept constant throughout all experiments and lengths on the image could be calculated by comparison with a reference length (maximum spatial resolution: 33 μm). To ensure a fine optical alignment, the camera, the heated surface and the backlight were fixed to an optical breadboard.

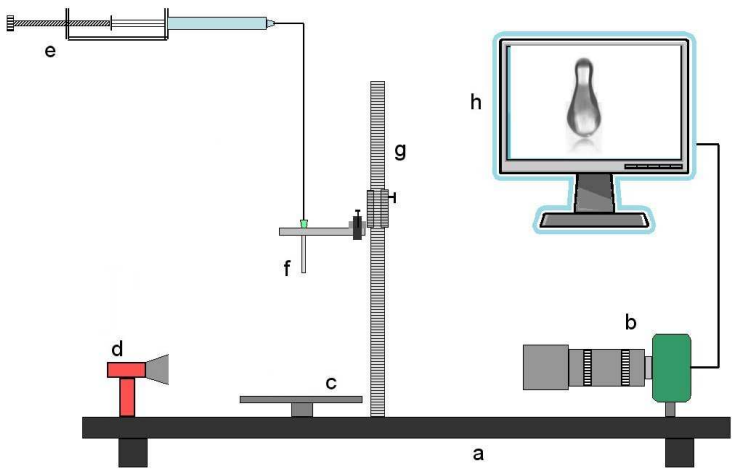

Figure 2. Experimental apparatus: (a) optical breadboard; (b) high-speed camera with zoom lens; (c) impact surface; (d) LED light; (e) dispenser; (f) needle; (g) height gauge; (h) data acquisition system.

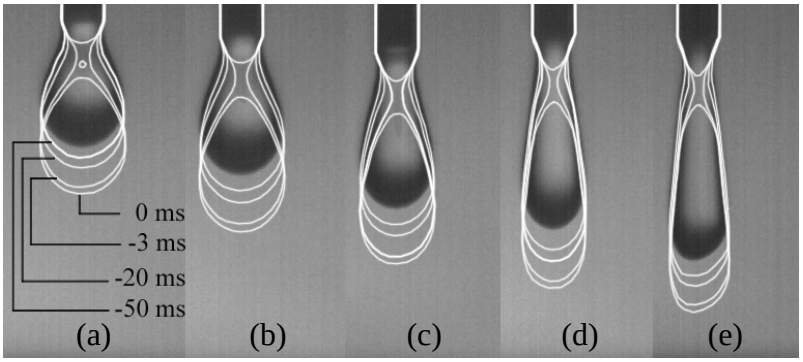

Figure 3. Shape of viscoplastic drops during detachment, for τ_0 = 0 Pa (a), τ_0 = 5.4 Pa (b), τ_0 = 11.5 Pa (c), τ_0 = 19.1 Pa (d) and τ_0 = 26.1 Pa (e). The origin of times corresponds to the drop pinch-off.

Drop weight measurements made with a precision balance (Mettler Toledo MT100) allowed calculation of the equivalent drop diameter at equilibrium, $D_0 = \sqrt[3]{6m/\pi\rho}$. Statistical measurements over 50 samples showed that the diameter is a linear function of the gel concentration in the fluid, x:

$$D_0 = 3.059 - 1.222x \tag{2}$$

The impact velocity was measured from digital images of falling drops. For small distances of the dispensing needle above the impact surface ($H \leq 15$ cm), it was found to be identical to the theoretical free-fall velocity, $u = \sqrt{2g(H - D_0)}$. Drop impacts were studied for fall heights between 7.5 and 200 mm, corresponding to a range of Weber numbers between 1 and 350.

RESULTS

Drop creation and free-fall

The process of drop formation when the fluid is released very slowly from a nozzle is well understood for Newtonian fluids (see e.g. [14]), and depends on the balance between capillarity and gravity. Drops take a spherical shape to minimise the surface energy, and fall by gravity when the liquid filament that connects them to the nozzle becomes unstable and breaks up. The pinch-off causes free oscillations of the drop during free-fall, which are dampened down by viscosity until the equilibrium spherical shape is retrieved.

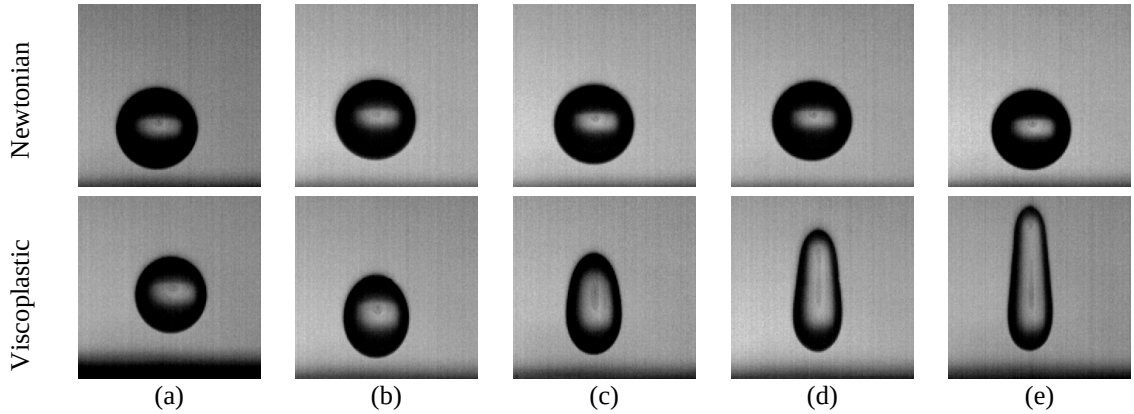

Figure 4. Comparison of Newtonian drops (glycerol solutions) with viscoplastic drops of increasing yield stress during free-fall. (a) η = 0.056 Pa·s, τ_0 = 0 Pa; (b) η = 0.213 Pa·s, τ_0 = 5.4 Pa; (c) η = 0.428 Pa·s, τ_0 = 11.5 Pa; (d) η = 0.631 Pa·s, τ_0 = 19.1 Pa; (e) η = 0.925 Pa·s, τ_0 = 26.1 Pa.

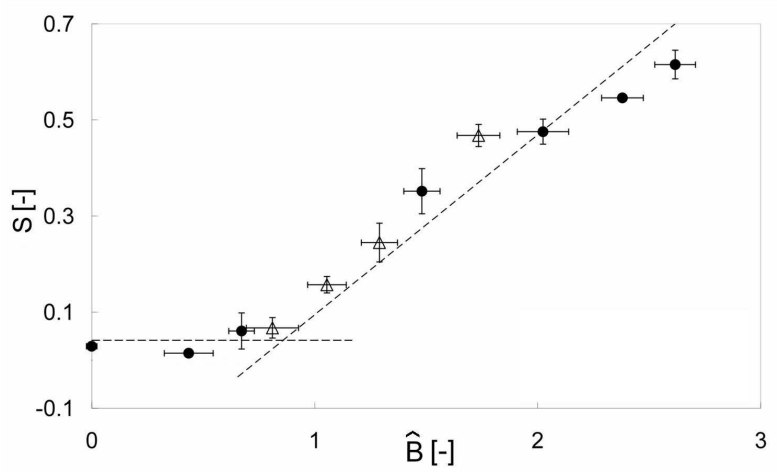

Figure 5. Shape factor as a function of the Bingham-capillary number.

The morphology of viscoplastic drops differs significantly from that of Newtonian drops. In particular, drops of yield stress fluids take a prolate shape as they are released from the nozzle, as shown in figure 3. This behaviour can be observed when the yield stress magnitude is greater than a certain value (in this case 11.5 Pa), which however may vary [8,15].
The prolate shape is conserved during free-fall as shown in figure 4, which compares Newtonian drops of different viscosities (obtained from water-glycerol solutions of different concentrations) and viscoplastic drops of increasing yield stress. While Newtonian drops always reach a spherical shape to minimise surface energy irrespective of the fluid viscosity, this does not happen in viscoplastic drops when the fluid yield stress overcomes the Laplace pressure.
To characterise the drop shape during free-fall one can introduce the following shape parameter:

$$S = \frac{H - D}{H + D} \tag{3}$$

where H and D are the drop dimensions in the vertical and the horizontal directions, respectively. Thus, $S = 0$ corresponds to spherical drops, while prolate shapes are characterised by $S > 0$. The competition between the capillary pressure and the yield stress can be represented in terms of the product of the Bingham and the capillary numbers, where the characteristic length scale is the equivalent diameter D_0:

$$\hat{B} = \frac{\tau_0 D_0}{\sigma} \tag{4}$$

This dimensionless group arises naturally, for example, from the analysis of the flow of a yield stress liquid inside capillary tubes [12].
Figure 5 displays the shape factor S as a function of the Bingham-capillary number, $\hat{B}$, showing a transition around $\hat{B} \approx 1$, where surface tension forces equal those arising from fluid-yield stress. For values of $\hat{B} < 1$, representative of drops whose capillary pressure exceeds the fluid yield-stress, the equilibrium free-fall shapes are spherical. For values of $\hat{B} > 1$, representative of fluid drops in which the yield-stress is higher than the capillary pressure, the equilibrium drop shape will be non-spherical, with a shape factor increasing as a linear function of the Bingham-capillary number.

Drop impact
Figure 6 shows image sequences describing the impact of viscoplastic drops on a Parafilm-M surface, for different values of the yield stress. Upon impact, drops take the shape of a disk spreading on the substrate. However, for the higher values of the yield stress, a peak can be observed in the centre of the lamella even at maximum spreading. This feature is enhanced at low Weber numbers.

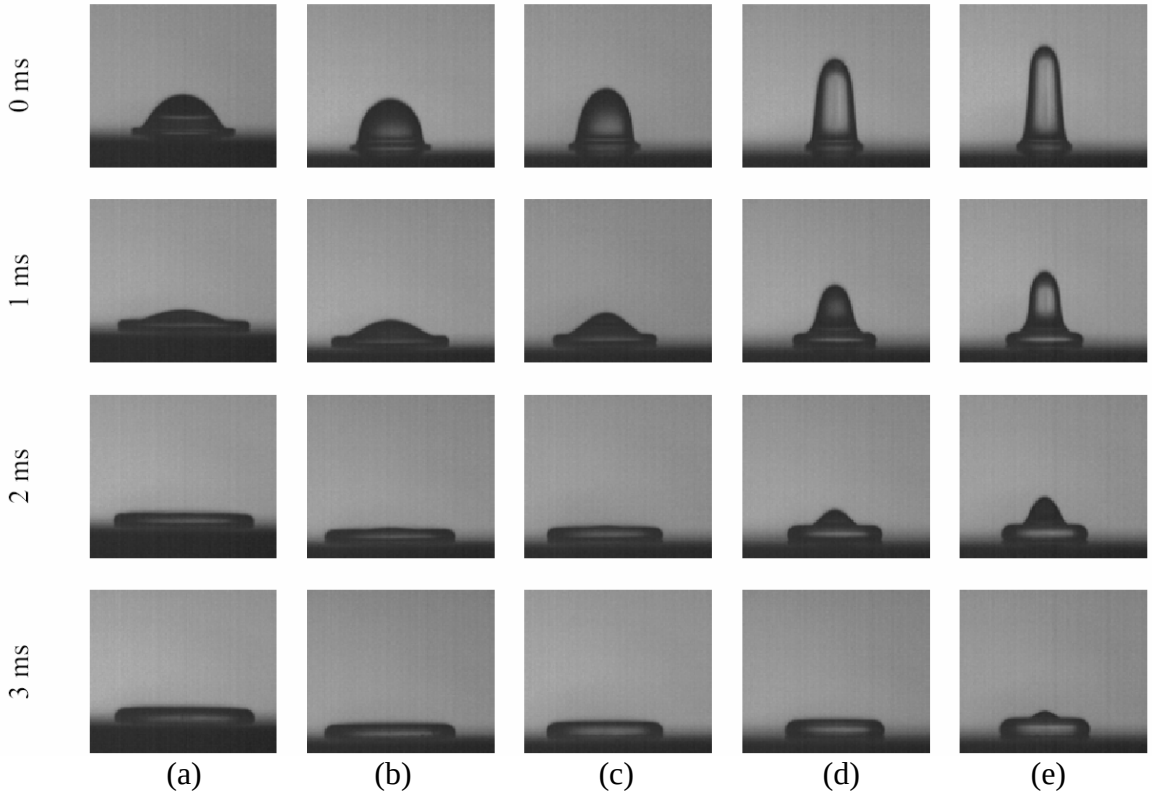

Figure 6. Impact morphology of viscoplastic drops (falling height: 100 mm), for τ_0 = 0 Pa (a), τ_0 = 5.4 Pa (b), τ_0 = 11.5 Pa (c), τ_0 = 19.1 Pa (d) and τ_0 = 26.1 Pa (e).

To study the influence of the surface wettability on the inertial spreading of viscoplastic drops, the maximum spreading diameter, D_{Max}, was measured for drops impacting on parafilm and glass substrates, which have different surface energies. Over the range 0 < We < 350, the results closely agree, with differences that fall within the experimental error, as shown in figure 7.

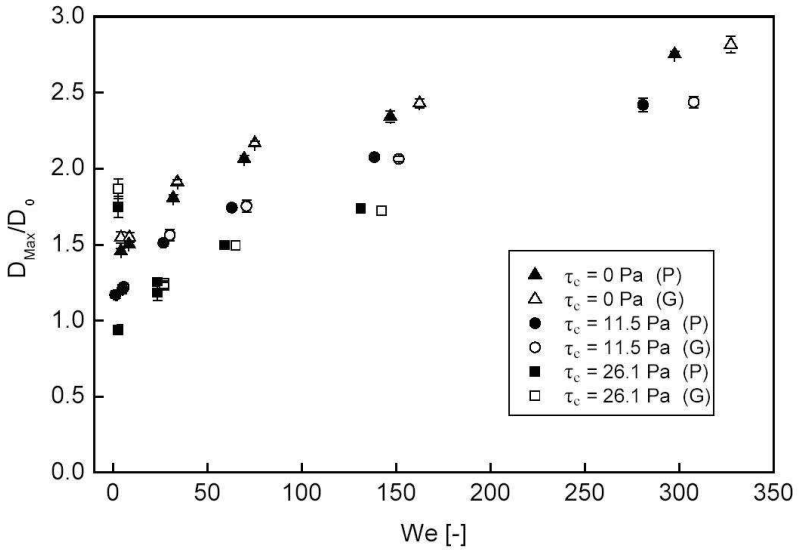

Figure 7. Maximum spreading diameter of viscoplastic drops impacting on glass (filled symbols) and Parafilm-M (open symbols) substrates, for different values of the yield stress.

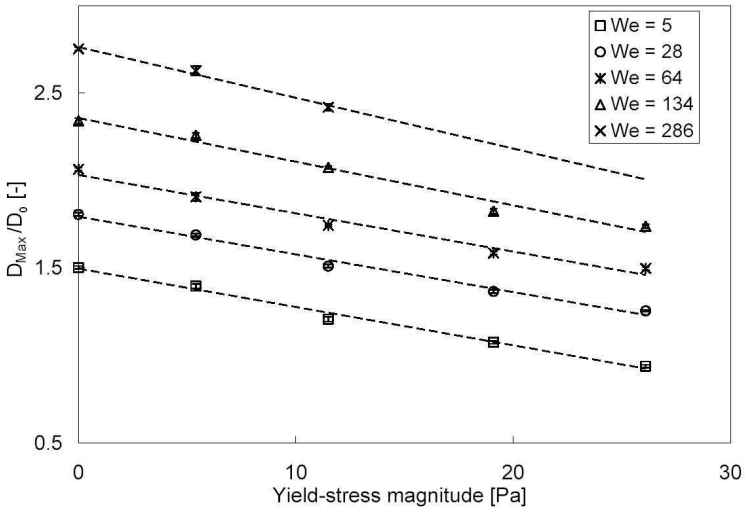

Figure 8. Maximum spreading diameter of viscoplastic drops impacting on a Parafilm-M substrate as a function of the fluid yield stress. The dashed lines correspond to the linear least square best-fit.

The maximum spreading diameter of viscoplastic drops is plotted in figure 8 with respect to the yield stress magnitude, for different Weber numbers. These values are systematically lower than those obtained with Newtonian fluids of the same apparent viscosity in the same range of Weber numbers [16]. The maximum spreading diameter decreases linearly with the yield stress; however, these results may include potential effects of shear-thinning, which have not been taken into account. It is not possible to establish the independent influence of yield-stress on impact dynamics directly from the experimental results because the viscometric behaviour of the shear-thinning and yield-stress solutions differ, therefore a like-with-like comparison cannot be made.

CONCLUSIONS

Systematic experiments show that drops of viscoplastic fluids exhibit peculiar behaviour during free-fall after detachment and when impacting on solid surfaces. Unlike Newtonian, viscoelastic and shear-thinning fluids, which assume a spherical equilibrium drop shape during free-fall, viscoplastic fluid drops may have a non-spherical equilibrium shape, with an aspect ratio that varies as a function of the yield stress. This relationship could be characterised by a dimensionless number which is the product of the Bingham and the capillary numbers, and represents the ratio of the Laplace pressure (which acts to minimise the surface energy) to the yield-stress. In drops where the Laplace pressure exceeds the yield-stress a spherical equilibrium drop shape is obtained; otherwise drops are prolate, and their aspect ratio grows linearly with the yield stress in the explored range of experimental parameters.
The inertial spreading of drops after impacting on a solid surface does not seem to be affected significantly by the surface wettability. The maximum spreading diameter appears to be smaller than that of Newtonian drops of the same viscosity and Weber number, however a direct quantitative comparison is difficult because one should also take into account the potential effects of shear thinning.
At the end of the expansion phase, the fluids with the higher yield stresses exhibit peaks at the centre of the lamella. This suggests that the drop deformation is localised in the external part, while the central part remains undeformed because the stress is smaller than the yield point of the fluid.

THREE DIMENSIONAL EFFECTS IN INCLINED FILM FLOWS

V. Leontidis[1], M. Vlachogiannis[2], N. Andritsos[1], V. Bontozoglou[1,*]

ABSTRACT. The characteristics and spatiotemporal evolution of free surface structures in inclined film flows are studied using the fluorescence imaging technique. Particular emphasis is placed on the effect of channel width, a parameter that has not previously been considered. Nominally two-dimensional solitary humps are observed to develop a curved crestline and a transverse variation of wave height. The relation between height and phase speed is shown to be always linear and to depend strongly on channel inclination and width. The critical Re for transition to a fully three-dimensional free surface is determined, and two alternative transition scenarios are identified, one active for small inclinations and low viscosity liquids and the other active for higher inclinations and/or viscous liquids.

Keywords: *inclined film flow, wall effect, three-dimensional waves, curved solitary waves*

INTRODUCTION

Today there is large amount of experimental and theoretical/numerical evidence that the spatiotemporal dynamics of gravity-driven film flows at low and intermediate Reynolds number is dominated by localized free surface structures separated by relatively long stretches of substrate, known as solitary waves [1]. Solitary waves consist of an asymmetric hump, with steep front and gently sloping tail, preceded by capillary, front-running ripples. These waves can occur either naturally, if the film is triggered only by random noise, or artificially by imposing a constant-frequency disturbance. The wave characteristics are the same in both cases; only in the latter the wave-train is more regular.

Theoretical/computational efforts treat this first nonlinear stage of development as a two-dimensional phenomenon, and focus on: (a) the prediction of the relation between wave height and phase velocity [2], and (b) the understanding of the interaction between neighboring humps [3]. A subsequent stage of flow development with increasing Re is the deformation and break-up of the crestline by three-dimensional effects.

Concerning problem (a), the relation between wave height and phase velocity, it is well known from the theoretical literature that the proper scaling involves the substrate thickness, h_{sub}, and the mean substrate velocity, u_{sub}. Using this scaling, Tihon et al. [4] confirmed experimentally the linear relation given in Equation (1). The constant term, which is equal to 3, corresponds to the linear phase velocity, i.e. the velocity of waves of infinitesimal height.

$$\frac{c}{u_{sub}} - 3 \approx 1.8 \frac{h_{max} - h_{sub}}{h_{sub}} \qquad (1)$$

Concerning problem (b), hump interaction and three-dimensional evolution, an overview has recently been provided by Demekhin and coworkers [5]. More specifically, these authors proposed that for vertically falling liquid films five possible wave regimes exist, depending on Re. The first regime is dominated from linear stability theory, which predicts that the primary instability occurs at zero Re, but for $Re<Re^{(1)}$=3-5 the instability is too week and the film appears visibly flat. The second regime, $Re^{(1)}<Re<Re^{(2)}$=40, is characterized as two dimensional and the waves are almost sinusoidal in the beginning and solitary at the end of the interval. They can be disturbed by transverse perturbations resulting in solitary waves with curved fronts, but they retain the main properties of 2D solitary waves and the film height across the crest-line is constant. In the third interval, $Re^{(2)}<Re<Re^{(3)}$=400, the 2D solitary waves become unstable to spanwise disturbances and brake-up into 3D structures. The main shape of the waves is horseshoe-like solitons ('Λ waves') with round fronts at the begging and pointed structures at end of the regime. The fourth interval, $Re^{(3)}<Re<Re^{(4)}$=800-1500, consists of large 2D roll waves, which have arise from the coalescence of the 3D waves. Finally, for $Re>Re^{(5)}$ the usual turbulence occurs. It is expected that for inclined film flows the observed flow regimes to be the same, but the transitions to occur in different Reynolds numbers depending on inclination angle.

Despite the above idealized transition sequence, experiments indicate that solitary waves in channels of finite width are always 3D in the sense that their crestlines are curved in the transverse direction [6]. Though this characteristic has been blamed as responsible for discrepancies between wave height measurements and predictions [5], it appears not to have been systematically investigated. Furthermore, the mechanism of the subsequent break-up of the crestline is not fully understood, neither is the effect of liquid properties and channel inclination angle. Last but not least, the possible dependence of the above phenomena on the width of the channel has not been questioned. Thus, the present work focuses on the experimental investigation of the detailed characteristics of waves -starting from the nominally 2D regime- with particular emphasis on the effect of channel width.

EXPERIMENTAL DESCRIPTION

Experimental apparatus

The facility where the experiments were carried out is represented in Figure 1. The main parts of the apparatus (flat wall and side walls) are made of glass. The length, L, of the channel is 3 m and the maximum width, W, 0.45 m. Installing long stripes of glass on top of the wall the channel width could be reduced. In the present work the studied widths were 0.25, 0.35 and 0.45 m. The inclination angle, φ, was varying between 3^o and 15^o. In order to disturb the liquid film and impose a disturbance of certain frequency, f, a timer-controlled on/off electro-valve was used. The frequency of the imposed disturbance was 0.5, 1 and 2 Hz. The working fluids were tap water and aqueous solutions of glycerol, with concentrations of 20-40% by weight. The viscosity of the water-glycerol solutions was determined by measuring the refractive index with a refractometer.

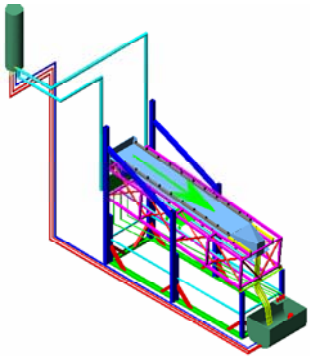

Figure 1. Sketch of the experimental apparatus

Fluorescence imaging method and image analysis

In order to obtain spatiotemporal measurements of the film thickness the fluorescence imaging technique was used, which has been developed by Liu and coworkers [8]. This method has been applied in a similar but smaller channel and has been described in details in a previous work [9]. The working fluid is being doped with a small concentration of dye (200-300 ppm of sodium salt of fluorescein-$C_{20}H_{10}O_5Na_2$) and the film fluoresces under ultraviolet illumination. Using a shuttered high-resolution black and white CCD camera and a monochrome frame grabber board we acquire and digitize images (576×768 pixels with 8-bit of resolution). In all experiments each frame corresponds to a 110 mm×147 mm window of channel area, with the 110 mm to be in the transverse direction. The CCD camera has been placed under the channel approximately 2.5 m from the inlet. Image processing is accomplished using the MATLAB® software. Generally, each photo frame is being transformed into a two dimensional matrix (576×768 elements) contained the film height in the streamwise and transverse direction.

EXPERIMENTAL RESULTS

Flow regimes

Three distinct flow regimes have been observed during the experiments, and these are depicted in Figure 2. For small Reynolds numbers the flow is stable to any disturbances. Figure 2 includes both the classical theoretical prediction, $Re_{cr,th}=5/6\cot\varphi$, and the experimentally determined critical Re. It is noted that prediction and experiment disagree, and the deviation increases at smaller inclinations. As we show in a different study [10], the deviation is the effect of finite channel width. Thus, narrow channels and small inclinations significantly stabilize the flow.

Beyond the critical Re, the flow develops travelling waves. This should ideally be a two-dimensional (2D) regime, but the waves actually observed are not rigorously 2D because their crestlines are symmetrically curved around the channel center plane and because the wave height varies in the transverse direction. The last curve in Figure 2 corresponds to the transition to fully three-dimensional (3D) flow. The 3D transition may proceed through the development of small-scale structures and/or the disintegration of the main crestlines. The eventual outcome of the 3D transition is the establishment of a chaotic distribution of 'horse-shoe' waves. The rest of the paper describes the main characteristics of the curved 2D solitary waves and the evolving 3D structures.

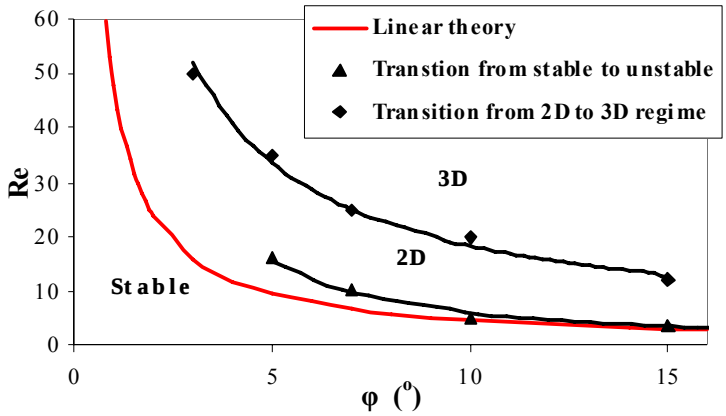

Figure 2. Flow regimes for W=250 mm

Curved 2D solitary waves

As already mentioned, the solitary waves are not fully two-dimensional. Measurements of the maximum local wave height across the crestline are shown in Figure 3, and indicate that the film thickness varies in the transverse direction, with maximum in the channel center plane and minimum near the side walls. With increasing Re, the difference in wave height between walls and center plane increases and the variation becomes steeper and is located closer to the walls. It is also observed that the wave height near the walls appears to be independent of Reynolds number.

The shape of the crestline of these nominally 2D solitary waves is symmetrically curved around the channel center plane. A typical example is shown in Figure 4, where colors represent iso-elevation contours. It is also observed from the figure that the wavelength of capillary ripples varies across the channel, and as expected is smaller at the center where the solitary hump is steeper.

Our observations indicate that the shape of fully-developed waves is always satisfactorily approximated by a parabola. Thus, the deviation from straight-crested dynamics is presently characterized by the curvature, k, at the apex of the parabola. The variation of curvature with Re is shown in Figure 5 for a large number of experiments corresponding to different liquid viscosities, and channel inclinations and widths. A universal trend is the decrease in curvature with Re, i.e. the higher the Re the flatter the wave. A similar effect is observed with channel width (open and filled triangles), indicating that the genuine 2D limit is approached by wide channels and high Re. Additionally, a comparison of the filled symbols shows that, at constant Re, curvature decreases with the increase in viscosity. This can be attributed to the second dimensionless number characterizing the flow, which also includes the effect of surface tension, σ. A popular choice that is only function of physical properties is the Kapitsa number, $Ka=\sigma/\rho g^{1/3}\nu^{4/3}$. Finally, higher inclinations are also observed to lead to sharper waves (compare open triangles and squares).

The above characteristics of fully-developed waves are better understood by observing their evolution with fetch. Indeed, at short distance from the entrance, disturbances appear as 2D. The subsequent change in shape may be explained by noting that the side walls locally provide resistance to wave growth, both because of viscous effects and contact-line hysteresis. Given the well-documented direct relation between wave height and phase velocity, it is expected that this side-part of the wave crest will tend to be left behind, leading gradually to a curved wave. The transverse curvature contributes a capillary force that decelerates the central part of the wave, eventually resulting in a fully-developed profile.

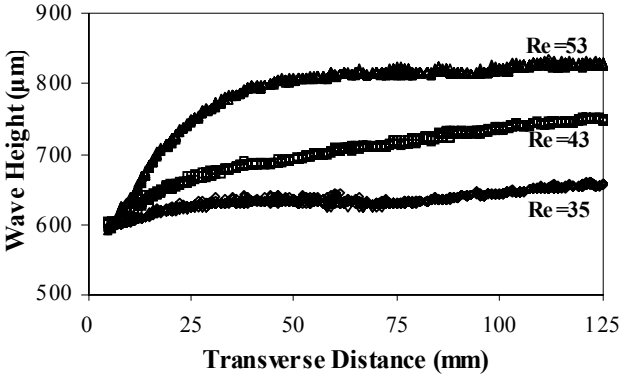

Figure 3. Variation of local film thickness across the crest-line of 2D waves ($\varphi=3^o$, W=250 mm)

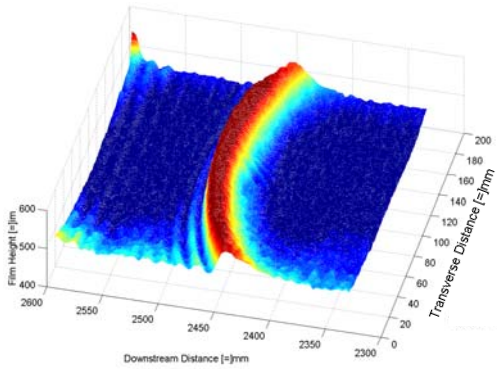

Figure 4. Representation of a curved 2D solitary wave (φ=5°, W=350 mm, Re=37, 1 Hz)

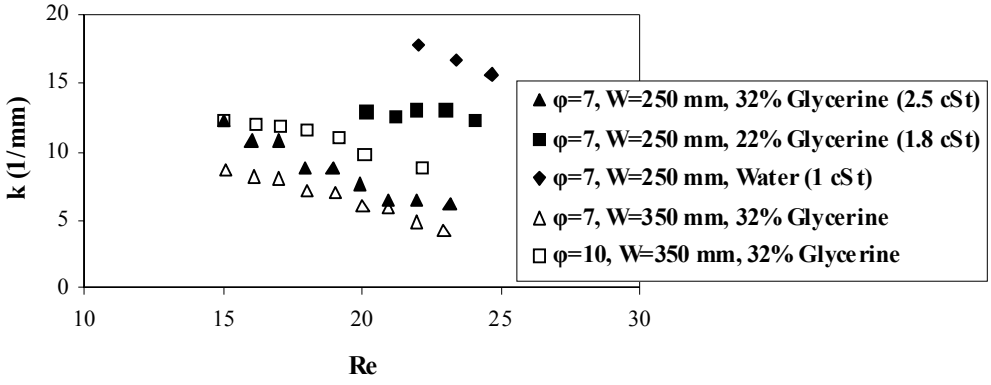

Figure 5. Effect of Re, channel width, inclination angle and fluid viscosity on wave shape

The above tentative explanation of wave evolution relies on the repeatedly observed strong correlation between wave phase speed and height. Thus, it is of interest to examine if such a correlation is also confirmed by the present data. More specifically, using the appropriate scaling based on substrate properties, it is always observed that the following linear relation is obeyed:

$$\frac{c}{u_{sub}} \approx S\frac{h_{max}-h_{sub}}{h_{sub}} + C_o \qquad (2)$$

Figure 6 provides a representative example of relevant data. The slope, S, is mainly a function of inclination angle, with steeper channels leading to faster waves (Figure 7a). It also increases slightly with channel width. On the other hand, the constant term (which corresponds to the linear phase speed and is theoretically predicted as equal to 3), C_o, shows a strong dependence on channel width and inclination, and approaches the theoretical limit only for wide enough channels (Figure 7b).

Three-dimensional transition

The first manifestation of 3D phenomena is characterized by a critical Re. Relevant data are shown in Figure 8, and demonstrate not only the expected inverse effect of inclination angle, but also a similar effect of channel width. More specifically, narrow channels postpone the 3D transition to higher Re, as they also do with the primary instability of the flat film. On the other hand, the fluid properties have no impact on transition, indicating that the second dimensionless number (e.g. Ka) is presently irrelevant.

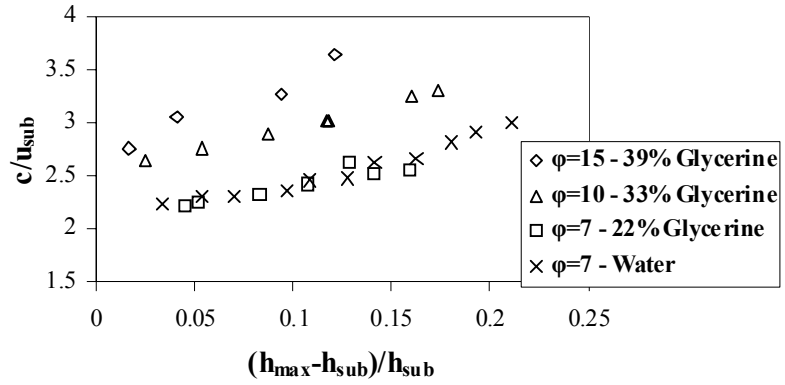

Figure 6. Normalization of the maximum wave height and phase velocity (W=250 mm)

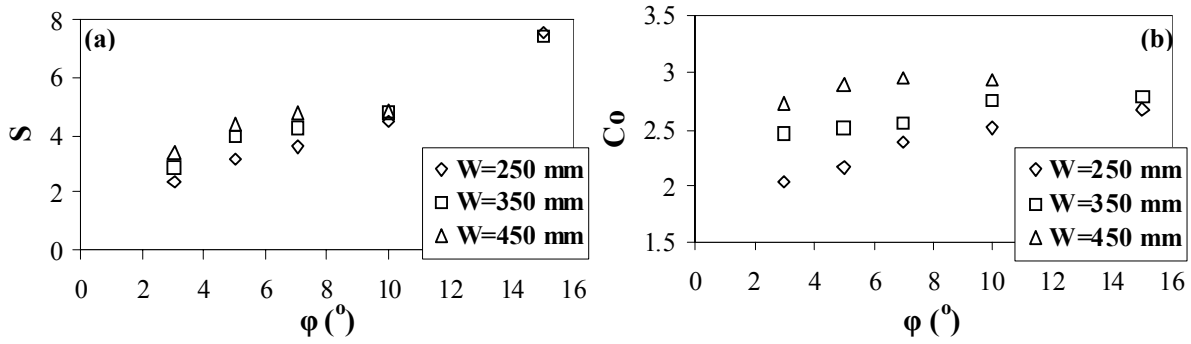

Figure 7. Effect of W and φ on slope and constant term of linear equation

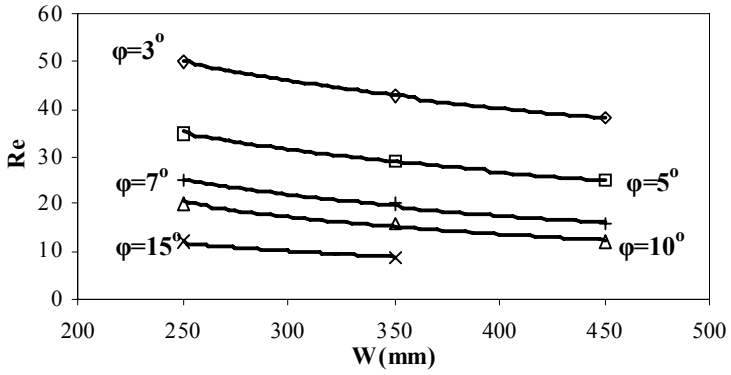

Figure 8. Transition from 2D to 3D flow regime

The phenomenology differs for nearly horizontal and for more inclined channes. More specifically, at inclinations up to 5°, solitary waves in water develop a front-running 3D structure that consists of a transversely periodic array of small depressions (Figure 9). Line profiles along the curved wave indicate that the 3D structure is sinusoidal with roughly constant height, A_d, and transverse wavelength, L_d, that decreases with Re (Figure 10). For larger inclinations (5-15°) either the solitary wave crest becomes skewed (Figure 11a) or 3D parasitic waves develop behind the major humps (Figure 11b). Finally, a combination of the above structures has been observed is some experiments.

CONCLUDING REMARKS

The fluorescence method was used in order to study experimentally the spatio-temporal evolution of the free surface of inclined liquid film flows at small and intermediate inclination angles. Experiments were done in a 3 meter long channel of variable width, and particular emphasis was placed on the effect of channel width on the observed transitions and on the characteristics of the waves. Three distinct flow regimes were identified: (i) the stable flat free surface, (ii) the disturbed

free surface with nominally 2D waves and (iii) the disturbed free surface with fully 3D waves. Both transitions (i)-(ii) and (ii)-(iii) were significantly influenced by the width of the channel, and in particular were postponed to higher Re for narrow channels.

The first travelling waves observed are not truly 2D, because their crestlines are symmetrically curved around the channel center plane and their height varies in the transverse direction. The curvature of the crestlines varies inversely with Re and also depends on channel inclination and width. For fully-developed waves, the wave height at the center plane and the wave speed are always linearly correlated when nondimensionalized with the respective substrate thickness and velocity. The slope and intercept of the linear relation have been systematically measured. The former depends mainly on channel inclination, with steeper channels producing faster waves. The latter corresponds to the phase speed of zero-amplitude waves and is theoretically predicted as equal to 3. Our data indicate that the intercept actually depends strongly on channel width and the theoretical limit is asymptotically attained only for wide enough channels.

Two alternative scenarios were identified for transition to a fully three-dimensional free surface. At small inclinations and with low viscosity liquids, the curved 2D solitary wave persists, but a small-scale 3D instability develops ahead of it. The instability consists of a regular series of periodic depressions with constant amplitude and with length inversely proportional to Re. This structure is believed to be the result of a capillary instability triggered by the high streamwise curvature in front of the solitary hump. The second scenario of 3D transition occurs at higher inclinations and for viscous liquids, and involves a disintegration of the main wave crest with concomitant generation of parasitic 3D waves behind it.

TIME RESOLVED HEAT TRANSFER TO AN IMPINGING SYNTHETIC AIR JET

D. I. Rylatt*, T.S. O'Donovan
Heriot-Watt University, Edinburgh, United Kingdom

ABSTRACT. Heat transfer to an impinging synthetic air jet is investigated experimentally. This investigation presents heat transfer data for a synthetic air jet at orifice to impingement surface distances of *1* to *8* jet diameters, and jet excitation frequencies of *45* to *85Hz*. The jet impinges on an ohmically heated constantan foil surface and a thermal imaging camera is used to acquire high spatial and temporal resolution surface temperature measurements. For the full range of heights studied, the heat transfer peaks at the stagnation point and decreases with increasing radial distance. At low H/D values (≤ 2) however secondary peaks are evident in the far wall jet region. These peaks have been attributed to the vortices which pass over the heated surface and do not occur at larger values of H/D as the vortices have broken down prior to impingement. The influence of the vortices of the time-averaged and time-varying surface heat transfer is reported.

Keywords: *synthetic jet, jet impingement heat transfer, vortices, infrared thermography*

INTRODUCTION

Continuous or steady air jet impingement has many applications in cooling due to the high localised and area averaged heat transfer coefficients they can achieve. Applications include, but are not limited to, the cooling of turbine blades, grinding processes and electronics. Synthetic air jet impingement is a promising new technology that can outperform continuous air jet impingement cooling. Both Smith and Swift [1] and Pavlova and Amitay [2] have shown that synthetic air jets can provide up to three times the cooling of continuous air jet impingement for a similar range of Reynolds numbers. Kercher [3] have shown that a synthetic air jet can provide twice the cooling of standard commercial electronics cooling technology. Synthetic air jets are compact, require no external plumbing and are therefore more easily integrated into various cooling applications.

The main variables to be considered in any study of continuous air jet impingement are the height of the nozzle above the impingement surface, the jet Reynolds number and angle of impingement. These parameters together with several others such as nozzle geometry, confinement, arrays, swirl etc are comprehensively reviewed by Martin [4]. It is, by now well established that the heat transfer to an impinging air jet is a maximum at the geometric centre where the flow is considered stagnant on a time-average basis. In general, the rate of heat transfer decreases monotonically with increasing radial distance from the stagnation point. At low nozzle to surface spacings however secondary peaks occur at a radial location and these have been attributed to an abrupt increase wall jet turbulence by Goldstein et al. [5]

More recently the effect of vortices in an impinging jet flow on the surface heat transfer has been investigated. Vortices occur naturally in a jet flow and are due to Kelvin Helmholtz instabilities in

the shear layer. They form at the jet exit, detach and flow downstream periodically. O'Donovan and Murray [6, 7] have shown that naturally occurring vortices in a continuous impinging air jet influence the magnitude of the secondary peaks that occur in the heat transfer distribution. Both Liu and Sullivan [8] and O'Donovan and Murray [9] have shown that acoustic excitation of an continuous air jet can be used to control the passing frequency of the vortices in the flow and this, in turn, can influence the shape and magnitude of the secondary peak in the heat transfer distribution. Hoffman et al. [10] have shown that pulsating a continuous impinging jet can also influence the overall magnitude of the surface heat transfer by increasing the mixing in the flow.

Synthetic air jet comprise almost entirely of successive vortex rings. A jet is formed by the periodic oscillation of a diaphragm bounded to a cavity containing an orifice; air is drawn into the cavity then ejected cyclically, thus generating a zero net mass flux jet flow that consists of chains of vortices. The ability of synthetic air jets to effectively remove heat is attributed to the high turbulence of the flow relative to continuous air jets. The current investigation is concerned with measuring the surface heat flux to an impinging synthetic air jet with high spatial and temporal resolution. The effect of successive impinging vortices is investigated at low H/D and compared to the heat transfer at high H/D where the vortices have broken down and are the flow is more uniform. The motivation for the current work is to better understand the mechanisms by which synthetic air jets transfer heat with a view to optimising jet design and operation.

EXPERIMENTAL SETUP

The experimental setup (figure 1) consists of two main components: a synthetic air jet, and a heated impingement surface. The synthetic jet is mounted directly above the heated surface with the jet flow directly perpendicular to it.

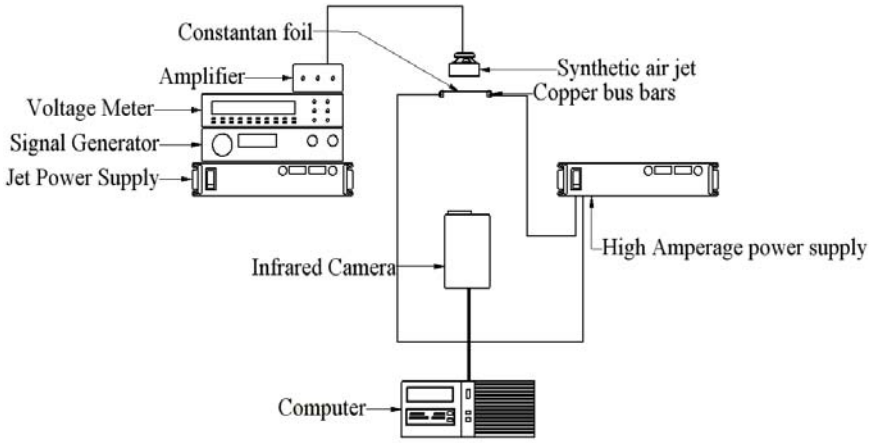

Figure 1: schematic diagram of the experimental set up

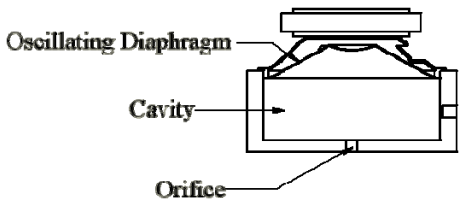

Figure 2: cross sectional view of a synthetic air jet

As indicated in figure 1, the synthetic air jet consists of a cavity with an oscillating diaphragm or actuator on one end and the jet orifice opposite it. The cavity diameter is *76mm* and has a depth of 30 mm and the circular orifice is *5mm* in diameter and *5mm* in length. The whole assembly is fabricated from a *90mm* by *90mm* by *35mm* aluminium block. All dimensions are accurate to within *0.1mm*. The synthetic jet actuator is a Visaton© FR8 *8Ω* acoustic speaker with a power rating of *10W*, a frequency range up to *20kHz*, a resonant frequency of *150Hz* and a maximum cone displacement of *4mm*. The actuator is powered by a sinusoidal voltage signal generated by a Thurlby Thandar instruments, TG315, *3MHz* function and sweep generator and amplified by a Kemo® MO 034 *40W* power amplifier which has a frequency range from *20* to *25kHz*, and a sensitivity of *~500mV*. The jet assembly is attached to a Manfrotto 454 micro positioning plate, to allow for fine adjustment of the distance between the synthetic air jet and the impingement surface.

The impingement surface consists of a thin resistance heater foil that has a surface area of *150mm* by *100mm* and approximates a uniform wall flux thermal boundary condition. Three different thicknesses of Constantan® Resistance Alloy (Cu55/Ni45) foil were used in this research; these thicknesses were *10*, *25* and *50μm* and were fabricated by Goodfellows Cambridge Limited. The undersides of the foils were lightly coated with a mat black paint to increase the surface emissivity value to approximately 0.98; this was necessary to ensure accurate surface temperature measurements with an infrared thermal imaging camera. The foils are clamped between two copper bus bars, with nominal electrical conductivity of $58.47Sm^{-1}$. The bus bars are held in place by two electrically insulating nylon struts, one of which is attached to two linear bearings to allow for positioning and tensioning of the foils. A direct current voltage is applied across the foil via the bus bars by a Farnel AP 20 - 80 regulated power supply which is capable of supplying up to *80Amps*. To ensure minimum losses in transmission a *35mm* core copper welding cable was used to connect the bus bars to the power supply.

All the components of the experimental setup are contained within a frame constructed of *45mm* by *45mm* extruded aluminium profile. The rig was enclosed on all sides by Perspex shielding to ensure that ambient air temperatures and velocities has minimal effect on the measurements.

As indicated in the diagram, a FLIR SC3000 high speed thermal imaging camera is mounted directly beneath the heated surface. The camera was used to measure the surface temperature of the foil with high spatial and temporal resolution. The maximum frame rate is *750Hz* which yields an image of *320 x 19* pixels. The field measured by the camera at this resolution was *100* by *6.3mm* which yields an image resolution of *3 pixels per mm*. The camera has a temperature sensitivity of *20mK* at *30°C* and a range of *-20* to *1500°C* with an accuracy of *±1%*. The minimum focal length is *300mm* with a plane lens, to allow for fine adjustments in the focus which is not easily achieved with the internal stepping motor focusing system; the camera is also attached to a Manfrotto 454 micro positioning plate. For all tests conducted the maximum operating temperature of the foils was less than *100°C*.

Heat transfer data are presented in the form of the time-average and time-varying Nusselt number which uses the diameter of the jet to normalise the surface convective heat transfer coefficient. This can be calculated as follows:

$$h = \frac{q''_{gen}}{\left(T_{surf} - T_{jet}\right)} \tag{1}$$

$$q''_{gen} = \frac{VI}{A_{surf}} \tag{2}$$

and V is the applied voltage, I is the current drawn by the foil resistance, A_{surf} is the surface area of the foil and T_{jet} is the jet temperature which is measured independently by a T-type thermocouple in the synthetic air jet cavity. This analysis assumes one dimensional heat conduction through the foil before convection to the impinging air jet. It is, however, well established that even for thin foils heat conducted laterally is significant. A correction for both lateral conduction and heat capacitance as used by Golobic et al. [11] was also used in this study to calculate the mean and time-varying surface heat transfer coefficient.

RESULTS & DISCUSSION

Time-average Nusselt number distributions to impinging synthetic air jets for a range of parameters are presented in this section. Time-varying heat transfer measurements are also presented and are used to discuss the differences between the time averaged data.

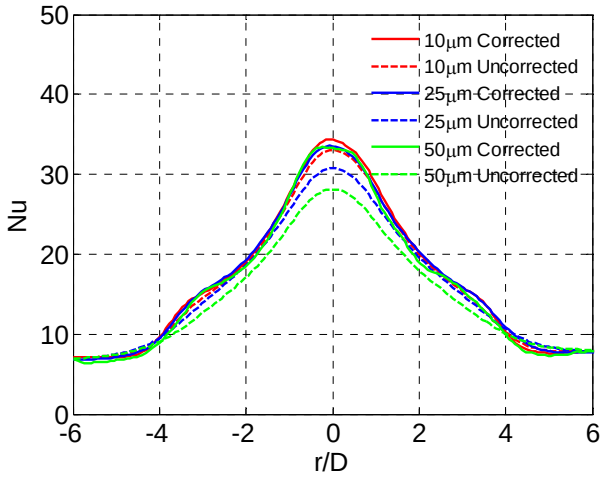

Figure 3: Corrected & Uncorrected Nusselt No. Distributions; $H/D = 2, f_e=45Hz$

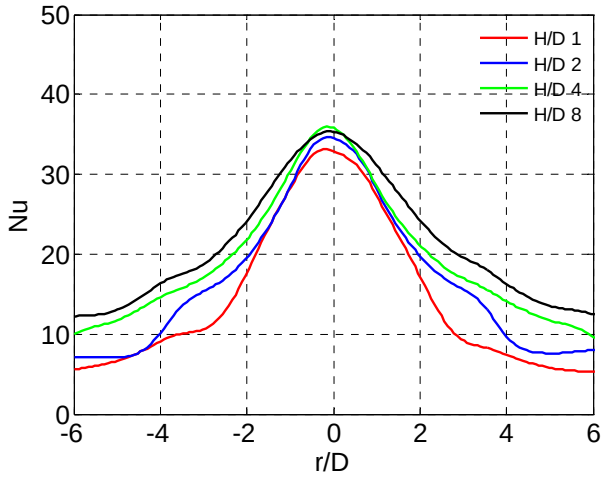

Figure 4: Nusselt No. Distributions; $f_e=45Hz$

As discussed in the experimental rig section, lateral conduction in the foil must be accounted for to accurately calculate the surface heat transfer coefficient. This has been done by using a finite difference technique which was also used by Golobic et al. [11]. In order to verify the correction technique, three foil thicknesses were used in the study (*10*, *25* and *50μm*). Figure 3 demonstrates that, for all foil thicknesses, the same heat transfer distribution results after the correction is applied. Before the correction is applied, both the peak in the heat transfer distribution and the rate at which the heat transfer decreases with increasing radial distance is lower for the thicker foils. Once the correction is applied all three distributions merge to give the same result irrespective of the foil thickness.

For the full range of heights studied, the heat transfer peaks at the stagnation point and decreases with increasing radial distance. The shape and magnitude of the heat transfer distribution changes significantly for different *H/D* values as illustrated in figure 4. At a certain radial location the rate at which the heat transfer decay which indicates the presence of a secondary peak as investigated by O'Donovan and Murray [7] who have shown that vortices in steady impinging jets contribute to the magnitude of secondary peaks. The distributions in figure 4 indicate that vortices in an impinging synthetic air jet may also results in a change of slope in the heat transfer decay; this is most evident for H/D $\leq$ 2 as the magnitude of these peaks decrease with increasing *H/D*.

Figure 5 presents the fluctuating heat transfer distribution which is an indication of instabilities in the flow along the impingent surface. As with the mean Nusselt number distributions, fluctuations in the surface heat transfer (*Nu'*) peak at the stagnation point and decrease with increasing radial distance. By comparing figures 4 and 5, it can be seen that areas of increased fluctuations in the heat transfer correspond to area of increased mean heat transfer. In particular, the change in slope in the mean heat transfer distributions at r/D ≈ 3 correspond to an increase in turbulence in the wall jet flow. This is similar to the observations of O'Donovan and Murray [7] for a steady impinging air jet where the abrupt increase in turbulence results from the breakdown of vortices in the jet flow. To further understand the convective heat transfer to a synthetic air jet the time varying heat transfer coefficient was examined.

Surface temperature measurements for each test setup were captured at *250Hz* for *20* seconds; the data were phase locked to convert the *5000* images to *50* averages of 100 images each at a distinct point in the jet cycle. An example of a surface Nusselt number distribution is presented in figure 6 and x's indicate the locations where the time-resolved heat transfer signals are examined.

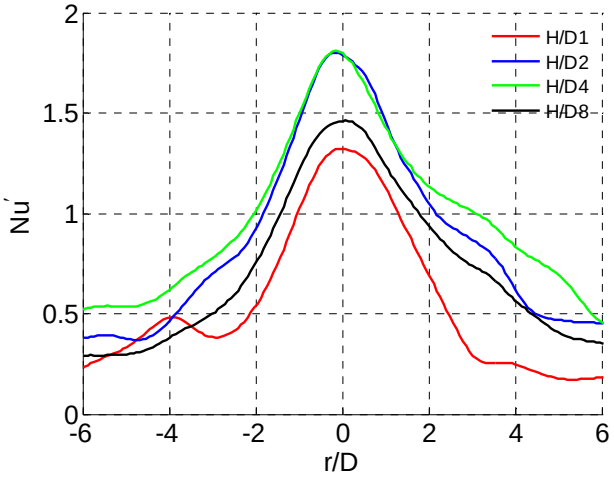

Figure 5: Fluctuating Nusselt No. Distributions; *H/D*=2; f_e=*45Hz*

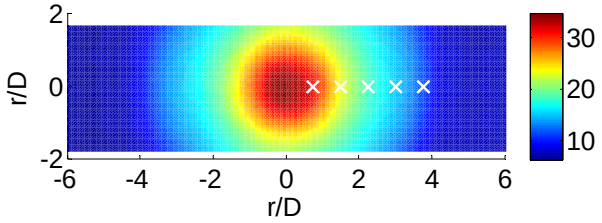

Figure 6: Nusselt No. distribution *H/D=2,* f_e*=45Hz*

Figure 7 shows the phase averaged Nusselt number timeline at a distance of *0.8* diameters from the stagnation point. It is clear that the heat transfer signal fluctuates sinusoidally at this location and this is true for all locations in up to secondary peak at *r/D=4*. This radial location corresponds to location of the secondary peak in the mean heat transfer distribution. Beyond this radial location however, at *r/D=4.5,* the heat transfer fluctuations are more random; this is clearly evident in figure 8. This supports the findings of O'Donovan and Murray that the secondary peak in the heat transfer distribution results from the break down of vortices in the wall jet. The heat transfer fluctuates sinusoidally before the secondary peak because the synthetic air jet vortices are strong and coherent structures which pass in the wall jet. The vortices break down in the wall jet which increases the turbulence and the results in a slight increase in heat transfer locally. The random fluctuations of the heat transfer signals beyond the radial location of the peak location indicate the vortices have been broken down into random turbulence.

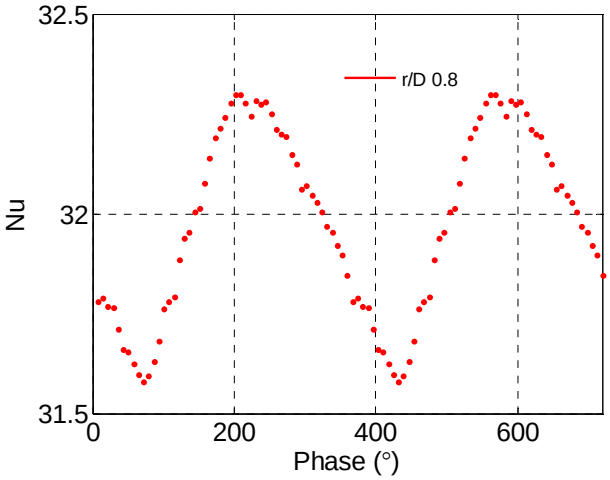

Figure 7: phase averaged Nusselt number f_e=45Hz, H/D = 2, r/D=0.8

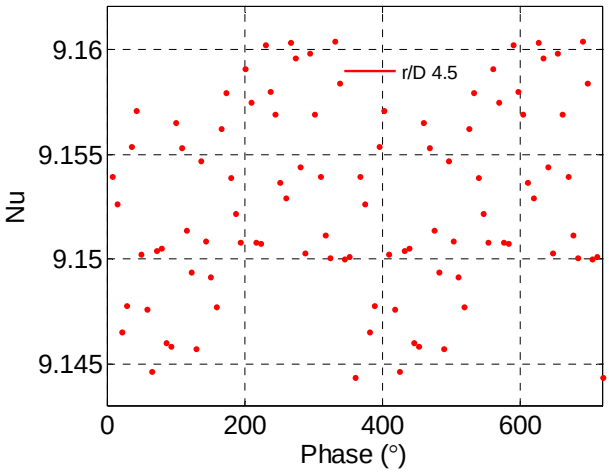

Figure 8: Phase Averaged Heat Transfer Signals; f_e=45Hz, H/D=2, r/D=4.5

In the following results only radial locations les *4.5* diameters have been examined. Figures 9 to 12 present normalised phase averaged signals for 4 different nozzle to impingement surface spacings and a single excitation frequency of *45Hz*. It can be seen that the heat transfer fluctuates sinusoidally at each radial location. Close to the stagnation region the heat transfer fluctuates in phase however at greater radial distances fluctuations occur further out of phase. For all frequencies studied the phase spread increases for *H/D=1* to *4* and has began to converge again at *H/D=8*.

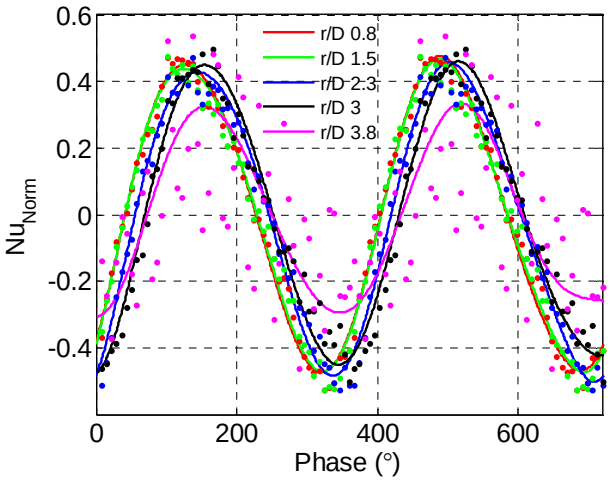

Figure 9: Normalised Phase Averaged Heat Transfer Signals; f_e=45Hz, H/D = 1

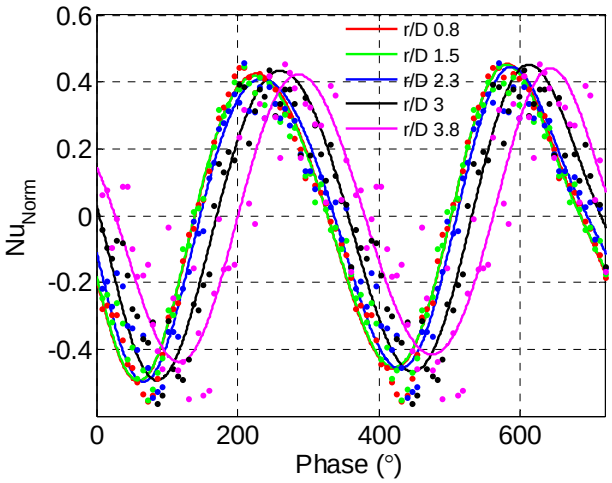

Figure 10: Normalised Phase Averaged Heat Transfer Signals; f_e=45Hz, H/D = 2

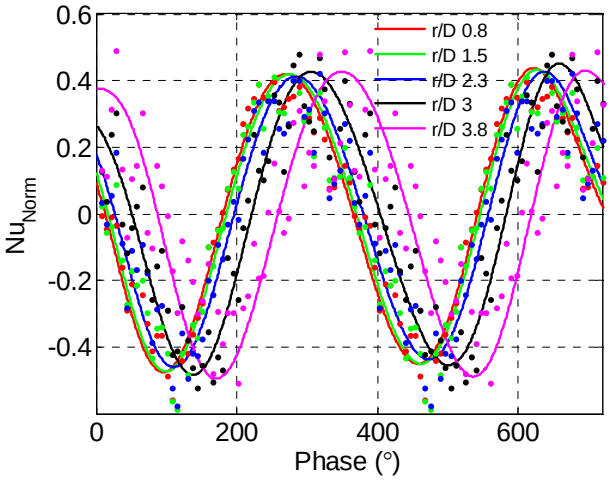

Figure 11: Normalised Phase Averaged Heat Transfer Signals; f_e=45Hz, H/D = 4

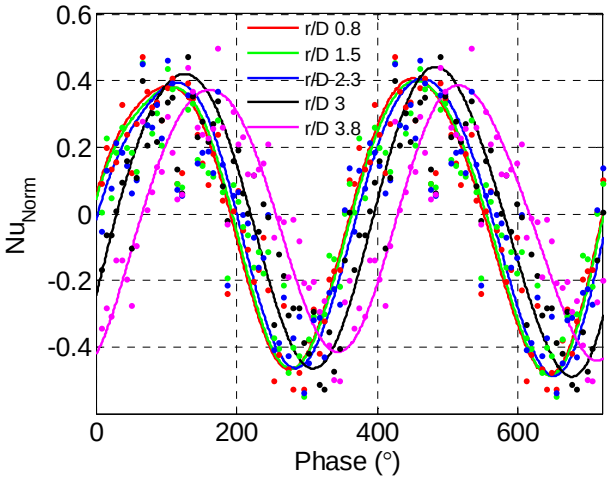

Figure 12: Normalised Phase Averaged Heat Transfer Signals; f_e=45Hz, H/D = 8

For *H/D=1* low fluctuations in the heat transfer imply that the flow is less turbulent than at higher *H/D*, which leads to relatively low heat transfer. As can be seen from figure 9 the flow across the impingement surface is quite closely in phase and remains strongly sinusoidal until *r/D=3.8* where it begins to break down this corresponds with a slight increase heat transfer and instabilities in the flow which can be seen in figures 4 and 5 respectively.

At *H/D=2* high *Nu* and *Nu'* indicates a more turbulent flow; this flow stays in phase up to a radial location of approximately *2* diameters from the stagnation point. Beyond this radial location, the heat transfer signals move radically out of phase but stay coherent/sinusoidal until *r/D=3.8* and by *r/D=4.5* it has all but lost remanence of a sinusoid. Again this corresponds with areas of increased heat transfer and instabilities in the flow which can be seen as of secondary peaks in figures 4 and 5 respectively. This is attributed to successive vortices impinging upon the surface and travelling out radially then breaking down into turbulence.

At *H/D=4*, similar to *H/D=2* high *Nu* and *Nu'* indicates a turbulent flow but the absence of secondary peaks implies that the vortices present in the flow at lower *H/D* values have begun to break down before impingement but have not fully broken down. The phase data is in general less coherent than at lower *H/D* values and moves out of phase more rapidly. For *H/D=8* the reduction in the *Nu'* is because the vortices has broken down the high *Nu* is because the jet is less confined and has entrained more and cooler air than at higher *H/D*.

CONCLUSIONS

Both mean and fluctuating heat transfer distributions to an impinging synthetic air jet have been presented for a range of experimental parameters. Phase locked time-traces of the heat transfer signals have been used to understand the convective heat transfer mechanisms in such a flow. It has been shown that the surface heat transfer fluctuates sinusoidally in the near wall jet region for low nozzle to impingement surface spacings. With increasing radial location however the fluctuations occur out of phase with each other indicting the passing of a vortex in the wall jet flow. At large *r/D*, beyond the secondary peak in the mean heat transfer distribution the sinusoidal nature of the heat transfer no longer exists indicating that the vortex has broken down into random turbulence. This is thought to have contributed to the magnitude/existence of a secondary peak in the mean heat transfer distribution.

From the phase information, it is apparent that at large values of *H/D* the vortex is broken down before impingement with the surface and this could explain why there is no secondary peak at larger *H/D*.

EFFECT OF FLUID PROPERTIES AND PIPE INCLINATION ON FLOW PATTERN IN TWO-PHASE GAS-LIQUID FLOW

Ch. Tzotzi[1], M. Vlachogiannis[2] and N. Andritsos[1,*]
[1]Department of Mechanical & Industrial Engineering, University of Thessaly, Volos, Greece
[2]Technological Educational Institute of Larissa, Greece

ABSTRACT. The present study investigates the effect of several fluid properties on flow pattern transitions in horizontal and near-horizontal pipes over a wide velocity range. The fluids chosen for the experiments were selected so as to allow changes in one property, without affecting significantly other properties. Experiments have been conducted using a 12.75-m long test loop with and i.d. of 24 mm and pipe inclinations of $\pm 0.25^o$ $+0.5^o$ and $\pm 1^o$. Apart from air, two other gases (CO_2 and He) were employed to vary gas density, while the effect of surface tension was examined using an aqueous solution of n-butanol. The various transitions were identified visually, coupled with a statistical analysis of film height and pressure drop measurements.

Keywords: *two-phase flow, physical properties, pipe inclination, flow regime transitions*

INTRODUCTION

The prediction of pressure drop and liquid holdup occurring during two-phase gas-liquid flow in pipes is of particular interest to the petroleum, chemical and nuclear industries. These design parameters are strongly dependent on the flow pattern that prevails in the pipe. To occurrence of a specific flow pattern depends upon the flow rates, the physical properties of the two phases and the geometrical characteristics of the pipe. Generally, the transition from one flow pattern to another is not abrupt, except for the transition to intermittent from stratified flow. Within the transitional zones, the flow behavior exhibits characteristics of the flow patterns on both sides of the transition.

The effect of fluids properties on two-phase flow phenomena has been a subject for study by a number of investigators over the past 50 years. Weisman et al. (1979) examined the effect of physical properties (liquid viscosity, gas density and surface tension) on flow patterns in horizontal lines. They also proposed semi-empirical corrections for the transitions to account for the fluid properties and pipe diameter. A systematic experimental investigation of the effect of liquid viscosity (in the range 1-80 cP) on flow characteristics was carried out by Andritsos and Hanratty (1987). Recently, Funada and Joseph (2001) studied the stability of stratified gas-liquid flow in a rectangular channel taking into consideration the liquid viscosity and surface tension effect. The effect of surface tension on the stability of the interface was also investigated by Guo et al. (2002). They concluded that the increase of surface tension "stabilizes" the interface.

The effect of pipe inclination on flow patterns for gas-liquid flow was investigated experimentally by Barnea et al. (1980). It was observed that in downflow the stratified region is considerably expanded as the angle of inclination increases and higher liquid flow rates are required for the transition to intermittent flow. Conversely, upward inclination results in the expansion of

intermittent flow region and stratified flow shrinks in a small bell-shaped region. Experimental investigations in slightly inclined pipes were also carried out by Andreussi and Bendiksen (1989) and Kokal and Stanislav (1989). Recently, Woods et al. (2000) and Simmons and Hanratty (2001) focused on the transition to intermittent flow in downward and upward inclined pipes, respectively, both experimentally and theoretically.

EXPERIMENTAL FACILITY AND TECHNIQUES

Experiments were carried out in a smooth, transparent Plexiglas pipe with an internal diameter of 24 mm and a total length of 12.35 m. A schematic of the experimental setup is shown in Figure 1. The carefully levelled pipe is placed on a steel frame that can be inclined slightly, up to ±3°. The liquid and gas phases were introduced into the pipe with a vertically placed Y-section, with water flowing in the lower branch. The two-phase mixture is emptied in plastic separator open to the atmosphere. Water is usually circulated through the system in a closed loop using a centrifugal pump. The air flow is supplied by an AIRCO M529 (4 HP) reciprocating compressor. The CO_2 flow is supplied by a bank of commercial CO_2 cylinders (Air Liquide), while the commercial-type He was provided by a single cylinder (Air Liquide) which limited the duration and the number of water-He runs. The volumetric flow rates of both phases were measured with a bank of three rotamerers for each phase. All three gas rotameters were calibrated using a Ritter BG 40 gas meter (minimum flow rate 0.4 m^3/h and maximum flow rate 65 m^3/h) for the three gas phases.

The liquid height and the wave velocity were measured at two locations in the pipeline (namely at 88D and 336D) using pairs of parallel wire conductance probes that extended in the vertical direction over the entire cross section of the pipe. The wires were 0.4 mm dia. chromel and their separation was 3 mm. An oscillating signal was sent to the probes and an analyser converted the response to an analogue signal. A HAMEG HM 8030 5-MHz function generator was used to provide the input sine signal at a frequency of 25 kHz. A demodulation circuit provided the peaks of the output signal synchronously using the square wave output of the function generator as a reference. The output voltage was found to vary linearly with the conductance only at very high resistances (R > 50,000 Ohm).

Pressure drops were measured in the gas phase at relatively low gas velocities with an inclined U-tube glass manometer. Most pressure drops data were taken in the liquid phase and were measured by a diaphragm-type ABB 2600T series differential pressure transmitter. The measuring range of the transmitter was 50-1000 Pa. Care was taken to keep air out of the connection lines, which were frequently purged of gas bubbles. The length over which the pressure drop was measured was varied depending on the phase flow rates.

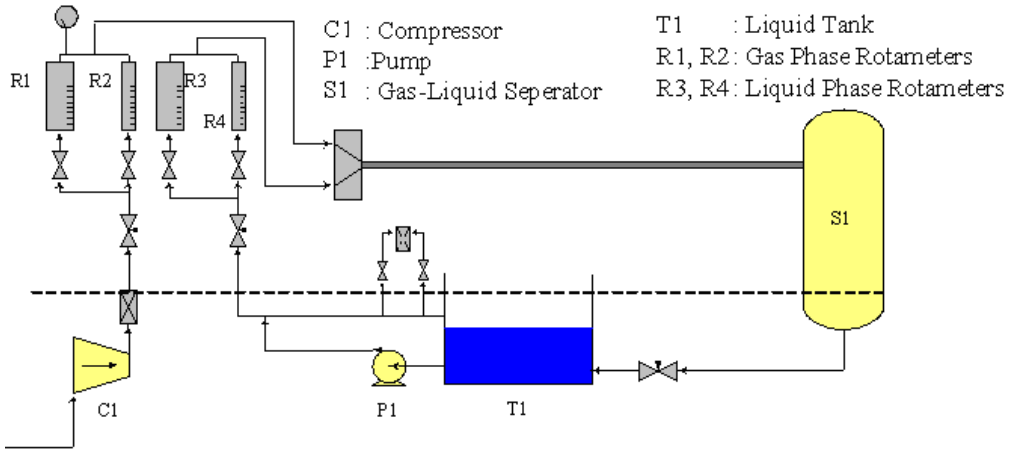

Figure 1. Schematic of the experimental apparatus

EFFECT OF FLUID PROPERTIES IN HORIZONTAL FLOW

The flow pattern that occurs in a pipe is affected not only by the flow rates, but also by the fluid properties and the system characteristics (diameter, roughness, inclination angle). In the present study CO_2 (ρ=1.81 kg/m^3 at 25ºC and 1 atm) and He (ρ=0.167 kg/m^3) were used as gas phases in order to explore the effect of gas density on the flow patterns. The effect of surface tension was examined using a n-butanol-water solution (measured value σ=0.04 N/m).

The effect of increasing the gas density is to decrease (at a constant liquid velocity) the gas velocity required for transition to 2-D (two-dimensional) and K-H (Kelvin-Helmholtz or large-amplitude) waves. This behaviour is clearly illustrated in Fig. 2a for the CO_2-water system. It is of interest that the only transition that remains unchanged is the transition from stratified to slug flow, although the slug-to-pseudo slug transition is affected by gas density.

The effect of surface tension is depicted in Figure 2b. The transitions to 2-D and to K-H waves are shifted to lower superficial gas velocities with decreasing surface tension (from 0.072 N/m to 0.04 N/m). The effect is stronger for 2-D waves, since for superficial gas velocities higher than 1 m/s employed in this study no smooth stratified region has been observed. As before, the transition to slug flow is not affected by a change in surface tension.

The transitions to 2-D and K-H waves for all the systems examined in this work can be described reasonably well by the semi-theoretical equations proposed in a previous work (Andritsos et al. 2008), as shown in Figures 3a and 3b.

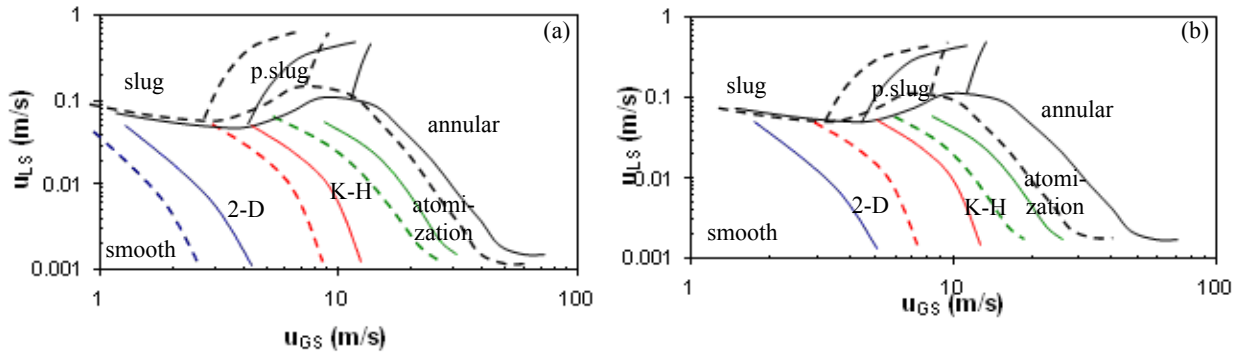

Figure 2. Comparison between air-water (continuous lines) and CO_2-water flow maps (left figure, dashed lines) and air-butanol+water flow map (right figure, dashed lines)

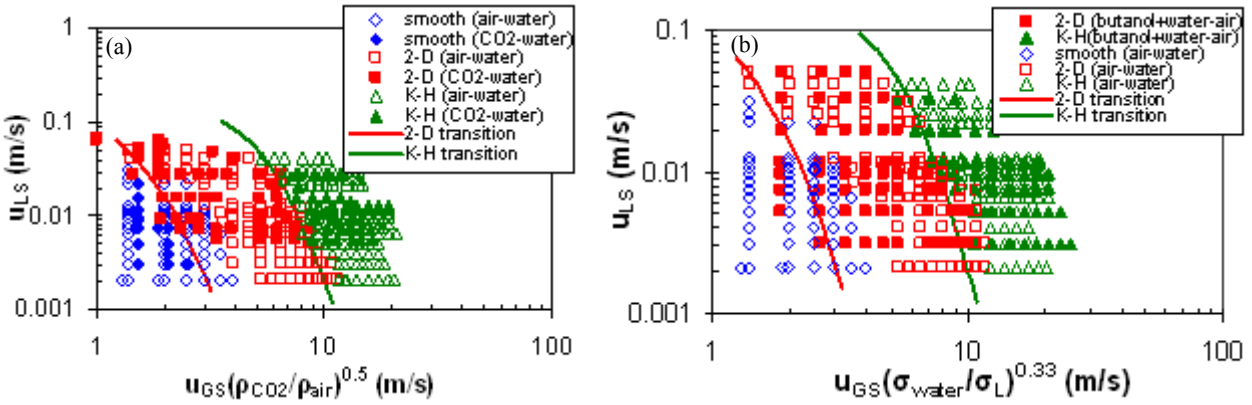

Figure 3. Comparison of semi-theoretical wave pattern transitions with CO_2-water (left) and n-butanol+water-air data (right)

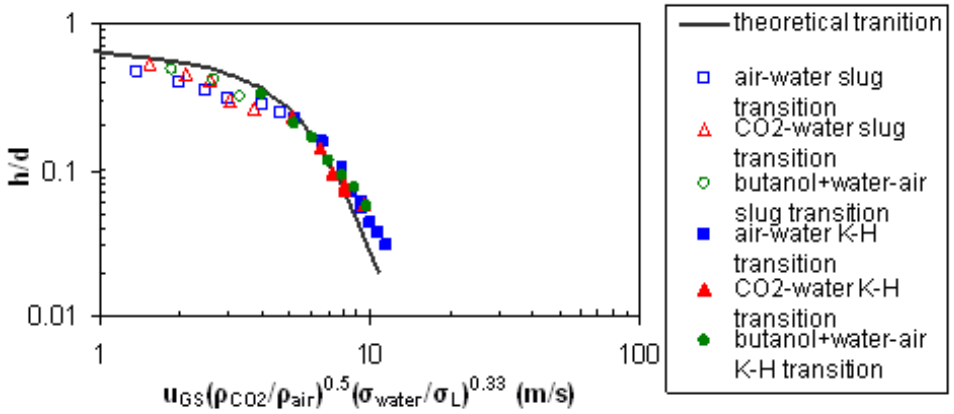

Figure 4. Comparison between experimental transition to slug flow and K-H waves with the proposed equations

The so-called K-H waves are irregular, large amplitude waves, which appear to be initiated by gas-phase pressure variations 180° out of phase with the wave height, i.e. due to Kelvin-Helmholtz mechanism, the same mechanism responsible for slug formation, when the height of liquid phase is high enough for these waves to grow and block the pipe cross-section (Andritsos et al. 1989). It was observed in this study (Figure 4) that the experimental transition to K-H waves and slug flow for systems with different physical properties agree quite well with the equation proposed in a previous work (Andritsos et al. 2008) with suitable modification of the system's co-ordinates.

As it is stated in the introduction, transition from one flow pattern to another does not take place abruptly, but a transitional zone exists, where the flow exhibits characteristics of the flow patterns on both sides of the transition. It is observed that transitional zone in the butanol+water-air system is wider than that of air-water and CO_2-water systems. Moreover, wave characteristics in this transitional zone are quite different for butanol solution compared to those for water.

At a liquid superficial velocity of 0.011 m/s the required gas velocity for the transition to K-H waves is ~9.4 m/s for the air-water system and ~7 m/s for butanol+water-air system, as can be seen in the film height traces presented in Figure 5. It can be also seen that for the butanol solution the transition zone is wider than that encountered for water. In addition, just before transition, some kind of "single" waves are observed with the butanol solution, but absent in the water. With increasing gas velocity these "single" waves coalesce and large amplitude waves are formed (u_{GS}=9.4 m/s). Finally, with further increasing gas velocity K-H waves are formed (u_{GS}=12.4 m/s). For air-water system (Figure 5b) at the beginning of the transition zone large amplitude small wavelength waves are observed (u_{GS}=9.4 m/s). With an increase in gas velocity (u_{GS}=10.2 m/s) the waves start to acquire K-H waves characteristics, as the amplitude of these waves become larger and their crests become steep. Finally, K-H waves are formed at u_{GS}=11.8 m/s. It is noted that this kind of "single" waves are not observed during the runs in the air-water and CO_2-water systems.

EFFECT OF DOWNWARD INCLINATION

In downflow the liquid moves obviously more rapidly and has a lower height in the pipe owing to downward gravity forces. As a result stratified flow region is considerable expanded as the angle of inclination increases. Figure 6 illustrates the shifting of the transition boundaries in flow maps as the inclination angle increases. In addition, for φ=1° the stratified smooth region was not observed even for zero gas velocity, obviously due to the effect of gravity.

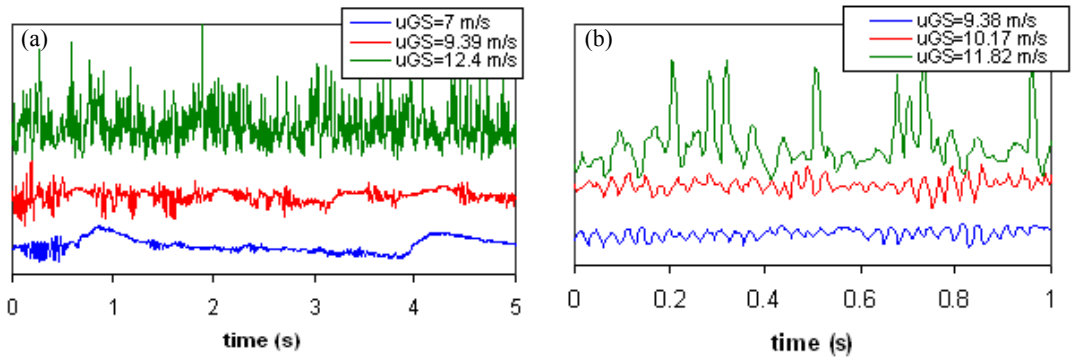

Figure 5. Wave evolution for and butanol+water-air (left) air-water system (right), u_{LS}=0.011 m/s

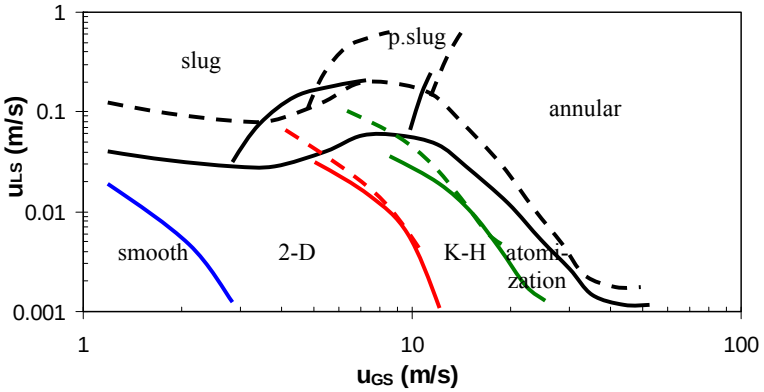

Figure 6. Comparison of air-water flow maps at φ=0.25º (continuous lines) and φ=1º (dashed lines)

Two different types of waves (2-D and K-H) were again identified in the stratified region and it turns out that, although the transition to 2-D waves is shifted to lower superficial gas velocities, the transition to K-H wave region remains rather unaffected by the inclination angle. As in horizontal flow, lowering the surface tension alters the appearance of waves in the "2-D" region. In the butanol+water-air system 2-D waves are not observed; instead some type of saturated periodic waves are formed, as can be seen in Figure 7b (for u_{GS}=3.97 m/s). On the other hand, K-H waves sustain their characteristics for all the systems examined in this study

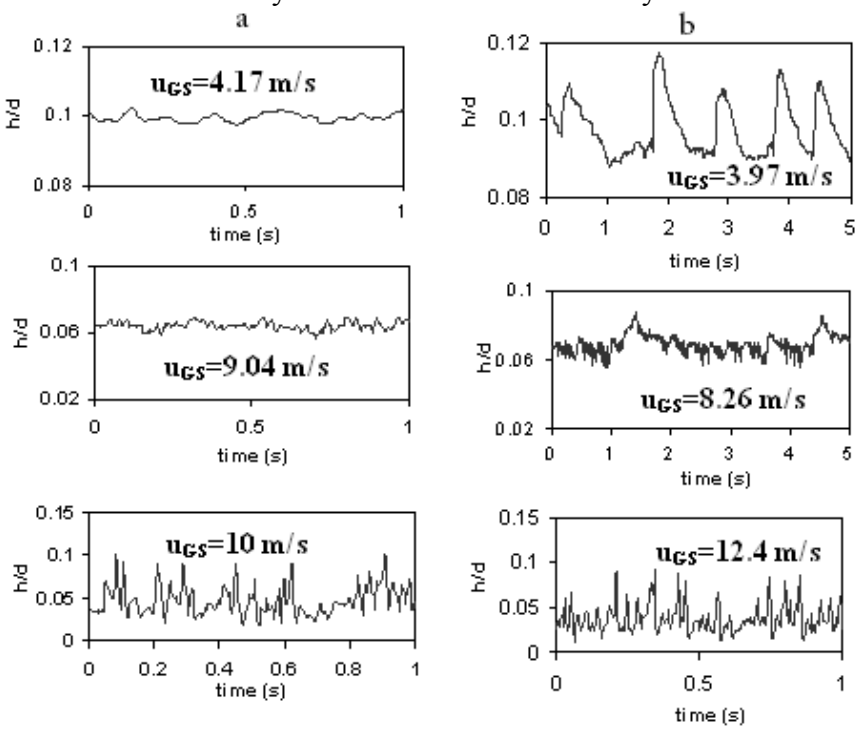

Figure 7. Film height traces in a CO_2-water system (left) and butanol+water-air system (right), u_{LS}=0.011 m/s

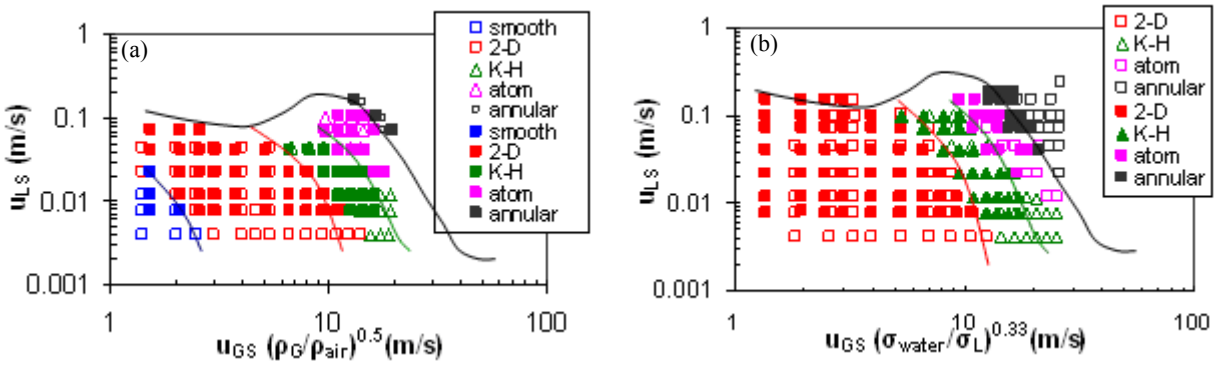

Figure 8. Comparison of flow maps at φ=0.25° (left, filled symbols air-water, open symbols CO_2-water) and at φ=1° (right, filled symbols air-water, open symbols butanol+water-air)

Both the gas density and the surface tension affect the various transitions in downflow in a similar manner with that found in horizontal flow. CO_2 and butanol solution were used in order to examine the effect of gas density and surface tension, respectively. It can be also shown that with proper modification of flow map axes the transitions to various subregimes of stratified flow almost coincide for the two systems, as depicted in Figure 8.

EFFECT OF UPWARD INCLINATION

For upward flows, even a small pipe inclination can cause severe slugging, even at low liquid velocities, while the stratified flow region takes the form of a bell-shaped area, as illustrated in Figure 9 for two pipe inclinations. In our study, a pseudo-slug flow is also considered, which is defined in a similar way as in horizontal flow, i.e. using as criterion the ratio of the slug velocity to the gas phase velocity. Following the above consideration, the pseudo-slug flow region precedes the transition from slug to stratified flow with increasing gas velocity at a constant liquid velocity.

Moreover, in the stratified flow region in upward flow two different types of waves were also identified, which retain 2-D and K-H wave characteristics. Both the transitions to 2-D and K-H waves were shifted to higher gas velocities as the inclination angle increases. Wave traces in stratified flow are presented in Figures 10 and 11. Following the transition from pseudo-slug to stratified flow, 2-D waves were first observed (illustrated in Figure 10a), while with an increase in gas velocity small amplitude irregular waves are formed (Figure 10b). Finally, at even higher gas velocities waves resembling the K-H one in horizontal flow appear in the pipe.

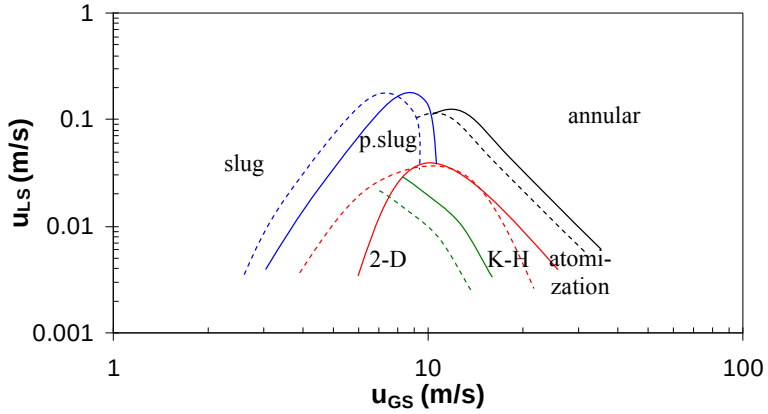

Figure 9. Comparison of air-water flow maps for two inclinations (φ=1° continuous lines, φ=0.25° dashed lines)

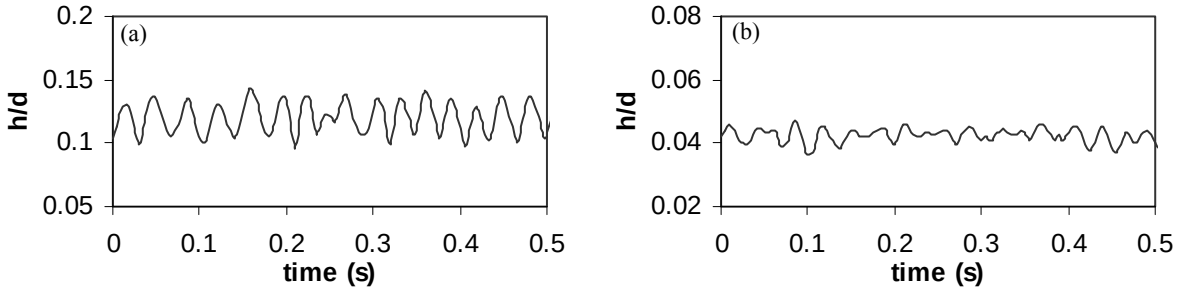

Figure 10. 2-D waves in stratified flow for air-water system at φ=0.25º in increasing superficial gas velocity

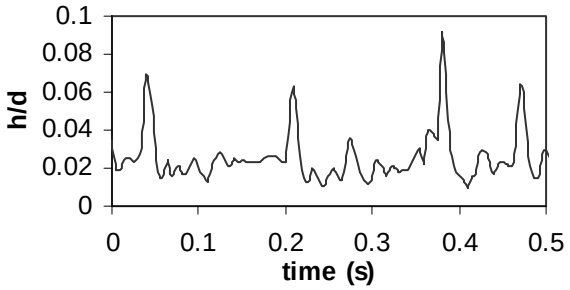

Figure 11. K-H waves in stratified flow for air-water system at φ=0.25º

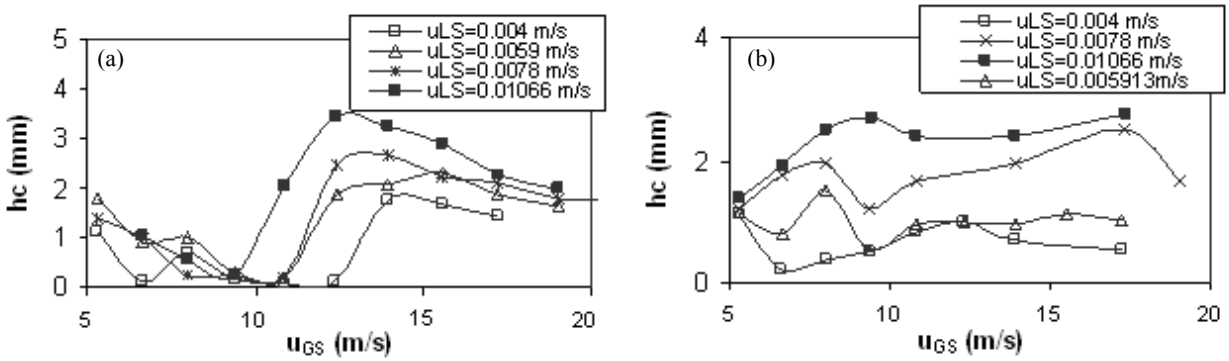

Figure 12. Wave amplitude in stratified region with increasing superficial gas velocity for air-water system (left figure) and butanol+water-air system (right figure) at φ=0.55º.

The wave amplitude decreases with increasing superficial gas velocity and the waves become steeper as shown in Figure 11. The two wave types are not distinct only from their appearance (which is also reflected in the large value of autocorrelation coefficient of the wave trace), but also from their amplitude as shown in Figure 12. It is evident that for the air-water system the transition from 2-D to K-H waves is rather abrupt, while the use of a low surface tension liquid results in roughly uniform wave amplitudes regardless of the wave type (Figure 12b).

CONCLUDING REMARKS

Experimental data are provided regarding the effect of fluid properties and pipe inclination for two-phase gas-liquid flow in a 0.024 i.d. pipe. Flow patterns were identified by a combination of visual and video observations and analysis of liquid height and pressure drop measurements.

In a horizontal pipe the transitions to the various flow patterns (bubbly flow has not been considered) are affected by changes in gas density and surface tension, apart from the transition between stratified and slug/plug flow. A decrease of the surface tension by using an aqueous solution of n-butanol results in the shifting of the transitions to the two main types of waves to

lower gas velocities. The transitions to 2-D and K-H wave regions can be predicted quite well by the semi-theoretical correlations (Andritsos et al. 2008).

For small downward inclination of the pipe, the stratified flow region is considerable expanded whereas for even a small upward pipe inclination the stratified flow regime shrinks to a bell-shaped area. Two different types of waves (2-D and K-H) can be identified for upward and downward inclinations for all the systems examined, exhibiting characteristics similar to those found in horizontal flow.

ABSTRACT. The technique for estimating the contact area between a cold water and a hot hemispheric surface is described. Synchronized measurements of pressure pulses in a liquid phase, those of a temperature in a solid body, and parameters of a contact of the superheated body with a coolant under the conditions of a sharp change of boiling regimes (from a film to nucleate one) are conducted. Specific features of the processes under study, which to a considerable extent are determined by the hemisphere temperature, its thermophysical properties, and the presence of surface oxides are determined. It is revealed that the maximum amplitude of pressure pulses of up to approximately 1 MPa are obtained in the range of the superheated body temperatures, which are close to the temperature of ultimate superheating of water. The dependences of the velocity of water spreading along the heated surface and the time lag of its boiling-up (flashing) on the hemisphere temperature are obtained. Interpretation of the results obtained using the methods of fluid dynamics and molecular-kinetic theory is made. An attempt to describe transfer processes and evolution of inter-phase surfaces at the initial contact of water with a hot hemispherical surface is done.

Keywords: *boiling, pressure pulses, boiling-up, wettability*

INTRODUCTION

The knowledge of regularities of transition from the film boiling regime to the nucleate one is very important for many technological processes [1]. Certain specific features of this process are of great importance while triggering steam explosion in the course of spontaneous fragmentation of hot-coolant droplets falling into a cold liquid. It is generally accepted that fragmentation of these droplets is connected with explosion-type destruction of vapor envelopes surrounding superheated droplets. In the literature, there are more than ten original ideas that describe fragmentation process [2]. At the same time, details of physical processes that accompany the vapor-cavity collapse are studied insufficiently thoroughly. In particular, in the past, rather small attention was paid to the problem of contact of the hot and cold media, as well as to studying specific methodological questions that appear while studying detail characteristics of pressure pulses. In our paper we describe and analyze new experimental data concerning these problems.

THE EXPERIMENTAL INSTALLATION AND MEASUREMENT TECHNIQUE

On the basis of our experiments conducted earlier [3] one can suppose that the destruction of the vapor envelope, including the first contact between hot and cold media, takes place similarly on the

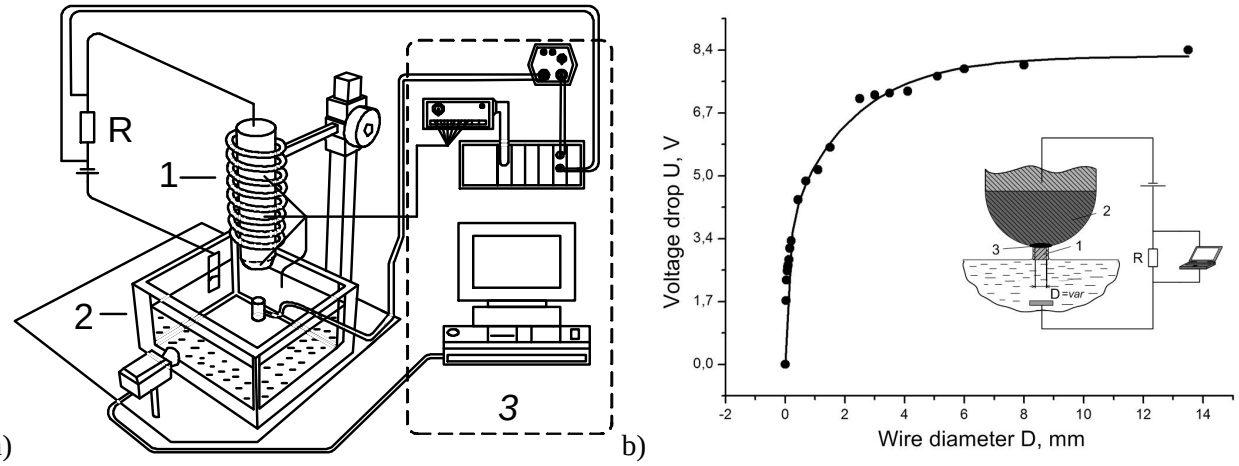

Figure 1. The layout of the experimental installation (a) and calibration curve of the electric-contact probe. *1*- working specimen; *2*- tank with water; *3*- measurement complex.

superheated solid and liquid-metal surfaces. Since to conduct experiments with solid metal specimens is considerably simpler and possibilities of the latter, as to physical properties variation and surface-condition control, are significantly larger, most experiments simulating the initial stage of the vapor film destruction were carried out with hemispherical highly heated surfaces immersed into cold water.

Figure 1a shows the layout of the experimental installation and the scheme of measurements. The test section was a cylindrical copper rod, at the end of which a changeable tip was mounted. Cylindrical rod of 10 mm in diameter with hemispherical end was used as a tip. Tips made of grade Kh18N10T stainless steel were used in the experiments. Electric current passed through the spiral wound on the copper rod was applied for heating the test section.

The experiments were carried out as follows. In the initial (taken from water) position the tip was heated by a propane jet for several tens of seconds. This led to formation of oxide film on the tip surface. After oxidation, the tip was cooled and heated again to the desired temperature by the electric heater in argon atmosphere. After this, the electric heater was switched-off and the heated test section with the use of special coordinate spacer was immersed into the vessel filled with distilled water at a depth equal to the hemisphere radius. The immersion velocity was several mm/s. The initial hemisphere temperature was approximately 500^{o}C. This value was chosen to ensure stable film-boiling regime. The technique applied made it possible to accomplish explosion-like vapor film collapse on the heated surface by a simple way. In experiments, distilled water at a room (~18^{o}C) temperature was used. Preliminarily boiling for two hours provided water degassing.

Monitoring of the processses under study was conducted with the use of microscopes and video cameras. Temperature measurements carried out by Chromel-Alumel thermocouples imbedded into stainless steel capillary tubes, along with monitoring temperatures in the hemisphere center and other pints of the test section, made it possible to determine heat flux value on the hemisphere surface under film boiling conditions. Kistler 601A piezo-sensors operated in combination with Kistler 5015 charge amplifiers were used as pressure gages. Measuring and treating the signals from different sensors were conducted with the use of Labview software and the National Instruments devices. A typical sampling rate was 5 10^{5} s^{-1}.

Characteristics of the process of water coming into with the hot surfaces were determined by measuring a voltage drop at the reference resistor, which was part of closed electric circuit

comprised direct-current source, two electrodes (the test section functioned as one electrode and the copper plate immersed into water pool, as another), connecting wires, water and steam volumes. When there was no contact between the water and the test-section surface, the total resistance of the circuit was determined by electric resistance of the steam layer and has the maximum value, respectively, the current and voltage drop on the reference resistor were minimal. At an instant of water contact with the test-section surface the electric current in the circuit increased sharply. When this happened, the voltage drop on the reference resistor changed depending on an area of the contact surface.

The calibration curve of the voltage drop on the reference resistor as a function of equivalent contact area (Fig. 1b) was obtained in the course of special experiment, when a contact spot was simulated by the end surface of the copper wire isolated from side surfaces (see the insert in Fig. 1b). The tip of the wire, whose diameter in the experiments was varied from 30 μm to 15 mm, was soldered to hemispherical surface of the test section, while the other was immersed into water by several millimeters. The trustworthiness of the technique proposed was confirmed by a good agreement of the contact-area value determined with the use of calibration curve with the total hemisphere-surface area in the case, when nucleate boiling occurred at the entire surface of the specimen.

An important methodological problem that arises in the course of pressure measurements with the use of piezo-electric gages is the influence of the pulse temperature impact on their readings. In our experiments, the gages were located in water at different distances from the lower part of the hemisphere; in so doing, the minimal distance was 5 mm. Under these conditions, in addition to the pressure action proper, the gage's reading can experience a temperature impact. In particular, these effects can be caused by a short-term entry of the transducer's sensitive element, which is usually located in a cold liquid, into relatively hot "vapor cloud", that is formed under explosion-like destruction of the vapor layer. According to the manufacturer's specifications, the temperature-sensitivity coefficient of the gage is $k = 0.0001\ K^{-1}$. Numerical estimates based on this value attest weak effect of the temperature factor should be anticipated. These specified characteristics, however, are valid under conditions, when all parts of the gage (membranes, casing, piezo-element, etc.) are equally heated and have one and the same constant temperature. In our case these conditions are not met. Therefore, special experiments were conducted to investigate possible effect of temperature pulses on piezo-electric gages readings. In these experiments, during relatively short time interval (~0.5 to 10 s) the sensitive element of the transducer experienced the impact of the hot air moved with a velocity of several m/s. The air temperature was within a range of 100-300^{o}C. The results obtained showed the existence of rather strong response of the gage to a sharp raise in a temperature (apparently, due to temperature distortions). The effect recognized generates false signals, such as incomprehensible recordings of low-frequency intense rarefaction pulsations that accompany the process of transition boiling after vapor-cavity collapse [3, 4]. This fact shows certain caution should be given when interpreting experimental data on pressure pulses.

RESULTS OF EXPERIMENTAL STUDIES

The experiments conducted made it possible to reveal that pressure oscillations accompanying explosion-like destruction of the vapor film constitute a pack of pressure pulses, the amplitude and typical shape of which are to a considerable extent determined by a temperature of the heated hemisphere (see Fig. 2 and the inserts in it). The explosion-like vapor film destruction is not observed (there are no significant pressure pulses) at relatively low ($T < 180^{o}$C) and high values ($T > 410^{o}$C) of the hemisphere temperature. Between these two values of a temperature, a pack of pressure pulses is formed, which is characterized by two (microsecond and millisecond) time scales. An amplitude of the pressure pulse can be as high as ~1 MPa, which is sufficient to trigger vapor explosion [5]. It is important to point out that, as it can be seen from Fig. 2, maximum pressure

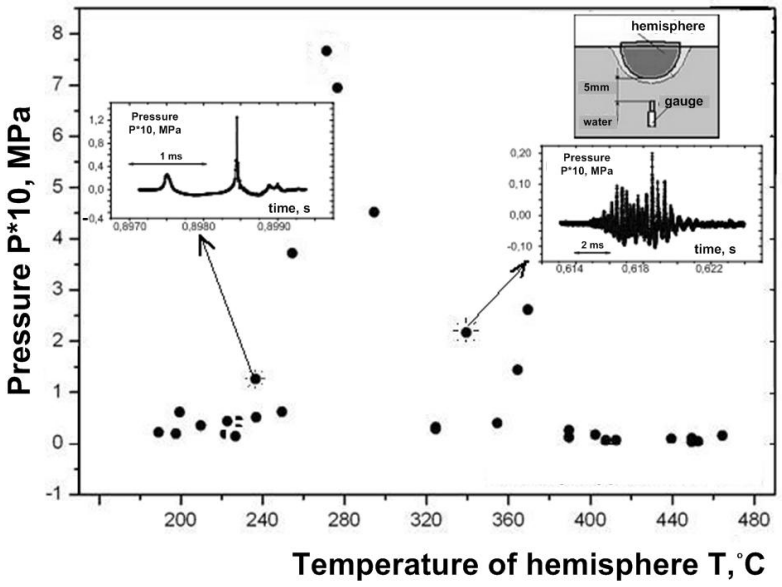

Figure 2. Dependence of the maximum amplitude of pressure pulses on the heated hemisphere temperature. Specimens are made of stainless steel. Water temperature is 20°C.

pulses are observed within a range a temperature of the heated-surface that is close to the temperature of the ultimate superheating of water. According to different experimental estimates, at atmospheric pressure, the latter is equal to about 250-280°C [6].

Along with the amplitude of the pressure pulse, a temperature of the heated surface considerably affects the frequency of pulsations and the number of them in the pack; they both increase with an increase in the temperature by an exponent law.

Detailed investigations into the phenomena under study can be accomplished by conducting finer comprehensive experiments. In particular, interesting additional information can be obtained from measuring pressure pulses, which is carried out simultaneously with determination of the degree of the cold liquid contact with the heated body (equivalent radius or the contact area) with the use of electro contact probe. Figures 3a – 3c shows typical results from such investigations obtained with specimens made of stainless steel.

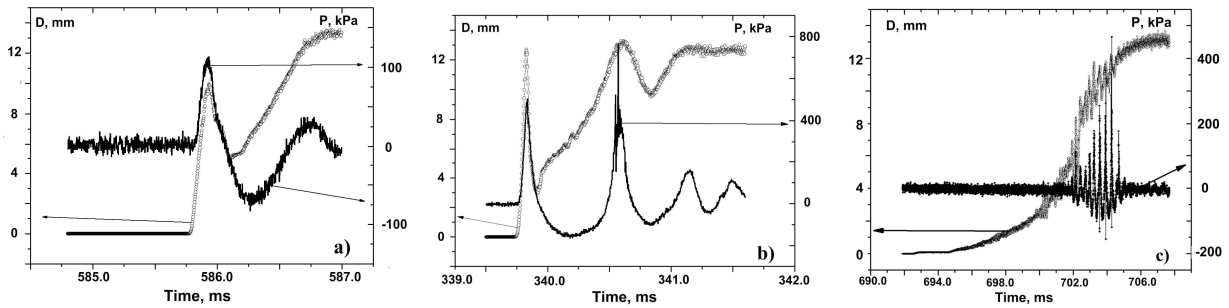

Figure 3. Simultaneous oscillograms of pressure and equivalent diameter of the contact spot. Specimens are made of stainless steel. Hemisphere temperature at a moment of explosion-like collapse (destruction) of the vapor film: (a) 219; (b) 279; (c) 315°C.

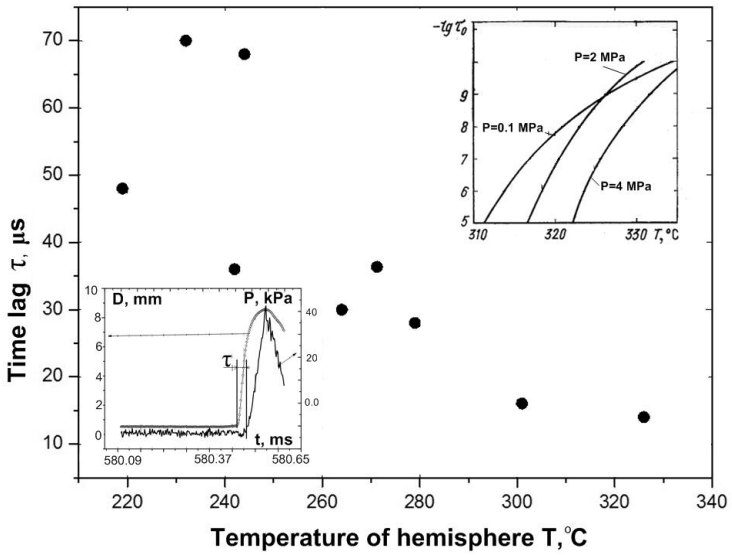

Figure 4. Dependence of the time necessary for heating cold water (water temperature is 20°C) till its boiling-up during water coming into contact with the heated surface on the hemisphere temperature. The insert in the right upper angle shows the calculated data from [6].

It is necessary to point out the fact that the cold liquid comes into contact with a hot surface, the temperature of which is higher than the ultimate temperature of the liquid superheating. The processes occurred on the specimens made of stainless steel and copper differ each other. In addition, we should point out the following. First, as it is seen from the curves in Fig. 3, the behavior of pressure pulses, at least at the initial stage of the contact, follows a change in the contact spot in time, i.e., the signals from the electric-contact and pressure sensors are correlated. Second, in all tests conducted, after coming the water into contact with the hot surface, an increase in pressure did not take place simultaneously with this event; certain time lag caused by the necessity of heating the cold liquid before its spontaneous boiling-up (flashing) was observed. The magnitude of this time lag in the tests conducted was tens of microseconds and it decreased with an increase in the hemisphere temperature (Fig. 4). We should note that the experimental data obtained well agree with the theoretical estimates of the time of contacting of cold water (T=20°C) and a hot surface under flashing in [6].

Finally, from the curves given in Fig. 3 we can assess the velocity of wetting the hot surface by water (the ratio of a change in the contact spot radius to the duration of this process), which, as it follows from the data presented, depends on the hemisphere temperature and can be rather high, of about 70 m/s.

INTERPRETATION OF EXPERIMENTAL DATA

Heat and mass transfer processes that occur in the case of coming into contact of a hot heater and cold liquid qualitatively can be described as follows. At the initial instant, one or some vapor bubbles are formed on a solid surface (Fig. 5a). A considerable increase in a volume of a liquid "tongue" due to evaporation leads to propagation of the latter along the heater surface (Fig. 5b). Condensation of the superheated vapor from the vapor film surrounding the hot surface accelerates contact spot expansion. Motion of liquid pulls away the vapor bubble from the nucleation cite and it begins to collapse inside the cold liquid (Fig. 5c). At the final stage of the collapse, the pressure in the liquid near the interface increases considerably. Single or cumulative bubble-collapse effects bring to the appearance of a pressure pulse in the liquid and subsequent explosion-like destruction of the vapor film. Contact spot expansion is completed by the transition to the developed nucleate

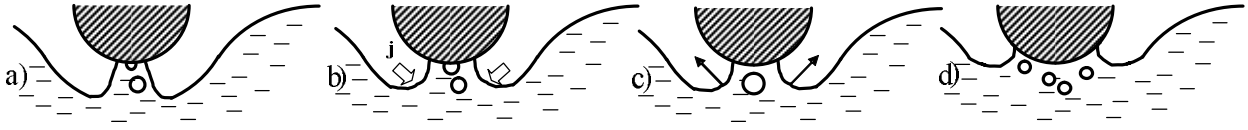

Figure 5. Qualitative description of the process

boiling (Fig. 5d). The velocity of propagation of the interface front is about 100 m/s, which is rather high for such type of problem.

Numerical results that we have obtained earlier on the basis of our technique for calculating characteristics of a smooth stationary axisymmetric interface formed during immersion of a hemispherical heater into cold water are in a good agreement with experimental data [7]. When so doing, the mathematical description of the problem included a set of equations that represent general and special compatibility conditions at the interface. Thus, to describe the problem under consideration, three equations of conservation, i.e., those of mass, momentum, and energy, are stated at the interface, which correlate respective characteristics of the liquid and vapor phases. Linear Labuntsov-Muratova correlation is used as a special compatibility condition (nonequilibrium boundary condition). This formula was obtained [8] with the use of principles of molecular-kinetic theory and makes it possible to calculate mass flow rate during evaporation and condensation, with an interface temperature and vapor pressure being known.

The model that describes vapor-bubble collapse near the interface shows a good agreement with experimental data as to a magnitude of the pressure jump [3]. Therefore, it was proposed to use this model to describe the propagation of the liquid "tongue" along the heater surface.

At the first step, the formation and collapse of a single vapor bubble in a liquid was analyzed. According to the known solutions to the traditional problems of the mechanics of two-phase systems [9] the time of the vapor bubble growth up to the departure diameter of 0.3 mm is not less than $8.2\ 10^{-4}$ s. In this case, the velocity of motion of the interface due to vapor-bubble expansion will be of about 0.1 m/s.

If we suppose that at the beginning of the vapor bubble collapse the temperature in the bubble is 100^{o}C and the corresponding pressure at the saturation line is 10^5 Pa, the bubble collapses due to action of hydrostatic pressure difference between the lower point of the heating surface and the free liquid surface, which is equal to approximately 50 Pa. The analysis of the vapor bubble dynamics with the use of the model based on Rayleigh's equation shows that under such conditions the bubble-collapse time is $6.1\ 10^{-4}$s. When this happens, the value of pressure in the liquid reaches 1 MPa, which is an agreement with experiments [3].

Another possibility of bubbles formation is their appearance not on heater surface but in liquid near this surface. Collapse of these bubbles can give corresponding addition to pressure pulse.

A rate of vapor condensation from the film on the cold-liquid surface is assessed with the use of the correlation following from the solution of the Boltzmann kinetic equation [8]; where P is the pressure of the gas removed, Pa; T_s is the interface temperature, K; P_s is the equilibrium vapor pressure at the saturation line corresponding to T_s; and T is the gas temperature far from the interface, K.

$$j = 1.67 \frac{P - P_s}{\sqrt{2\pi R T_\infty}} \qquad (1)$$

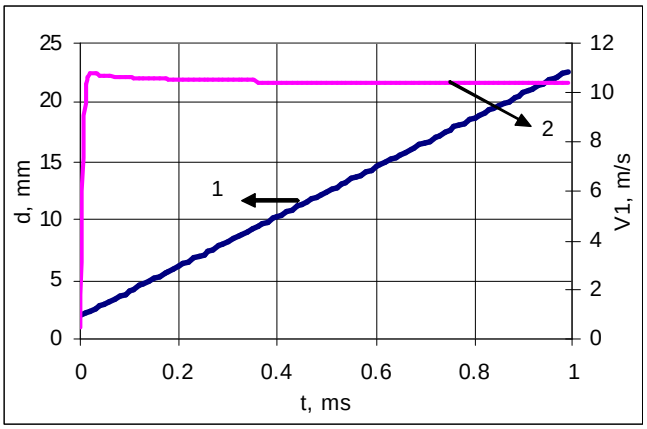

Fig. 6. Dimension of the contact spot (*1*) and corresponding velocity of the vapor-liquid interface motion (*2*) as functions of time.

With the pressure difference at the interface of 50 Pa the mass flow rate is 5.75 10^{-2} kg/(m^2 s) and the corresponding interface velocity is 5.75 10^{-5} m/s. We see from these calculations that, with the above parameters of the two-phase medium, condensation does not affect considerably the liquid-vapor interface motion.

The final stage of the process is as follows. Due to pressure pulse impact the liquid moves in lateral directions, with depth layers being included in this motion. The velocity of liquid propagation at the initial stage of the process and an increase in the contact spot dimension are estimated using the non-steady solution of Gromeko's problem about the motion of viscous liquid plug in the duct [10]. The duration of the pressure pulse is 10 μs; the initial dimension of the contact spot is 2 mm.

Comparison of the calculation results with experimental data shows that characteristic times of heat and mass transfer processes agree, at least by an order of magnitude (see table).

Table.
Comparison of characteristic values

Characteristic values	Experiment	Calculations
Time from coming into contact till a pressure pulse, μs	10-100	100-1000
Pressure pulse in a liquid, MPa	1	1
Velocity of liquid front propagation, m/s	10-100	11
Averaged time of contact spot spreading after pressure pulse, ms	1-5	-

The differences between the experimental and calculation data are caused, first of all, by the fact that a behavior of only a single bubble was analyzed, while, in reality, several bubbles can be formed. Nonisothermal condition of the heater and certain dynamic effects connected with surface wettability were not accounted for also. Collective phenomena lead to noise appearance and to changing liquid-front velocity. When this happens, both acceleration and deceleration of the front motion can take place.

Hence, the dynamics of the interface during vapor-bubble collapse in a cold liquid determines expansion of the contact spot and it is favorable for explosion-like vapor film destruction. The speed of the dynamic effects motion on the interface is comparable with a sound velocity.

CONCLUSIONS

1. A simple technique was developed, which made it possible to recognize the existence of contact and determine contact area during interaction of the cold water and hot surface.

2. Synchronized measurements of pressure pulses, solid body temperature, and contact area were carried out. It was found that depending on the velocity of water spreading over the heated surface single pressure pulse or a pack of successive pulses can occur.

3. Pressure pulses of up to 1 MPa were seen in the regimes with single pulses. They took place at a heating surface temperature close the temperature of ultimate superheating of water. Attempt to calculate the value of pressure pulse can give same order of these characteristic as in measurements.

4. The time lag, which is necessary to heat liquid before explosion-like boiling-up is about 10 μs, which is in agreement with corresponding theoretical estimates.

The authors gave their appreciations to V. V. Glazkov, V. G. Zhilin, O. A. Sinkevich, and V. V.Yagov for fruitful discussion and comments of the results of this work.

EXPERIMENTAL ANALYSIS OF DROPLET GENERATION

G. Wojciechowski*, P. Domagała, S. Drobniak

Czestochowa University of Technology,
Institute of Thermal Machinery, Czestochowa Poland

ABSTRACT. The paper presents results of experimental analysis concerning the primary breakup of liquid jet. The experiment was carried out for two test conditions with and without excitation with the injector based on Rayleigh phenomenon. The breakup process was investigated by optical methods based on fast micro photography. The results obtained constitute the data base for verification of numerical modelling of liquid jet breakup.

Keywords: *liquid jet primary breakup, atomization*

INTRODUCTION

The atomization of liquid jets is of great importance for several industrial processes, such as generation of sprays, fuel injection in internal combustion (IC) and jet engines and combustion of liquid fuels. The dominant trend in liquid fuel combustion systems is the increase of fuel injection pressure (in IC engines) or injection to high shear stress environment (in aeroengines) that leads to the decrease of mean diameter of generated droplets. In most combustion systems reduction of fuel droplets diameter provides easier ignition, a wider range of burning conditions and lower concentrations of pollutants in exhaust gases as well as the improvement of engine efficiency.
Disintegration of a liquid jet emerging from simple cylindrical nozzle may be affected by several factors i.e. the turbulence in the liquid jet and in the surrounding air, cavitation in the nozzle atomizer, and the interferential friction between emerging liquid jet and surrounding medium, which were identified as the most important ones [1], [2]. It should also be stated that atomization and jet breakup are the instability – driven processes and therefore they are highly unsteady. Most of the research concerning the atomization problem was performed experimentally, the numerical modelling encounters severe difficulties resulting from the presence of two separate phases with discontinuous change of phase properties and from the unsteady nature of jet breakup processes, which can not be properly accounted for with the use of RANS methods. That is why it is only recently that the first successful attempts of jet primary breakup numerical modeling could be performed [3]. One should notice however, that this solution was obtained with low order solver, while the proper capturing of interaction between turbulence and jet breakup processes will require higher order accuracy solver, especially when application of LES is considered [4].
The interest of industry in the problem stated above was the reason for establishing EU STREP project TIMECOP [5], devoted to experimental and numerical investigations on atomization and evaporation of liquid fuels in jet engines. Within TIMECOP project the researchers from Institute of Thermal Machinery CzuT are responsible for LES modelling of liquid jet primary breakup and generation of high quality experimental data needed for verification of numerical modelling.

The motivation for the present study is twofold. First reason is, that the existing knowledge concerning disintegration of liquid jets and evaporation of droplets was obtained for comparatively large diameters of jets and droplets [1], while currently designed aircraft engines utilize much smaller fuel nozzle diameters [6]. Second motivation is, that most of experimental results concerning the jet primary breakup have been obtained in the first part of last century [1] and even if these results are very accurate and reliable, they contain at most the basic statistics like mean and variance of analyzed quantities.. The above statement outlines the main motivation for the present study which is devoted to the experimental analysis of liquid jet primary breakup in the range of jet diameters of the order of ~ 100μm.

The phenomenon of uniform liquid – jet breakup was theoretically studied by Rayleigh [7]. A more general theory for disintegration of jet at low speed was developed by Weber [8] who extended Rayleigh's analysis to include viscosity and the effect of air resistance on the disintegration of jet into drops. Typing level headings.

APARATUS AND MEASUREMENTS TECHNIQUES

Injector used in current study shown in Figure 1. was designed by T. Kowalewski and used at IPPT PAN [9]. This injector is based on Rayleigh instability phenomenon. The plenum chamber of this injector is made of copper, while nozzle and bottom plate are fabricated of stainless steel. Piezoelectric transducer fixed to bottom plate introduced controlled disturbances to the liquid jet (for non excited case this feature was not used).

Injector is equipped with replaceable nozzles with different exit diameters in the range from 50μm to 2mm. During the present research the 100μm nozzle was used.

The schematic diagram of the test rig is shown in Figure 2. This test facility consists of two main parts. The first part serves for the droplet generation and the second part of this facility serves for recording of generated droplets. The main components of the test facility are as follows

- Atomiser (1) equipped with replaceable nozzles
- Digital camera (2) Canon 400D placed on micromanipulator (13),
- LED lamp (4) with (3), driven by impulse generator (5),
- Synchronisation unit (6),
- Harmonic Generator (7) with controlled amplitude and frequency of excitation,
- Amplifier (8) exciting piezoelectric transducer of atomizer (1)
- Oscilloscopes (9) i (10) and frequency meter (11),
- High pressure tank manometer (15) and flow meter (14).

Figure 1. Injector based on Rayleigh instability from IPPT PAN

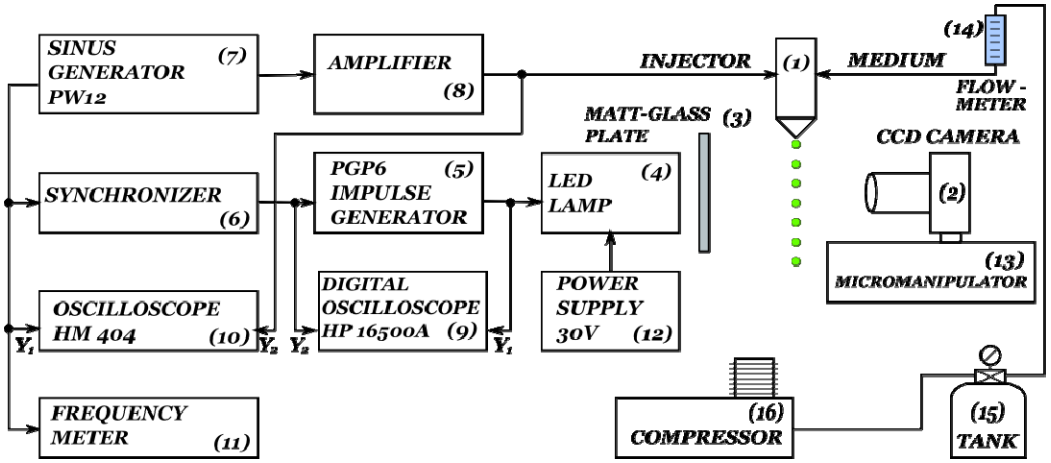

Figure 2. Scheme of equipment used for experimental investigation of atomisation process.

The atomised liquid was supplied to atomizer (1), from the pressure stabilising in tank (15). Determination of flow velocity was based on flow meter (14).
The part of test facility responsible for recording of generated droplets is composed of:

- CCD camera (2)
- LED lamp (4),
- Flash synchronizer (6),
- Impulse generator (5),

Synchronizer (6) and impulse generator (5) allow for precise adjustment of flash duration and delay with respect to driving signal of piezoelectric transducer. The measurements of flash duration and delay was done by digital oscilloscope HP16500A (9). The duration and the delay of flash was achieved by impulse generator PGP6. Amplitude and frequency of driving signal of piezoelectric transducer was determined by generator of harmonic signal (7), those parameters were measured by oscilloscope HM 404 (10) and frequency meter (11). The details of experimental setup and measuring techniques may be found in [10]
As a liquid chemically clean water was supplied to injector. The temperature of liquid and ambient temperature were recorded and controlled during the measurements.
Recorded images were analysed with ImageJ software [11]. Recorded images had uniform brightness and there was no need for image equalisation.

RESULTS

Non excited case

The first quantity needed for verification of numerical modeling was the length of liquid jet column before its disintegration into droplets. It is a non-stationary process and not only the mean value of disintegration length but also the range of variation of this parameter had to be determined. Figure 3 presents the variation of jet column length for four test cases analyzed, mean values are presented together with bars corresponding to minimum and maximum values of jet disintegration length recorded for particular test cases.
Jet length is presented in Figure 3a while sample images of jet disintegration process have been shown in Figure 3b. One may notice (Figure 3a), that the linear growth of mean disintegration length was obtained for first three test cases, which was accompanied by the gradual increase of the range of L/d_0 variation as it is indicated by the width of bars. It must be noticed however, that the data for Re=346 deviate from this tendency, because not only mean value is above linear fit but also the width of bars is

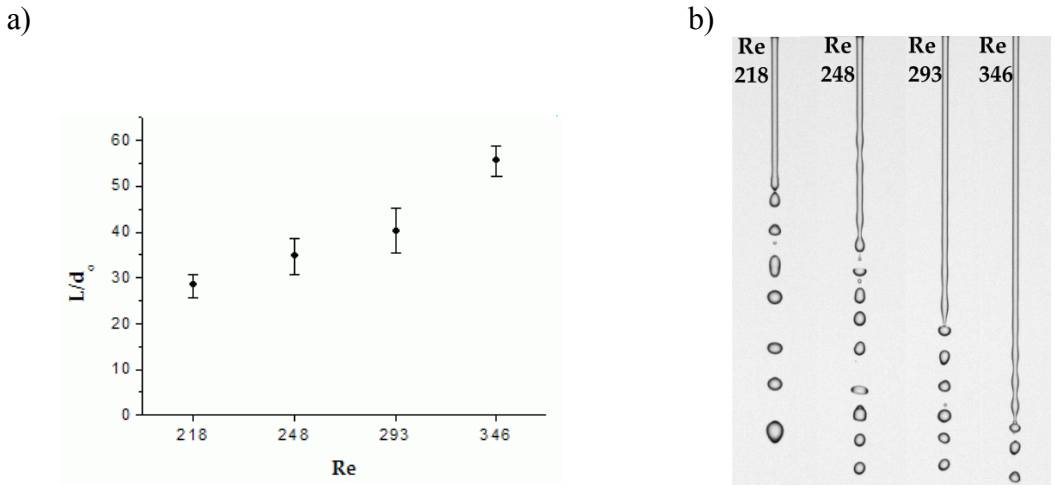

Figure 3. Distribution of jet length a) versus Re number, and b) sample images.

smaller then for Re=293. It should also be stated that results obtained for non excited case in low range of Reynolds number confirm the theoretical predictions of Weber, more information about this problem may be found in [10].

The next stage of present investigations concerned the pdf distributions of droplets generated as a result of liquid jet breakup. Particular distributions for all test cases analyzed have been shown in Figures 4 to 7. All pdf distributions reveal three characteristic peaks. First peak of all pdf distributions obtained for smallest values of d/d_0 confirms the presence of pilot droplets. On the average the diameter of pilot droplets is 4 to 5 times smaller then the diameter of "main" droplets. The second peak corresponds to the appearance of droplets generated as a result of jet breakup. For comparison the line corresponding to theoretical value obtained by Rayleigh

$$d_R = 1.89Dj \tag{1}$$

has also been plotted at this figure and one may notice the perfect agreement of experimental results with equation (1). The third peak corresponds to the presence of droplets resulting from amalgamation of neighbouring droplets and also in this case the line corresponding to droplet diameter d_a resulting from amalgamation of two identical droplets with diameter d, i.e.

$$d_a = \sqrt[3]{2}d \tag{2}$$

has been marked at pdf distributions. One may notice that for the lowest Reynolds numbers applied Re=218-293 (see Figures 5-7), the peak corresponding to droplets resulting from primary jet breakup is dominant in pdf distributions. It is interesting to note, that the average size of amalgamated droplets is greater then the value calculated as a simple connection of two neighbouring droplets, it may be caused by participation of pilots which become amalgamated with neighbouring large droplets, that leads to the increase of diameter of the resulting droplets. The Re=346 test case differs considerably, because the probabilities of primary and amalgamated droplets appearance are almost equal. It is interesting to note that the third peak of pdf for Re=346 indicates the value lower then the average diameter of amalgamated droplets. It may result from the possible breakup of amalgamated droplets which is due to their large diameters, which in turn makes them more susceptible to aerodynamic forces.

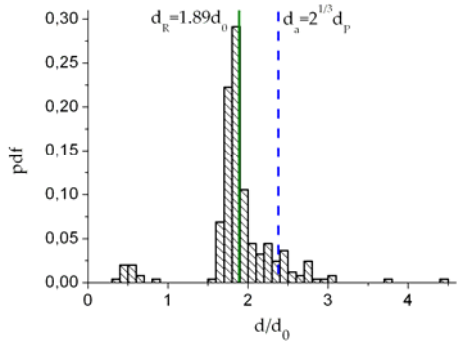

Figure 4. Pdf distributions of droplet size for Re=218

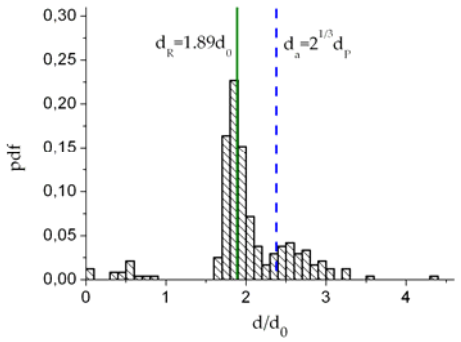

Figure 5. Pdf distributions of droplet size for Re=248

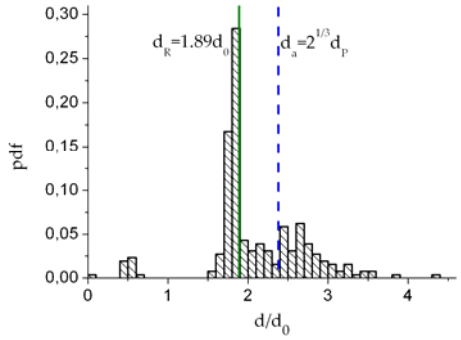

Figure 6. Pdf distributions of droplet size for Re=293

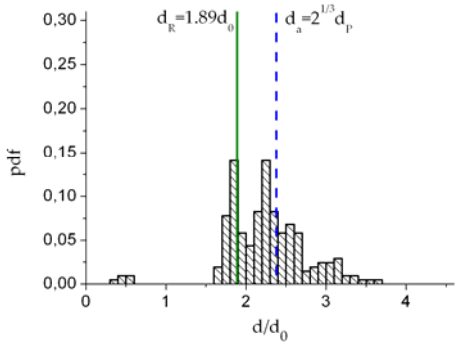

Figure 7. Pdf distributions of droplet size for Re=346

Excited case

For the selected Reynolds numbers the influence of frequency of excitation was investigated in order to find out the most sensitive frequencies of the liquid jet column, this information was also needed for numerical experiments. Investigations were performed for the Reynolds number Re=250, the excitation frequency was supplied to piezoelectric element mounted in the plenum chamber of the injector. Again the instantaneous pictures were recorded and processed with the use of techniques described in [10]. Figure 8 presents the variation of jet column length for sample Reynolds number equal Re=250 for different frequencies of excitation. The jet length was normalized by nozzle exit diameter denoted as d_0, the frequency of excitation was normalized by Rayleigh frequency (denoted as f_R) defined as:

$$f_R = \frac{U_L}{\lambda_{opt}} \tag{3}$$

where:

$$\lambda_{opt} = 4.508 D_j \tag{4}$$

For illustration, sample of recorded images of jet disintegration process have been shown in Figure 8b for frequencies marked at the plot.

One may notice the appearance of the minimum of the jet length for a range of excitation frequencies and good agreement of present experiment with literature data [1], with give the following range:

$$3.5 D_j < \lambda < 7 D_j \tag{5}$$

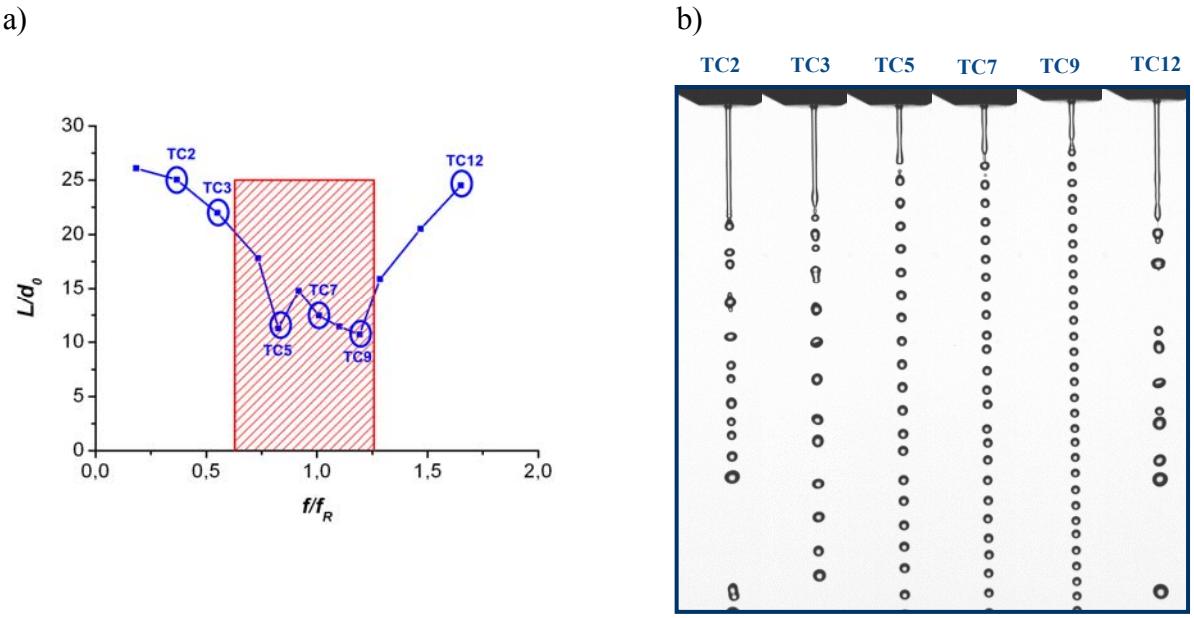

Figure 8. Distribution of jet length a) versus frequency of excitation, and b) sample images for sample test cases.

For comparison the hatched area corresponding to theoretical data defined by equation (5), was plotted in this graph. It should be noticed that the reaction of the jet to excitation frequency is not monotonous, in particular two neighboring minima may be observed in the picture (the reason for this behaviour are currently investigated)

The next stage of investigations concerned the determination of pdf distributions of droplet sizes generated as a result of liquid jet breakup due to excitation. Particular distributions for test cases analyzed have been shown in Figures 9 to 14. Table 1 presents all test conditions and test cases investigated, which were collected as a data base for comparison with the results of numerical simulations.

Table 1
Summary of investigated test cases for excited test case Re = 250

Test Case	TC1	TC2	TC3	TC4	TC5	TC6	TC7	TC8	TC9	TC10	TC11	TC12
f [Hz]	1000	2000	3000	4000	4500	5000	5500	6000	6500	7000	8000	9000
f/f_R	0,18	0,37	0,55	0,73	0,83	0.92	1,0	1,1	1,19	1.28	1,46	1,65
L [mm]	x	x	x	x	x	x	x	x	x	x	x	x
d [mm]		x			x	x	x		x			x

All pdf distributions have been normalized by the injector nozzle diameter d_0, also for comparison the line corresponding to theoretical Rayleigh value denoted as d_R and line corresponding to amalgamated droplets denoted as d_a were plotted at these figures. One may notice that for the lowest value of frequency of excitation the pdf distribution of droplet size is quite flat, that means that injector is producing wide range of droplets sizes, what is undesirable from future work point of view. But as the frequency of excitation is increased the pdf distributions reveal more selective distribution of droplets frequencies, especially for frequencies close to the theoretical value of Rayleigh frequency equal for this case f_R=5.45 kHz. As we move to TC9 (second minimum of jet length see Figure 8) one may notice that the mean diameter of generated droplets shown in Figure 13 is smaller than defined by

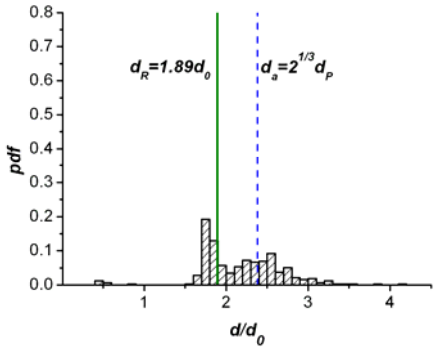

Figure 9. Pdf distributions of droplet size for TC2

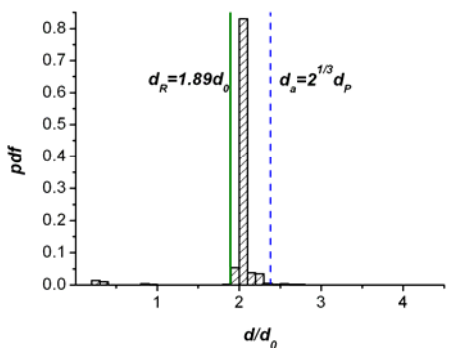

Figure 10. Pdf distributions of droplet size for TC5

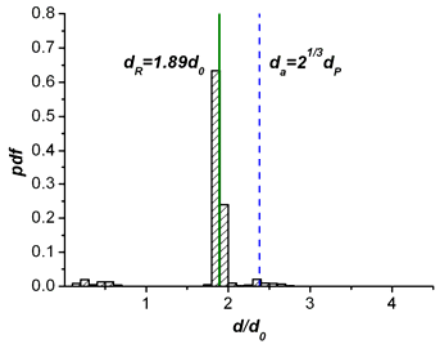

Figure 11. Pdf distributions of droplet size for TC6

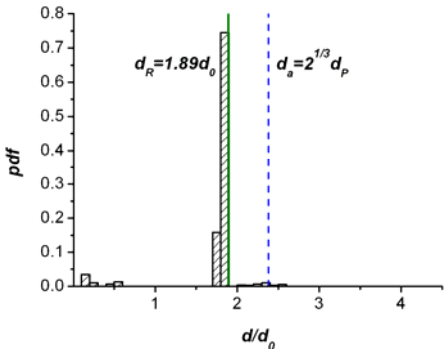

Figure 12. Pdf distributions of droplet size for TC7

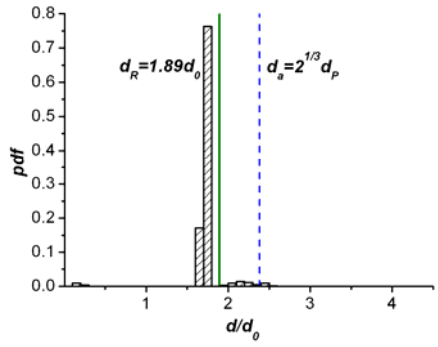

Figure 13. Pdf distributions of droplet size for TC9

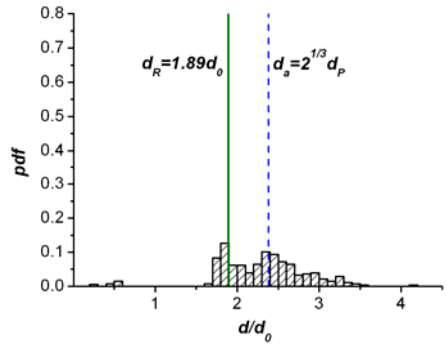

Figure 14. Pdf distributions of droplet size for TC12

Rayleigh. And finally for the last test case TC12 (Figure 14) one may notice similar pdf distribution of droplets like for first pdf distribution for the lowest frequency of excitation (compare Figures 14 and 9). Even if the pdf distributions in Figures 9 and 14 are rather flat one may still notice two characteristic peaks corresponding to droplets generated due to primary jet breakup and due to amalgamation of two neighboring droplets.

SUMMARY

For the injector based on Rayleigh injector two test cases were investigated i.e. with and without excitation. For both cases the length of the liquid jet column before disintegration and the size

distributions of resulting droplets were investigated. The histograms of droplet size distributions reveal three peaks corresponding to presence of pilots droplets, to droplets generated due to jet breakup, and to droplets resulting from amalgamation of neighboring droplets. It was also found that dominant peaks correspond to droplets generated due to primary jet breakup for Reynolds numbers below Re=300, while for the largest Re number investigated the probability of primary and amalgamated droplets were found equal.

Experimental investigations for the case with excitation show the appearance of the minimum of the liquid jet length for certain range of frequency of excitation. These results are in good agreement with literature data. Again the histograms of droplet size distributions reveal three peaks corresponding to presence of pilots droplets, droplets generated due to primary jet breakup, and droplets resulting from amalgamation of neighboring droplets with dominant peak corresponding to droplets generated due to primary jet breakup.

NOMENCLATURE

d – droplet diameter, m
d_a – amalgamated droplet diameter, m
d_P – primary droplet diameter, m
d_R – droplet diameter defined by Rayleigh, m
d_0 – injector nozzle diameter, m
D_j – liquid jet diameter, m
f – frequency of excitation, Hz
f_R - frequency of excitation defined by Rayleigh, Hz
L – breakup length, m
U_L – velocity of liquid, m/s
Re – Reynolds number
λ – wavelength, m
λopt – optimal wavelength, m

DOE SCHARDIN'S SCHLIEREN #2 IN INVESTIGATING FREE CONVECTION IN VERTICAL CHANNELS

D. Ambrosini[1,*], D. Paoletti[1], G. Galli[2]
[1]University of L'Aquila, L'Aquila, Italy
[2]University of Roma "La Sapienza", Roma, Italy

ABSTRACT. Recently flow visualization by fringe projection, through a test section with non-uniform refractive index distribution, was proposed using a diffractive optical element (DOE) to generate fringes. Information about temperature gradient, encoded in the deformed fringe pattern, is obtained by correlation algorithms or by Fourier Transform algorithms. The main feature of this proposed procedure is the flexibility in suiting to different heat transfer phenomena.
The aim of this paper is to evaluate the performance of this system and consider the sensitivity problems that can arise when working fluid is air. Some experimental results are given for a particular case study: free convection in vertical channels in air, which is encountered in many technological applications. It was found that this technique can work in air but its sensitivity should be increased. Some possible ways to increase sensitivity are suggested.

Keywords: *heat transfer, free convection, flow visualization, Schlieren, holographic interferometry*

INTRODUCTION

Flows having a variable fluid density can be visualized by optical methods [1, 2].
Practical investigations frequently involve operation under less than ideal condition. In particular, operating conditions may include vibration, difficult optical access and short data sampling times when studying transient processes. Therefore, key features of a successful optical method for studying convection in transparent media include: low sensitivity to external disturbance in comparison with traditional interferometric techniques; good measurement sensitivity; low cost and simplicity of the system; possibility of use by non-optically skilled operators; full digital data elaboration, to take advantage of the current progress of computer hardware and software.
Recently [3], a fringe projection technique was proposed to study the refractive index variation in fluid and hence to measure the convective heat transfer. This method, which can be considered a type of Schardin's schlieren #2 [4], uses a simple and cheap fringe generator, realized with a diffractive optical element (DOE) illuminated by a spherical wave [3].
The idea of mapping refractive fields through a distortion of an otherwise regular pattern is old, simple and effective. It was fully exploited and developed in the correct context by schlieren pioneer Hubert Schardin [4, 5].
The technique discussed in this paper is similar to "synthetic schlieren" [6, 7] and to "Background Oriented Schlieren" (BOS) [8].

Synthetic Schlieren [6, 7] involves the study of the deformations induced by the test section in a regular (lines, dots) or random dots pattern. Similar methods, based on grid pattern distortions, were almost simultaneously proposed [9-11], not always realizing they can mostly be traced back to Schardin's schlieren # 2 [5].
BOS [8] used background artificially generated by splashing tiny droplets of white wall paint or background naturally presents (i.e. grass).
The main features of both synthetic schlieren and BOS are present in the early pioneering work of Giglio et al. [12]
In DOE Schardin's schlieren #2 the fringe patterns, generated by the DOE, are projected on a ground glass plate. The phase object (test section) is placed in front of the ground glass (in other words, in front of the fringe pattern), which is imaged by a digital video camera. Grating patterns, during the evolution of heat transfer phenomena, are captured by a TV camera and stored in a computer. The images can then be processed, for instance with the aid of Fast Fourier Transform (FFT) and signal demodulating techniques, to obtain a visualization of temperature gradient and the heat transfer coefficient.
All data processing that follows the acquisition is accomplished inside the PC, and there is no need for a skilled technician, since no special operations are to be performed to handle the system. The inherent simplicity and the fact that only readily available and unsophisticated equipment is required, characterize the method.
Unfortunately, this system may exhibit poor performances when working fluid is air. Therefore, the aim of this paper is to evaluate the system performance in this case and search for possible ways to improve it.
In the next section, the principles and some details of the proposed system are described. Furthermore, we present a discussion of system performances and some experiments on free convection in vertical channels in air, which is encountered in many technological applications.

BASIC THEORY

The optical scheme of DOE Schardin's schlieren method #2 is shown in Figure 1.
The fringe generator (see [3] for details) is a phase saw-tooth grating, illuminated by a laser diode (Lasiris by StockerYale, wavelength 638.5 nm, output power 5 mW) pigtailed to a single-mode optical fiber.

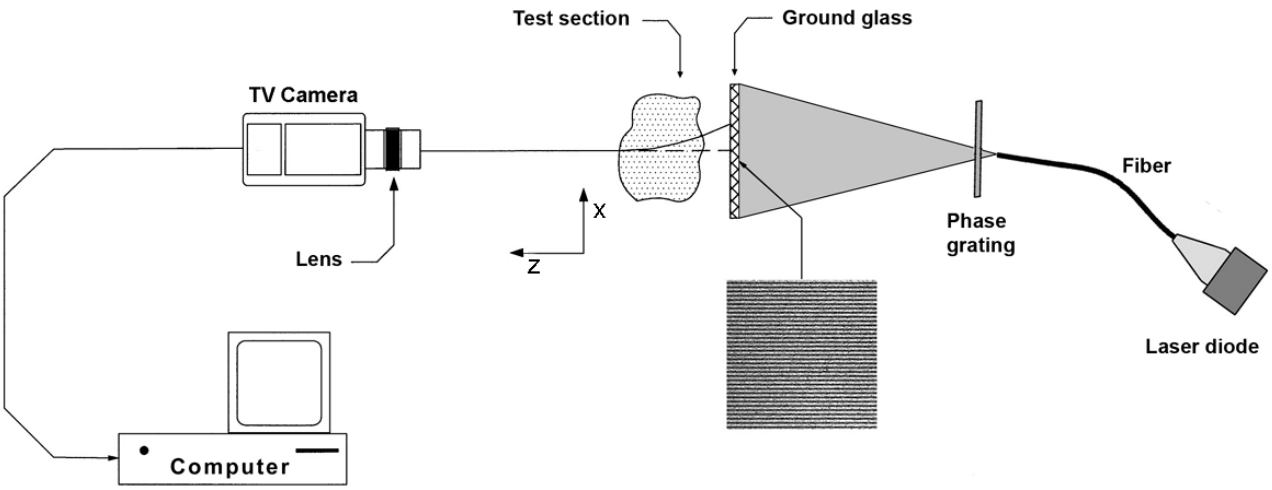

Figure 1. Schematic layout of experimental setup.

The fiber end acts as a point source. Therefore, a spherical wave comes out from the fiber. This light impinges on the grating, which acts as a beam divider. In the superposition region of the two exiting beams, interference fringes are formed.
The DOE should concentrate most of the output energy on two diffraction orders, thus behaving as a beam splitter. The performance of a DOE can be evaluated by its diffraction efficiency, which is the ratio between the power of the desired order and the power of the incident beam. If the maximum phase shift introduced by the saw-tooth grating is π we obtain a zero order and a +1 order with the same ideal diffraction efficiency of about 0.405 and a total diffraction efficiency (ratio of the power exiting in the desired orders and the incident power) of 0.81.
In practice, the diffraction efficiency of the used DOE is lower: 0.4 for the zero order and 0.31 for the +1 order; however the diffraction efficiency, relatively to the interesting orders, remains reasonably good (about 0.71). Because the two beams have comparable intensity, good quality fringes are obtained. The key feature of this fringe generator is the ability to change fringe period by simply changing the distance between fiber end and grating (see [12] for details).
The DOE is a blazed grating (with a saw-tooth profile) realized on index-matched epoxy. The grating size is 25×25 mm^2 and its period is 70 grooves mm^{-1}.
The fringe pattern obtained with the DOE-based fringe generator is projected on a ground glass plate. The test section is placed just in front of the ground glass (i.e., no distance between test section and screen), which is imaged by a TV camera, through a narrow bandpass filter matched to the laser diode wavelength.
The TV camera was a Silicon Video® 9T001C with PIXCI® D2X imaging board by EPIX Inc., with a resolution of 2048 × 1536 pixels. The camera was equipped with a TEC-55 55mm F/2.8 Telecentric Computar Lens and connected to a PC.

DATA PROCESSING AND DISCUSSION

If refractive index n in the test section is non-uniform, the rays through the test object will be deflected. In other words, if the refractive index changes, the deflection angle will also change. The change of the deflection angle can be regarded as a local translation of the fringe pattern [3]. In strict analogy with speckle photography [14], this displacement is proportional to the temperature gradient [3]. It can be shown [3] that, for a simple geometry allowing 1D refraction, the deflection angle of a ray, entering the test section in $x = x_0$ and passing through the test section can be written as

$$\beta = \frac{dx}{dz} \cong \frac{\ell}{n(x_0)} \left. \frac{\partial n}{\partial x} \right|_{x_0} \tag{1}$$

where ℓ represents the thickness of the test cell (measured along the propagation axis) and the relative apparent translation of the fringe pattern is

$$\xi(x_0) = \ell \tan\beta \cong \frac{\ell^2}{n(x_0)} \left. \frac{\partial n}{\partial x} \right|_{x_0} \tag{2}$$

Assuming temperature as a function of only one space variable (say x), equation (2) can be rewritten as

$$\xi(x_0) \cong \frac{\ell^2}{n(x_0)} \left. \frac{\partial n(T)}{\partial T} \frac{\partial T(x)}{\partial x} \right|_{x_0} \tag{3}$$

In literature are available several relations for calculating n and its derivative for different wavelengths and fluids [1].
The intensity of the projected fringe pattern, as seen from the TV camera on the ground glass through the non-uniform refractive index field is

$$I(x,y) = 2A^2\left\{1+\cos\left[2\pi f_x x + \varphi + \phi_\xi(x)\right]\right\} \tag{4}$$

where A is a real amplitude term, fringe frequency f_x and phase φ depend on geometric parameters, laser wavelength λ and the period of the saw-tooth grating [3] and $\phi_\xi(x) = 2\pi f_x \xi$ is the phase modulation introduced by local translation.
A qualitative visualization of the temperature gradient field can be obtained by subtracting the image recorded with a refractive index gradient, equation (4), from a reference image (no temperature gradient in the test field) and performing some image filtering [10, 11]. No complicated numerical calculations are required; therefore visualization can be recorded in quasi-real time (25 frames/s).

Quantitative data processing

PIV-mode. Considering equation (3), the temperature gradient field can be obtained calculating the pattern displacement $\xi(x_0)$ by using a cross-correlation approach of the PIV (Particle Image Velocimetry) type: sub-images are extracted from the reference image (thermal equilibrium in the test section) and the deformed image (temperature gradient in the test field), then the correlation surface is obtained using suitable correlation filters. The peak location in the correlation surface gives the relative displacement between the two sub-images.

Phase analysis-mode. Considering equation (4), quantitative data processing can be performed using a demodulation algorithm based on the Fourier transform and unwrapping procedures [3, 15-16] to obtain the phase term ϕ_ξ and then the pattern displacement $\xi(x_0)$.

Discussion

PIV-mode is the simplest quantitative data processing, due to the possibility of using existing PIV software with only minor modifications. However, it may exhibit some loss of resolution, due to the dimension of the sub-images.
Some problems may arise when working fluid is air. Water refractivity (defined as n - 1) is about 1125 times air refractivity. Water refractivity change, per 1 K temperature change, is about 129 times greater than air refractivity change [5]. Considering beam deflection, the difference is more evident: 1 K temperature change in water gives rise to a deflection of 47 arcseconds (1 rad = 206264.8 arcseconds); in air 10 K give rise to a deflection of 3.6 arcseconds [5].
To alleviate these problems when working in air, methods are needed to increase the sensitivity.
The sensitivity of the method can be defined as the amount of change of the measured quantity for a given refractive index (or temperature) gradient.
Considering equation (2) and the definition of ϕ_ξ, for both PIV-mode and Phase analysis-mode the sensitivity increases with ℓ; in other words, in analogy with conventional schlieren [5], extensive test sections along the propagation axis z are easiest to see.
Sensitivity can be increased, for both PIV-mode and Phase analysis-mode, by introducing a distance between the ground glass and the test section (say W). In fact, reconsidering its derivation [3], equation (2) can be rewritten as

$$\xi(x_0) \cong \frac{\ell(\ell+W)}{n(x_0)}\left.\frac{\partial n}{\partial x}\right|_{x_0} \tag{5}$$

In other words, image displacement (and thus sensitivity) can be increased if the screen is moved away from the test section; this added distance practically acts as an amplification factor. However, this usually lead to problems in proper focusing and should be adopted moderately.
A further way to improve sensitivity can be devised by considering Phase analysis-mode [3]: from previous relations, its sensitivity increases with fringe frequency f_x, which can be modified in the system by simply changing the distance between fiber end and DOE (see Figure 1).
However, about 10-15 pixels per fringe are needed to correctly process the fringes, thus limiting the maximum number of fringes (i.e. maximum frequency) that can be used.
A final way to improve sensitivity is to use more sophisticated phase extraction techniques [17].
To gain further insight about the combination of these improving strategies, let us consider an example. The deflection angle β can be rewritten as

$$\beta = \frac{\phi_\xi(x)}{2\pi f_x(\ell + W)} \tag{6}$$

The numerical value of β, in radians, in conventional schlieren analysis is routinely converted to arcseconds. Now, we can estimate the minimum detectable deflection angle, which, as said, depends on measured phase, fringe frequency, test section dimension ℓ and amplification factor W.

Table 1
Minimum detectable deflection angle (β) for a combination of improving strategies.

	W = 0 65 fringes	W = 0 85 fringes	W = 0.1 m 65 fringes	W = 0.1 m 85 fringes
Takeda method [18]	159 arcseconds 0.8 mrad	121 arcseconds 0.6 mrad	53 arcseconds 0.25 mrad	40 arcseconds 0.2 mrad
"Takeda improved"	80 arcseconds 0.4 mrad	60 arcseconds 0.29 mrad	26 arcseconds 0.13 mrad	20 arcseconds 0.1 mrad

Table 1 shows examples of minimum β combining different improving strategies: for all cases the test object had a length ℓ = 0.05 *m* and the field of view was 0.05 x 0.05 m^2, TV camera had 1024 x 1024 pixels, thus limiting maximum number of fringes at about 100. In Takeda method [18], used in [3], phase values can be obtained with a resolution of about π / 10. We consider as "Takeda improved" a phase extraction technique capable of a resolution of about π / 20 [17]. Sensitivity can be further increased using a higher resolution TV camera and/or reduced field of view and/or different phase extraction techniques.

EXPERIMENTAL RESULTS

The test section consisted of a vertical heated plate, made up of two aluminium sheets with a plane electrical resistance in between, and two shrouding vertical walls. The shrouding walls were smooth, unheated and placed so as to form two adjacent, symmetrical, vertical channels.
The heated plate had five transverse, square-cross-sectioned ribs on each side. The ribs were made integral with the baseplate to guarantee the absence of contact resistance. The dimensions of the heated plate were: overall thickness (without ribs) 0.012 *m*, height H = 0.175 *m*, length L =0.3 *m*. The length was set much greater than the other dimensions in order to favor a two-dimensional thermal field in the channels. The square ribs had a height of 0.00485 *m* and were regularly spaced at an interval of 0.035 *m*.

The spacing *S* between each unheated wall and the heated plate, set equal on both sides, was chosen in order to yield a channel aspect ratio *S/H* equal to 0.2. The plate was instrumented with fine-gauge, chromel-alumel thermocouples, calibrated to ± 0.1 K.
In the following, pattern displacements are evaluated using correlation algorithms (PIV-mode) based on the package MatPIV 1.6.1 by J.K. Sveen [19]. This package has the distinctive feature of being Open Source and of working in the MATLAB environment, thus sharing its capabilities of technical calculations and data visualizations.
This same test section was investigated in past years using holographic interferometry and schlieren [20, 21]. It was found that for all the S/H values, *h* starts from a high value at the leading edge and then sharply decreases, reaching a very low value at the junction between the baseplate and the first rib. From this point on, the h variations along the vertical coordinate are periodic in nature and the periodicity is equal to the rib pitch P. Two regions showing different thermal behavior can be identified: the rib and the inter-rib regions. Vertical sides of ribs show highly efficient heat transfer conditions. Along the inter-rib regions, *h* distributions are characterized by very low values close to the ribs (since they act as obstacles to the natural convection currents) and by relative maxima approximately at the midpoint of each inter-rib region.
A double exposed hologram is shown, for comparison, in Figure 2, right, for S/H = 0.2 and a temperature difference of 11 K: fringes are isotherm lines [20, 21]. The yellow rectangle shows the region of the channel depicted in DOE Schardin's schlieren #2 results.
Preliminary experimental measurements were performed taking two images, one with the plate at thermal equilibrium with ambient air (293 K) and the second with the heated plate at constant temperature (304 K). To increase sensitivity an amplification factor $W = 0.2$ *m* was used.
Then the two images were processed according to the PIV-mode data reduction previously outlined.

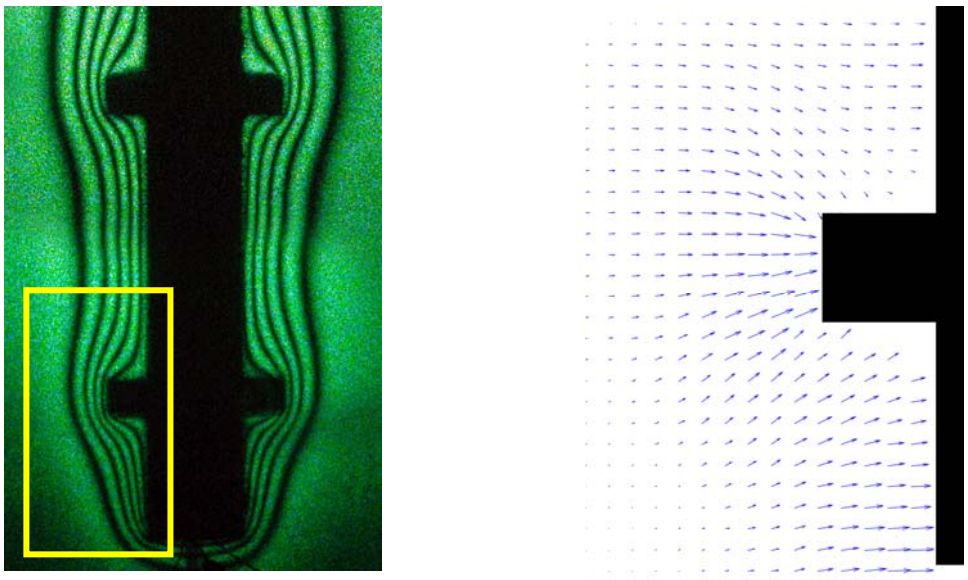

Figure 2. Holographic interferometry (left) and displacement field (right), proportional to the temperature gradient. S/H = 0.2, wall-to-fluid temperature difference 11 K.

The displacement field (Figure 2, right) was obtained in the simplest way, with a single iteration through the images and a 50% overlap of the interrogation windows.
The displacement field (proportional to the temperature gradient field) clearly identifies a laminar region: temperature gradients are not negligible (i.e. different from deep blue) only near the plate. Furthermore, minimum displacements (i.e. minimum temperature gradient) can be observed close to the ribs, while high displacements occur at the leading edge as well as at ribs vertical side.

This behavior can be appreciated more clearly from Figure 3, left, where the displacement magnitude is shown.
Finally, Figure 3, right, shows the lines of iso-displacement magnitude. This map agrees very well with the "equal light shift" lines obtained by the focal filament method traditional schlieren on the same test section [21].

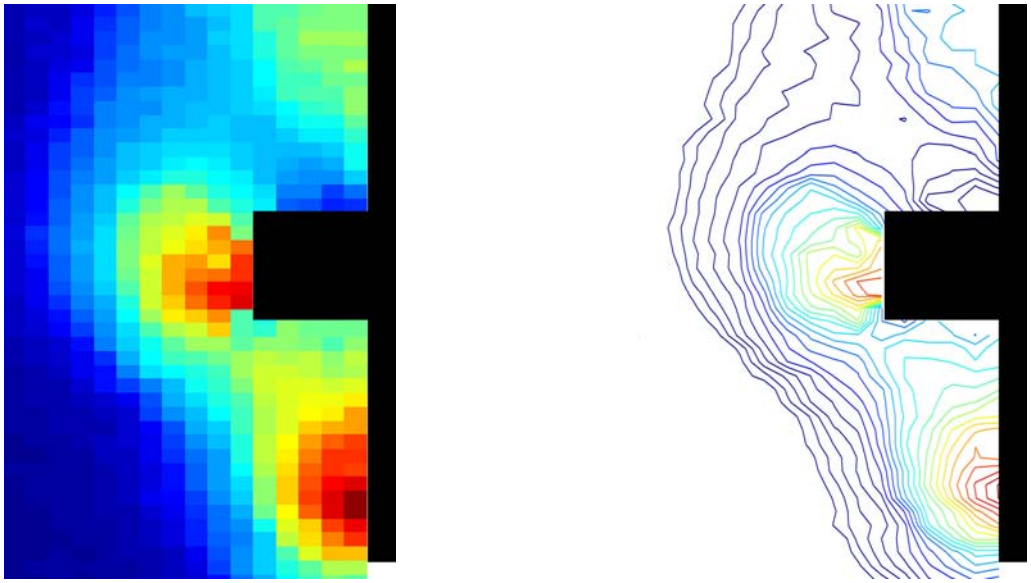

Figure 3. Displacement magnitude (left) and iso-displacement magnitude lines (right). S/H = 0.2, wall-to-fluid temperature difference 11 K.

CONCLUSIONS

In this paper we consider the DOE Schardin's schlieren #2 technique to investigate free convection in air. It was found that the application in air may give rise to sensitivity problems. As a solution was proposed a combination of strategies for improving sensitivity, such as modifying the experimental setup (introducing a distance between test section and ground glass), increasing the frequency of the projected pattern and/or using a different data processing.
Preliminary experiments, conducted using the MatPIV package in a MATLAB® environment, were performed in a vertical channel with an aspect ratio S/H = 0.2.
The technique was able to work in air and to give detailed information about many flow field features identified by holographic interferometry and traditional schlieren.

NOMENCLATURE

f_x	pattern frequency
ℓ	thickness of test section
A	Amplitude term
I	light intensity
S	spacing between heated plate and lateral wall
S/H	aspect ratio of the channel
W	geometric parameter

INFLUENCE OF POLLUTIONS ON THE THERMAL CHARACTERISTICS, HEAT EFFICIENCY AND OPTIMAL DIMENSIONS OF TUBES WITH LONDITUDINAL FINS

V. Gorobets*, A. Dolinsky, V. Mendeleyev
Institute of engineering thermophysics NAS of Ukraine, Kiev

ABSTRACT. In this report the results of experimental investigation the influence of polluting on heat characteristics of tube with longitudinal fins are presented. The thickness of polluting on the finned surface in the different time moments is measured. The dynamic of growth for polluted thickness is determined. As follow from experiments the profile of polluting along the height of fins is near to trapezoidal . The temperature distributions in fins and total heat flux leading by finned wall for the different time moments are found. The presence of pollution on the finned surface leads to change of temperature distribution in fins which substantially differ from the similar distributions for "clean" fins. The questions connected with the choice of the optimum dimensions of fins having the polluting are discussed. It is showed that optimum dimensions of fin are depended from the value Biot number of polluting.

Keywords: *polluting, fin, tube, temperature*

INTRODUCTION

In the process of exploitation of finned heat exchanges, which work in polluted environment there is aggravated of their heat efficiency. It is caused by precipitation of pollution on the extended surface. The profile of this polluting along the fin height may be complicated and the influence of pollution on the thermal characteristics of finned surface can be considerable.

Modelling of heat transfer processes in the fins with polluting or coating which possess a low heat conductivity was showed [1, 2], that in this case the thermal characteristics of finned surface have a considerable distinction from characteristics of "clean" surfaces. For example, the temperature distributions in fins with polluting have the great differences from the similar distributions for fins without polluting. Besides, the presence of polluting on the finned surface lead to necessary to take into account the influence of polluting on the choice the optimum dimensions of fins [1,2].

In this report there are presented the results of experimental investigation in which the processes of growth the polluting on the finned surface and influence of pollution on the temperature distributions, heat efficiency of fins and summary heat flux from tubes with the longitudinal fins were studied. Also, there are studied the questions connected with the calculated heat transfer methods and the choice of fin optimum dimensions for conditions of pollution of the extended surface.

EXPERIMENTAL APPARATUS AND PROCEDURES

There was created the experimental set up for investigation of influence the polluting on heat transfer conditions in tubes with longitudinal fins (Figure 1). As a source for producing of the waste gases with the polluted components was used the diesel-generated engine having power 48 kWt

*Corresponding author: Dr. V. Gorobets

E-meil address: gorobetsv@ukr.net

which work using the fuel-oil. The experimental test section consists of the finned tube, which is concluded within the outside tube (system “tube in tube”). The heating surfaces of this section had the next dimensions: outside tube diameter – 89 mm, inside tube diameter – 30 mm, length of tube – 2500 mm; fin height – 20 mm; fin thickness – 1 mm; number fins on the tube – 12.

The experiments were carried out in three directions:

1) Carrying out of balance tests
2) Measuring the temperature of heat carriers in an interpipe channel and into a pipe, in the wall of pipe and along the fin height in the differentsections of test section.
3) Determination the thickness, and thermophysical properties of polluting.

In balance tests the expenditure of exhaust-gas and water, and output temperatures of gas and water were determined. Also the aerodynamic resistance in gas highway was determined.

For realisation of the works to second and third direction of finned pipe was prepared in three sections for the distances L_1=200, L_2=1250 and L_3=2300 from the beginning of fins (Figure 2). In these sections for measuring of temperatures in finned pipe were set thermocouples - in the pipe under a fin, in a middle part of pipe between the fins and also few thermocouples along the height of fin with distance 5 mm between them (Figure 2a).

With the purpose of determination the thickness, and thermophysical properties of polluting on the fin were made the insertions of type «swallow tail» with toothed base (Figure 2b). For each from three sections on the length of pipe were made three insertions. It gives the enable to take out of insertions in different time moments. For providing of reliable contact between insertions and fin an aluminium foil was . In different moments of time the measuring of expenditures, pressures, temperatures were conducted and the collection of insertions were . Further the thickness of polluting on the different height of fin was measured, weighing the insertions with polluting and measuring the coefficient of heat conductivity for the samples of polluting was made.

There are conducted the measuring for the time period right up to complete stabilising of thickness of polluted layer. Such measuring are conducted in a few stages:

I. tests with a clean surface period of time);
II. in 72 hours (3 days) the work of setting;
III. in 144 hours (6 days) the work of setting;
IV. in 216 hours (9 days) the work of setting;
V. in 288 hours (12 days) the work of setting.

RESULTS AND DISCUSSIONS

As the conducted measuring have showed after expiration of 216-220 hours (9 days) the thickness of pollution on the surface of finned pipe is stabilised. The results of measuring of expenditure for gas and heat carriers, their temperatures on and of experimental section for different time periods are presented in a Table 1.

In a Table 2 the results of measuring the thickness of pollution are presented for different sections

along the length of finned pipe and along the height of fin for the different distances from fin base. Besides in a Table 2 the average thickness and average increase of thickness of pollution along the height of fin are presented for the different sections of pipe. As follows from the measuring, the thickness of polluting increases on a measure approaching to fin base, and of pollution along the height of fin for all sections is near to trapezoidal (Figure 3). The thickness of polluting is decreased along the length of fin (Figure 4). The dynamics of change the polluted thickness on the fin in time is presented on a Figure 5. From a figure ensues, that for the initial periods of time

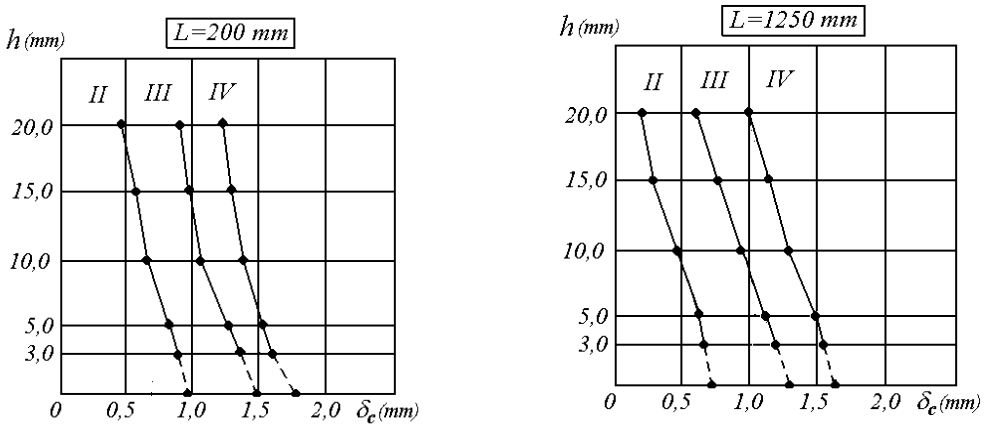

Figure 3. The distribution of thickness of polluting along the fin height in the different cross-section of fin: a) L =200 mm; b) L =1250 mm

the growth of deposit takes a place most intensively. In time a speedof increase falls not increased in future, therefore there is stabilising of deposit thicknessThis process is typicalfor all sections along length of pipe. However, the processes of stabilisation of pollution have some displacement at times (late of process) as far as approaching to areas of finned surface. Characteristically, that on the initial areas of finned pipe the increase of depositsis substantially greater, than on the areas.

Measuring the coefficientof heat conductivity for material of polluting is conducted. It is received, that this value near $\lambda_c = 0.11$ Wt/m ^{0}C. Some deviations from this value are caused the different structure of pollution as far as their growth on the finned surface in the different time moments. In the initial periods of time they have more dense structure, and in time soot pollution have more friable structure, and its thermophysical properties are changed. Measuring was showed that maximal deviations from the middle value 0.11 Wt/m ^{0}C no exceed 10%.

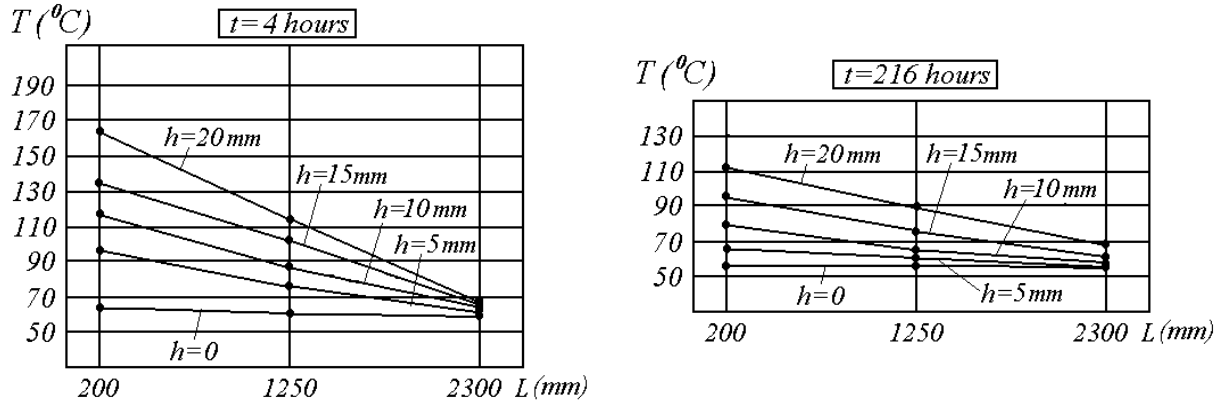
The results of measuring the temperature of pipeand fins, in the differentpoints on height for the different sections along the length of finned pipe, are presented in a Table 3. The typical temperature distributions along the height of fin, in one of sections for different time moments are showed on a Figure 6. As follows from a figure, the temperature distributing in the fins at presence of polluting substantially differ from the distributing for fins without polluting. The presence of deposits on the finned surface leads to more uniform distribution of temperature along the height of fins the more, the greater a thickness of deposits.

On a Figure 7 the distributing of temperatures along the length of fins in the different sections on the height of fin for the initial moment of time, when t =4 hours and for the terms of stabilising of deposit thickness at t =216 hours are shown.



a) b)

Figure 7. The temperature distributions along the length of fin for the different sections on the fin height: a) t =4 hours; b) t =216 hours

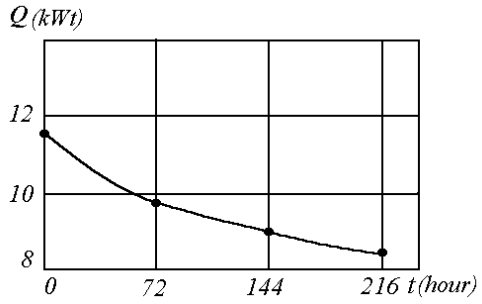


Figure 8. The total heat flux leading from finned tube in the different periods of time

Using the balance measurement of the expenditures and temperatures for gas and water heat carriers the total heat flux leading from finned tube in the different moments of time were calculated. The results of calculation are presented on a Figure 8. As follow from the figure a presence of polluting on the surface of finned tube leads to considerable decreasing of total heat flux which consists of nearly 30%.

The numeral modelling of heat transfer in pipes with longitudinal fins at presence of polluting on an external surface is conducted. Decisions are for the temperature distributing and heat efficiency of finned tubes with deposits at using the simplified, two-dimensional and conjugated model for this task. The comparison of results, which are found in these models, with experimental data is showed the satisfactory their coincidence. Maximal errors, which are in the calculations, consist of about 15%.

By an important question at design of heat-exchanges, which work in polluted environment is question of choice the optimum of fins. In paper [2] are the formulas for calculation of optimum thickness and height of longitudinal fins with polluting or coating

$$\delta_{f,opt} = 0{,}632\frac{1+Bi_c}{\alpha\lambda_c}\left(\frac{Q_f}{T_0 - T_g}\right)^2, \quad (1)$$

$$h_{f,opt} = 0{,}7979\frac{1+Bi_c}{\alpha}\left(\frac{Q_f}{T_0 - T_g}\right), \quad (2)$$

where α is heat transfer coefficient, h_f, δ_f - accordingly, height and thickness of fin, δ_c is a thickness of polluting or coating, T_0 is a temperature of fin base, T_g is a temperature of external heat carrier, $Bi_c = \alpha\delta_c / \lambda_c$ is Biot number of polluting, Q_f - heat flux leading by fin.

As follows from the expressions (1), (2) an optimum heightand thickness of fins depends on Biot number of polluting. These are increased with growth of Biot number. If to conduct the of Biot number value for the middle thickness of deposit after stabilising of process than the of Biot number consist of about 0,5. With such conditon the optimum thickness and height of fins in 1,5 time exceed as compared with optimum of «clean» fins. Influence of nonuniformity of polluting along the fin height on the optimum fin dimensions may be take into account using the correct coefficients [2].

The correct choice of optimum of fins for heat exchanges with extended surfaces which subject to pollution enables to improve the mass and dimensional characteristics of such heat exchanges.

CONCLUSIONS

1) Dynamic of change the thickness of pollution on the surface of finned tube is determined. It is found that maximal speed of growth the thickness of polluting takes place on the initial section of finned surface. In the course of time the thickness of pollution is stabilised and besides the process of stabilisation is late as far as approach to end of the finned tube. Profile of polluting along the height of fins is near to trapezoidal profile for all sections along the length of longitudinal fin.
2) The temperature distributions in finned tube for the different moments of time are measured. It is found that the presence of pollution on the finned surface leads to more uniform distribution of temperature along the height of fins if to compare with the temperature distribution of

"clean" finned surface. This uniformity of the temperature distribution the more, the greater a thickness of polluting. Presence of polluting on the surface of finned tube leads for considerable decreasing of total leaded heat flux.

3) The optimum dimensions of polluted fins depend on the Biot number of polluting and increase with the growth of this value. For the studied condition the optimum height and thickness of longitudinal fins may exceed in 1,5 time the optimum dimensions of "clean" fins.

EMPIRICAL INVESTIGATION ON HEAT TRANSFER AND PRESSURE DROP DURING FLOW BOILING OF R-134a INSIDE MICROFIN FLATTENED TUBES

M.A. Akhavan-Behabadi*, M. Nasr and S.E. Marashi
Faculty of Mechanical Engineering, University College of Engineering, University of Tehran, Tehran, Iran

ABSTRACT. In this study, pressure drop and heat transfer characteristics of R-134a under convective boiling conditions in horizontal microfinned flattened tubes were investigated. The test set-up was a well instrumented vapor compression refrigeration system. Microfinned copper tubes with internal diameter of 8.92 mm and thickness of 0.3 mm were flattened into oblong shape with different internal heights of 6.6 mm, 5.5 mm, 3.8 mm and 2.8 mm. Refrigerant R-134a flowing inside the flattened tube was heated by an electrical heating coil wrapped around it. The experiments were carried out for mass velocities from 74 $kgm^{-2}s^{-1}$ to 106 $kgm^{-2}s^{-1}$ and vapor qualities from approximately 25% to 95%. The results shows that the heat transfer coefficient and the pressure drop increase for a given mass velocity and vapor quality, as the tube profile is flattened. The maximum heat transfer enhancement and pressure drop increasing relative to the round tube values was achieved by the flattened tube with the lowest internal height of 2.8 mm. For the tube with lowest inside height, the highest heat transfer coefficient enhancement of 239% was achieved at mass velocity of 85 kg m^{-2} s^{-1} and vapor quality of 85%. , while the highest pressure drop increasing of 400% was gained at mass velocity of 74 kg m^{-2} s^{-1} and vapor quality of 30%. Also, the heat transfer coefficient and pressure drop increase by increase of mass velocity and vapor quality for all the tube profiles.

INTRODUCTION

The heat transfer equipments like evaporators and condensers have an important role to play in different industries such as refrigeration, air-conditioning, power plant, and chemical industries. To save the limited available energy resources, design and manufacturing of efficient heat transfer equipments is essential. Different methods have been used by numerous investigators to increase the heat transfer rate in these equipments. The methods of increasing heat transfer coefficients are divided into two categories; active techniques and passive techniques. In passive methods, enhanced tubes with specific geometry or adding fluids are used for increasing the heat transfer rates. On the other hand, in active methods, external forces like electrical or acoustic field or surface vibrations are used. Although these methods increase the heat transfer rates, they also usually increase the pressure drop .

One of the passive techniques to enhance the heat transfer rates in heat exchangers is using of flattened tubes instead of round tubes. A study conducted by Wilson et al. [1] investigated refrigerant behaviour (pressure drop, heat transfer coefficient and void fraction) in flattened copper passageways in a condenser. They reported the enhancement of condensation heat transfer coefficient and pressure drop as the tube was flattened.

Another method to augment the heat transfer coefficients is using of extended surfaces. Bandarra Filho and Saiz Jabardo [2] performed a study on convective boiling of R-134a in herringbone and standard microfin copper tubes. The ranges of vapor quality was from 5% to 90% and mass velocity from 100 to 500 kg m^{-2} s^{-1}. Experimental results indicated that the herringbone tube has a distinct heat transfer performance for the mass velocity ranges considered in their study. Thermal performance of the herringbone tube has been found better than that of the standard microfin tube at high mass velocities, while at the lowest mass velocity (G=100 kg s^{-1} m^{-2}), for vapor qualities higher than 50%, the performance of the herringbone tube was worse than that of the standard microfin tube.

In the present research, an experimental investigation has been carried out to study the enhancement of heat transfer coefficient and pressure drop increment in an evaporator with micro fin flattened tubes.

EXPERIMENTAL FACILITY AND PROCEDURE

The test apparatus was a well instrumented vapor compression refrigeration system. The schematic diagram of experimental set-up has been shown in figure 1. The test apparatus included a pre-evaporator, a test-evaporator, and an after-evaporator. Refrigerant R-134a flowing inside the tube of these three evaporators was heated by the electrical coil heaters wrapped around the tubes. The input power to each heater was controlled by a dimmer.

Figure 1. Schematic diagram of experimental apparatus

The pre-evaporator was used to achieve the desired vapor qualities at the inlet of test-evaporator by heating the refrigerant which enters the pre-evaporator after expansion valve. The after-evaporator was used to ensure that the vapor leaving the test-evaporator has been changed to superheated vapor before entering the compressor.

The test-evaporator was a horizontal copper tube with 1.2 m long which 1.1 m of it, is wrapped with electrical coil heater to heat Refrigerant R-134a flowing inside the tube. Microfinned tubes which were used in this study were helical (Standard) type. Figure 2 shows the shape and dimensions of microfinned tubes used in this study.

For determining the effect of flattening the tubes on increasing heat transfer and pressure drop, round tubes flattened into oblong shapes with inside heights of 6.6 mm, 5.5 mm, 3.8 mm, and 2.8 mm.

To measure the outside tube wall temperatures, wall-mounted T-type (cu-con.) thermocouples were placed at four stations along the test-evaporator tube length with 22 cm distance from each other. At each station, four thermocouples were mounted on the top, bottom, and two sides in the middle of the tube. The refrigerant pressures and temperatures at the inlet and outlet of the test-evaporator were also measured. The provisions were also made to measure the other necessary parameters.

In this study, R-134a was used as refrigerant, because of its non-destructive effects on environment. The mass fluxes varied from 74 to 106 kg $m^{-2}s^{-1}$.The test-evaporator inlet vapor quality ranges varied from approximately 25% to 95%. During each test run, the difference between the inlet and outlet vapor qualities of test-evaporator was about 10%. The mean vapor quality of test section was taken as the average of its inlet and outlet vapor qualities.

Figure 2**.** Dimensions of microfinned tubes.

The heat transfer coefficient of test-evaporator was determined using the heat gain from electrical heater and the temperature difference between the evaporator inside wall surface and the boiling refrigerant. The temperature of tube outside wall was taken as the average of temperatures reading by thermocouples. The temperature of refrigerant was the saturation temperature corresponding to the average pressure of the inlet and outlet of test evaporator. The thermo-physical properties of R-134a were taken from [3].For reading the pressure drop in the evaporator, PMD-75, which is an equipment for measurement of pressure drop with a calibrated accuracy of 0.075*SPN% (SPN is pressure in the evaporator), is used in a by-pass line between inlet and outlet of test evaporator.

PRESSURE DROP RESULTS

Figure 3 shows the variation of pressure drop gradient versus vapor quality for flattened tubes at mass velocity of 85 kg/m^{2}s. The results for round tube is also presented here for comparison.

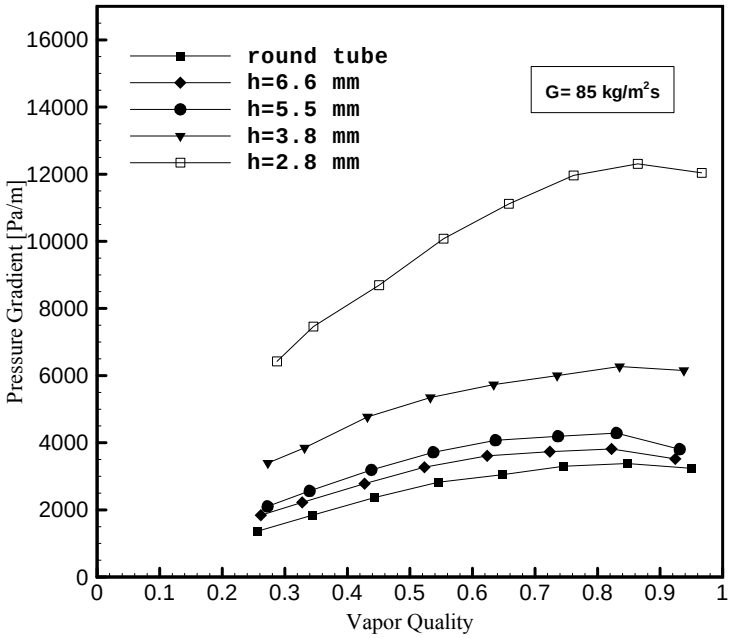

Figure 3. Pressure drop gradient versus vapor quality for different tubes at G=85 kgm^{-2}s^{-1}

From figure 3 it is evident that, the pressure drop increases by increase of vapor quality in flattened tube similar to the round tube. Moreover, pressure drop increases at a given mass velocity, as the tube profile is flattened. The main effect of flattening tube profile at a constant mass velocity is the increased vapor velocity. As an illustration, when a tube cross section is reduced in half, the velocity essentially doubled which is a quadrupling of the vapor's kinetic energy. This increase in vapor kinetic energy results in a higher shearing of the liquid layer, thinning the liquid phase, which reduces the mass in the tube and increase the pressure drop.

Flattened tubes results shows that the pressure drop ratio, respect to round tube decreases with the increase of vapor quality, especially in flattened tubes with high internal heights. This is due the fact that, flattening the tube profile causes changing of flow pattern from stratify-wavy to annular flow pattern mostly in low vapor quality region, while at high vapor quality region, the flow pattern inside the round tube is mostly annular flow. Moreover, the pressure drop ratio increases, as the tube profile is flattened. The minimum pressure drop ratio of 1.006 is achieved in flattened tube with the highest internal height of 6.6 mm, while the maximum pressure drop ratio of 5 is obtained in the flattened tube with the lowest internal height of 2.8 mm.

In order to predict pressure drop during flow boiling of R-134a inside microfinned flattened tubes, ΔP_{fri}, the following correlation was developed using the present experimental data.

$$\Delta P_{fri} = \Delta P_f \varphi^2 \tag{1}$$

Where, ΔP_f is the liquid single phase pressure gradient calculated with the assume that all the refrigerant flows as liquid phase in the tube. φ^2 is the two phase correction multiplier obtained as below:

$$\varphi^2 = 12.80 X_{tt}^{-1.5} (1-x)^{1.8} G^{*0.06} h^{*0.26} \tag{2}$$

In which, X_{tt} is Martinelli parameter, $\overset{*}{h}$ and $\overset{*}{G}$ are the dimensionless internal height and mass velocity calculated as below:

$$\overset{*}{G} = \frac{G}{G_0} \qquad \overset{*}{h} = \frac{h}{h_0} \tag{3}$$

h_0 is reference internal height and is equal to 2.8 mm and G_0 is reference mass velocity and is equal to 74 $kgm^{-2}s^{-1}$.

Figure 4 compare the flattened tubes empirical pressure drop data with the values predicted by Eq. (1). As we can see, Eq.(1) predicts the present experimental data within an error band of ± 20%.

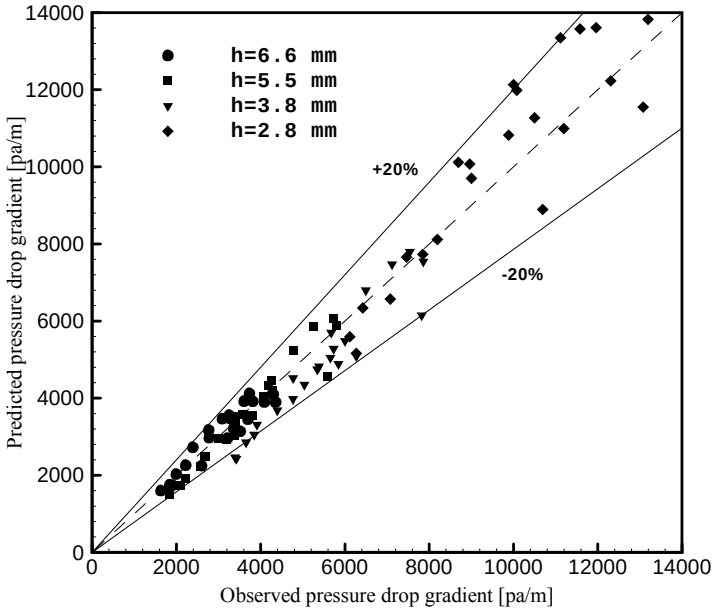

Figure 4. Comparison of observed pressure drop gradient with equation (1)

HEAT TRANSFER RESULTS

The variation of heat transfer coefficient with vapor quality has been shown in Figures 5-6. Figure 5 is for round tube, while figure 6 has been drawn for the flattened tube with inside height of 3.8 mm.

Nearly a similar trend can be seen from figures 5-6. Heat transfer coefficient elevates when vapor quality increases until it gets to a maximum value, then it falls. The reason for this phenomenon is the fact that by increasing of the vapor quality, the thickness of liquid film on the tube inside wall decreases, as a result, the thermal resistance decreases. Finally, at the top of the tube inside wall, the partial dryness will be happened and the film of liquid is disappeared. Then, with the progress of increasing of vapor quality, the wet surface area of the tube is reduced and the heat transfer coefficient decreases.

Moreover, as we can see from figures 5-6, by increasing the mass velocity, heat transfer coefficient is increased. This is due the fact that, at high mass velocities, the flow pattern will be changed from stratified flow to annular flow earlier than low mass velocities. The annular flow has higher rate of heat transfer rather than stratified flow. Actually in the annular flow, the liquid film around the tube inside wall increases the turbulent interaction between the vapor and liquid phases through the roughness of the liquid-vapor interface.

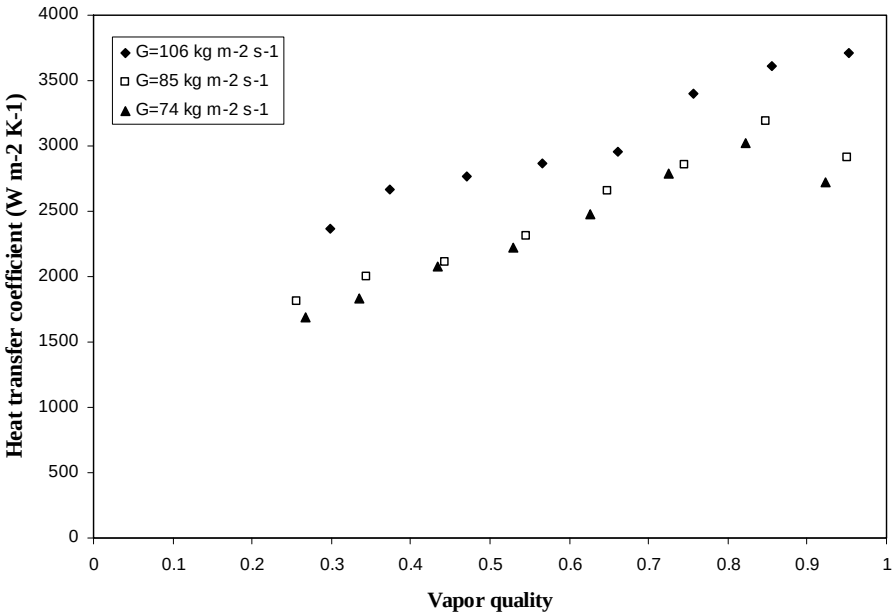

Figure 5. Heat transfer coefficient versus vapor quality for microfin round tube

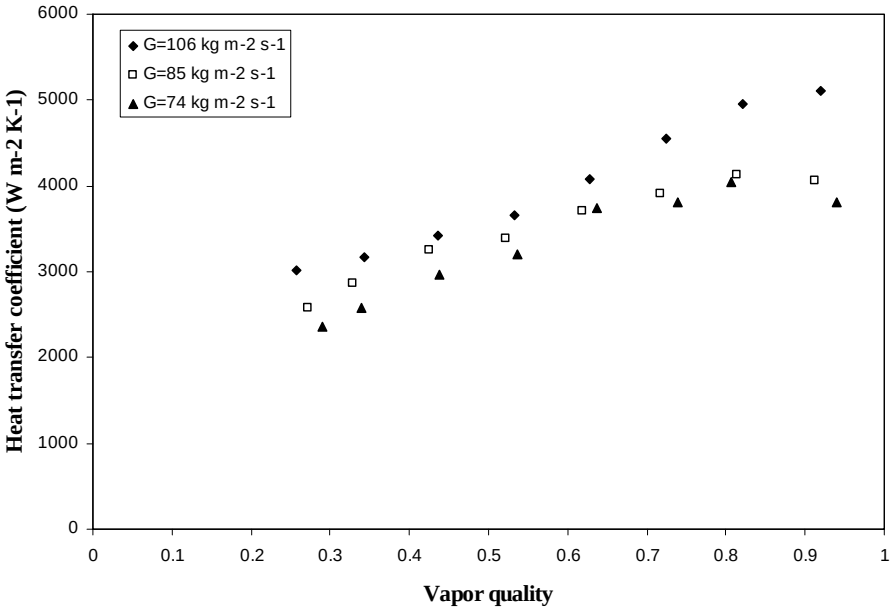

Figure 6. Heat transfer coefficient for microfin flattened tube with inside height of 3.8 mm

The variation of heat transfer coefficient with vapor quality for round tube and the flattened tube with internal height of 2.8 mm at mass velocity of 106 kg/s.m^2 has been shown in figure 7. We can study the effect of both flattening the tube and existence of microfinsfin in figure 7. As we can see, heat transfer coefficients increases by using of micro finned tube instead of smooth tube and also by flattening the tube.

Reasons for increasing the heat transfer rates due to using microfin tube are as follows:
First, helical fins by increasing turbulence in flow and tangential velocity near the wall, and also producing of vortex flow, increase the coefficients of heat transfer. Second, existence of fins increases the surface of heat transfer. Third, microfins by decreasing the flow cross sectional area, increase the velocity of flow and as a result ,the coefficient of heat transfer is enhanced.

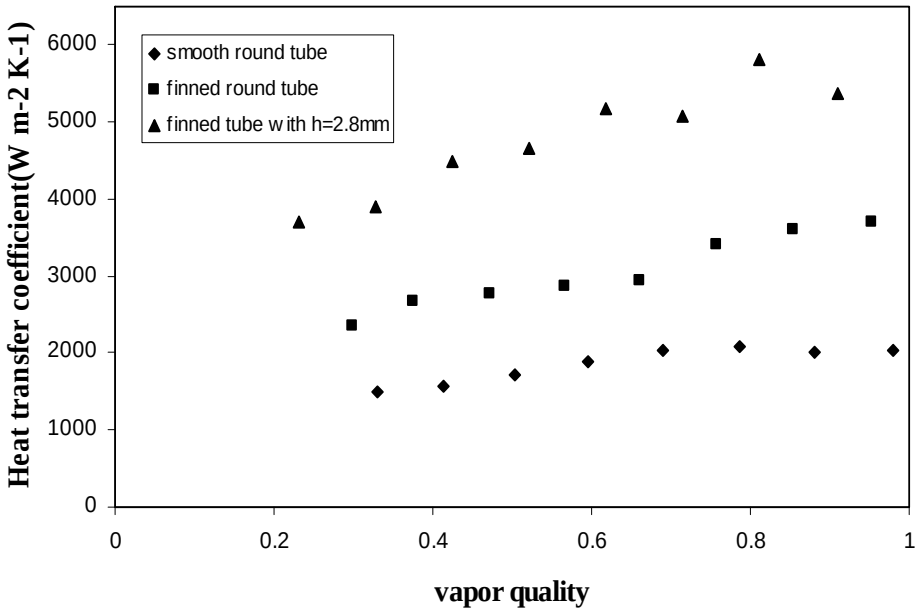

Figure 7. Heat transfer coefficient versus vapor quality at mass velocity of 106 kg m-2 s-1

In figure 8, the variation of heat transfer coefficient for different tubes at mass velocity of 85 kg m^{-2} s^{-1} were depicted. It is observed that, the heat transfer coefficient increases by flattening the tube. At a same mass velocity and vapour quality, the highest heat transfer coefficient enhancement obtained in the flattened tube with the lowest internal height of 2.8 mm. The same trend was also seen in other mass velocities.

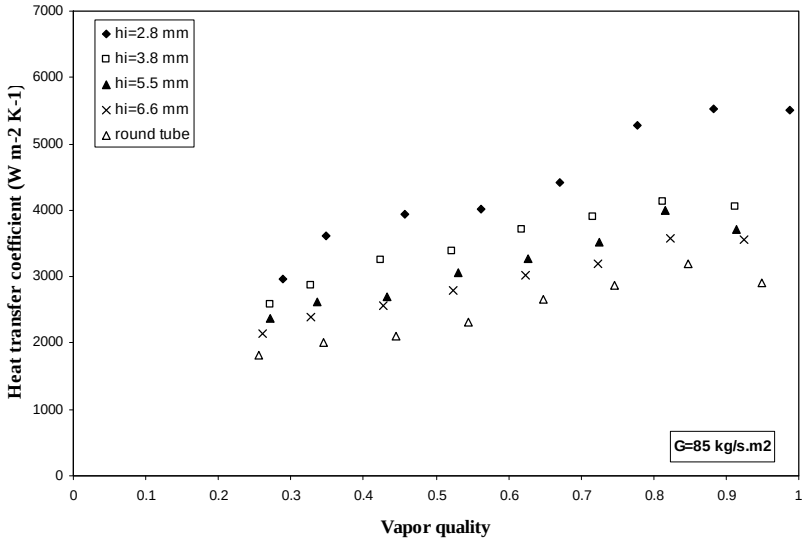

Figure 8. Variation of heat transfer coefficient with vapor quality for different tubes at constant mass velocity of 85 kg m^{-2} s^{-1}

The reasons for elevated heat transfer in flattened tube are unknown, but Wilson et al [1] made some speculation for condensing heat transfer coefficient. First, transition from stratified flow to annular flow is earlier, as the lowered height of the tube reduces the energy needed to wet upper tube surface. Annular flow tends to have higher rates of heat transfer because the film around the tube increases the turbulent interaction between the vapor and liquid phases through the roughness of the liquid film. Second, the flattened tube may alter the flow field in a manner that increase the heat transfer without changing the flow field configuration. That is, the flow field may be unaltered

from a stratified or annular flow configuration, but the flow field within that configuration may be affected. For example, some annular flows have “disturbance wave” or “ring wave” structures while others do not. Third possibility is the formation of a different flow field configuration from that commonly observed in round tubes.

CONCLUSIONS

The following conclusions have been drawn from the present study:

1- As it was expected, the heat transfer coefficient and pressure drop were elevated by increasing the mass velocity and vapor quality in flattened tube like round tube.
2- The flow boiling heat transfer coefficient and pressure drop are increased when the flattened tube is used instead of the round tube.
3- In the tube with lowest inside height The highest heat transfer coefficient enhancement of 239% was achieved at mass velocity of 85 kg m^{-2} s^{-1} and vapor quality of 85% and, the highest pressure drop increase of 400% was achieved at mass velocity of 74 kg m^{-2} s^{-1} and vapor quality of 30%
4- Pressure drop ratio respect to round tube in flattened tubes decreased by increment of vapor quality when mass velocity is fixed.

TEST PROCEDURE BASED ON A MASS BALANCE TO EVALUATE STEAM TRAP LOSSES OPERATING UNDER NO LOAD CONDITIONS: EXPERIMENTAL VALIDATION

B. Beauchamp[1], S. Kajl[1,*], L. Lamarche[1]
[11]Ecole de technologie supérieure, Montreal, Canada

ABSTRACT. This paper presents the experimental validation of a test procedure based on a mass balance to evaluate steam trap losses under no-load (live steam) conditions. The evaluated method is a modified version of an initial test procedure proposed by the authors. The validity of the method was accomplished by realizing several series of steam loss tests and comparing the results with the energy balance proposed per *ASTM* performance test code *PTC39.1, Condensate removal devices for steam system.*

Keywords: *steam trap, steam loss test, energy balance, mass balance, energy efficiency*

INTRODUCTION

Steam is a widely used heat transport medium. In any steam system, steam traps are used to improve the overall efficiency of the system. One of the main tasks of a steam trap is to evacuate condensate and non-condensable gas as they accumulate. To maximize the efficiency of the system, steam traps must also minimize steam losses as these losses are generally quite costly and thus undesirable. It is therefore important to identify and quantify steam trap losses in order to reduce energy waste and operating costs. On-site accurate quantification of steam trap losses is currently not realizable. However, to quantify steam trap losses it is possible to proceed as per performance test code ASTM PTC39.1, *condensate removal devices for steam system* [1] by using a test rig. Test code ASTM PTC39.1 describes a procedure to quantify the steam trap losses for two kinds of operating conditions: load conditions and no-load conditions. The procedure is based on an energy balance conducted in a calorimetric tank that collects condensate downstream of the steam trap. This procedure, established for tests done under load conditions, is conclusive based on the authors' experience by conducting multiple steam loss tests. However, for tests done under no-load conditions where steam trap losses are low or non-existent, this method often fails. This paper proposes a test procedure based on a mass balance to evaluate steam trap losses operating under no-load conditions. The method is a modified version of an initial test procedure proposed by the authors.

TEST CODE PROCEDURE AS PER ASTM PTC39.1

The test code ASTM PTC39.1 for quantifying steam trap losses is based on an energy balance. Figure 1 presents the schematic representation of the testing bench respecting test code ASTM PTC39.1. To conduct tests under no-load conditions it is possible to empty the cooling water from the heat exchanger. The main steps for the test are:

- Warm up the installation to achieve the desired steady state conditions. Position valve 3 in order to send condensate to the drain device.
- Fill the calorimetric tank approximately half full with water that is at least 8 Kelvin below ambient temperature.
- Once the setup is completed, start test by positioning valve 3 to send condensate to the calorimetric tank. Note all initial parameters: time, temperatures, pressure, mass, etc.
- When the temperature of the water in the calorimetric tank is as many degrees above ambient temperature as the initial temperature was below, position valve 3 to send condensate to the drain device. Note all final parameters: time, temperatures, pressure, mass, etc.

For tests under no-load conditions involving low or non-existent steam losses, the required increase in water temperature in the calorimetric tank is usually not achievable. In order to achieve the required increase in water temperature, the tests would need to be conducted with either (i) different size of calorimetric tank according to the range of expected steam losses or (ii) for a long test period.

- Using different sizes of calorimetric tank is not an interesting solution. For each test, the size of the calorimetric tank to be used to insure an appropriate increase in water temperature depends of the steam losses which are unknown a priori. Preliminary tests would therefore need to be conducted to select the appropriate size of calorimetric tank.

- Conducting the test for a sufficient long test period to achieve the required increase in water temperature using a unique calorimetric tank is not considered an appropriate solution. The calorimetric tank needs to be large enough for tests where high steam losses are expected. This results in an oversized calorimetric tank for tests where low steam losses are expected. To achieve the required increase in water temperature when steam losses are low the tests would need to be conducted over an extended time period. Although the required increase in water temperature could be achieve in such conditions, the uncertainty of the tests results would be greatly penalized. The calorimetric tank is insulated but heat losses from its walls are unavoidable and would alter the results over extended time period especially when steam losses are low.

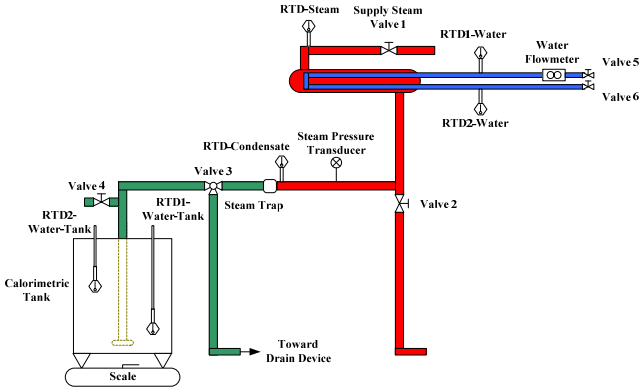

Figure 1. Testing bench respecting test code ASTM PTC39.1

TEST PROCEDURE BASED ON A MASS BALANCE

Initial test procedure proposed by the authors

The test procedure proposed in this paper is a modified version of an initial test procedure proposed by the authors [2] to quantify steam trap losses under no-load conditions based on a mass balance. The initial version of the procedure did not imply any modifications to the test rig. Its limitations mainly concerned the fact that the unavoidable condensation of operation, occurring in the steam line upstream of the steam trap and resulting from the heat losses through convection and radiation from the piping, has to be evaluated for each required operating pressures. This test procedure is presented for clarity purposes.

It is important to note that although tests are considered to be conducted under no-load conditions, there is always a small load that results from radiative and convective heat exchange between the test bench and the surrounding environment. The main steps for the test procedure based on a mass balance are:

- Warm up the installation to achieve the desired steady state conditions. Position valve 3 in order to send condensate to the drain device.
- Quantify the small load that results from testing bench radiative and convective heat losses (referred to here as the condensation of operation)
- Fill the calorimetric tank approximately half full with water that is at least 8 Kelvin below ambient temperature.
- Once the setup is completed, start test by positioning valve 3 to send condensate to the calorimetric tank. Note all initial parameters: time, temperatures, pressure, mass, etc.
- Two cases can occur:
    - Water temperature in the calorimetric tank increases quickly which indicates that steam losses are relatively high. Therefore, total steam loss can be evaluated from an energy balance as per test code ASTM PTC39.1
    - Water temperature in the calorimetric tank increases very slowly or not at all which indicates that steam loss is relatively low or non-existent. Here, steam loss can be evaluated from a mass balance as proposed.
- Tests must be conducted over a significant period of time to allow a reasonable amount of condensate to be collected in the tank. A test time of one hour has been used.
- Once the test time is completed, position valve 3 to send condensate to the drain device. Note all final parameters: time, temperatures, pressure, mass, etc.

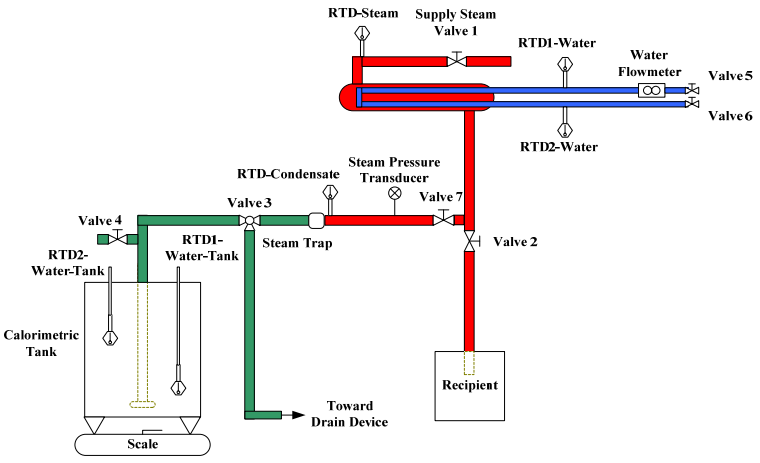

Figure 2. Testing bench used for the initial mass balance procedure

As mentioned above, in order to evaluate steam loss based on a mass balance, the small load, called condensation of operation, must be evaluated for each operating pressure. Valve 7 is installed, on our test bench (figure 2), just upstream of the steam trap to allow accumulation of condensate in the line. The condensation of operation represents the condensation that occurs in the steam line upstream of the steam trap. In operation, the steam trap will therefore have to evacuate this condensation. The main steps of the proposed procedure are:

- Determine the amount of condensate resulting from the steam pressure setting of the installation at the required operating pressure ($W_{setting}$).
- Determine the amount of condensate resulting from the testing bench condensation during no-load conditions at the required operating pressure ($W_{operation}$).

From the time interval, the condensation of operation can be expressed as a flow rate of condensation. This steady state condensation of operation represents the small load resulting from heat losses due to radiation and convection.

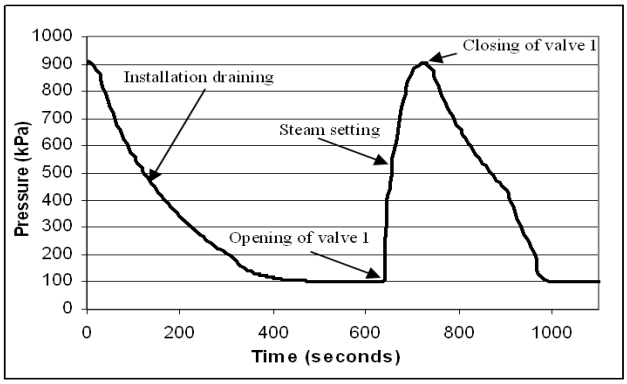

Figure 3. Steam setting of the installation

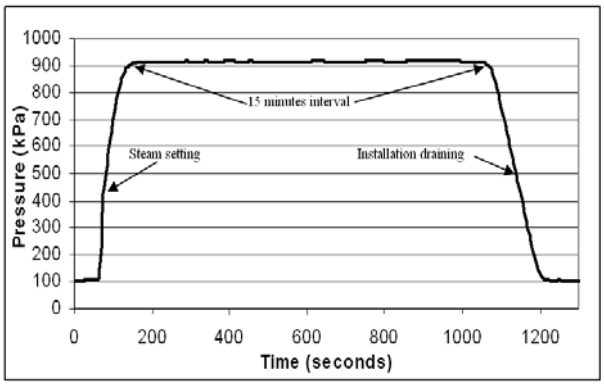

Figure 4. Operation under no load conditions

Table 1
Procedure to determine the condensation of operation and steam pressure setting condensation

Operation step n°.	**Steam pressure setting of the installation (See figure 3)**	**Operation under no-load conditions (See figure 4)**
1.	Warm up installation (valve 1 open, valve 2 closed, valve 3 to drain device, valve 7 open)	
2.	Fill a recipient (about 20 L) half full with water and note its weight (W_{beg})	
3.	Close steam valve 1	
4.	Drain the installation by opening drain valve 2 and closing valve 7 until the installation pressure is null	
5.	Close valve 2 and open steam valve 1 in order to build required pressure	
6.	When required operation pressure is reached, close steam valve 1	When required operation pressure is reached start timing interval, wait for 15 minutes and close steam valve 1
7.	Open valve 2 to accumulate condensate in the recipient filled with cold water	
8.	When installation pressure is null, close valve 2	
9.	Measure final mass of recipient ($W_{end,\ setting}$)	Measure final mass of recipient ($W_{end,\ operation}$)
10.	Condensation resulting from the steam setting of the installation $W_{setting} = W_{beg} - W_{end,\ setting}$	Condensation resulting from the operation under no load conditions $W_{operation} = W_{beg} - W_{end,\ operation} - W_{setting}$

Modified version of the test procedure

The modified version of the initial test procedure based on a mass balance required minor modifications of the initial test rig. The main advantage of the modified test procedure is that it applies for every required operating pressure without the necessity to pre-evaluate the condensation of operation.

The modified version of the test procedure required the installation of an additional steam trap downstream of valve 2 to ensure that the tested steam trap is fed with live steam. Furthermore, fluid flow downstream of the steam trap is collected in an additional tank and scale assembly using drain device through valve 3. The additional tank must be filled with an initial known mass of cold water in order to condensate any steam collected in the tank. Since tested steam trap is fed with live steam, the evaluation of the condensation of operation, occurring in the steam line upstream of the tested steam trap and resulting from the heat losses through convection and radiation from the piping, is not required. We note that the additional tank and scale assembly is not necessarily essential but greatly facilitates and improves in some ways the uncertainty of the results. Steam leakage from steam traps in good working condition fed with live steam is expected to be low. Therefore, the use of a large calorimetric tank and scale to collect a small amount of fluid downstream of the traps combined with the possibility of fluid being trapped in the piping between the tested trap and the calorimetric tank increases the uncertainty of the results. To conduct our tests, we selected the dimensions of the additional tank and scale assembly so that they would suit the possible range of the expected results and positioned that assembly as close to the trap as possible (through valve 3).

The main steps for the modified test procedure based on a mass balance are:

- Warm up the installation to achieve the desired steady state conditions. Position valve 3 in order to send condensate to the calorimetric tank.
- Once the setup is completed, start test by positioning valve 3 to send condensate to additional tank. Note all initial parameters: time, temperatures, pressure, mass, etc.
- Two cases can occur:
    - Water temperature in the calorimetric tank increases quickly which indicates that steam losses are relatively high. Therefore, total steam loss can be evaluated from an energy balance as per test code ASTM PTC39.1
    - Water temperature in the calorimetric tank increases very slowly or not at all which indicates that steam loss is relatively low or non-existent. Here, steam loss can be evaluated from a mass balance as proposed.
- Tests must be conducted over a significant period of time to allow a reasonable amount of condensate to be collected in the tank. A test time of one hour has been used.
- Once the test time is completed, open valve 3 to send condensate to the calorimetric tank. Note all final parameters: time, temperatures, pressure, mass, etc.

It is important to note that the modified test procedure based on a mass balance for traps fed with live steam considers convection and radiation heat losses from the body of the trap as steam losses. In order not to include those heat losses as steam losses it would be necessary to estimate or experimentally evaluate the heat losses from the body of each tested trap. The mass balance principle applied under no-load (live steam) condition considers all the fluid discharge through the trap as steam. For some particular needs, this way of measuring fluid discharge through a trap can be interesting. Even though fluid discharge through a trap resulting from its body heat losses is not a steam leakage, it nevertheless represents live steam that must be supplied to the trap.

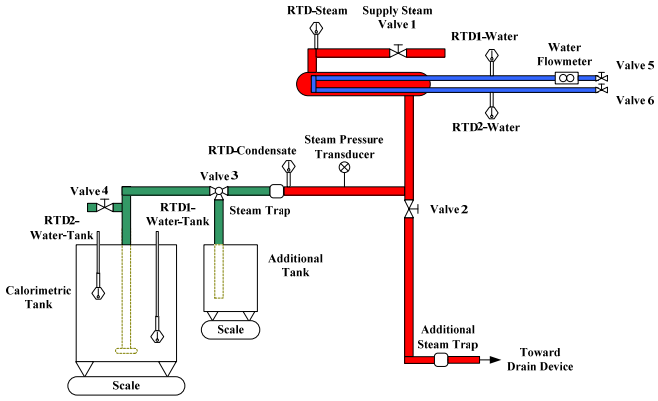

Figure 5. Modified test bench to conduct steam loss test using mass balance

The energy balance, proposed in ASTM PTC39.1, does not consider convection and radiation heat losses from the body of the trap as steam losses. The energy balance only considers fluid that is collected in the calorimetric tank in steam phase as steam losses. Furthermore, the unavoidable convective and radiative heat losses from the piping and other equipment between the tested trap and the calorimetric tank are also not considered by using the energy balance. Even though efforts are made to keep the piping and other equipment heat losses as low as possible, the steam losses evaluated with the energy balance are considered lightly underestimated.

EXPERIMENTAL RESULTS

Tests results for live steam feeding of the steam traps

Over 81 individual tests for operating pressures of 204 and 791 kPa have been conducted to ensure steam traps were fed with live steam. Such measurements were conducted with new steam traps installed on the test rig. These steam traps were considered in good working condition. Heat losses (by radiation and convection) from the steam traps' body are unavoidable for most tested steam traps. Such heat losses either condense the steam or cool the condensate and therefore cause the closing mechanism of the steam trap to open. Condensate (and possibly live steam) is discharge and is then replaced by steam. Therefore, even if a steam trap is fed with live steam and is in good operating condition (not leaking), some condensate could be discharge by this trap. Laboratory test conducted by Spirax Sarco [3] stated that energy loss from different steam traps could approximately vary from 0.25 to 1.40 kg/hr for a 500 kPa operating pressures. As noted in their results these energy losses are referred as a guide since heat losses will vary according to operating conditions, ambient environment conditions, steam trap size and steam trap type.

In our laboratory, for different types of traps, the measured amount of mass accumulated downstream of the traps varied between 0.0 to 1.3 kg/hr for an operating pressure of 204 kPa (figure 6) and between 0.0 to 2.6 kg/hr for an operating pressure of 791 kPa (figure 7). Some small thermostatic and balanced pressure & thermostatic (BP&T) steam traps were reported with zero (0) mass accumulation as could be expected from good operating conditions of such type of steam traps. Other type of steam traps (inverted bucket, float & thermostatic (F&T), thermodynamic and bi-metallic) were reported with mass accumulations varying from 0.1 to 2.6 kg/hr. Those measured mass accumulations were considered as normal condensation caused by heat losses through convection and radiation from the body of the steam trap. It is part of a subsequent research project to evaluate those heat losses for different steam traps.

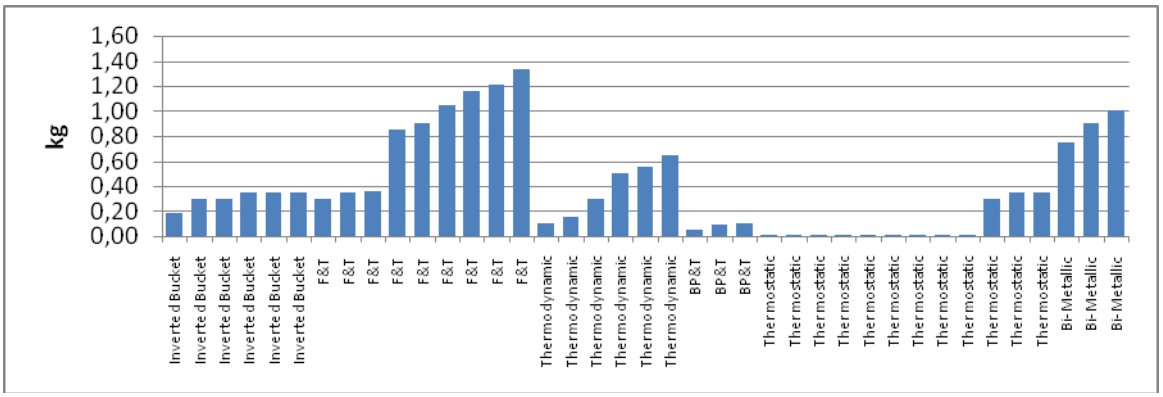

Figure 6. Mass accumulation for one hour for different traps (204 kPa)

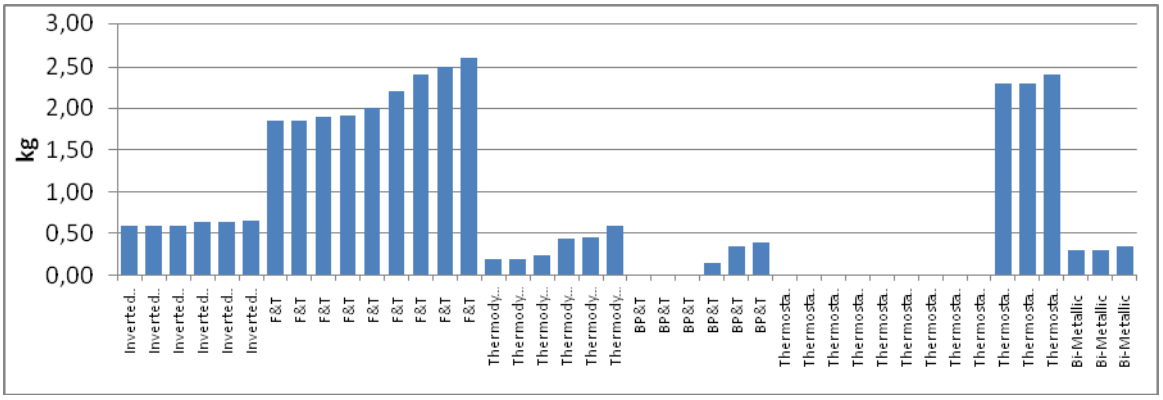

Figure 7. Mass accumulation for one hour for different trap (791 kPa)

Steam loss test results for defective steam traps

Over 78 individual tests for operating pressures of 204 and 791 kPa have been conducted to measure steam losses from defective steam traps fed with live steam. The defective steam traps had their valve intentionally held open by different means depending on their type. Since the traps' valves were held open, live steam was expected to blow through. Steam leakage measurements were therefore conducted using both the energy balance method proposed in ASTM PTC39.1 and the mass balance method presented in this paper. In order to compare the results of both methods, the mass balance is conducted in the initial calorimetric tank instead of the additional tank and scale assembly installed.

As presented in figures 8 and 9 the energy and mass balance methods give comparable results for both tested operating pressures and all type of traps tested. For an operating pressure of 204 kPa, the absolute difference between the steam losses evaluated using both method varies between 0.0 to 1.8 kg/hr. The relative error using the energy balance results as the reference varies between 0.0 to 7.0%. For an operating pressure of 791 kPa, the absolute difference between the steam losses evaluated using both method varies between 0.0 to 6.4 kg/hr. The relative error using the energy balance results as the reference varies between 0.0 to 11.0%.

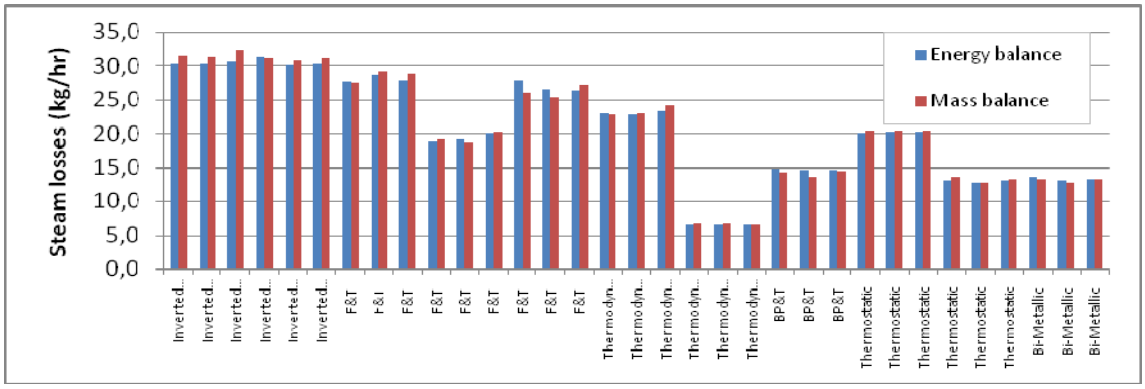

Figure 8. Steam losses results for defective traps fed with live steam (204 kPa)

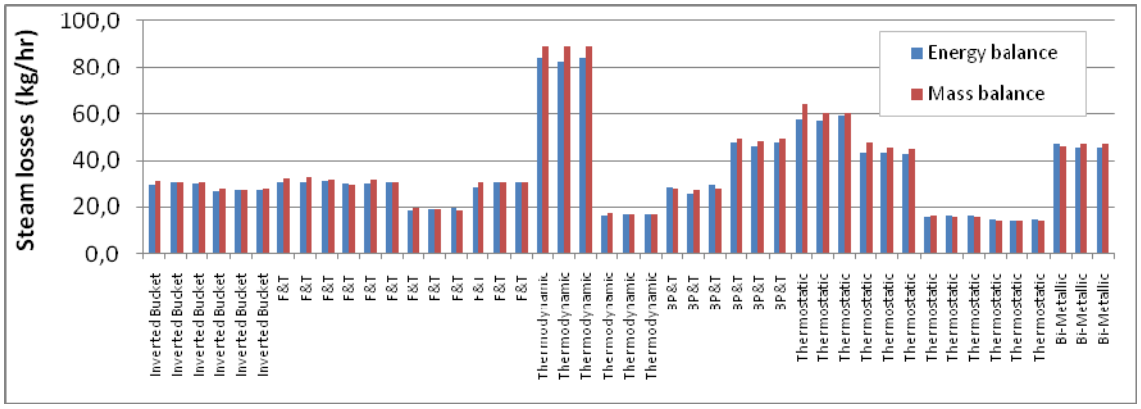

Figure 9. Steam losses results for defective traps fed with live steam (791 kPa)

CONCLUSIONS

A test procedure based on a mass balance to evaluate steam trap losses under no-load (live steam) conditions has been developed and experimentally validated. This procedure has been developed to be able to evaluate steam losses for steam traps fed with live steam when the proposed energy balance in ASTM PTC39.1 fails. From the authors' experience, the energy balance fails when steam losses are low or non-existent. Only minor modifications are necessary to the proposed test rig in ASTM PTC39.1 standard. Experiments conducted by the authors for moderate to high steam losses revealed that steam losses evaluated using the mass balance are in agreement with those from the energy balance. For over 78 tests, the relative error for the results obtained using the mass balance varies between 0.0 to 11.0% which is considered acceptable. Care must nevertheless be taken when interpreting the results because the mass balance method does consider traps' body heat losses as steam losses while energy balance doesn't. However, piping and equipment heat losses between the trap and the calorimetric tanks influence the energy balance method but not the mass balance method. The experimental evaluation of steam traps' body heat losses would allow a better comparison between the energy and the mass balance methods.

PREDICTION OF FLUIDIZATION BEHAVIOUR AND A QUASI-STATIONARY APPROACH TO DRYING KINETICS OF IRREGULAR PARTICULATE FOOD MATERIALS

Wijitha Senadeera*
School of Engineering Systems, Queensland University of Technology
2 George Street GPO Box 2434, Brisbane QLD 4001, Australia

ABSTRACT**.** Changes in fluidization behaviour behaviour was characterised for parallelepiped particles with three aspect ratios, 1:1, 2:1 and 3:1 and spherical particles. All drying experiments were conducted at 50^0C and 15 % RH using a heat pump dehumidifier system. Fluidization experiments were undertaken for the bed heights of 100, 80, 60 and 40 mm and at 10 moisture content levels. Due to irregularities in shape minimum fluidisation velocity of parallelepiped particulates (potato) could not fitted to any empirical model. Also a generalized equation was used to predict minimum fluidization velocity. The modified quasi-stationary method (MQSM) has been proposed to describe drying kinetics of parallelepiped particulates at 30^o C, 40^o C and 50^o C that dry mostly in the falling rate period in a batch type fluid bed dryer.

Keywords: *Fluidization, Generalised model, Quasi-stationary approach, irregular particulate*

INTRODUCTION

The minimum fluidisation velocity of a material is the superficial velocity at which material bed starts to fluidise The Ergun equation (Ergun, 1952) is the widely accepted model to determine *minimum fluidization velocity* of a fluid to fluidize the particle (Kunii and Levenspiel, 1969; Zenz and Harbor, 1971; Michelis and Calvelo, 1994).The Ergun equation (Equation 1) is used to calculate minimum fluidization velocity of baker's yeast (Egerer et al., 1985), peas (Rios et al., 1984) and diced potato and potato strips (Vazquez and Calvelo, 1980; Vazquez and Calvelo, 1983). An equation similar to Ergun is valid for peas (Michelis and Calvelo, 1994). The values for velocity obtained by the Ergun equation are mostly reliable for spherical and relatively small particles. Most agro-food particulates however comprise of various shapes and sizes, and consist of larger particles. Therefore, the minimum fluidization values obtained from Ergun equation do not conform to the experimental values (Mclain and McKay, 1980, 1981a, 1981b; McKay et al., 1987)

$$(1-\varepsilon_{mf})(\rho_s-\rho_f)g = 150\frac{(1-\varepsilon_{mf})^2}{\varepsilon_{mf}^3}\frac{\mu u_{mf}}{(\phi d_p)^2} + 1.75\frac{(1-\varepsilon_{mf})}{\varepsilon_{mf}^3}\frac{\rho_f u_{mf}^2}{\phi d_p} \qquad (1)$$

where ε_{mf} – bed porosity at minimum fluidization velocity, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), μ - viscosity (N s/m^2), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), ϕ - sphericity

* Corresponding author: Wijitha Senadeera

E-mail: w3.senadeera@qut.edu.au

The Ergun equation consists of *viscous* and *kinetic energy* terms. In the case of larger particles at higher Reynolds numbers (Re > 1000) the fluidization behaviour is mainly governed by the kinetic energy term in the Ergun equation. Hence the Ergun equation can be simplified for (Kunii and Levenspiel, 1969) a wide variety of systems and a generalized equation can be applied to predict minimum fludisation velocity for larger particles when Reynolds number > 1000 using some modification.

$$u_{mf}{}^2 = \frac{\phi d_p}{1.75}\frac{(\rho_s - \rho_f)}{\rho_f} g \varepsilon_{mf}{}^3 \quad (2)$$

where, ε_{mf} – bed porosity at minimum fluidization velocity, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), ϕ - sphericity, g - acceleration due to gravity (m/s^2)

For wide variety of systems it was found that value $\frac{1}{\phi\, \varepsilon_{mf}{}^3} \cong 14$ (Wen and Yu, 1966) and a generalized equation can be applied to predict u_{mf} for larger particles when Re > 1000.

$$u_{mf}{}^2 = \frac{d_p(\rho_s - \rho_f)}{24.5\rho_f} g \quad (3)$$

where, ρ_s – particle density (kg/m^3), ρ_f – fluid density (kg/m^3), u_{mf} – minimum fluidization velocity (m/s), d_p – particle equivalent diameter (m), Re – Reynolds number

There is a continuous change in physical properties of the particulates during drying, which also changes the fluidization behaviour of the particles. It is very important to understand these changes, so that the air-flow during drying can be controlled to achieve an optimum fluidization.

Some limitations of the empirical models derived to describe drying characteristics could be eliminated by using a semi-empirical approach. Such a method is the modified quasi-stationary method (Efremov, 1999). This method has been proposed to describe drying kinetics of parallelepiped particulates at three drying temperatures where particles dry mostly in the falling rate period in a batch type fluid bed dryer. The model is based on mass conduction of solid materials in bulk, given in terms of effective moisture diffusivity, resulting in the following semi-theoretical equation for drying kinetics;

$$MR = \frac{m - m_e}{m_i - m_e} = \frac{1}{1 + \left(\frac{t}{\sigma}\right)^p} \quad (4)$$

Where, MR – dimensionless moisture, m – moisture at given time (kg/kg db), m_e – equilibrium moisture (kg/kg db), m_i – initial moisture content, t-drying time (h), σ – characteristic time (h) and p – dimensionless parameter

The objective of this study is to understand changes in minimum fluidization velocity for a parallelepiped food material during drying and relate this to moisture content by a suitable model, and compare the experimental minimum fluidization velocity with the generalized model predictions. Also a modified quasi-stationary method (MQSM) has been proposed to describe drying kinetics of parallelepiped particulates at 30^{o}C, 40^{o}C, and 50^o C in a batch type fluid bed dryer.

MATERIAL AND METHODS

Material preparation

Potato *Solanum tuberosum* of the variety Sebago was purchased from the same supplier in 50 kg bags. Parallelepipeds were made in a Dicing Machine (Hobart, Australia), by incorporating a cutter which makes 6.5mm X 6.5mm square cross-section. According to the required aspect ratios of 3:1, 2:1 and 1:1, the particles were cut carefully to lengths of 19.5, 13 and 6.5 mm respectively using a cutting blade. Immediately after cutting, all the samples were immersed in a sodium metabisulphite solution (0.1 % w/w) for 15 minutes to prevent browning during drying. The samples were drained on a mesh tray. Then samples were placed in a plastic bag and kept it in a cold room for 24 hours at 4^{o} C in order to produce uniform moisture distribution within the sample.

Particle density determination. To determine the particle density, a known number of particles were weighed by an electronic balance (Sartorius), and the volume was measured by the difference in meniscus levels before and after immersion of particles in liquid paraffin in a measuring cylinder. The difference in meniscus levels was measured by a vernier caliper (accuracy 0.05mm). This value was used to calculate the equivalent diameter of the particle, which was used in the generalized equation (Equation 3).

Moisture content determination. Moisture content was determined by measuring the loss in weight of finely chopped samples held at 70^{0} C and 13.3 Kpa vacuum for 24 hours (AOAC, 1995).

Experimental method for fluidisation experiment

First, fluidisation characteristics of the un-dried samples were measured in the fluidizing column with the prepared samples. After that samples were dried on a fixed bed in a heat pump dehumidifier system and samples were withdrawn at nine pre-determined time intervals during drying and used for measurement of fluidisation characteristics at different moisture contents. Fluidisation characteristics measured were minimum fluidisation velocity at four bed heights of 100, 80, 60, and 40 mm in a fluidized bed column (Figure 1).

Figure 1. Fluidisation column connected to the heat pump dryer

Drying in a fixed bed. Samples for studying fluidisation behaviour were dried in a heat pump dehumidifier system (Baleden Pty Ltd, Brisbane, Australia) in Food Science and Technology, School of Land and Food Sciences, University of Queensland, Gatton, Australia (Figure 1). The drying was undertaken at an air temperature of 50^{o} C (which is a common drying temperature) and

relative humidity of 15 %. Before materials were loaded in the dryer, the dryer was run for 2 hours to achieve steady state conditions. Materials were placed into the drying system on mesh trays as thin layers, and stacked vertically to achieve maximum exposure to the air-flow. Samples were removed at nine pre-determined time intervals. They were placed into a sealed container and immediately used for fluidizing experiments. For moisture determination, samples were stored immediately in a pre-dried sample bottle.

Determination of minimum fluidisation velocity All fluidisation trials were conducted in a batch type flexi-glass fluidizing column of 185 mm inside diameter and length 1 m (Figure 1). The hot air was taken from a heat pump dehumidifier system (Intertherm P/L, Brisbane, Australia) coupled to the fluidizing column by flexible ducts. Bed height was measured from a scale attached to the column. The change of bed pressure drop was measured while increasing the velocity through the bed for each height. In order to determine the optimum bed height for improved fluidisation bed heights of 100, 80, 60 and 40 mm were used. Measurements of pressure drop for each bed height took less than 3 min.

Visual observation of the bed at an instance of fluidization after bed expansion was the criteria considered to categorise minimum fluidization. Also this value was compared with graphical variation of the pressure drop of the bed with velocity. Both observed and graphical values were identical.

Drying in a fluidised bed One batch stored in the cold room was taken for fluidised bed drying experimentation. Fluidised bed dryer was connected to the heat pump dehumidifier system (Figure 1). The drying conditions of 30^0 C, 40^0 C and 50^0 C were set by the temperature controller in the heat pump dehumidifier system, and the drying set up was run for 2 hours to achieve steady state conditions of drying before material introduction. Initial bed height of 150 mm was used. The hot air velocity passing through the material bed was kept at a constant value of 2.2 m/s for all drying experiments. This velocity was selected, because it was within the limit of fluidisation and terminal velocity of the material concerned and within the capability of the fan. The air-flow entering the dryer was controlled by flow control valves. Samples were collected from the dryer at 30 minutes intervals through the sample outlet. Each time they were collected in a sealable container and immediately used for moisture determination and volume measurements.

ANALYSIS OF EXPERIMENTAL DATA AND MODELLING PROCEDURE

Fluidisation data were analysed for the analysis of variance (ANOVA) to evaluate differences, and, linear and non-linear regression to obtain suitable models. The coefficients of Equation 4 were estimated using Matlab (2008) Curve Fitting Tool Box on a personal computer. Model validity was tested using measures of coefficient of determination (R^2) and mean absolute error percentage (MAE%). Mean absolute error percentage (MAE%) (Equation 5) was calculated according to the methods given by Mayer and Butler (1993) for different L:D ratios and are given in Table 1.

$$\mathrm{MAE\%} = 100\left[\Sigma\left(\left|y_i - \hat{y}_i\right| / \left|\hat{y}_i\right|\right)\right] / n \quad (5)$$

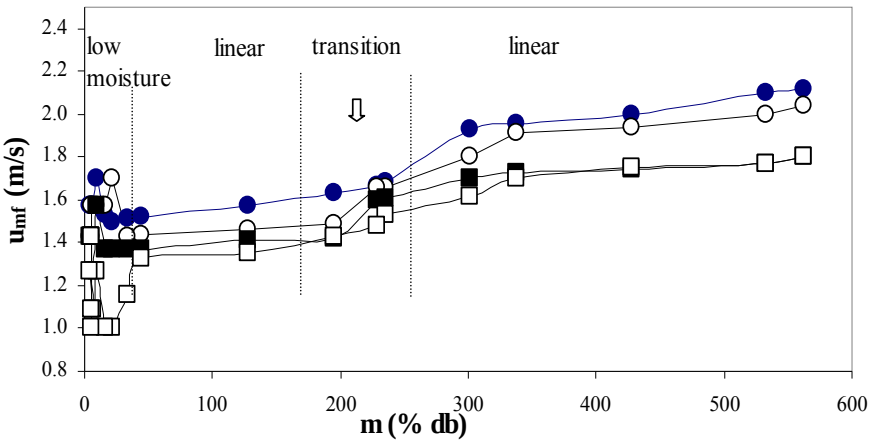
RESULTS AND DISCUSSION

Fluidisation behaviour

For aspect ratio 1:1, minimum fluidization occurred together with slugging and channeling at the moisture 560 % db for all bed heights. Reduction in minimum fluidization velocity was fairly linear down to 300 % db moisture. Between moisture contents values 220~260 % db, there existed a sudden change of minimum fluidization value for all bed heights (which described as the transition region in Figure 3). The magnitude of this change in minimum fluidization velocity decreased as bed height decreased. At low moisture values irregular behaviour in fluidization velocity was observed due to uneven shrinkage and interlocking of particles. Figure 2 shows fluidization behaviour of potato with aspect ratio 1:1, which shows some what regular fluidization behaviour.

In the case of aspect ratio 2:1 (graph not shown), when moisture content of particles was initially 570 % db, fluidization did not start until 310 % db moisture for the bed height of 100 mm, and at 340 % db moisture for the remainder of the bed heights. Sudden changes in minimum fluidization velocity were observed between moisture values of 140 % and 160 % db, a very narrow moisture range. This may be due to change in bed porosity. Below 140 % db moisture content minimum fluidization velocity was reduced showing irregular behaviour below 40 % db moisture, similar effect as 1:1.

For aspect ratio 3:1 at 100 mm bed height particles tend to fluidise after they have been dried too a moisture content of 300 % db from initial moisture of 540 %. In all other bed heights, fluidization started when moisture content was less than 326 % db. Suden change in minimum fluidization velocity was observed in the middle ranges of moisture content (60% - 70 % db). As moisture reduced during drying also resulted in increasing sphericity value (which was not measured) could have been contributed to better fluidization.



• 100 mm o 80 mm ■ 60 mm □ 40 mm

Figure 2. Fluidisation behaviour of potato aspect ratio = 1:1

Modelling of minimum fluidisation velocity with change in moisture content. Fluidisation behaviour of potato particles could not be modelled due to the irregular trend of change of minimum fluidisation velocity with moisture content for all aspect ratios. The change of minimum fluidization velocity with moisture reduction was less for lower bed heights. The change of minimum fluidization velocity with the moisture reduction was less for lower bed heights. For aspect ratio of 1:1 u_{mf} ($m \sim 0$) increased from 1.1 m/s to 1.6 m/s when bed height increased from 40 mm to 100 mm. For aspect ratio of 2:1, u_{mf} ($m \sim 0$) increased with increased bed heights and changed from 1.3 m/s to 1.7 m/s for the bed heights of 40 mm to 100 mm respectively. This change for aspect ratio 3: was in the range 1.8 m/s to 2.1 m/s.

Minimum fluidisation velocity calculation based on the generalized equation. The Generalized model was used to calculate the predicted values of minimum fluidisation velocity. For all three aspect ratios, this generalized model value was compared with the experimental value. The mean absolute error percentage value is more than 10% for the aspect ratio 3:1, for the bed heights of 100, 80 and 60 mm (Table 1).

Table 1
Mean absolute error percentage (MAE %) of observed and predicted values

Aspect ratio	**MAE%**			
	100mm	**80mm**	**60mm**	**40mm**
1:1	8.83	4.09	2.75	2.03
2:1	7.55	6.26	1.03	1.02
3:1	13.46	12.98	10.80	3.68

The generalized model predicted minimum fluidization velocity changes from 1.30 m/s (5 % db moisture) to 1.68 m/s (562 % db moisture) for the aspect ratio 1:1. The predicted minimum fluidization velocity for the aspect ratio 2:1 varied from 1.45 m/s (4.3 % db moisture) to 1.76 m/s (338 % db moisture). The variation in predicted minimum fluidization velocity for the aspect ratio 3:1 was 1.58 m/s (4.7 % db moisture) to 2.12 m/s (326 % db moisture). (Predicted and observed plots are not shown).

Quasi-stationary approach to drying kinetics

Table 2 shows the value p (Index of Hydrodynamic Intensity) in equation 4, which is a representation of hydrodynamic condition of the bed during drying experimentation for different aspect ratios.

Table 2
Index of hydrodynamic intensity (p) for different aspect ratios

L:D Ratio	**p**
1:1	1.81
2:1	1.69
3:1	1.67

From the values given in Table 2 it was observed that Hydrodynamic intensity (p) of the fluidized bed is vary with the size. The slight variations observed among sizes, may be attributed to channeling and slugging behaviour of the particles at higher initial moisture contents. Also it can be both material shape and aerodynamic of the bed dependent. Table 3 shows the characteristic times (σ) for different aspect ratios and drying conditions.

Table 3

Characteristic time for different aspect ratios at drying temperatures

	30°C	**40°C**	**50°C**
1:1	0.9268	0.7814	0.5797
2:1	1.059	0.9392	0.7720
3:1	1.122	1.038	0.7920

Good agreement of experimental data with predicted values indicate that the parameters obtained for hydrodynamic intensity and characteristic time (For all the cases coefficient of determination R^2 was above 0.99). It was also observed that characteristic time was proportional to the drying air temperatures and decreased with increased temperature.

CONCLUSION

Fluidisation behaviour with moisture could not be modelled for parallelepiped (potato) particles due to its irregular nature. But generalised equation predicts the minimum fluidisation with a reasonable accuracy for the particles. If sphericity changes during drying is measured an accurate predictions of minimum fluidisation velocity could be obtained using Ergun Equation. Onset of fluidisation of particles depended on bed height, sphericity and moisture content. Good fluidisation was observed only at low moisture levels. The magnitude of the minimum fluidisation velocity decreased with the decreased bed height and with decreased moisture content. The modified quasi stationary could be used to describe drying kinetics of the fluid bed drying accurately and characteristic drying time decreased with increased drying temperature.

THE EFFECT OF IMPELLER-VOLUTE GAP ON PRESSURE FLUCTUATIONS INSIDE A DOUBLE-VOLUTE CENTRIFUGAL PUMP OPERATING AT REDUCED FLOW RATES

Attia E. Khalifa*, Amro M. Al-Qutub
King Fahd University of Petroleum & Minerals, Dhahran 31261, Saudi Arabia

ABSTRACT**.** One of the main causes of flow-induced vibration at blade passing frequencies in centrifugal diffuser pumps is the inappropriate radial gap between impeller and volute vanes. A small gap may be preferable for pump performance, head and efficiency. However, it may initiate strong impeller/volute interaction, resulting in high pressure pulsation inside the pump and consequent high vibrations to the pump components. In the present study, the effect of the radial gap and flow rate on pressure fluctuations due to impeller-volute interaction has been investigated experimentally on a double volute boiler feed pump stage. Results showed that pressure fluctuations inside the pump are sensitive to the radial gap as well as the flow capacity. Increasing the gap from 2.5% to 4.25% of impeller diameter gave the maximum reduction in pressure fluctuations and their energies, especially at reduced flow rates. The reduction in amplitude and energy of the fluctuations (from 20 to 06% depending on flow rate and measuring location) was achieved at the expense of 0.92% loss in pump head and 0.5% in efficiency for the rated capacity.

Keywords*: Radial gap, impeller-volute interaction, reduced flow rate, pressure fluctuations, double volute centrifugal pump.*

INTRODUCTION

Optimization of the gap selection depends on the pump design and expected dynamic operating conditions. In high-pressure high-speed pumps, the minimum radial gap is an important design parameter that controls the pressure pulsation resulting from the impeller-volute interaction. Under off-design conditions, the pressure fluctuations are excited around the impeller due to this interaction, leading to additional radial loads on the pump shaft and general vibration behaviour of the pump. Reducing the impeller/volute interaction by increasing the radial gap can reduce the pressure fluctuations. However, the performance of the pump is degraded with the increasing gap. Experimental testing is needed in order to determine the suitable gap design for the pump under consideration. Pressure fluctuations due to this interaction occur mainly at blade passing frequency (BPF) and its higher harmonics. Khalifa et al. [1] studied a high vibration problem in a double volute Boiler Feed Pump (BFP) operating at reduced flow rates. Vibration spikes appeared mainly at 5xRPM frequency, which corresponds to the first blade passing frequency. The energy content of these fluctuations was found to be sensitive to the flow rate and is location-dependent. It becomes more significant at partial flow rates.

Unsteady pressure signals measured at suction and discharge pipes do not reflect properly the behaviour of fluctuations inside the pump. The impeller/volute interaction results in circumferential unevenness of fluctuations around the impeller and the unevenness become more significant at off-design flow rates [2]. The pump geometry and impeller/volute combination play an important role in the severity of the pressure pulsation inside the pump [3]. Large high-head pumps are usually available only in the double (split) volute design to minimize the net radial force on the pump shaft when a pump has to operate away from the BEP. Studies on the effect of flow rate on pressure fluctuation at the blade pass frequency at different axial planes in the pump showed that it is maximum at the central impeller plane [4]. The flow-induced vibration in high-pressure pumps has specific characteristics that can be clearly observed in the frequency domain [5]. Harmonics of the blade passing frequency dominate the spectrum, and there is a particular relation among their amplitudes. The rise in the amplitudes is not equal for all harmonics. The time variant and spatial nature of these pressure distributions (pressure mode shapes) can be visualized [6].

Increasing the impeller to diffuser clearance, or changing the number of impeller blades, is a common solution for the high-pressure pulsation problems in high pressure centrifugal pumps. The pressure pulsations arising from the interaction of the impeller and vaned diffuser were measured at 2 times the impeller blade pass frequency in the discharge pipe [7]. The gap was increased from 3% to 12% of the impeller diameter. A reduction of 10 % in the flow capacity, at the rated head, resulted from this modification while the efficiency remained almost the same. The effect of radial gap between impeller and diffuser on vibration, noise, and performance was examined, under different flow rate conditions, by trimming the impeller to achieve different gaps [8]. At the maximum radial gap between the impeller and diffuser, the overall levels of vibration and noise were minimum. The present study continues the experimental investigation on flow-induced vibration problem presented by Khalifa et al. [1] for a boiler feed pump at SEC power plant. It aims to study the effect of increasing the radial gap between the impeller and volute vanes on pressure fluctuations at different flow rates and pump performance.

EXPERIMENTAL SETUP

The model pump has a speed of 3540 rpm, actually measured at 60 Hz. The flow rate is measured by an orifice meter; which has a discharge coefficient of 0.618. Orifice pressure taps are connected to a PDCR 4170, 700 mbar differential pressure transducer which has ±0.08% FS accuracy. Balance on the flow rate is checked using a U-tube manometer. The flow rate is controlled by a gate valve in the discharge pipe. A schematic diagram for the test loop is shown in the Figure 1. Reverse engineering was done to produce the model single-stage volute and impeller. Collected geometrical data from the original boiler feed pump were used to generate CAD files and then the impeller and volute were produced by CNC machines. A scale factor of 0.4 for the model pump was selected, taking into consideration similarity laws and practicality of the experimental setup. The impeller was balanced dynamically on a two-plane balancing machine to minimize the effect of rotor imbalance as a source of vibration. A shaft-like extension was attached to the impeller to simulate the actual flow characteristics at the suction of the original boiler feed pump. Locations of the static and dynamic pressure transducers were arranged in geometrical symmetry positions around the impeller as shown in Figure 2. The coordinates of these locations relative to the volute horizontal centreline are given in reference [1].

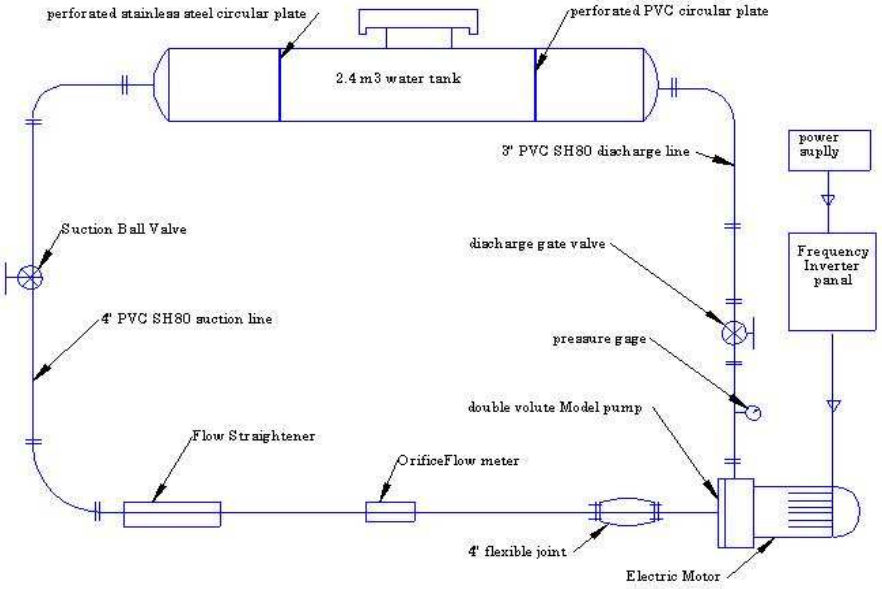

Figure 1. Schematic diagram for the test loop

Nine pressure transducers were placed flush within the volute plexiglass cover plate at the impeller discharge. One pressure transducer was placed at the discharge pipe, and another one at suction pipe. OMEGA's DPX101-250 high-responses dynamic pressure transducers were used to measure the pressure fluctuations. Figure 3 shows the model pump components and assembly.

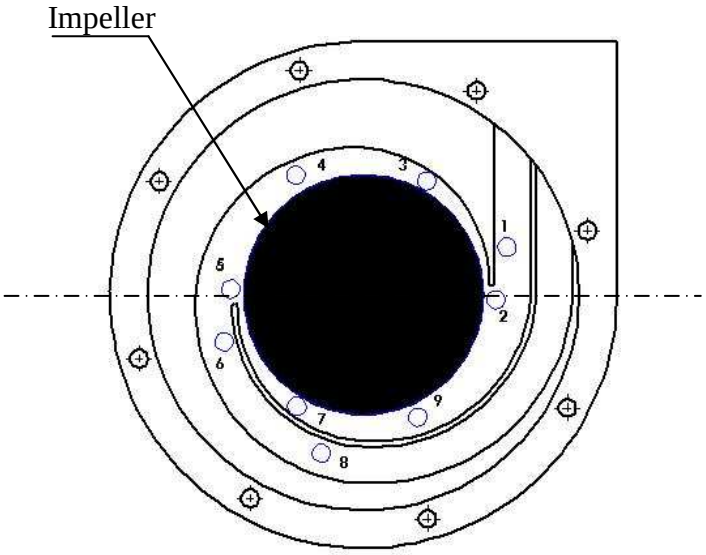

Figure 2. Model pump design and measuring locations

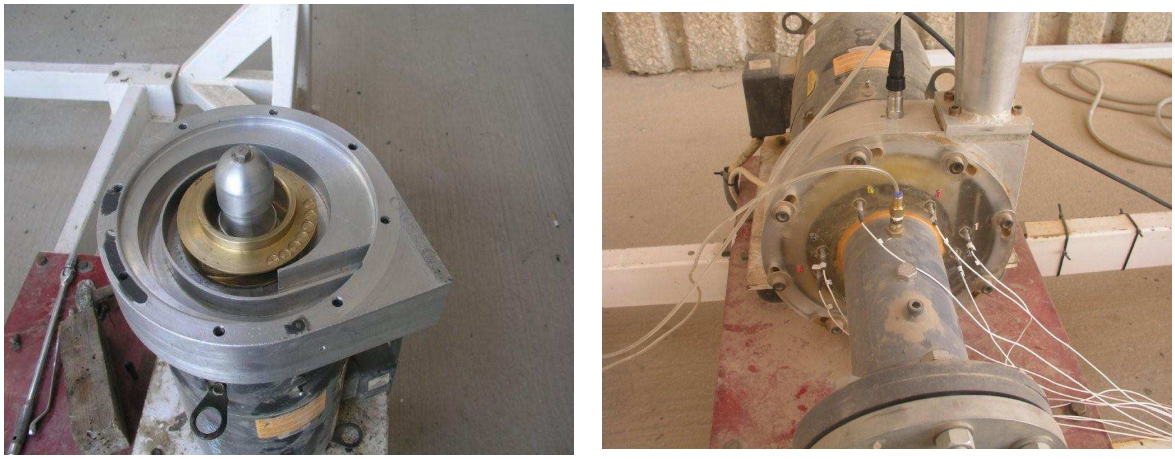

Figure 3. Model pump components and assembly

RESULTS

The original gap design for the scaled model pump is 3.6 mm, which is equivalent to 2.5 % of the impeller diameter. The experimental matrix was designed to test gaps of 3.6, 4.85, 6, and 7 mm at different flow rates ratios (Q/Qn) of 1, 0.75, 0.5, and 0.25. Qn represents the nominal flow rate corresponding to best efficiency point for the original gap design of 3.6 mm, and it was measured to be 12 l/s. The pressure distribution, the fluctuations inside the pump, and the pump performance, were examined. The consecutive gaps were achieved by cutting back 10 mm from the volute vanes each time. For example; figure 4 shows the original gap design (3.6 mm, a) and the maximum gap (7 mm, b), achieved by cutting back the volute vanes 30 mm in the vertical direction. This is equivalent to increasing the gap from 2.5% to 5% of impeller diameter. The measuring locations were fixed for all gaps. Uncertainty analysis for the measured and calculated variables showed that the uncertainty values at the best efficiency point are limited to 1% for the total head, 1.5% for the flow rate, and 2% for the efficiency. Pump specific speed is 1620.

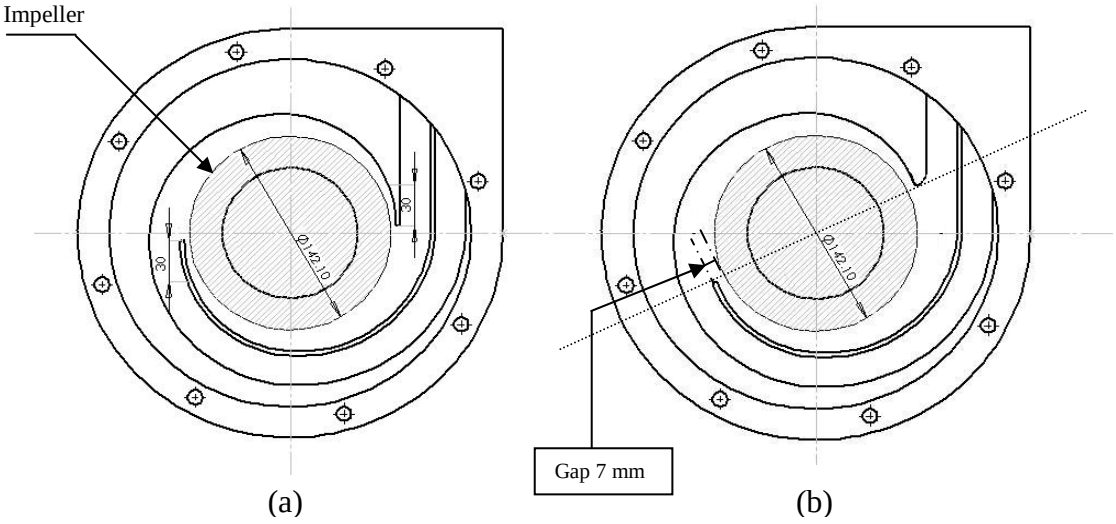

Figure 4. (a) Original gap (3.6mm); and (b) the max gap (7 mm), dim. in mm

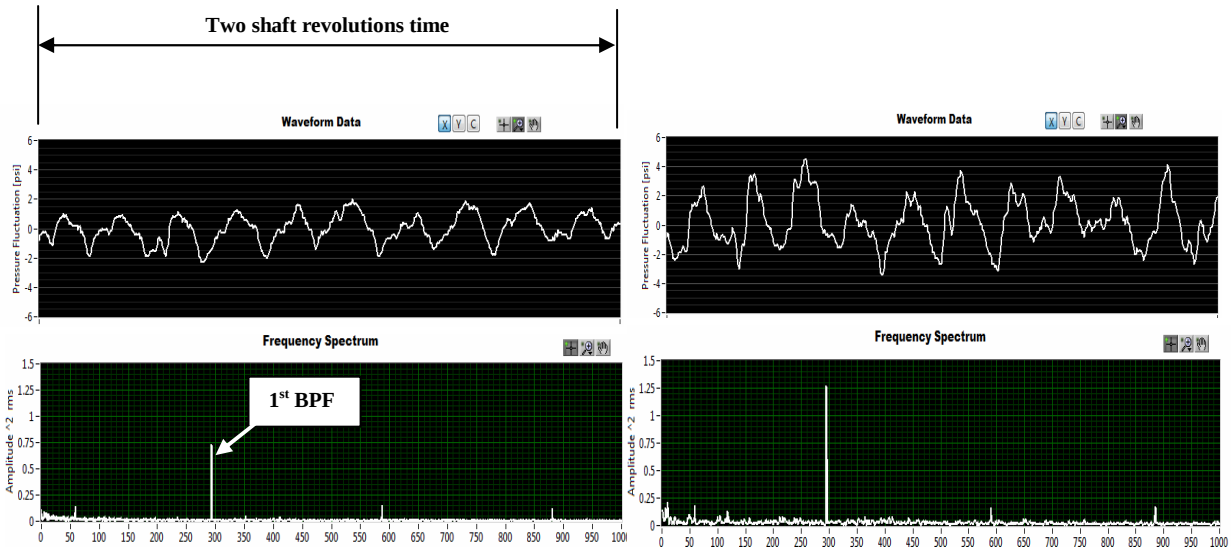
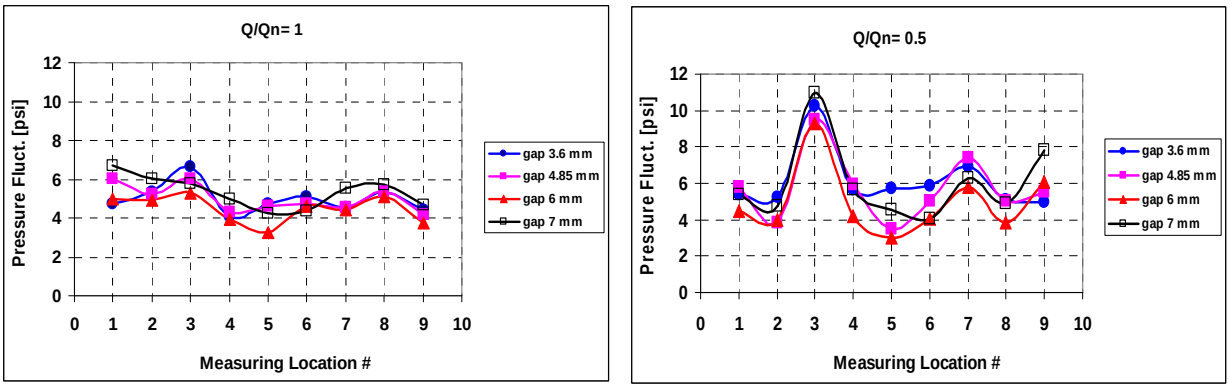
As an illustration, Figure 5 displays a typical fluctuation time history (for two shaft revolutions time, 0.034 sec) and the frequency spectrum (FFT) for location # 3 and gap 3.6 mm, at two different flow ratios of 1 and 0.5. Dominant peak occurred at a frequency of 295 Hz which corresponds to 5xRPM or the first blade passing (1st BPF). Smaller peaks appeared at 10xRPM (2nd BPF) and 15xRPM (3rd BPF). The amplitude and strength of these fluctuations were found to be sensitive to the flow rate. All other locations inside the pump experienced similar behaviour [1].



(a) Q/Qn=1 (b) Q/Qn=0.5

Figure 5. Real time pressure fluctuations and frequency spectrum at location 3: gap 3.6 mm

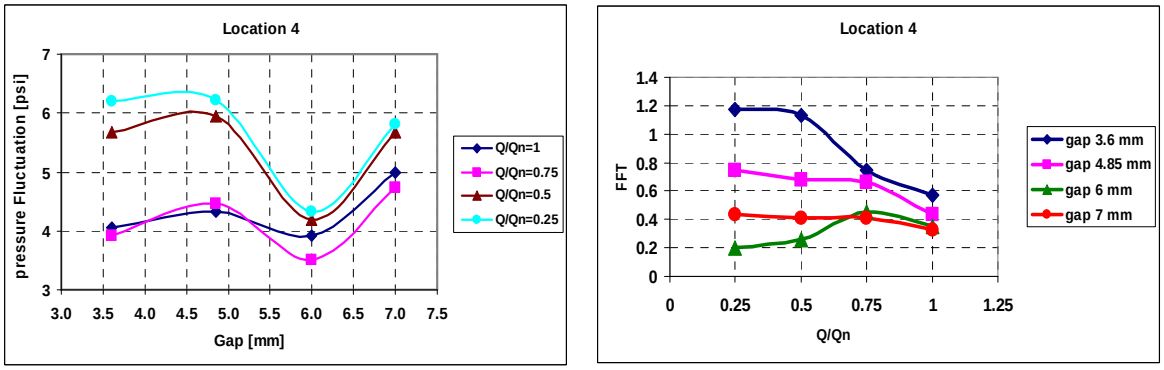
The combined effect of gap and flow rate on pressure fluctuations (peak-to-peak) inside the pump, at two different flow ratios of 1 and 0.5, is shown in Figure 6. When the pump operates at the designed flow rate, figure 6-a, the gap of 6 mm gives the lower fluctuations at almost all measuring locations, but it is still comparable to fluctuations resulting from other gaps. If the flow rate is reduced to 50% of the nominal value, figure 6-b, pressure fluctuations become higher (by 50% to 90% according to the location) and are not uniform around the impeller. Points 3 and 7 show remarkable peaks at reduced flow rates; they are the closest points to the interactions zone which is the source of pressure pulsation.



(a) Q/Qn=1 (b) Q/Qn=0.5

Figure 6. Effect of gap on pressure fluctuations (peak-to-peak) inside the pump

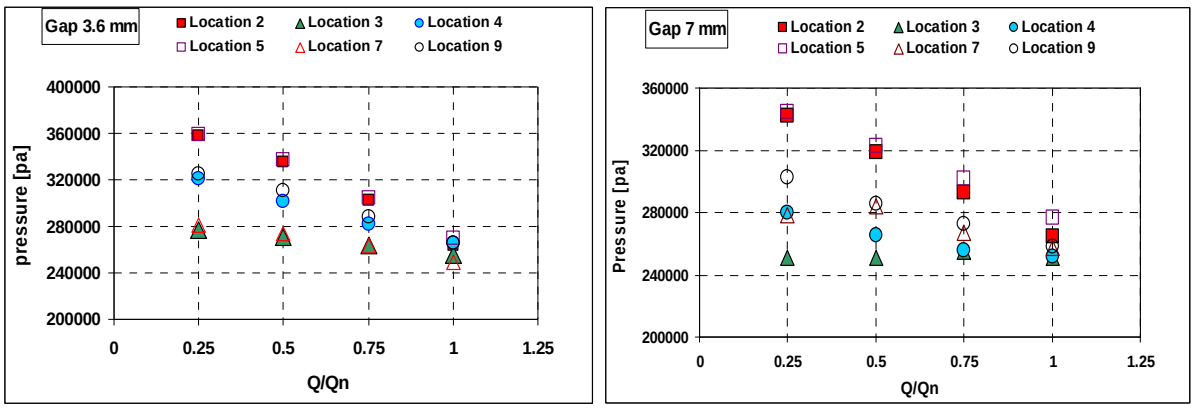
The gap of 6 mm still performs well, giving lower pressure fluctuations for all measuring locations. Since the measuring locations are fixed, cutting back the volute vanes brings the interactions source closer to points 3, 4, 7, and 9 around the impeller. The effect of gap and flow rate on fluctuation and FFT measured at location # 4 is given in Figure 7 for deeper investigation. As the flow is reduced, the fluctuations amplitude increases. Gap 6 mm always gives the lower fluctuation for all flow rates, and it is more effective at lower flow rates. In contrast to the original gap of 3.6 mm, the FFT magnitude (which was shown to increase with reducing the flow rate [1]) decreased with the reducing flow rate if the gap of 6 mm is used. The behaviour of measuring point # 4 is not typical, but it is quite general inside the pump.



(a) Pressure fluctuation (b) FFT magnitude

Figure 7. Gap/flow rate effect on fluctuations amplitudes and FFT Mag. at location # 4

Since increasing the gap has a positive effect on the fluctuations, the gap of 7 mm was expected to perform better. However, cutting back the volute vanes more than a certain limit produces unsuitable flow angle at the leading edges of volute vanes, and it has a negative effect on the symmetry of the pressure distribution around the impeller. Figure 8 is a comparison between pressure distributions at geometrically similar pairs of locations around the impeller for the gaps of 3.6 mm and 7 mm. At the rated capacity, pressure values are equivalent for all measuring locations inside the pump. For the original 3.6 mm gap, the double volute design keeps the pressure distribution symmetry around the impeller, at all flow rates. When the larger gap of 7 mm is implemented, the pressure around the impeller becomes asymmetric, particularly at reduced flow rates. This gives rise to higher amplitudes of local fluctuations, and it produces a net radial force on the impeller.



(a) Gap 3.6 mm (b) Gap 7mm

Figure 8. Static pressures at geometrically similar points around the impeller

Pumps are designed to operate at their best efficiency. Changing the gap design shifts the operating point, usually to a lower head when the gap is increased. The exact effect of changing the gap between the impeller and volute vanes is a matter of experimentation. The effect of different gaps on pump performance is shown in Figure 9. Considering the 6 mm gap to be optimum for the pump design under study, a reduction of 0.5% in efficiency and 0.92% in head was recorded at a constant flow rate of 12 l/s. This reduction falls within the uncertainty limits of the measurements. However, if the pump operates at flow rate above 125% (above 15 l/s), increasing the gap has a significant negative effect on the pump performance.

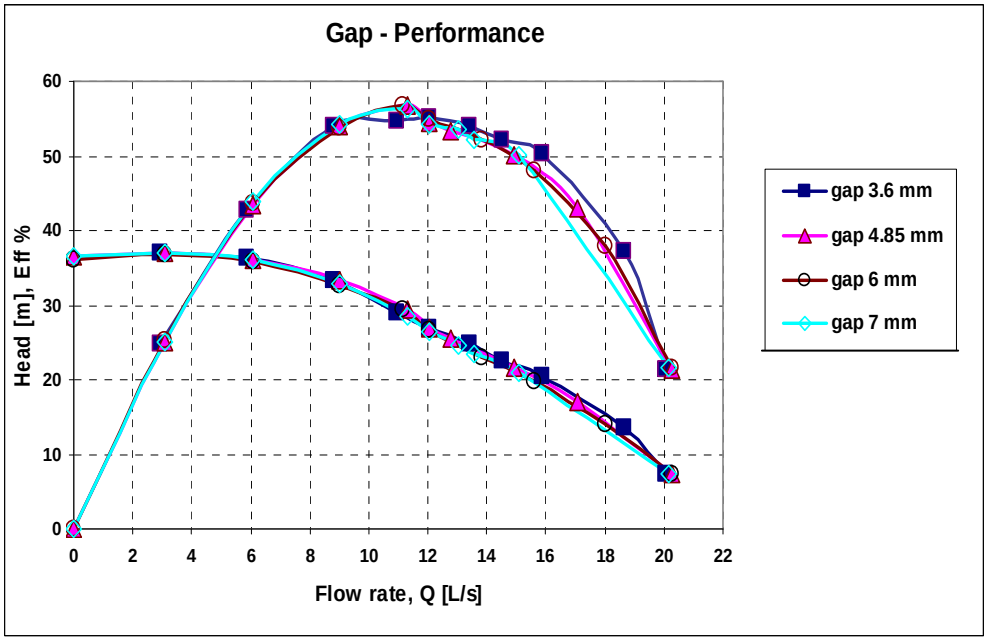


Figure 9. Effect of gap on pump performance at 3540 rpm

CONCLUSION

Experiments were carried out on a high-pressure double-volute model pump stage to study the effect of increasing the radial gap on pressure fluctuations due to impeller-volute interaction at different flow rates. The effect of different gaps on pump performance is also examined. The impeller/volute interaction is an important design parameter in developing high-energy pumps like the double-volute boiler feed pumps. The optimum gap is selected by experimentation based on the pump design and operating conditions. For the present pump, it is desirable to increase the radial gap from 3.6 mm to 6 mm (from 2.5% to 4.25% of the impeller diameter). This gap serves very well in reducing the pressure fluctuations at part-load conditions as well as at design conditions. Gaps larger than this optimum value may produce reverse effects. The improvement in fluctuations amplitude was achieved at the expense of 0.92% loss in pump head and 0.5% in efficiency for the rated capacity.

ABSTRACT. This paper presents experimental data on the axial flow topology of vertical, upward, air-water bubbly flows. The flow structure was investigated using an ultrasonic apparatus consisting of one emitter transducer and three receivers at different positions along the pipe circumference; in addition, high-speed motion pictures of the flow patterns were made. The ultrasonic signals from all sensors were cross-analyzed so that meaningful information about the two-phase flow could be sorted out. Upon analyzing mean values of the acoustic energy attenuation as a function of the void fraction for all sensors, a clear correlation was obtained. Investigation of instantaneous values of the acoustic attenuation allowed for identification of specific gas structures, which was corroborated by the high-speed filming. As the paper main result, the potential of the ultrasonic technique for void fraction and flow structure determination was further established.

Keywords: ultrasonic technique, high-speed filming, air-water flow, void fraction, flow patterns

INTRODUCTION

Multiphase flows are very common in the petroleum industry, oftentimes involving harsh media, strict safety restrictions, access difficulties, long distances, and aggressive surroundings. Accordingly, there is a growing interest in the use of non-invasive techniques for measuring basic variables in multiphase flows such as the concentration of dispersed phases. In addition, knowledge of the flow structure is essential for a better understanding and assessment of the transport processes involved. The ultrasonic technique apparently can fulfill these requirements; the main ultrasonic parameters normally used are sound pressure intensity, energy attenuation and the wave transit time. As the concentration and size distribution of the dispersed media (bubbles, oil droplets or solid particles) change these signal properties vary due to the combined effect of acoustic attenuation and transmission phenomena — reflection, refraction, and scattering of the sound beam by the dispersed phases and acoustic attenuation by the continuous phase.

The ultrasonic technique has been used for the characterization of flow patterns in horizontal gas-liquid flows [1]. The authors presented and discussed the general features of the waveforms obtained, but signal processing was not discussed. A detailed discussion of the acoustic signals and the computation of the signals amplitude and energy from the waveforms were presented in [2]; these acoustic parameters correlated closely with the void fraction. Ultrasound computerized tomography (UCT) has been studied by many researchers since the early 1980s. The authors in [3]

were able to successfully reconstruct the distribution of simulated and actual gas-liquid two-phase flows over the cross-section of a pipe using the UCT technique. The reconstructed image resolution was 0.6% of the cross-sectional area, but the image reconstruction time was much longer than the data acquisition time and could only be done off-line.

For many years, visual techniques have been an important tool for the study of the structure of two-phase flows. Particle image velocimetry (PIV) was used to investigate the flow field in a bubbly gas-liquid system [4]. As discussed by the authors, digital cameras and automatic image analysis have made quantitative optical measurements easier; however, the success of bubble identification depends on image quality and lighting conditions.

The main goal of the present paper is demonstrate the use of the ultrasonic technique to measure the void fraction and to identify specific gas structures present in an air-water bubbly flow. The ultrasonic instrumentation used is much simpler than UCT instrumentation and the ultrasonic identification of gas structures was corroborated by a careful analysis of the high-speed filming.

EXPERIMENTAL APPARATUS AND PROCEDURE

An experimental apparatus was designed and built specifically for the study of the ultrasonic measurement of the void fraction in vertical, upward air-water flows (Figure 1a). This apparatus is described in detail in [2]. The air-water mixer consists of a water-filled tank where the lower end of a 54-mm inner diameter acrylic pipe is inserted. Inside this pipe there is a cylindrical porous medium through which compressed air is injected into the water flow. The ultrasonic test section is actually a 10-cm long segment of the same 54-mm diameter acrylic pipe onto which the ultrasonic probes are attached. A 1.6-m long segment of the acrylic pipe then discharges the air-water two-phase flow into a phase separator; the air is vented into the atmosphere while the gravity driven water flow returns to the liquid reservoir. A centrifugal pump driven by a frequency inverter then forces the water back to the air-water mixer, thus closing the flow loop.

The main reasoning behind the transducers arrangement in Figure 1b was that there should be one ultrasonic sensor in each quadrant of the pipe circumference; however, assuming the bubbly flow to be radially symmetrical from a statistical point of view only half the circumference was instrumented. Due to limitations in the equipment available, the emitter transducer at $\theta = 0^o$ was not set to operate in the pulse-echo mode; however, this will be done in the near future in order to capture the acoustic energy reflected backwards off the gas structures. The direct transmission receiver ($\theta = 180^o$) was expected to get the energy transmitted through the bubbly flow; the side sensors ($\theta = 45^o$ and 135^o) were expected to receive at least part of the energy scattered off the acoustic beam. It is expected that a cross-analysis of the signals from all receiver transducers will disclose features of the instantaneous bubbly flow topology as well as the main aspects of the phase distribution over the pipe cross-section. The ultrasonic sensors used were Panametrics Videoscan 2.25 MHz, 13 mm diameter ultrasonic transducers. The filming station located just downstream of the test section allowed for high speed motion pictures (1000 fps) of the gas-liquid flow. The camera used was a REDLAKE Motion Pro X3 with 1280 x 1024 resolution.

In view of the limitations of the acquisition equipment used, two different experimental procedures were adopted. The first procedure referred to data acquisition from the 180° receiver only in conjuction with the high-speed filming; the second procedure consisted of simultaneous data acquisition from all receivers. In the first procedure the emitter transducer was excited at 8.45 kHz, the maximum allowed by the ultrasonic pulser, and the sampling period was set to 5.0 sec. In the second procedure, the sampling period was set to 2.98 sec in view of data storage limitations and the emitter transducer was excited at 1.72 kHz. In this case, no synchronized filming was made. Data were acquired at 20 MHz sampling frequency in both procedures. Ultrasonic data were obtained for the entire bubbly flow regime, i.e. zero to 15% void fraction range, in 1% steps. The ultrasonic wave sound intensity and energy were calculated by an independent MatLab signal processing algorithm. The energy ratios were referenced to the value at the same sensor for single-

phase water flow. In order to correlate these acoustic attenuation results with the void fraction, data from [5], collected at this same test section, were used.

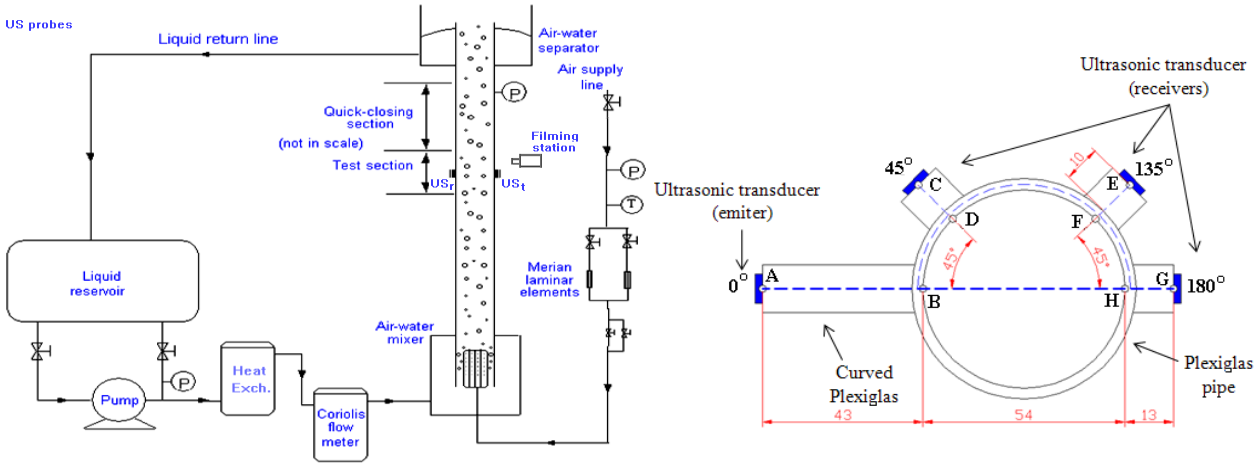

Figure 1. Schematic view of: (a) air-water bubbly flow test rig, (b) ultrasonic instrumentation.

ANALYSIS OF THE HIGH-SPEED FILMS

The fast pictures were analyzed for different flow patterns as the void fraction increased within the so-called bubbly flow regime. In broad terms, lower void fractions produced discrete bubbles; their distribution seemed to be the most uniform over the pipe cross section for 4 ~ 6% void fraction. Clustering then appeared and coalescence started taking place at 8%, at which point small mushrooms were clearly seen. For slightly higher void fractions, cap bubbles were already present. Incipient Taylor bubbles first appeared at 12%; they grew longer and appeared regularly at 14%. For this void fraction, the flow pattern was the well known axial intermittent topology of Taylor bubbles and aerated liquid slugs. Referring to Figure 4, on the basis of these visual analysis alone the bubbly flow regime was broken down into three sub-regimes [2]: (1) the discrete and clustering bubble sub-regime ($\alpha < 8\%$), when both spherical-ellipsoid discrete bubbles and larger distorted discrete bubbles would flow separately or in bubble clusters; (2) the cap bubbles sub-regime ($8 \leq \alpha < 12\%$), when coalescence took place to form small mushrooms and cap-bubbles; (3) the transition to slug flow ($\alpha \geq 12\%$), when incipient Taylor bubbles first appear.

As will be discussed shortly, these sub-regimes boundaries were superimposed to ultrasonic data from all sensors and very consistent trends were found; the main focus now was to identify very specific gas structures to be matched to the ultrasonic data. Some of these images are shown in Table 2. The main contention here is that these same gas structures occur not only for the indicated void fractions, but as a specific feature of the axial flow topology for other void fractions as well. If so, they can be interpreted as the letters of an alphabet whereby the axial flow topology is written and can be unequivocally detected by the ultrasound.

ANALYSIS OF THE ACOUSTIC SIGNALS

Preliminary Data Reduction

The acoustic trace signals captured by the ultrasonic apparatus are made up of longitudinal and shear waves and base noise. However, not all waves carry meaningful information about the two-phase flow. Hence, the meaningless waves and the base noise should be filtered out of the trace signals so as to eliminate systematic errors from the calculations of the acoustic parameters. In this regard, in a preliminary study it was verified that all captured waves displayed very similar

frequency makeup, thus precluding the application of the usual frequency domain filtering techniques. Therefore, a time domain filtering approach was tried.

Figure 2 depicts average ultrasonic paths for longitudinal and shear waves in the ultrasonic assembly shown previously in Figure 1b; Table 1 provides further details on the acoustic waves likely to propagate in this apparatus. It can be seen that only LW1 and SW3 are affected by and carry information about the two-phase flow. In addition, LW1 is the only wave that can be reflected and diffracted to the side sensors by the gas structures.

The approximate transit times associated with these waves as shown in Table 1 allowed for their identification in the acoustic signals from each sensor. As shown in Figure 2, only LW1 and SW3 are unmistakably identified in the trace signals from the 180° receiver. For the 45° sensor, only LW2 shows up very clearly. For the last sensor, none of the waves could be identified.

The overall conclusion seems to be that only LW1 and SW3, the waves that carry information about the two-phase, have a clear direct imprint on the 180° sensor trace signals. For the remaining sensors, they are either too weak or could not be unmistakably identified so as to be of any use for measurement purposes. Moreover, SW3 carries very little energy relative to LW1 and is rapidly attenuated by increasing void fraction. Therefore, SW3 was dropped as a measurement tool and attention was focused on LW1 only.

Table 1
Main features of the acoustic waves likely to occur in the ultrasonic assembly.

Acoustic Wave	**Acoustic Path**	**Propagation Velocity (water / acryl.)** [m/s]	**Average Length of Acoustic Path [mm]**	**Transit Time [μs]**	**Ultrasonic Transducer**	**Remarks**
LW 1	A-B-H-G	1,480 / 2,730	110.0	57.0	180º	Longitudinal wave generated in A that goes through the two-phase flow
	A-B-H-F-E		120.8	64.6	135º	
	A-B-H-F-D-C		165.5	81.3	45º	
LW 2	A-B-D-C	0 / 2,730	75.4	27.6	45º	Longitudinal wave generated in A that travels through the acrylic only
	A-B-D-F-E		120.0	44.0	135º	
	A-B-D-F-H-G		142.2	52.2	180º	
SW 1	A-B-D-C	0 / 1,430	75.4	52.7	45º	Shear wave generated in A that travels through the acrylic only
	A-B-D-F-E		120.0	83.9	135º	
	A-B-D-F-H-G		142.2	99.4	180º	
SW 2	A-B-D-C		75.4	40.5	45º	Shear wave generated in B that travels through the acrylic only
	A-B-D-F-E		120.0	70.1	135º	
	A-B-D-F-H-G		142.2	85.9	180º	
SW 3	A-B-H-G		110.0	61.3	180º	Shear wave generated in H from LW 1; it travels through the acrylic only
	A-B-H-F-E		120.8	67.9	135º	
	A-B-H-F-D-C		165.5	100.1	45º	

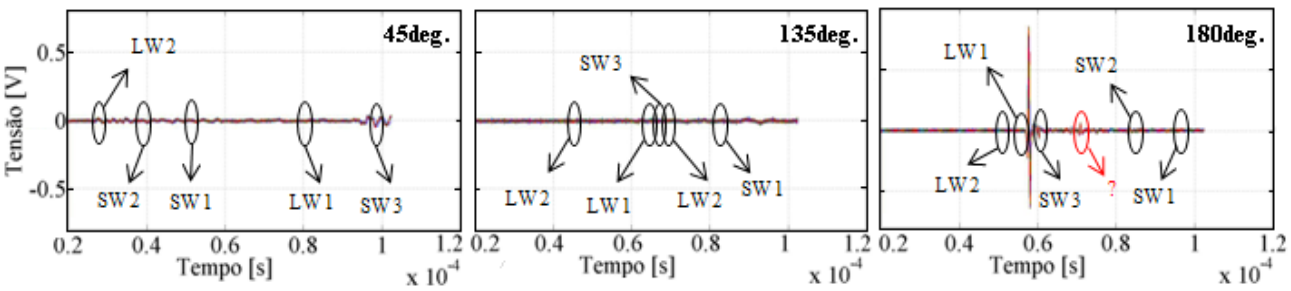

Figure 2. Identification of the likely acoustic waves (single-phase water flow).

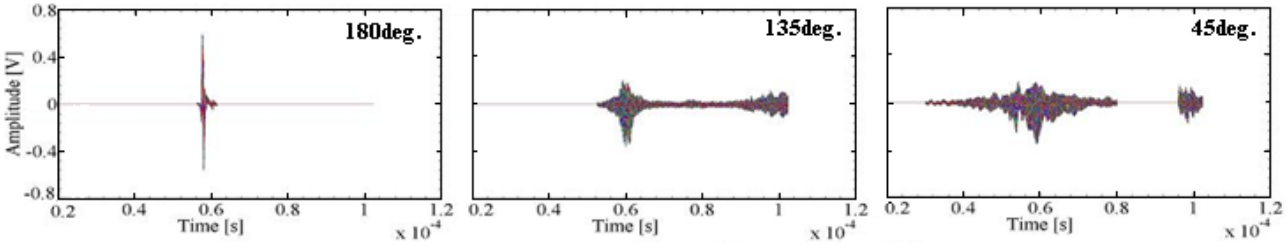

Figure 3. Data reduction windows for the sensors (1% void fraction).

In this connection, the trace signals for all receivers were analyzed as a function of void fraction so as to corroborate the conclusions drawn for the acoustic waves detailed in Figure 2. For the 180° sensor, it was a fairly straightforward matter to cross out time intervals of the acquisition window that were not related to LW1 and SW3. The remaining "data reduction window" is shown in Figure 3. For the 45° and 135° sensor, random reflection and diffraction of LW1 by gas structures made this task more difficult. Imprints of these acoustic phenomena in the trace signals spread out through most of the acquisition window, the only restriction being that it can only happen after the 15.75μs time instant. This corresponds to the time LW1 hits point B in Figure 1b and thereupon starts crossing the two-phase flow.

From this consideration and from observations of which regions of the acquisition window were sensitive to void fraction variations, the selected data reduction windows for the 45° and 135° sensors are as shown in Figure 3. It is believed that by using the data reduction windows systematic errors are greatly diminished in the calculations of acoustic parameters and, hence, the resulting numerical values become more meaningful.

Main Results

As can be seen in Figure 4, the average energy ratios revealed clear trends for all receivers. Whereas the energy received by the 180° sensor continually decreased with void fraction, an eleven-fold increase in the energy received by 135° sensor can be observed; meanwhile, the energy increase for the 45° sensor is about three-fold only for the entire void fraction span. In trying to associate the acoustic behavior with the flow patterns, one verifies a rapid increase in the energy received at the 135° sensor up to 4% void fraction. Keeping in mind that $\alpha = 5\%$ corresponds approximately to the most uniform discrete bubbles distribution, one could say that the rapid orderly increase in bubble population throughout the pipe cross-section causes a substantial increase in the amount of acoustic energy diverted to the 135° sensor. It is noteworthy that the data for this sensor started leveling off at 5% and not at 8% void fraction, which is when coalescence started taking place; this indicates that energy diversion to the 135° sensor by discrete bubbles reaches an asymptotic limit irrespective of any possible hindering action by coalesced gas structures. In fact, the data leveling off in the 5 to 11% void fraction range suggests that relatively small coalesced gas structures such as mushrooms and cap bubbles neither hinder nor contribute significantly to energy diversion to the 135° sensor. The behavior observed for $\alpha \geq 12\%$, which corresponds to the first appearances of Taylor bubbles, can be explained in terms of the flow pattern intermittence. It is conceivable that Taylor bubbles either greatly attenuate or effectively block the acoustic path to the 180° and 135° sensors. However, discrete bubbles in the liquid aerated slugs can freely divert the acoustic energy from the former to the latter sensor. The step increase observed in Figure 4 for the 135° sensor at 12% void fraction can then be explained on the assumption that the effect of liquid aerated slugs is far greater than that of Taylor bubbles. For the 45° sensor, clear trends can be identified as shown in Figure 4. A systematic increase can be observed up to 8%; the data then level off for the remaining void fraction range tested. It could thus be said that discrete bubbles increasingly reflect or otherwise direct acoustic energy to the 45° sensor, a process that is hindered by randomly occurring and randomly positioned coalesced gas structures in the cap bubbles sub-regime.

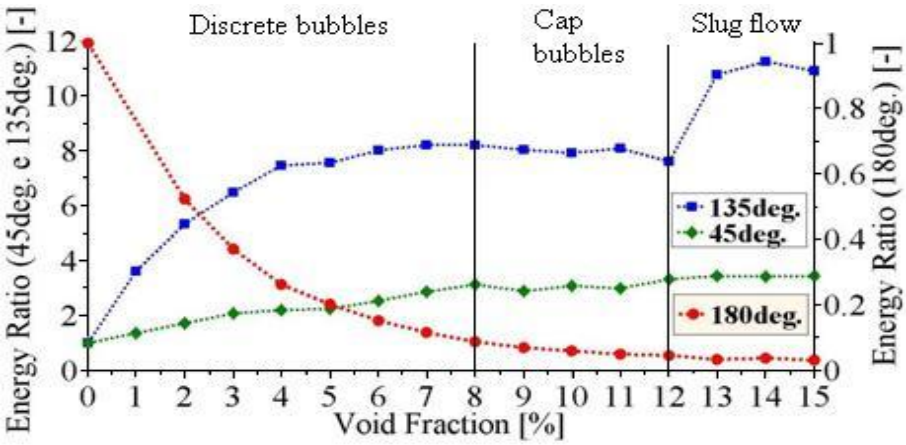

Figure 4. Average energy ratios as a function of void fraction for all receivers (j_{water} = 25.5 cm/s).

It is once again speculated that the onset of the slug flow with the intermittence between Taylor bubbles and liquid aerated slugs precludes the interference in their acoustic action by one another; however, their effects cancel each other out in the overall balance and energy diversion to the 45° sensor remains essentially constant.

The energy ratios of the individual ultrasonic pulses were analyzed in an attempt to identify specific gas structures imprinted in the ultrasonic signals. Due to limitations of the ultrasonic apparatus, it was only possible to synchronize data acquisition from two sensors at a time. Hence, data were simultaneously obtained from the 180° and 135° sensors; then for the same operating conditions, data were once again obtained for the 180° and 45° sensors. The 180° sensor was selected as reference due to its clear-cut behavior, thoroughly discussed in previous studies [2]. This procedure was repeated for all void fractions in the bubbly flow regime (0 to 15%). Figure 6 shows the resulting energy ratio distributions at the 180º, 135º, and 45º transducers whereas Figure 5 illustrates the instantaneous energy ratios at the 45° and 135° sensor corresponding to instantaneous energy ratios at the 180° sensor.

Upon analyzing similar plots for all void fractions tested, the energy ratios for the 45° sensor were observed to remain within a very limited range throughout the entire bubbly flow regime. Apparently, the amount of acoustic energy diverted to this sensor changes very little despite great variations in the gas structures at the pipe cross-section. The 135° sensor, on the other hand, displayed significant variations with the nominal void fraction and with the instantaneous energy ratio as measured by the 180° sensor; moreover, there seemed to be a split in its behavior at about 0.7 energy ratio. Up to this value, which indicates the presence of large gas structures in the cross-section or denser bubble populations, the 135°sensor exhibited repeatable trends. For energy ratios above 0.7, which indicates smaller gas structures or less dense bubble populations, great variability in the 135° sensor response was observed. This was checked by comparing plots like these in Figure 5 for different acoustic samples for the same operating conditions.

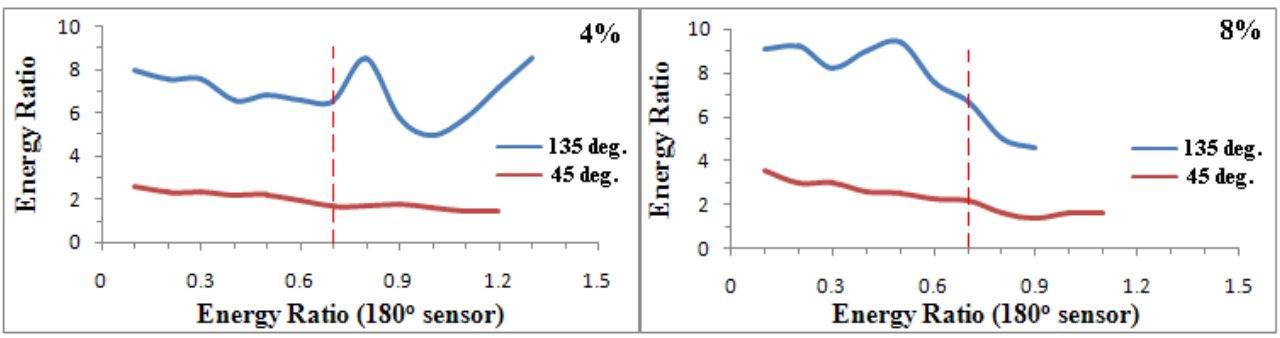

Figure 5. Individual pulses energy ratios for 4% and 8% void fraction.

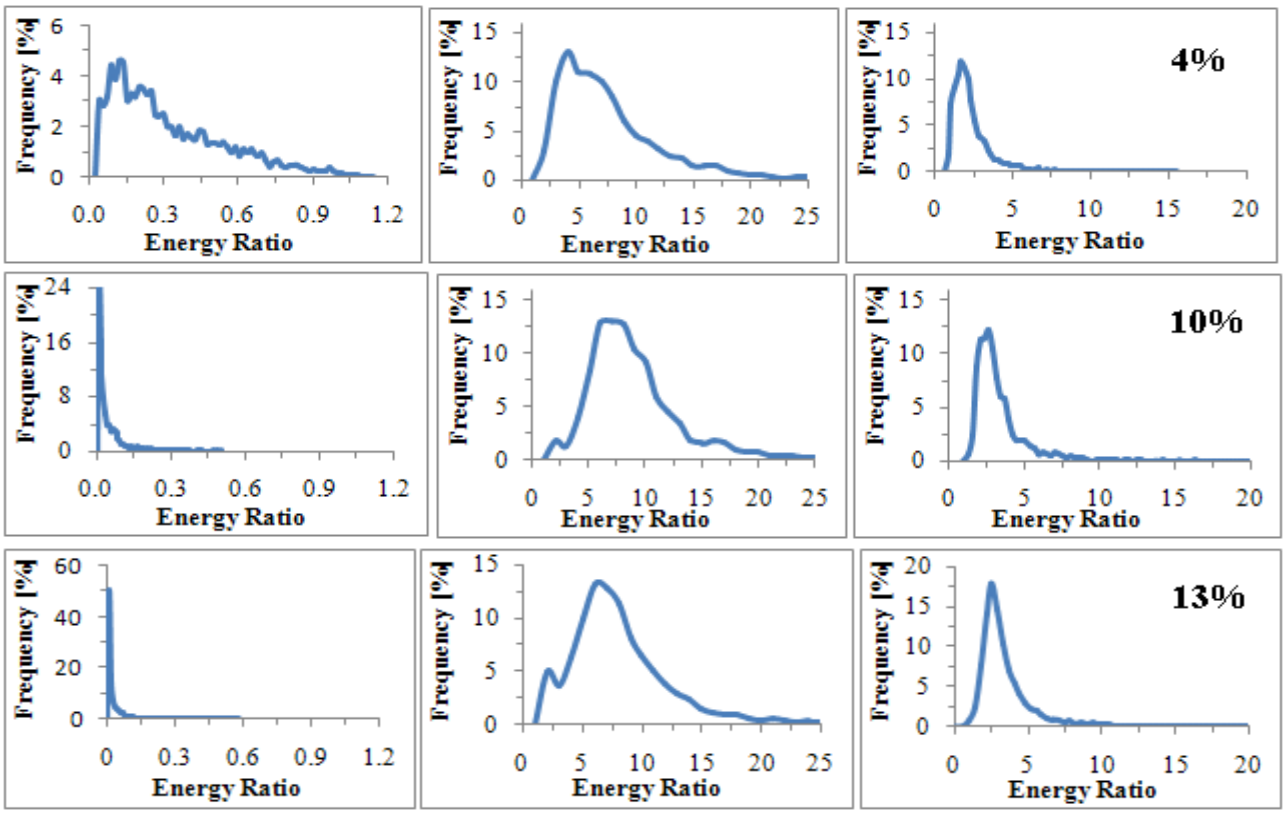

Figure 6. Energy ratio distributions at the 180º, 135º and 45º for different void fraction.

Table 2
Energy ratios corresponding to the specific gas structures.

Gas Structure		Small bubbles very near the wall	Scattered discrete bubbles	Sparsely populated discrete bubbles	Denser bubble population	Cap bubbles	Taylor bubbles
$\frac{E_{2\emptyset}}{E_{1\emptyset}}$	**180º**	0.0-0.3	0.3-0.6	0.0-0.3	0.3-0.6	0.0-0.03	0.0-0.03
	135º	4.0-5.5	3.5-4.5	7.5-9.0	8.0-12.0	6.0-8.0	8.0-12.0
	45º	0.9-1.0	0.9-1.0	0.9-2.5	2.0-2.5	2.0-4.0	2.0-4.0
Figure							
The conclusion is drawn that the main pieces of information about specific gas structures come from the 180º sensor followed by the 135º sensor; information from the 45º sensor can be used as fine tuning. Unfortunately, no information is available at the present time from the 0º sensor in pulse-echo mode; backward reflections should be a more recurrent, less random phenomena than side reflections to the 45º and 135º sensors. Once available, simultaneous information from all four sensors combined will make for unmistakable identification of specific gas structures. For the time being, an extensive analysis was made to identify combinations of the energy ratios from the 180º, 135º and 45º sensors that could be associated with specific aspects of the flow axial topology (Table 2). Each three-digit combination in ranges as shown in Table 2 is expected to always indicate the presence of a particular gas structure in the pipe cross section regardless of the nominal void fraction. For instance, the distribution called *scattered discrete bubbles*, which is typical of very low

void fractions, was associated with the (0.3-0.6; 2.5-4.0; 0.9-1.0) triad. These energy ratios combination occurs fairly often for 4% nominal void fraction, less so for 10% (the first and third ranges are almost absent from the corresponding sensor distribution), and does not occur at all for 13% void fraction (the 0.3 to 0.6 range is not covered by the 180° sensor). The (0.0-0.03; 6.0- 8.0; 2.0-4.0) and (0.0-0.03; 8.0- 12.0; 2.0-4.0) triads were observed to be associated with cap bubbles and Taylor bubbles; respectively; accordingly, they do not occur at 4% void fraction. Even though they are both present in the distributions in Figure 6 for 8% and 13%, the frequency of occurrence is consistent with the fact that cap bubbles evolve into Taylor bubbles. In addition, inspection of plots similar to those in Figure 5 reveals that on an instantaneous time basis the 135º sensor does allow for a clear distinction between cap bubbles and Taylor bubbles.

From these empirical observations summarized in Table 2, one could conjecture that energy diversion to the 45º sensor is mainly associated with backward acoustic reflections regardless of the specific gas structures at the pipe cross-section. This backward reflection would be more evenly distributed along the pipe circumference in the 45º quadrant and thus would not change much at the 45º sensor. Conversely, energy diversion to the 135º sensor would be due to forward scattering and multiple reflections off large gas structures and denser bubble populations (energy ratios below 0.7 as measured by the 180º sensor); this would lead to the repeatable trends mentioned previously. For scattered bubbles and smaller gas structures energy would hit the 135º sensor due to diffraction of the acoustic beam. The amount of energy diverted would be very much dependent upon the exact position of the gas phase, hence the great variability observed.

CONCLUSIONS

Acoustic attenuation and high-speed filming data have been presented on the axial flow topology of vertical, upward, air-water bubbly flows. Time average attenuation data correlated very closely with the void fraction; instantaneous data were shown to be a promising tool for detection of specific gas structures. The potential of the ultrasonic technique for void fraction and flow structure determination then seems further established.

HEAT TRANSFER AND FRICTION CHARACTERISTIC OF A SINGLE ROW HELICALLY FINNED COMPACT HEAT EXCHANGER

H. Huisseune*, C. T'Joen and M. De Paepe
Department of Flow, Heat and Combustion Mechanics,
Ghent University – UGent, Gent, Belgium

ABSTRACT. Single row heat exchangers with individually finned tubes are widely used in applications where a rugged configuration and low pressure drop are desirable. However, experimental data in open literature are rare. In this study, the heat transfer and friction correlation of a single row heat exchanger with helically finned tubes are experimentally determined in an open air wind tunnel. During the experiments the geometry of the tubes was fixed, but the transversal tube pitch was parametrically varied. The experimental data show that a decrease in transversal tube pitch results in higher Nusselt numbers (due to higher velocities in the minimum cross section) and higher friction factors (due to increasing blockage). The proposed heat transfer correlation can describe 95% of the data within ±12% and shows a 4.24% mean deviation. The friction correlation predicts 95% of the data within ±19% and gives a mean deviation of 6.84%. Comparison with literature illustrates that none of the existing literature correlations can accurately predict the results of this study.

INTRODUCTION

When exchanging heat with air, the main thermal resistance is located on the airside of the heat exchanger (more than 85%). To improve the heat transfer rate, the heat transfer surface is increased by adding fins. However, these fins also result in a significant pressure drop penalty.
Tubes can be individually finned, or multiple tubes can pass through each fin (these are the so called continuous fins). This study focuses on individually finned tubes for compressed air cooling using water. These tubes are more rugged than the continuous fin designs, but also less compact.
Heat exchangers consisting of individually finned tubes have been studied extensively in the past. Jameson and Schenectady [1] tested various tube arrangements. The values of the proportionality constants, which are needed to evaluate the suggested pressure drop relations, were tabulated. Further, they deduced a relation of the form of the fanning equation which correlates the data for all the tube sizes and arrangements tested. A pressure drop correlation applicable to both bare and finned tube bundles was established by Gunter and Shaw [2]. In the discussion accompanying their article, Jameson validated this correlation with his own test data and suggested a revised expression. Also other authors have questioned the Gunter and Shaw relationship [3,4,5]. Two widely cited correlations for a staggered tube layout are the Briggs and Young [6] (heat transfer) and Robinson and Briggs [5] (pressure drop) correlation. These relations were recommended by Webb [3].
Mirkovic [7] performed tests on heat exchangers with helically finned tubes in a staggered eight row configuration to determine the thermal and hydraulic characteristics. Correction factors for other numbers of tube rows were reported. The heat transfer and pressure drop correlations suggested by the ESDU [8] are based on data for bundles containing four or more tube rows. For bundles less than four rows deep, the ESDU [8] advises to multiply the Nusselt number with a

E-mail address: Henk.Huisseune@UGent.be

correction factor as recommended by Huber and Rabas [9] and to calculate the pressure loss coefficient of a single row bundle as about 80% of that of a deep bundle (Eckels and Rabas [10]). Using experimental data from open literature, Genic et al. [11] established new pressure drop correlations for in-line and staggered helically finned tube bundles. The correction factors of Brauer [12,13], Yudin [14] or Weierman [15] were suggested to calculate the pressure drop for a one row heat exchanger. Eckels and Rabas [10] demonstrated that the effect of the row number on heat transfer in finned tube bundles is dependent on the Reynolds number, a point which is not considered in the previously mentioned correction factors. They also discussed the row effect on pressure drop: comparing the data of several authors, they concluded that the friction factor can increase or decrease with the row number. In contrast to the heat transfer row effect, the influence of the number of rows on the pressure drop is not only dependent on the Reynolds number, but also on the tube diameter, tube pitch and fin density. Consequently, correcting the correlation of a multiple row tube bank to obtain the heat transfer coefficient or pressure drop of a single row heat exchanger (as studied in this work) does not result in accurate predictions. However, research on the thermal hydraulic behaviour of heat exchangers with one row of tubes is little. Jameson and Schenectady [1] reported pressure drop data for a single row bundle. Lapin and Schurig [16] experimentally determined the effect of the number of staggered rows on the airside convective heat transfer coefficient. They studied finned tube banks from one to eight rows deep. Schmidt [17] established a Nusselt correlation for one tube row of a multi row heat exchanger. Sparrow and Samie [18] determined the heat transfer and pressure drop characteristics for one and two row tube bundles. For the one row tube bundle, the transversal tube pitch was parametrically varied. They concluded that the Nusselt numbers increase with decreasing transversal pitch. This is explained by the higher velocities in the minimum cross section for smaller transversal tube pitches at a fixed free stream velocity. The same trend is found in the ESDU correlation [8]. However, Mirkovic [7] observed that the Nusselt numbers increase when the transversal tube pitch is enlarged. This result of Mirkovic [7] is questionable. By correlating the Nusselt numbers using the Reynolds number Re_c based on the maximum velocity in the heat exchanger instead of the free stream Reynolds number Re_∞ based on the inlet velocity, Sparrow and Samie [18] established a heat transfer expression independent of the transversal tube pitch. Most authors reported similar results [1,6,10,17]. The transversal tube pitch also has an important influence on the pressure drop over the bundle: the pressure drop increases with decreasing pitch, due to the increasing blockage [1,5,6,8,18]. Again Mirkovic [7] observed the opposite effect: an increase in pressure drop with transversal pitch.

The above discussion reveals the need for more experimental data of single row annular finned tubes. These heat exchangers are used in applications where a rugged configuration and low pressure drop are desirable, e.g. compressed air cooling. To the authors' knowledge, only two heat transfer correlations [16,18] and one pressure drop correlation [1], deduced from data of single row heat exchangers, are available in open literature for design purposes. In this study, the heat transfer and friction characteristic of a single row heat exchanger with helically finned tubes were experimentally determined. The transversal tube pitch was parametrically varied.

METHODOLOGY

Experimental equipment

The test rig consisted of an open air wind tunnel and a closed water cycle. Measurements were performed on the airside as well as the waterside of the heat exchanger. A radial fan sucked air through a calibrated nozzle (ISO5167). To determine the air mass flow rate, the pressure drop over the nozzle was measured using a differential pressure transducer. The fan was driven by a frequency controller which allowed setting an air mass flow rate between 0.1 and 1 kg/s. The air passed through the diffuser, the settling chamber and the sinusoidal contraction section, before entering the test section. The honeycomb and screen flow straightener in the settling chamber as well as the sinusoidal contraction ensured a uniform air flow at the inlet of the test section.

A single row heat exchanger with helicoidally finned tubes was placed in the test section. The helical fins were extruded out of the aluminum base tube, eliminating the contact resistance. The

Table 1
Dimensions of the Helicoidally Finned Tubes Used in This Work

d_{ext} (mm)	13
t_{fin} (mm)	0.65
D_{fin} (mm)	24.8
F_p (mm)	2.4

geometry of the tubes is listed in Table 1. During the experiments these dimensions were fixed. Only the transversal tube pitch X_t was varied, yielding the dimensionless values:

$$X_t / d_{ext} = 1.92;\ 2.27;\ 2.45;\ 2.84;\ 3.27$$

Depending on the transversal tube pitch, 8 or 10 tubes were positioned. The remaining gap was filled to $X_t/2$ to avoid bypass flow.

The closed water cycle consisted of an electric boiler with a power limit of 6 kW, several valves and a circulation pump. The water temperature was controlled with a PID controller. The pump was driven by a frequency controlled engine. The water mass flow rate was measured with a calibrated electromagnetic flow meter. The tubes and distributors bringing the hot water to the heat exchanger were well insulated. The water flew through the heat exchanger in two passes (4 by 4 or 5 by 5 depending on the transversal tube pitch).

All temperatures were measured using calibrated K type thermocouples and read with a Keithley 2700 Multimeter/Data Acquisition System. The measurements were performed at steady state conditions for different Reynolds numbers.

Data reduction

The air mass flow rate and temperature measurements were used to determine the overall heat balance on the water and air side of the single row bundle. The difference between both heat transfer rates was for all measurements smaller than 5%. Next, the overall heat transfer resistance $(UA)^{-1}$ was calculated using the effectiveness-NTU relationships for the given configuration [19]. As is clear from equation (1), the overall heat transfer resistance $(UA)^{-1}$ consists of convection and fouling on the airside, contact resistance between the fins and tube, conduction through the tube wall and fouling and convection on the waterside. The contact resistance of the tested heat exchanger was zero, because the fins were extruded out of the base tube, and clean air and filtered water were used during the experiments resulting in negligible fouling. Taking this into account and using the Gnielinski correlation [20] on the waterside, the airside convection coefficient h_{ext} was determined from equation (1).

$$\frac{1}{UA} = \frac{1}{\eta_{ext} h_{ext} A_{ext}} + R_{f,ext} + R_c + \frac{\ln\left(\frac{d_{ext}}{d_{in}}\right)}{2\pi\lambda_T L_T} + R_{f,in} + \frac{1}{h_{in} A_{in}} \tag{1}$$

The dimensionless airside convection coefficient is defined by the Nusselt number (equation (2)).

$$Nu = \frac{h_{ext} \cdot d_{ext}}{\lambda_{air}} \tag{2}$$

The pressure measurements were performed under isothermal conditions and the friction factor was calculated according to equation (3) [21].

$$f = \frac{A_c}{A_{ext}} \cdot \left[\frac{2\Delta p \cdot \rho_{air,in}}{G_c^2} \right] \tag{3}$$

RESULTS AND DISCUSSION

Heat transfer

The Nusselt numbers for the tested single row heat exchangers are plotted versus the freestream Reynolds number Re_∞ (based on the inlet velocity and external tube diameter) in Figure 1. The

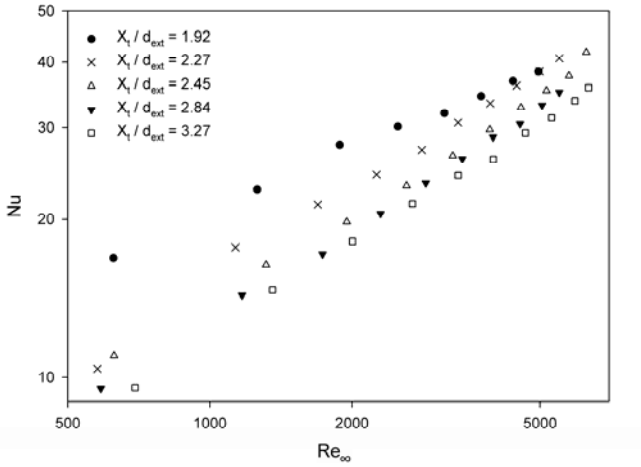

Figure 1. Experimental Nusselt numbers plotted versus the freestream Reynolds number Re_∞ for different transversal tube pitches

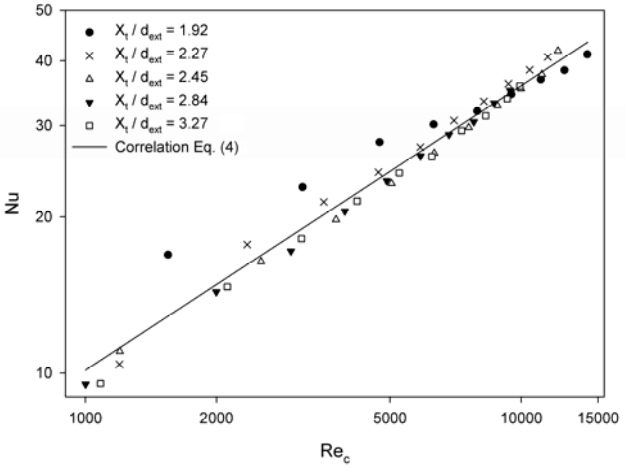

Figure 2. Experimental data and Nu correlation independent of X_t/d_{ext} (equation (4)) plotted versus the minimum-area Reynolds number Re_c

results are parameterized by the dimensionless transversal tube pitch X_t/d_{ext}. Mirkovic [7] reported that a decrease in transversal tube pitch results in a heat transfer rate decrease. However, most authors state that a decrease in X_t results in an increase of the Nusselt number, because of the higher local velocities in the minimum cross sectional area [8,18]. This is also seen in our measurements, see Figure 1. To take the effect of X_t into account, Sparrow and Samie [18] suggested correlating the Nusselt number results by using the minimum-area Reynolds number Re_c (based on the external tube diameter and the air velocity at the minimal cross-sectional area), instead of the freestream Reynolds number Re_∞. Figure 2 shows the experimental data as function of Re_c.

A correlation independent of the transversal tube pitch was determined via a least-mean-squares fit:

$$Nu = 0.2290 \cdot Re_c^{0.5486} \tag{4}$$

This correlation, also plotted in Figure 2, is able to predict 95% of the experimental data within ± 15% and gives a mean deviation of 4.76%. The prediction capability of the correlation is poorer for small values of Re and X_t. To obtain a better match with the experimental data, a dimensionless group dependent on the transversal tube pitch X_t is added to the correlation in addition to using the minimum-area Reynolds number Re_c. The regression analysis resulted in:

$$Nu = 0.2995 \cdot Re_c^{0.5396} \cdot \left(\frac{X_t}{d_{ext}} \right)^{-0.2068} \tag{5}$$

Figure 3 compares equation (5) with the experimental data. The proposed heat transfer correlation can describe 95% of the data within ± 12% and shows a 4.24% mean deviation.
Figure 4 compares the new correlation with correlations for a single row heat exchanger with annular finned tubes found in literature. Table 2 shows the data ranges used in the correlations. Data from open literature were recalculated to Reynolds numbers based on the external tube diameter and the air velocity at the minimal cross-sectional area. The Nusselt numbers are evaluated for the heat exchanger geometry of Table 3. The transversal tube pitch is set to the value of Lapin and Schurig's tests [16]. Mirkovic [7] and the ESDU [8] predict the highest Nusselt numbers. However, these are multiple tube row correlations corrected with a constant factor to apply them on a single row heat exchanger. Figure 4 shows that correcting multiple row correlations for single row arrays does not result in reliable predictions. Moreover, Eckels and Rabas [10] showed that the influence of the number of rows on the heat transfer in finned tube bundles is dependent on the Reynolds number, a point which is not considered in the correction diagram of Mirkovic [7] and by the ESDU [8]. Schmidt presented a Nusselt correlation for one tube row of a multi-row tube bundle. It was expected that the average Nusselt number of one tube row in a multi-row bundle is lower than the Nusselt number of a single row heat exchanger, because the first row in a multi row heat exchanger transfers more heat than the subsequent rows. However, this is not seen in Figure 4: even

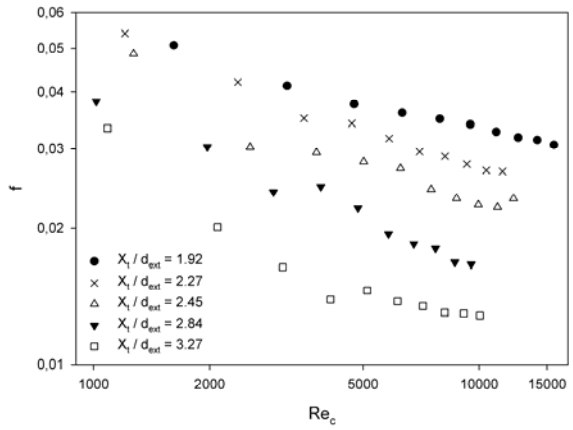

Figure 5. Experimental friction factors plotted versus the minimum-area Reynolds number Re_c for different transversal tube pitches

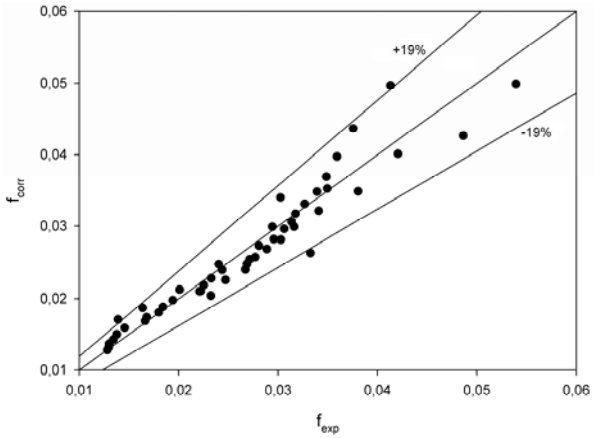

Figure 6. Comparison of the friction correlation (equation (6)) with the experimental data

though the geometry of our heat exchanger is within the application range of Schmidt [17], his correlation lies above our equation (5). The correlations of Lapin and Schurig [16] and Sparrow and Samie [18] are correlations for single row heat exchangers. The expression of Lapin and Schurig [16] underestimates our correlation (equation (5)). A possible explanation is that their tests were performed on a heat exchanger with larger fin spacing. The correlation of Sparrow and Samie [18] is only applicable for higher Reynolds numbers (which were not reached in our tests because of fan restrictions). In the overlapping Reynolds range the correlation well corresponds to our relation.

Pressure drop

The friction factors, calculated according to equation (3), are presented in Figure 5. They are plotted as function of Re_c for the different values of the transversal tube pitch. Unlike the heat transfer data, the use of the minimum-area velocity does not bring the pressure drop data together (compare Figure 5 with Figure 2). This is due to the vena contracta effect: the geometrically minimum free flow area is not the actual minimum free flow area [18].

For a given X_t, the friction factor decreases with increasing Reynolds number. For a fixed Re_c, the pressure drop across the heat exchanger increases with decreasing transversal tube pitch (i.e. increasing blockage). This is in accordance with the results of most authors [1,5,6,8,18]. The finding of Mirkovic [7] – the pressure drop increases with the transversal tube pitch – should be questioned.

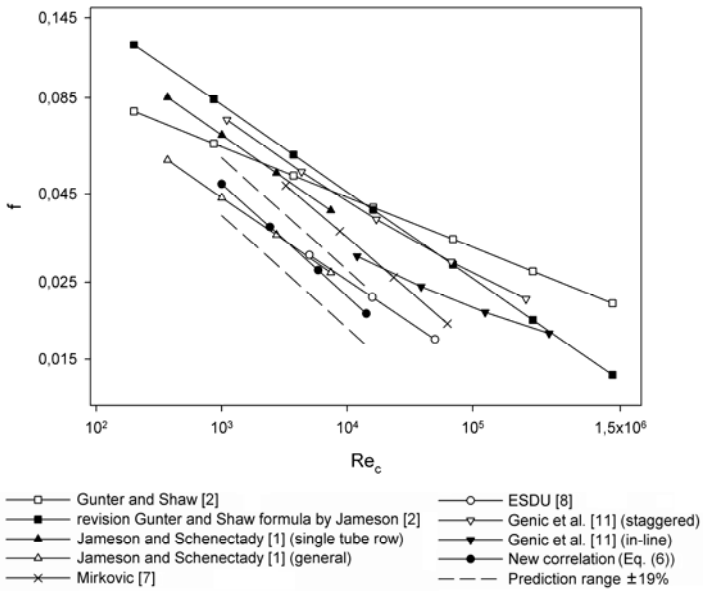

Figure 7. Comparison of equation (6) with friction characteristics from open literature

Table 4
Application Ranges of Friction Correlations from Open Literature

Authors		**Re_c**	**d_{ext} (mm)**	**X_t / d_{ext}**	**D_{fin} / d_{ext}**	**s / d_{ext}**

Jameson and Schenectady [1] (general correlation)		370 - 7400	15.875 - 25.4	1.959 - 3.633	1.737 - 1.951	0.102 - 0.213
Mirkovic [7]		3250 - 63000	25.4 - 50.8	1.969 - 4.724	1.375 - 1.75	0.053 - 0.142
ESDU [8]		5000 - 50000	9.5 - 51	1.85 - 4.75	1.220 - 4.474	0.014 - 0.990
Genic et al. [11]	Staggered	1100 - 265000	9.65 - 32	0.952 - 3.5	0.841 - 4.572	0.068 - 0.350
	Inline	12000 - 406000	32	2 - 4	1.563	0.147
New correlation (equation (6))		1000 - 14200	13	1.92 - 3.27	1.91	0.135

These experimental data were correlated via a least-mean-squares fit, resulting in:

$$f = 2.271 \cdot Re_c^{-0.3245} \cdot \left(\frac{X_t}{d_{ext}} \right)^{-1.8486} \quad (6)$$

Figure 6 compares equation (6) with the experimental data. This friction correlation predicts 95% of the data within ± 19% and gives a mean deviation of 6.84%.

In Figure 7 the new friction characteristic equation (6) is compared with correlations from literature. Their application ranges are listed in Table 4. Data from open literature were recalculated to friction factors as defined by equation (3) and Reynolds numbers based on the external tube diameter and the air velocity at the minimal cross-sectional area. The correlations are plotted for the heat exchanger geometry of Table 3. Jameson and Schenectady [1] reported data to calculate the friction factors of a single row heat exchanger. The higher values compared with the results of this paper are probably due to the fact that their correlation is not applicable to the heat exchanger geometry of Table 3. Their general expression, which correlates the data for all the tube sizes and arrangements tested (ranging from 1 to 8 tube rows), shows better agreement. The Gunter and Shaw relationship [2] predicts friction values which are much too high. This was also observed by other authors [2,3,4,5]. The slope differs from most other correlations and shows similarity with the in-line configuration of Genic et al. [11]. In the discussion accompanying their article, Jameson suggested a revised version of the Gunter and Shaw equation [2]. The slope of this revised correlation is consistent with our results, but the friction factors are still overestimated. Mirkovic [7] and the ESDU [8] presented a per row pressure drop correlation for staggered, multi-row arrays. Mirkovic' correlation [7] is based on heat exchangers with large tube diameters. This may explain the higher friction values. The ESDU [8] suggests a correction factor of 0.8 for a single row bundle, which results in a better match with the correlation developed in this study. Genic et al. [11] considered staggered and in-line multiple row tube bundles. They advised the correction factors of Brauer [12,13], Yudin [14] or Weierman [15] for a heat exchanger with one tube row. Similar to the heat transfer results, correcting multi-row pressure drop expressions for a single row heat exchanger does not lead to accurate predictions.

UNCERTAINTY ANALYSIS

In order to be able to indicate the quality of the measurements a thorough error analysis was performed. The error of the manometer (pocket manometer of Furness Controls) used to measure the pressure drop across the nozzle was 0.5 Pa. This resulted in a maximum relative error of 0.9% on the air mass flow rate. The maximum relative error of the electromagnetic water flow meter (Kent Veriflux VSC) was found to be 3.0%. The K type thermocouples had an accuracy of 0.1°C. The error on the thermodynamic properties of water and air can be found in literature [22-24].

For each measurement, the relative error was determined. An average was then taken from all the results. The average relative error on the Nusselt number was 7.5% and on the friction factor 5.8%.

CONCLUSIONS

In this study the heat transfer and friction characteristic of a single row heat exchanger with helically finned tubes were determined. The transversal tube pitch was parametrically varied. A thorough error analysis was performed to validate the results. The measurements show that a decrease in transversal tube pitch results in larger heat transfer coefficients (due to higher velocities in the minimum cross sectional area) and larger pressure drops (due to increasing blockage). The Nusselt numbers and friction factors were correlated using the minimum-area Reynolds numbers. The heat transfer correlation can describe 95% of the data within ± 12% and shows a 4.24% mean deviation. The friction correlation predicts 95% of the data within ± 19% and gives a mean deviation of 6.84%. Both equations are dependent on the transversal tube pitch. These new correlations were compared with correlations from open literature. Experimental data on single row heat exchangers are rare. It is concluded that correcting multi-row expressions to apply on single row heat exchangers does not lead to reliable predictions. In general, the new correlations show the

same trend as most literature correlations, but none of the literature correlations can accurately predict the results of this study.

OSCILLATIONS INDUCED BY A FIN ON THE SIDEWALL OF A DIFFERENTIALLY HEATED CAVITY

F. Xu*, J. Patterson, C. Lei, T. Bednarz
James Cook University, Townsville, QLD 4811, Australia

ABSTRACT Temperature measurements of the thermal flow around a fin placed on the heated sidewall of a differentially heated cavity were performed. The oscillations of the thermal flow around the fin in the transition from sudden start-up to a quasi-steady state were observed based on the temperature time series. Spectral analyses of the temperature signals reveal the frequency characteristics of the oscillations. The temperature measurements also show that the oscillations of the thermal flow around the fin depend on the Rayleigh number. Furthermore, the temperature time series were compared with those obtained in the cases without a fin.

Keywords: *Oscillations, thermal flow, fin, differentially heated cavity*

INTRODUCTION

Natural convection flows in a differentially heated cavity are of significance in many industrial systems such as solar collectors and nuclear reactors. Previous studies [1-3] demonstrated that following sudden heating, perturbations on the thermal boundary layer, which are referred to as the leading edge effect (LEE), arise in the vicinity of the leading edge of a vertical wall and propagate downstream. The LEE plays a fundamental role in the early development of the thermal boundary layer, and its propagation speed is therefore of interest. Initial views on the propagation speed of the LEE suggested that the LEE travelled at the boundary layer flow velocity [1], but it was demonstrated that this propagation speed lags behind the experimental results [2, 3]. Armfield and Patterson [4] showed that a better model for estimating the LEE propagation is to use the maximum speed of the travelling waves in the thermal boundary layer, which was confirmed by experiments [3]. Previous studies (e.g. [5-7]) also showed that the ceiling of the cavity forces a horizontal intrusion into the interior, which separates from and then reattaches to the ceiling, resulting in a series of trailing waves. The intrusion may develop a cavity-scale oscillation after it reaches the opposing wall. As the flow approaches a steady or quasi-steady state, the interior fluid in the cavity is stratified, and a double-layer structure of the vertical thermal boundary layer is formed [8].

Apart from understanding the basic flows in a differentially heated cavity, enhancing or depressing the heat transfer through the cavity is of practical significance in numerous industrial applications. Placing a fin on the sidewall of the cavity provides a simple way to change the thermal flow adjacent to the sidewall and in turn enhance or depress the heat transfer [9]. Studies of the thermal flow induced by a fin on a heated or cooled sidewall of a cavity have also been extensively reported in the literature, most of which examined the effects of the material properties, geometry and position of the fin. Clearly, the fin may be either conducting or adiabatic. It is expected that a conducting fin attached to the sidewall increases the surface area for heat transfer, and in turn increases the overall heat transfer through the cavity. Accordingly, the effect of the thermal

E-mail address: feng.xu@jcu.edu.au

conductivity of different fin materials on heat transfer through the finned sidewall was investigated extensively [10-14].

An adiabatic or poorly conducting fin may also have a significant impact on the natural convection flows in a differentially heated cavity and the heat transfer through the cavity, and in particular the geometry and the location of the fin may play an important role. The study in [9] demonstrated that, as the thickness of a fin which has a poor thermal conductivity and is located at the mid height of the hot sidewall is reduced, the heat transfer through the cavity initially decreases until a critical thickness is reached. If the thickness is reduced further below the critical thickness, the heat transfer through the cavity increases again. The fin length is another factor affecting natural convection flows in the cavity. If the length of the adiabatic fin is sufficiently large, secondary circulations arise at the upper and lower base corners of the fin [14]. The heat transfer through the finned sidewall is reduced as the fin length increases since natural convection flows adjacent to the finned sidewall are depressed. Furthermore, comprehensive investigations of the effect of the position of a fin on natural convection flows in the cavity may be found in [14].

Steady natural convection flows induced by an adiabatic fin have been the focus of previous studies (see e.g. [14]). However, since unsteady natural convection in the cavity has many applications in industry, experimental investigations of the transient thermal flow around an adiabatic fin have been performed by the present authors [15, 16]. The flow visualizations in [15, 16] show that, following sudden heating, the fin on the sidewall blocks the upstream boundary layer flow and forces an intrusion front beneath the fin which eventually reattaches to the downstream sidewall after it bypasses the fin. Indeed, the fin significantly changes the transient thermal boundary layer flow.

It was demonstrated that for different Rayleigh numbers the adiabatic fin may play different roles in the thermal flow adjacent to the finned wall [14, 17]. For low Rayleigh numbers, the thermal flow around the adiabatic fin is laminar and the heat transfer through the finned wall is depressed (see e.g. [14]). On the other hand, for high Rayleigh numbers, the adiabatic fin may trigger instabilities of the thermal flow, and thus enhance the heat transfer through the finned wall, in comparison with that through a wall without a fin [17]. However, understanding of the instabilities induced by the adiabatic fin is still incomplete, and thus further temperature measurements were performed in this study. The oscillations of the thermal flow around the fin were observed and the frequency features of the oscillations were characterized.

EXPERIMENTAL SETUP

In this study, temperature measurements were carried out in the model cavity shown in Figure 1. Briefly, the cavity, containing water as the working fluid, is 1-m long (L), 0.24-m high (H) and 0.5-m wide (W) with a fin of cross-section 0.04-m × 0.002-m attached at the mid height of the hot

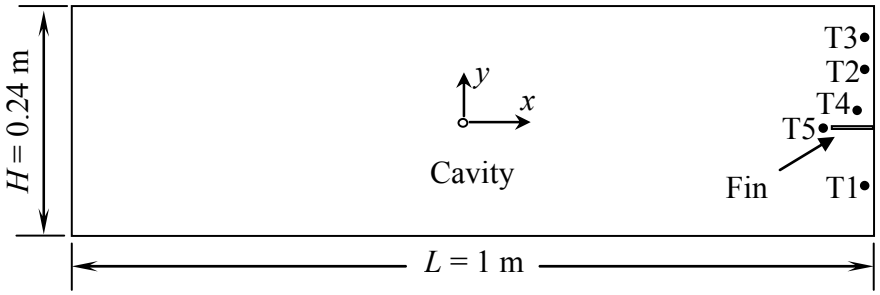

Figure 1. Schematic of the experimental model: Points T1 to T5 denote Thermistor locations, which are corresponding to Thermistor 1 (0.4983 m, -0.0624 m), Thermistor 2 (0.4978 m, 0.0628 m), Thermistor 3 (0.4974 m, 0.0866 m), Thermistor 4 (0.4956 m, 0.007 m), and Thermistor 5 (0.4572 m, -0.0013 m) respectively.

sidewall. The cavity walls and the fin are all made from Perspex sheets except the cooled and heated sidewalls, which are made of 0.00113-m thick gold-coated copper plates (note that due to the poor thermal conductivity of Perspex compared with the thermal conductivity of the copper plate, the Perspex fin may be considered approximately adiabatic).

The sidewall with the fin is heated by the hot water in a water bath, and the opposing sidewall without a fin cooled by the cold water in another water bath. Each water bath is initially separated from the sidewall by a pneumatically operated gate with an air gap between the gate and the sidewall. When the experiment starts, the gates are rapidly lifted, and the hot and cold water in the two water baths flushes against the copper sidewalls. An approximately instantaneous isothermal boundary condition is established at each end of the cavity because this process is completed within a second. During the experiments, the temperatures of the water in the water baths, connected to two separate refrigerated/heating circulators, are kept constant with a temperature stability of ± 0.01 K.

In the experiments, Thermometrics FP07 thermistors were employed. The body of the thermistor has a maximum diameter of 2.2 mm and a length of 12.6 mm, and is mounted in an insulated tube in order to minimize thermal disturbances to the flow field. Since the thermal flow around the fin is the focus of this paper, all five thermistors were placed in the vicinity of the fin and the hot sidewall. Three of the thermistors were placed along the sidewall at different heights, with the other two located around the fin, as shown in Figure 1. Note that for the description of the physical locations, the origin of the coordinates is at the center of the cavity.

The runtime of each experiment is dependent on the development of natural convection flows in the cavity, which is determined by three dimensionless parameters governing the flow: the Rayleigh number (Ra), the Prandtl number (Pr) and the aspect ratio (A). They are defined as follows,

$$Ra = \frac{g\beta\Delta T H^3}{\nu\alpha}, \tag{1}$$

$$Pr = \frac{\nu}{\alpha}, \tag{2}$$

$$A = \frac{H}{L}. \tag{3}$$

Note that the fin length is also a dimensional parameter controlling the thermal flow around the fin on the sidewall. However, a fix fin length is considered in this study.

Table 1. Experimental parameters for temperature measurements

Experiment	Initial temperature of water in cavity (T_0, K)	Temperature difference between sidewalls (ΔT, K)	Ra ($\times 10^9$)	Pr
1	296.65	4	1.01	6.45
2	296.55	8	2.00	6.47

RESULTS AND DISCUSSION

Four experiments with temperature differences between the two sidewalls ranging from 4 to 32 K were performed, and the corresponding ranges of Ra and Pr are $1.01 \sim 7.54 \times 10^9$ and $6.45 \sim 6.63$ respectively. All experimental conditions are listed in Table 1. In this section, the results of the

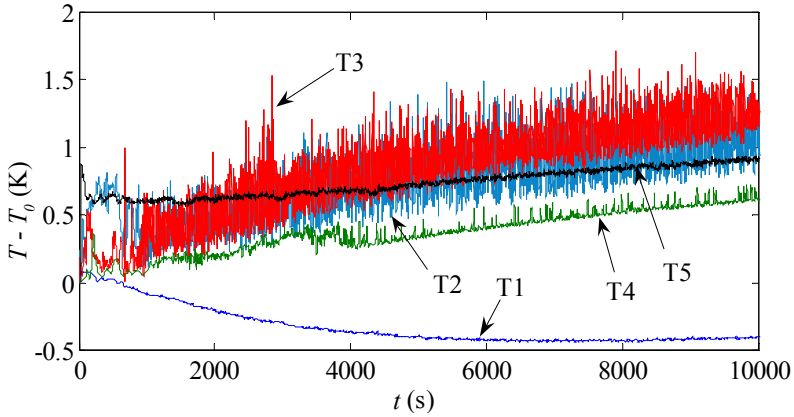

Figure 2. Temperatures measured at the locations shown in Figure 1.

temperature measurements are described based on $Ra = 2 \times 10^9$ (Experiment 2) unless specified otherwise.

Figure 2 shows the time series of the temperatures measured at the five locations. Clearly, the temperature time series are oscillatory and eventually approach respective quasi-steady states. Furthermore, the temperatures in the upper part of the cavity increase with time and the temperature measured by Thermistor 1 in the lower part of the cavity decreases with time. This indicates that a stable stratification of the fluid in the cavity is continuously reinforced [8].

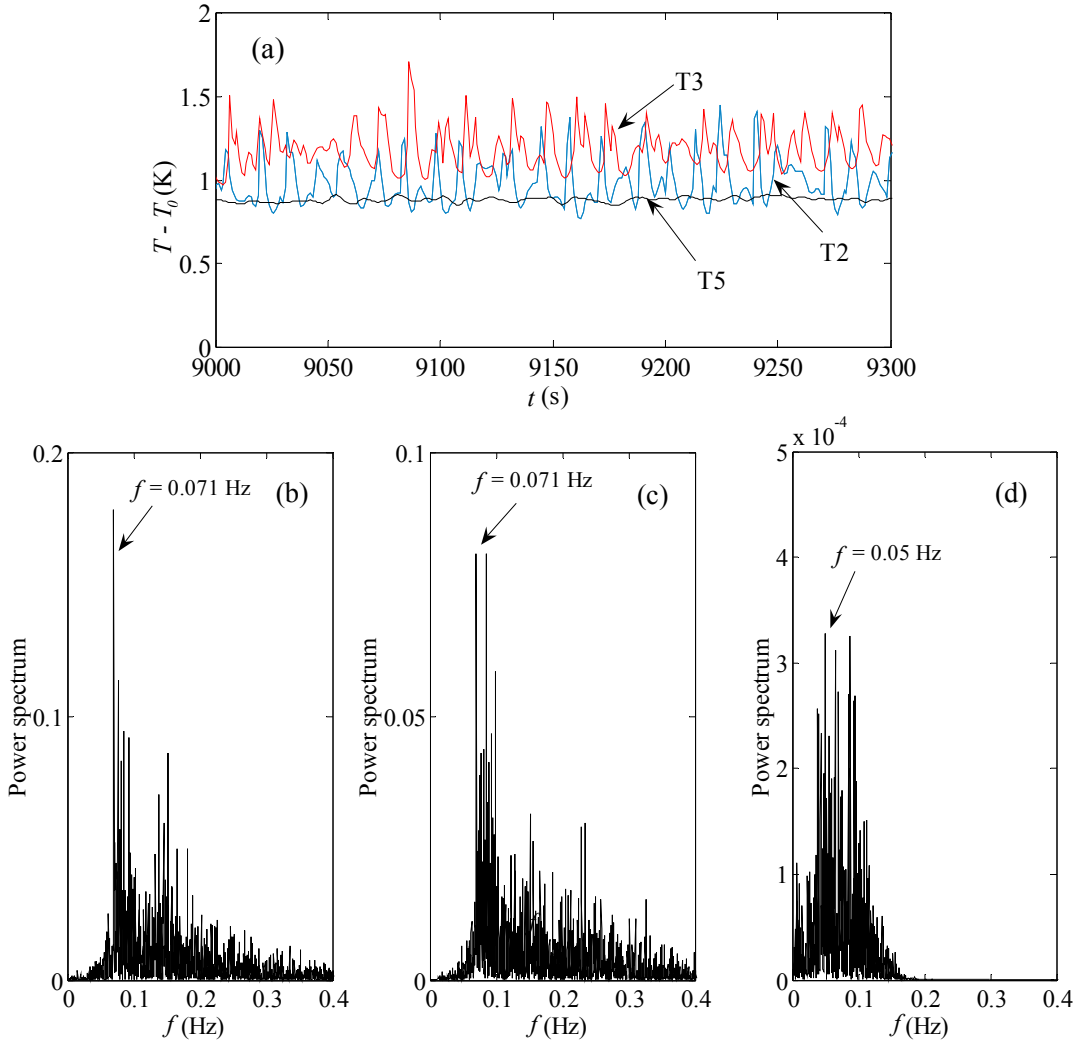

Figure 3. Temperatures and power spectra from Thermistors 2, 3 and 5 in the quasi-stage stage. (a) Temperature time series from Thermistors 2, 3 and 5. (b) Spectrum for Thermistor 2. (c) Spectrum for Thermistor 3. (d) Spectrum for Thermistor 5.

For the purpose of displaying the wave features of the thermal flow around the fin at the quasi-steady state, Figure 3(a) replots the temperature time series from Thermistors 2, 3 and 5 over a period of 300 s in this stage. It is seen in this figure that the amplitude of the temperature waves at this stage is strongly dependent on the spatial location but less dependent on time. The temperature time series from Thermistor 5 shows the oscillations of the thermal flow around the fin, that from Thermistor 2 shows the travelling waves in the vertical boundary layer induced by these oscillations, and that from Thermistor 3 shows the travelling waves in the further downstream boundary layer.

Figures 3(b), 3(c) and 3(d) show the power spectra for Thermistors 2, 3 and 5 respectively. It is clear that the frequency characteristics of the temperature waves are different at these locations. However, it is seen in Figures 3(b) and 3(c) that both the dominant frequencies of the temperature time series from Thermistors 2 and 3 are around 0.071 Hz; that is, the dominant frequencies do not change when the oscillations in the thermal boundary layer propagate downstream of the fin. Figure 3(d) shows that the peak of the spectrum for Thermistor 5 (upstream of Thermistors 2 and 3, refer to Figure 1) is around 0.05 Hz, lower than those for Thermistors 2 and 3. The above results indicate that for the present Rayleigh number ($Ra = 2 \times 10^9$), the oscillations within a narrow band of frequencies around 0.071 Hz are selectively amplified in the downstream side of the fin, which could be caused by the unstable thermal layer above the fin which has an adverse temperature gradient with warmer fluid underneath colder fluid [17].

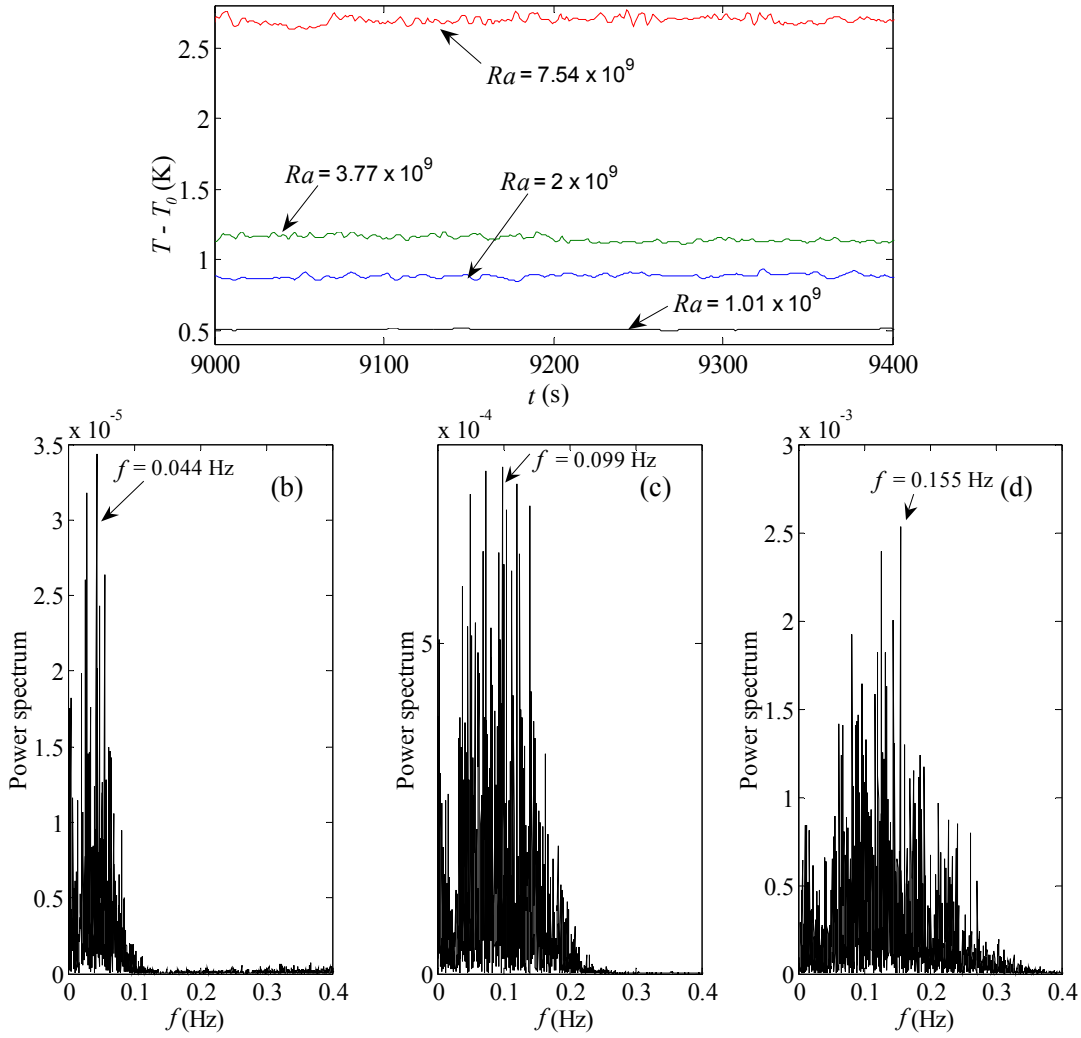

Figure 4. Temperatures and spectra from Thermistor 5 (0.4572 m, -0.0013 m) in the quasi-steady stage for different Rayleigh numbers. (a) Temperature time series. (b) Spectrum for $Ra = 1.01 \times 10^9$. (c) Spectrum for $Ra = 3.77 \times 10^9$. (d) Spectrum for $Ra = 7.54 \times 10^9$.

Indeed, the oscillations of the thermal flow around the fin depend on the Rayleigh number. Figure 4(a) shows the temperature time series from Thermistor 5 in the quasi-steady stage for different Rayleigh numbers. It is clear that the average temperature from Thermistor 5 increases with the temperature difference between the two sidewalls (see Table 1). Furthermore, both the amplitude and dominant frequency of the oscillations change with the Rayleigh number. The power spectra of the temperature time series in Figures 4(b), 4(c) and 4(d) show that the dominant frequency of the oscillations increases as the Rayleigh number increases.

Figure 5 shows the comparisons of the temperature time series in the downstream thermal boundary layer in the cases with and without a fin (note that the temperature measurements for the case without a fin are reported separately in [18]). It is seen in this figure that the fin apparently changes the character of the oscillations in the thermal boundary layer on the downstream side of the fin. For instance, Figures 5(a) and 5(b) show that due to the presence of the fin, the thermal flow at the downstream side of the fin is more unstable; that is, the amplitudes of the oscillations are larger than those in the cases without a fin. This is consistent with the numerical results reported in [17] which also demonstrated that these unstable flows at the downstream side of the fin may in turn enhance heat transfer through the finned sidewall. Further comparisons of the temperature measurements between the cases with and without a fin are currently being conducted.

CONCLUSIONS

In this paper, the temperatures of the thermal flow around a fin placed at the mid height of the hot sidewall of a differentially heated cavity were measured by a set of fast-response thermistors. The transient and quasi-steady state flow features were characterized based on the temperature

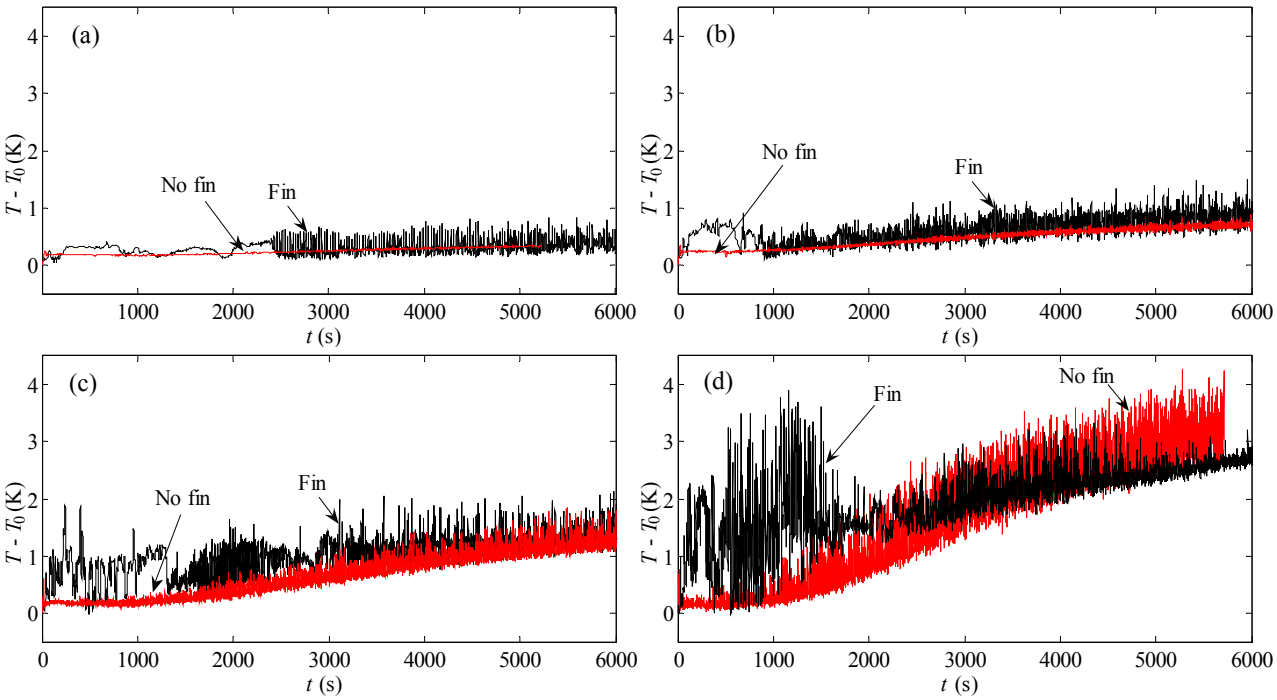

Figure 5. Temperatures in the cases with a fin at (0.4978 m, 0.0628 m) and without a fin at (0.4974 m, 0.0624 m) for different Rayleigh numbers. (a) Cases with a fin for $Ra = 1.01 \times 10^9$ and without a fin for $Ra = 0.88 \times 10^9$. (b) Cases with a fin for $Ra = 2 \times 10^9$ and without a fin for $Ra = 1.75 \times 10^9$. (c) Cases with and without a fin for $Ra = 3.77 \times 10^9$. (d) Cases with a fin for $Ra = 7.54 \times 10^9$ and without a fin for $Ra = 6.87 \times 10^9$.

measurements.

The temperature measurements clearly show the stratification of the fluid in the cavity and the oscillations of the thermal flow around the fin. Furthermore, the spectral analyses of the temperature time series in the quasi-steady stage have revealed the dominant frequencies of the oscillations of the thermal flow around the fin and its dependence on the Rayleigh number.

Nomenclature

A	aspect ratio
f	frequency (Hz)
g	acceleration due to gravity (m/s^2)
H, L, W	height, length and width of the cavity (m)
Pr	Prandtl number
Ra	Rayleigh number
t	time **(**s**)**
T_0	initial temperature of the fluid (K)
ΔT	temperature difference between sidewalls (K)
x, y	horizontal and vertical coordinates (m)
β	coefficient of thermal expansion (1/K)
α	thermal diffusivity (m^2/s)
ν	kinematic viscosity (m^2/s)

T.

TRANSITION OF FLOW IN FREE LIQUID FILM EXPOSED TO TEMPERATURE GRADIENT

I. Ueno[1,*], T. Watanabe[2] & T. Matsuya[2,]
[1]Tokyo University of Science, Chiba, Japan
[2]Graduate School at Tokyo University of Science, Chiba, Japan

ABSTRACT. Flow transition in a thin free liquid film exposed to a temperature difference is concerned. A free liquid film of O(1 mm) in width and length is formed in a rectangular hole in a thin plate of O(0.1 – 1 mm) in thickness. A designated temperature difference is added between the both end walls to realize a thermocapillary-driven flow on the both free surfaces. One can realize several flow patterns in the film by varying the temperature difference imposed. The authors focus on the formations and occurring conditions of such unique flows in the free liquid film.

Keywords: *free liquid film, flow pattern, transition, thermocapillary effect, particle*

INTRODUCTION

The authors have been inspired by a series of scientific performances by Dr. Donald Pettit, a NASA astronaut, on The International Space Station during his stay in 2003. Among his invaluable performances, one can see a unique behavior of free liquid film of O(10 cm) in diameter sustained in a metal ring [1]. A microgravity condition would enable a liquid film to be sustained stably with its surface tension and wettability of the sustainer against the liquid concerned. This unique system is a potential way to realize a new kind of crystallization process of materials. A free liquid film has a great feature that a contact area with a solid sustainer can be minimized. This is a vigorous advantage to avoid the liquid contaminated by impurities supplied from the solid. It is of great importance to accumulate knowledge on a thermal-fluid dynamics of a free film of a liquid with a non-zero temperature coefficient of the surface tension exposed to a non-uniform temperature field.
In the case of a thin liquid film form in a rectangular cavity (i.e., a liquid film with a single free surface) with a temperature difference between both-end walls, Smith & Davis [2] predicted that a new type of thermal-fluid instability would arise in the film beyond a critical temperature difference. Under a temperature difference smaller than the critical value, a two-dimensional steady flow parallel to the imposed temperature gradient is induced in the film. After the onset of the transition, roll structure emerges in the film and propagate in a direction inclined to the imposed temperature gradient. This unique instability was named as 'hydrothermal wave instability,' and was revealed by an experimental approach by Riley & Neitzel [3]. After their beautiful experimental work, a number of experimental and numerical works have been carried out with a liquid film with a single free surface for a decade [4].
In the case of free liquid films, on the other hand, little knowledge has been accumulated on a flow dynamics in such a thin film with two free surfaces; one can easily imagine that a long-lasted stable free liquid film is hardly formed in a terrestrial experiment.
In the present study, the authors carry out a three-dimensional numerical simulation and a series of experiments with their special attention to a flow field inside the free surface under non-uniform

temperature distribution; that is, a thermocapillary-driven flow induced in a free thin liquid film under a temperature gradient parallel to the free surfaces.

TARGET GEOMETRY

Target geometry is shown in Fig. 1. A thin liquid film with two free surfaces parallel to x-z plain is concerned. Length in the direction of the temperature gradient is defined as L_x, and that in the span-wise direction L_z. The thickness of the film is presented as d. In the present geometry, two kinds of aspect ratios are defined; that is, $\Gamma_x = L_z/L_x$ and $\Gamma_y = L_x/d$. One end wall is maintained at a temperature of T_h, and the other at T_c ($T_h > T_c$). Thus the film is exposed to a temperature difference $\Delta T = T_h - T_c$. Intensity of the thermocapillary effect imposed to the film is described by non-dimensional Marangoni number;

$$\mathrm{Ma} = \frac{\sigma_T \Delta T \cdot d^2}{\rho \nu \kappa L_x} = \frac{\sigma_T \Delta T \cdot d^2}{\rho \nu^2 L_x} \cdot \frac{\nu}{\kappa} = \mathrm{Re}_\sigma \cdot \mathrm{Pr}$$

where σ_T is the absolute value of the temperature coefficient of the surface tension ($\equiv |\partial\sigma/\partial T|$), ρ the density, ν the kinematic viscosity, κ the thermal diffusivity. The Marangoni number can be described as the product of the thermocapillary Reynolds number Re_σ and Prandtl number Pr.

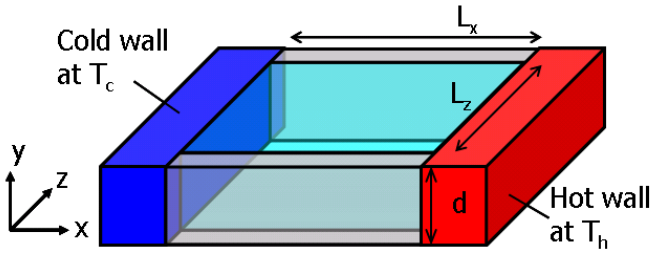

Figure 1. Target geometry: a free liquid film exposed to a temperature gradient.

NUMERICAL SIMULATION

In the numerical simulation, the authors solve following non-dimensional equations of continuity, momentum and energy by a finite differential method.

$$\nabla \cdot \mathbf{u} = 0$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla \mathbf{P} + \frac{\mathrm{Pr}}{\mathrm{Ma}} \nabla^2 \mathbf{u}$$

$$\mathrm{Ma}\left(\frac{\partial T}{\partial t} + (\mathbf{u} \cdot \nabla) T \right) = \nabla^2 T$$

Free surfaces are assumed to be flat without any dynamical deformation. Stress balance on the free surface leads so-called 'Marangoni' boundary conditions. Non-slip condition is applied to the both of hot and cold walls. The Prandtl number is fixed at 10.0 through the simulation. The present numerical code is validated under the condition of the single-free-surface thin film by comparing the incident angle, the wave number and the travelling velocity of the HW with the theoretical prediction by Smith & Davis [3].

EXPERIMENT

In order to realize a stable free liquid film in a series of experiments under the normal gravity, the authors prepared a rectangular hole in aluminium plates of 0.2 mm and 0.6 mm in thickness, and the one of iron of 1.0 mm in thickness as the liquid film holder. A liquid film is formed and sustained inside the rectangular hole. Figure 2 shows one example of the prepared holders; one side of the plate is heated, and the other cooled to expose the hole to a designated temperature difference. Silicone oils of 2 and 5 cSt were employed as the examined fluids. Temperature near the end walls sustaining the free liquid film was measured with thermocouples to evaluate the temperature difference ΔT.

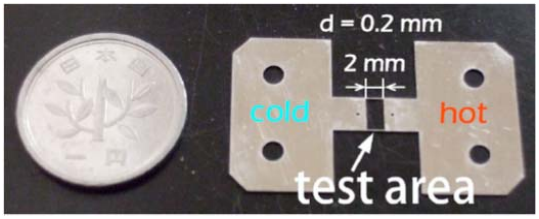

Figure 2. Example of liquid film holder (right). Liquid film is formed in a square region indicated by a circle. Thickness of the holder in the figure is of 0.2 mm.

Induced flow was visualized by suspending silver-coated hollow glass particles of 10 μm in diameter. The visualized flow was detected by a CCD camera whose frame rate was 30 frame/s. Shutter speed was 1/60 s. Temperature variation over the top free surface was measured by use of an infrared camera.

RESULTS & DISCUSSION

Three dimensional numerical simulation indicates a two-dimensional flow inside the film is realized in which the fluid returns in the middle region of the film under a small temperature gradient. By increasing the temperature difference between the end walls, instability takes place to realize a three-dimensional flow. Figure 3 indicates (1) top view of the deviation of the temperature over the top free surface and (2) cross-sectional view in x-y plane of 'oscillatory' flows. Case (a) indicates a single free surface (top surface is free) and case (b) two free surfaces under the same intensity of the thermocapillary effect. In the figure right wall is hot, and left wall cold. Lines in the film in the frames (2) indicate the isotherms. In the case of (b) free liquid film, one can clearly observe a typical inclined thermal wave propagating with a certain angle. There exists a slight difference in the propagating angle, the speed of the hydrothermal wave between the cases (a) and (b). Clear difference is emerged in the cross-sectional view; the free film has a double-layered structure of rolls with a constant phase shift. That is, an effective thickness of the liquid film to realize the hydrothermal wave instability must be different for the free liquid film case.

Typical examples of the induced flow field observed from above are shown in Fig. 4. Under small-enough temperature difference, a similar basic flow is realized inside the film (Fig. 4-(a)). That is, thermocapillary effect drives the free surfaces towards the cold wall, and the fluid returned towards the hot wall in the middle region of the film between the free surfaces. By increasing the temperature difference between the walls, a three-dimensional oscillatory flow emerged in the film (Fig. 4-(b)). The oscillatory flow, however, never exhibits an ordered hydrothermal wave instability with a certain wavelength and propagation speed as predicted by the simulation aforementioned, but a span-wise cellular pattern (Fig. 4-(b)). That is, the film is divided into two cells in a span-wise direction, and the flow indicates a three dimensional pattern. The particles in one cell seldom penetrate into another cell. This span-wise cellar pattern has not been indicated by the present

numerical simulation. and could be a unique flow structure in the case of the free liquid film. Such a pattern has not been reported in the case of the thin liquid film in the cavity.

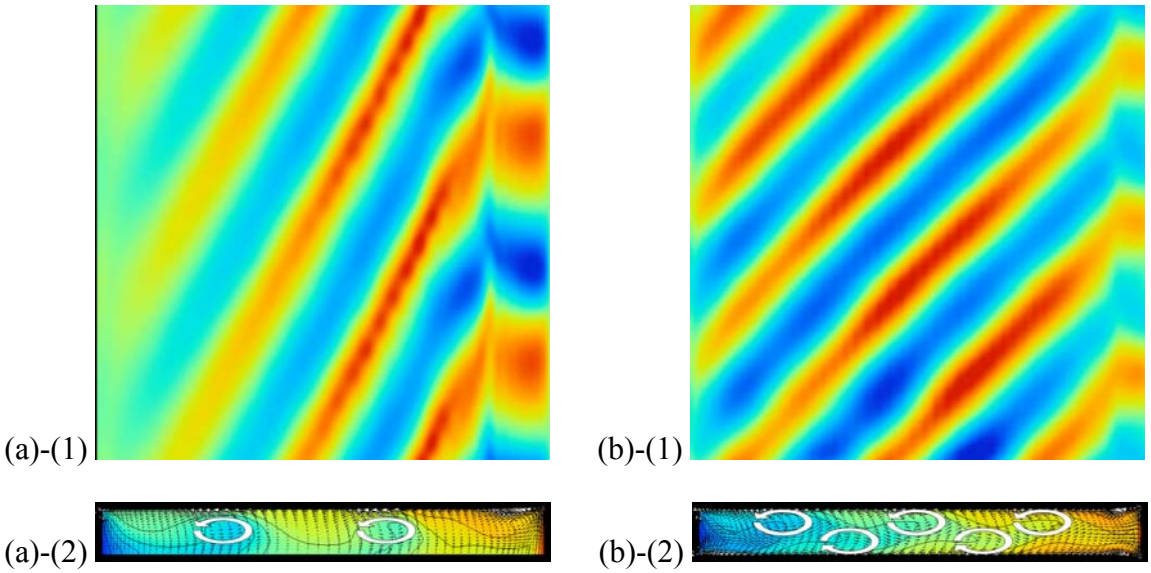

Figure 3. Typical example of 'oscillatory' flow; (1) top view of the deviation of the temperature over the top free surface and (2) cross-sectional view in x-y plane in the cases of (a) a thin liquid film in the cavity (a single free surface (top surface is free)) and (b) two free surfaces under the same intensity of the thermo- capillary effect. Right-hand side is the hot wall, and the opposite is the cold wall for each frame. Marangoni number Ma is kept constant at 1×10^3.

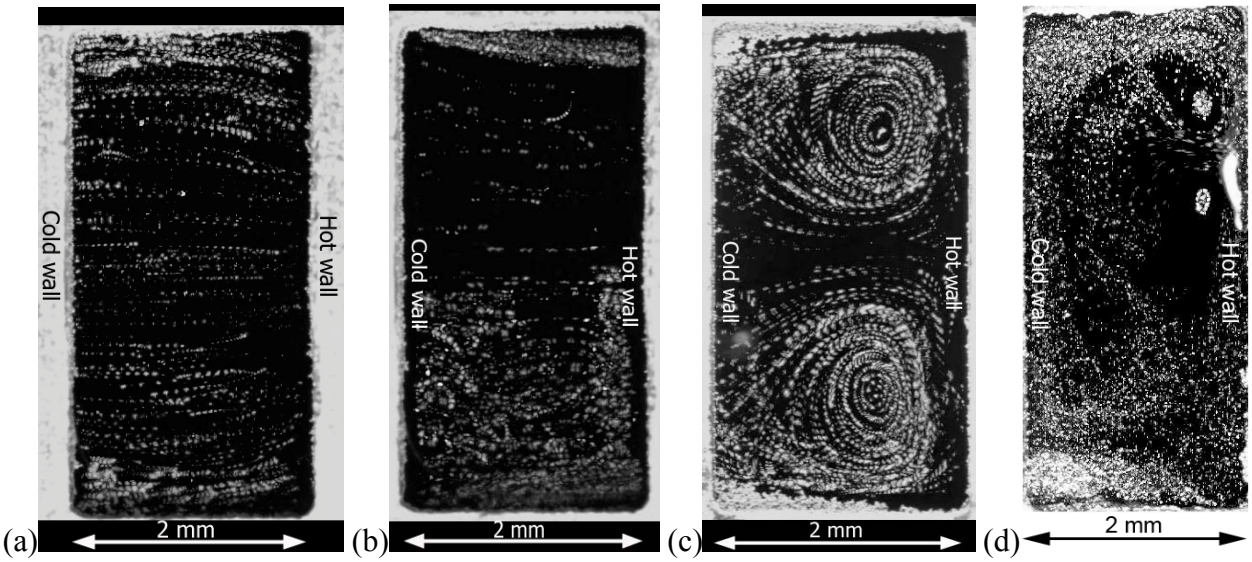

Figure 4. Typical examples of the induced flow in the free liquid film of (L_x, L_y) = (2.0 mm, 4.0 mm) observed from above; (a) ΔT = 4.7 K (Ma = 2.2×10^2) and (b) ΔT = 31.5 K (Ma = 1.5×10^3) in the case of d = 0.6 mm, and (c) ΔT = 6.8 K (Ma = 26) and (d) ΔT = 17.8 K (Ma = 68) in the case of d = 0.2 mm. These images are obtained by integrating the obtained frames for 1.0 s.

In the case of thin liquid film of 0.2 mm in thickness, two-dimensional basic flow is hardly realized; even under a small thermocapillary effect, or at small Marangoni number, a single-layered span-wise cellular pattern emerges in the film shown in Fig. 4 (c). Further increasing ΔT, the flow exhibits a chaotic behavior as shown in Fig. 4 (d). This could be the first capture of the route to the chaotic flow in a free liquid film by the present authors' group, to the best of their knowledge.
Nonetheless, a double-layered hydrothermal wave instability as predicted by the numerical simulation (Fig. 3-(b)) hardly emerges in the film in the experimental runs so far. The authors continue further investigation on occurring conditions of induced flow patterns and mechanism of these instabilities by both of numerical and experimental approaches.

CONCLUSIONS

Thermocapillary-driven flow induced in a free thin liquid film under a temperature gradient parallel to the free surfaces is investigated. By a series of three-dimensional numerical simulations, a double-layered return flow emerges as a basic flow at a small thermocapillary effect, and then a double-layered hydrothermal wave instability arises in the film as increasing the thermocapillary effect. By an experimental approach, the authors realize to form a stable free liquid film under a designated temperature gradient between the end walls. A double-layered basic flow appears at a small thermocapillary effect as the prediction by the simulation. A stable hydrothermal wave instability, however, is never realized in the film so far, but a single-layered span-wise cellular flow emerges.

EXPERIMENTAL INVESTIGATION OF SHEDDING MODE II BEHIND A ROTATING CYLINDER

I. Yildirim[1], C.C.M. Rindt[1,*], A.A. van Steenhoven[1]
[1] Eindhoven University of Technology, Mechanical Engineering Department, Energy Technology Section, Eindhoven, the Netherlands

ABSTRACT. The transition of the flow behind a circular rotating cylinder is investigated experimentally. In literature it has been shown numerically that for a rotating cylinder there exist two instability areas where the vortex shedding is not suppressed [1, 2, 3]. Shedding mode I is predicted to appear and also measured experimentally at low rotation rates whereas shedding mode II is predicted to occur around rotation rates of about $\alpha \approx 5$, where α is defined as the ratio between the circumferential velocity at the cylinder surface and the incoming free-stream velocity. Shedding mode II is numerically associated with one-order-of-magnitude lower shedding frequencies and is found only in a narrow range of the parameter α. With the use of the tin-precipitation method, we were able to visualize and quantify Shedding Mode II. The experimentally found Strouhal numbers associated with the second instability mode are 0.017 for $\alpha = 4.96$ and 0.011 for $\alpha = 5.1$

Keywords: rotating cylinder, shedding mode II, tin precipitation method, experimental fluid mechanics

INTRODUCTION

The two-dimensional flow passing a rotating cylinder has been an interesting subject for research for long time. The interest in this type of flow not only comes from understanding of the wake dynamics but also from the flow control applications. The flow around a rotating cylinder is categorized according to two non-dimensional parameters; the Reynolds number and the rotation rate:

$$\mathrm{Re} = \frac{U_\infty D}{\nu} \tag{1}$$

$$\alpha = \frac{D\omega}{2U_\infty} \tag{2}$$

Here D is the cylinder diameter, ω the angular velocity of the rotating cylinder, U_∞ the free-stream velocity and ν the kinematic viscosity.

Previously, it has been shown numerically and for low rotation rates also experimentally that for a rotating cylinder there exist two instability areas where the vortex shedding is not suppressed. These areas are indicated as mode I and II in a sketch of the instability diagram, Figure 1 [1]. In between these areas the flow is steady.

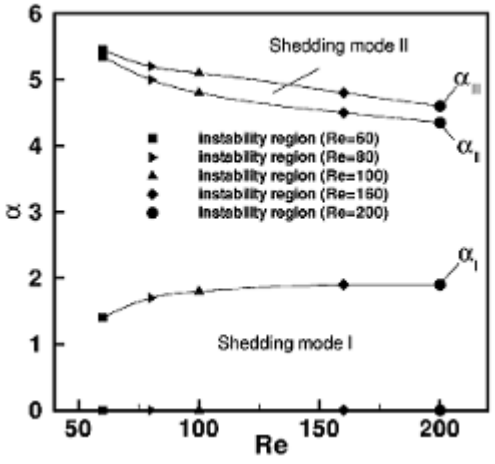

Figure 1. Stability diagram for different Reynolds numbers and rotation rates [1].

Shedding mode I is appearing at low rotation rates whereas shedding mode II is observed around rotation rates of about $\alpha \approx 5$. Mode I corresponds to the classic von Karman vortex street, which becomes asymmetric when the cylinder is rotating and is eventually quenched for values $\alpha \approx 2$. Mode II, conversely, is associated with one-order-of-magnitude lower shedding frequencies and is found only in a narrow range of the parameter α, which can be found in numerical studies of Stojkovic et. al. [1], Mittal and Kumar [2] and Elkoury et. al. [3].

In this work the transition of the flow behind a circular rotating cylinder is investigated experimentally. Therefore, the aim of the present work is to experimentally verify the existence of shedding mode II and to compare its main features with those obtained in the numerical studies [1-3]. To the best of our knowledge mode II has never been identified experimentally.

After the brief description of the experimental method and the set-up the results from the experiments are summarized. The final section consists of the discussion of the experiments and possible future work about the rotating case.

EXPERIMENTAL SET-UP

Experiments were done in a towing tank [4]. It has dimensions $L \times W \times H = 500cm \times 50cm \times 75cm$. Reynolds number is fixed to 100 during the experiments and the rotation rate of the cylinder is changed only. The diameter of the circular cylinder is $D = 10mm$ and it is placed between two square shaped plexiglass end plates. The rotation rate α was changed from 0 to 5.1 by an electric motor. Information about the flow physics is obtained from flow visualization experiments which are performed in a towing tank using the electrochemical tin-precipitation method. Flow visualizations are performed in a two-dimensional configuration where the tin sheet is oriented vertically with respect to the cylinder, Figure 2.

In this method tin-ions are separated from a tin-anode by applying a voltage difference. This voltage difference causes very small tin-hydroxide particle to form. Since those tin-hydroxide particles do not dissolve in water, they can be used to visualize the flow [5].

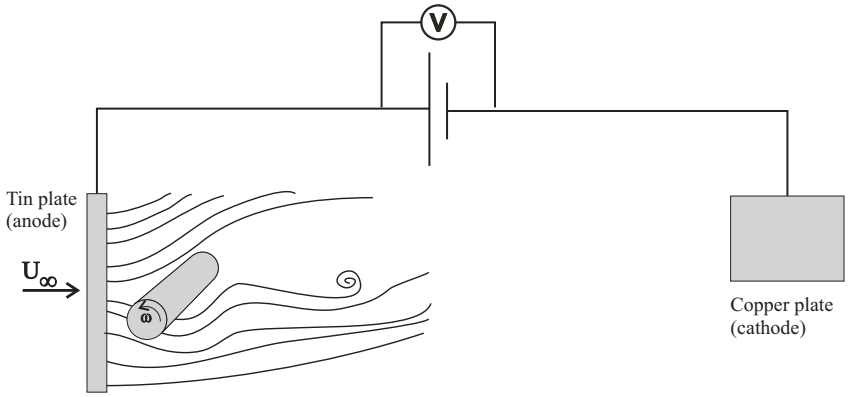

Figure 2. Sketch of the tin-precipitation method set-up.

RESULTS

Verification of the experimental method

As the first step the reliability of the experiments was assessed, in order to do these different $\mathrm{Re}-\alpha$ combinations are chosen for evaluation.

α=0, Re=100. For this parameter set the flow is expected to be two-dimensional with von Karman vortex shedding patterns. The results from the experiments can be seen in Figure 3. The flow in the image is from the left to the right and the vertical structures behind can easily be seen. The calculated shedding frequency from the image sequence is $St = 0.166$, which is in good agreement with the values from the literature [6, 7]. Based on this comparison, it can be concluded that the results of this experiment is consistent with the results of the literature and the method produces reliable results.

α=1.6, Re=100. Shedding Mode I can be seen at this parameter set. From Figure 4 it can be noted that the vortex shedding is not suppressed completely but changed due to the rotation. The strength of the upper shed vortices seems to be reduced since they are not distinctive as in the non rotating case. On the other hand the lower shed vortices are clearly visible.

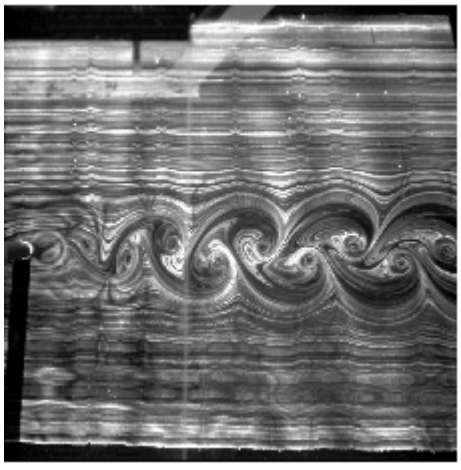

Figure 3. Flow visualization of von Karman vortex street, $\mathrm{Re} = 100, \alpha = 0$.

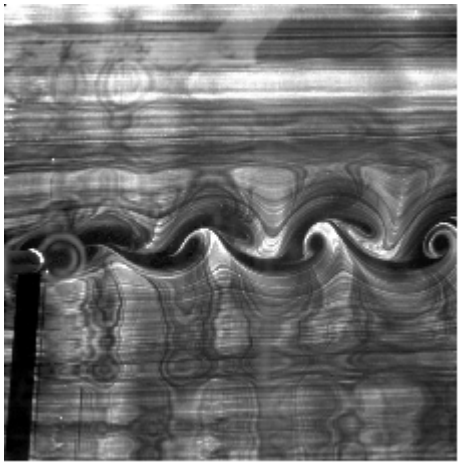

Figure 4. Vortex shedding in first instability region, $\mathrm{Re} = 100, \alpha = 1.6$.

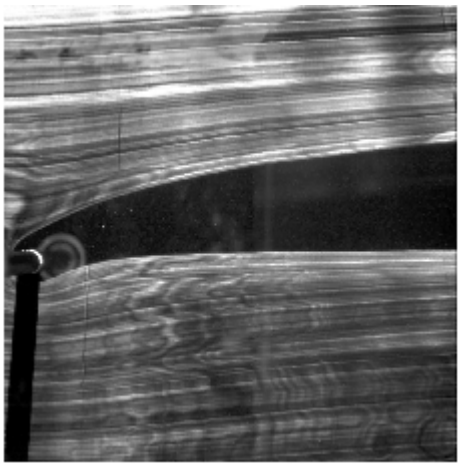

Figure 5. Suppressed vortex shedding by rotation, $\mathrm{Re} = 100, \alpha = 3$

α=3, Re=100. In the stability diagram $\alpha = 3$ is between the two shedding modes. In this rotation rate the vortex shedding is completely suppressed and there is no vortex shedding from the cylinder. This can be clearly seen from the visualization results in Figure 5.

As the result of these initial experiments, it can be concluded that the tin-precipitation method gives reliable results about the nature of the flow and about some quantitative properties of the flow.

Shedding mode II

Further increase of the rotation rate of the cylinder puts the flow regime into another instability region which is denoted as *second instability mode* or *shedding mode II*. In this mode, shedding of a single vortex exhibits itself. The period of the shedding is quite large when compared to the shedding period of von Karman vortices and it requires large experiment time in order to see the phenomenon.

α=4.96, Re=100. The experiments at this parameter set made it possible to identify four single vortices which can be seen in Figure 6. At this stage the wake behind the rotating cylinder is not as stable at it was at $\alpha = 3$. This feature can be realized form the behaviour of the tin sheet. On the other hand, on the lower part of the wake four distinct and counter clockwise rotating vortices are easily seen. The period between the vortices is calculated using the image sequence. The resulting Strouhal

number of the vortex shedding is $St \approx 0.017$. This value of the non-dimensional shedding frequency is of the same order-of-magnitude as of the numerical simulations in the literature [1]. From this similarity it can be concluded that those vortices are likely to be shedding mode II vortices.

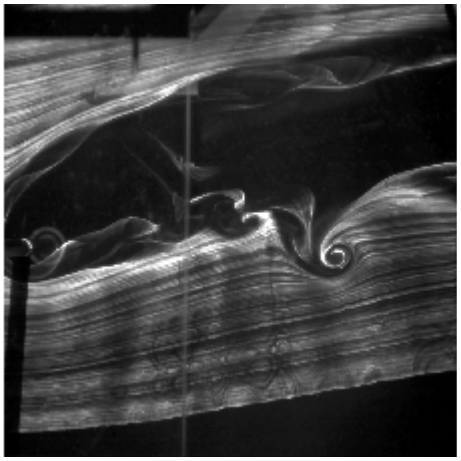

Figure 6. Captured vortex of shedding mode II at Re=100 and α=4.96.

α=5.1, Re=100. When the angular velocity of the cylinder is slightly increased the wake behind the cylinder becomes more organized and the shedding vortices are detected easily. The three shed vortices and the wake are shown in Figure 7. Again the counter clockwise rotating vortices are located at the lower portion of the wake. However, in this case the calculated mean Strouhal number from the image sequences is 0.011. This Strouhal number is again consistent with the numerical results that were obtained by Stojkovic et. al.[1].

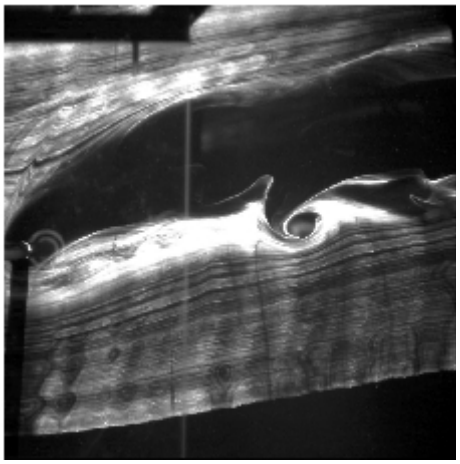

Figure 7. Captured vortex of shedding mode II at Re=100 and α=5.1.

CONCLUSIONS

In this research flow visualizations are performed in a two-dimensional configuration where the tin sheet is oriented vertically with respect to the cylinder. In order to reduce the number of experiments and to avoid the three-dimensional effects of the cylinder flow, the experiments were done at a fixed Reynolds number of $\mathrm{Re} = 100$. At two different rotation rates $\alpha = 4.96$ and $\alpha = 5.1$ single vortices with large shedding periods were observed. The analysis of pictures revealed that for α=4.96 there are four distinct vortices shed from the rotating cylinder. The calculated mean Strouhal number from the image sequences is 0.017. For the slightly higher rotation rate, α=5.1, the experiment showed three distinct vortices. The calculated mean Strouhal number in this case was 0.017. These Strouhal numbers are consistent with the numerical results that were obtained with the results that can be found in literature [1, 2, 3].

Based on the results and observations during the experiments, it can be concluded that those vortices actually proves the existence of Shedding Mode II. However, due to the large shedding period of the vortices and physical limitation of the towing tank, the analysis till so far is limited. A more quantitative analysis and detailed comparison with numerical results will be the topic of future study.

ABSTRACT. The performance and accuracy of conductance probes, employed in phase distribution measurements in gas-liquid flow, was addressed. The conventional calibration method for annular-type flows was extended for a 127mm vertical pipe to allow for gas entrainment into the liquid film travelling at the pipe wall. Glass beads with different diameters were placed between the non-conductive insert and the pipe wall to simulate the gas bubbles entrained in the liquid film. Furthermore, an experimental campaign was executed in order to investigate the transition boundaries for two-phase air-water flow between churn and annular patterns in large diameter pipes. A direct relation between phase distribution and pressure drop was found. High fluctuations in the film thickness amplitude led to an increase in pressure drop. With an increasing gas superficial velocity, both film thickness and pressure drop decreased dramatically into the transition area. In this area features of flow-reversal were found. Approaching annular flow, both parameters decreased gradually.

Keywords: *gas-liquid flows, conductance probes, pressure drop, film thickness, measurement techniques.*

INTRODUCTION

Multiphase flows are encountered in the petroleum, power generation, chemical and process industries [1]. Given that the majority of studies in vertical gas-liquid flows are carried out in relatively small diameter tubes, the existing literature shows no common consensus with regard to phase distributions in large diameter pipes. For instance, the absence of typical slug flow in large diameter pipes has been reported [2-4]. In addition, other fundamental differences have also been observed. Wave mechanisms in vertical annular-type two phase for a large 125mm pipe diameter have been characterised [5]. This showed that the waves are circumferentially localized around the pipe periphery. In contrast, for small pipe diameters (32mm), the waves show a reasonable coherence [6]. Transitions between flow patterns is one of the complicated features in two phase flow, especially those between slug and churn to annular flow. Work was carried out in this particular area for small pipe diameter previously by some researchers. For instance, it was suggested that the transition to annular flow can be related to the superficial gas velocity at which flow-reversal takes place [7]. They also showed that the pressure gradient passes through a minimum as the gas velocity is reduced and therefore the liquid film thickness increases. The present study addresses vertical two-phase air-water flows in a large diameter (127mm) vertical pipe. An intensive experimental campaign was devised to understand the flow behaviour at the transition boundary from the annular to churn flow through analysing the time series of the measured liquid film thickness and pressure drop signals.

EXPERIMENTAL FACILITY

The experiments conducted in the present study are primarily carried out on a closed loop facility, containing a 127mm id, 11 m tall riser (Figure 1). Liquid is stored in the main separator and pumped into the riser base. The gas phase is compressed by two liquid ring vacuum pumps operated

* Corresponding author: B.J. Azzopardi
Phone: + (44) (0) 115 951 4160
E-mail address: barry.azzopardi@nottingham.ac.uk

in parallel and delivered to the riser base. The phases come together in the mixer and from this point the flow develops along the tall riser. The flow is then directed horizontally into the downcomer and back into the separator. Here the gas is separated from the liquid and the fluids are fed to the compressors and pump. The flow of both fluids can be regulated by valves and the flow rates monitored by flow meters. System pressure can be up to 5 barg. Gas and liquid superficial velocities of up to 17 m/s and 1.5 m/s, respectively, can be achieved. Temperatures and pressures are measured at various points throughout the experimental facility. The vertical pipe is equipped with a transparent acrylic resin section (Figure 1 Insert) wherein pressure drop and void fraction measurements are acquired and which is 11.8 pipe diameters long. The conductance probe rings, used for phase distribution measurements in the present study, are located at 62.7, 63.5 and 65.5 pipe diameters from the riser base, respectively. The stainless steel rings are flush mounted with the pipe wall. They were located using cylindrical dowels placed at either side of wall sections

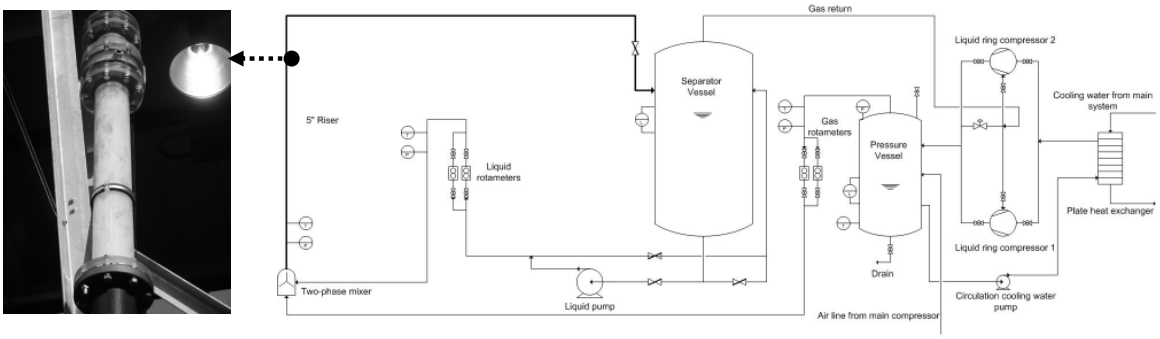

Figure 1. Closed loop facility. (Insert - Transparent Riser Section)

The thickness s of the rings is 3mm and the distance D_e between the probes is 25 mm, insulated by non-conducting acrylic resin. This is a electrode separation distance to pipe diameter ratio, D_e/D_t, of 0.20. The total, time averaged, pressure drop is being measured by an electronic differential pressure detector/transmitter (Rosemount 1151 smart model), with a range of 0- 37.4 kPa and an output voltage from 1 to 5 V, i.e. a resolution of 9.35 kPa per volt. Two pressure tappings, separated by an axial distance of 12.9 pipe diameters, across the transparent section, are connected to the differential pressure device via stainless steel tubes. The tubes were filled with water to keep the density constant. This was assured by an efficient purging procedure which eliminated the risk of gas fractions in the pressure lines. The latter procedure was repeated at the start of each set of the experiments. Data acquisition was performed through a PC equipped with a National Instrument (NI) DAQ card. An existing data acquisition programme in Labview [9] was adapted to convert the voltage output of the probes into a cross section averaged void fraction. The data acquisition rate was 1 kHz

CONDUCTANCE PROBE THEORY

In gas-liquid annular-type flow, the instantaneous wall film thickness can be determined by measurements of the electrical conductance between two electrodes in contact with the liquid film. Different types of electrodes such as parallel wires, flush-wires, flush-mounted pins and flush-mounted rings have been adopted [10,11,12,13,14,15,16,17,18]. Among these probes, the flush-mounted parallel ring probe is attractive to researchers because it provides non-intrusive measurements, can pick up small impedance and allows electric field to be efficiently confined. It was proposed that the apparent conductance K_{app} for two parallel strips embedded flush onto a flat surface can be defined as [19];

$$K_{app} = K^*_{app} L\gamma \tag{1}$$

with

$$K_{app}^{*} = \frac{k(m)}{k(1-m)} \tag{2}$$

and

$$m = \frac{\sinh^2(\pi s/2h)}{\sinh^2[\pi(s+De)/2h]} \tag{3}$$

Where, K_{app}^{*} is the dimensionless apparent conductance, L electrode length, s electrode width, γ liquid conductivity h liquid film thickness and Function k the complete elliptic integral of the first kind,

$$k(m) = \int_0^{\pi/2} \left(1 - m\sin^2\theta\right)^{-0.5} d\theta \tag{4}$$

Furthermore, it was proposed that the conductance of annular liquid film can be quantified by above equations by replacing h to a liquid equivalent thickness h_E [19].

$$h_E = -\frac{D}{D_E}\ln(1-2h/D) \tag{5}$$

h_E can also be defined as $h_E = A_L / P_L$ [16], where A_L is the cross-sectional area occupied by liquid and P_L the wetted length of electrode for the application of the annular and stratified flow [19]. The analytical solution to the apparent conductance of the ring probe is according [17],

$$K_{app}^{*} = \frac{\pi^3}{32}\left(\frac{2s}{L}\right)^2\left[\sum_{i=0}^{\infty}(2i+1)^{-3} b_i^2 f_i\right] \tag{6}$$

With

$$b_i = \cos[(De+s)\theta] - \cos[(De-s)\theta] \tag{7}$$

and f_i is the product of modified Bessel functions I_0, I_1, K_0, K_1,

$$f_i = \frac{I_0(D\theta)}{I_1(D\theta)}\left[\frac{1+\dfrac{I_1[(D-2h)\theta]K_0(D\theta)}{K_1[(D-2h)\theta]I_0(D\theta)}}{1-\dfrac{I_1[(D-2h)\theta]K_1(D\theta)}{K_1[(D-2h)\theta]I_1(D\theta)}}\right] \tag{8}$$

Where

$$\theta = \frac{(2i+1)\pi}{2L} \tag{9}$$

A different expression for b_i was adopted by [18],

$$b_i = \cos[(De-2s)\theta] - \cos[(De)\theta] \tag{10}$$

CONVENTIONAL CONDUCTANCE PROBE CALIBRATION

The unique resistive characteristics of the individual conductance probes need to be identified. When the probe pair is subject to an electrical current, the relationship between the dimensionless resistivity E of the probe ring and its voltage output V_{out} should be linear in the form of;

$$E = aV_{out} + b \tag{11}$$

Gradients a and b can be obtained from this relationship. The resistance R_x of the two phase flow is being simulated by a variable resistor in between each of the probe pairs. Hence, the probe resistance R_{probe} is the product of the applied voltage V_{app}, the voltage measured subject to the applied variable resistor V_x and R_{ref}, the internal circuit variable resistance, by using;

$$R_{probe} = \frac{V_x}{(V_{app} - V_x)} R_{ref} \tag{12}$$

By plotting the expression;

$$E^{*} = \frac{(R_x/R_{ref} - 1)}{(R_x/R_{ref} + 1)} \tag{13}$$

against V_{out} , Equation 11 was deduced. The regression data for the relationship was $a = 3.21$, $b = 0.042$ and $R^2 = 0.99$. Equation 11 can then be substituted into the expression for the dimensionless conductance G_e^* of the two phase flow

$$G_e^* = \frac{(1+E_{full})/(1-E_{full})}{(1+E_{TP})/(1-E_{TP})} \tag{14}$$

In which E_{full} is the dimensionless resistance for the flow domain fully occupied by liquid ($\varepsilon_l = 1$) and E_{TP} the dimensionless resistance for two-phase flow. Ultimately, by decreasing the diameter of the insert and subsequently repetition of a significant number of calibration steps, one can relate the phase distribution at each probe to the dimensionless conductance. The relationship of the calibration curve can be mathematically expressed in the form;

$$\varepsilon_l = c(G_e^*)^3 + b(G_e^*)^2 + a(G_e^*) + d \tag{15}$$

NEW APPROACH TO CONDUCTANCE PROBE CALIBRATION

The conductance probes need calibration before it can be employed for measurements. Annular-type flow is usually simulated by placing a non-conductive rod inside the pipe and the conductive liquid is filled in the annulus between the rod and pipe wall. This is an "ideal" situation that no bubbles exist in the liquid film. In contrast, in gas-liquid annular-type flow, the continuous trapping and folding actions of the disturbance waves transport gas bubbles into the liquid film. The presence of a considerable amount of bubbles in the liquid film was reported in air/water horizontal and vertical annular-type flow systems [20,21,4]. More recently, the bubble size distribution, bubble mean diameter and bubble number concentration in the wall film of a horizontal annular flow in a pipe of 15.1 mm diameter was quantified [22]. Bubble size has an exponential distribution with the average of diameters between 15% and 45% of the film thickness at the gas superficial velocity ranging from 28 to 65 m/s and the liquid superficial velocity from 0.019 m/s to 0.14 m/s. Around 100 bubbles/cm^2 exist in the wall film at the gas superficial velocity 28 m/s. Therefore, a new approach for probe calibration was devised. In order to simulate gas bubbles in the liquid film during annular-type flows, packing of spherical glass beads was used. While the diameter of the insert decreased with calibration steps, beads with a larger diameter were used to occupy a fraction of the annulus between the insert and pipe wall. The diameter of beads used was 3, 4 and 6mm. The procedure, carried out off-line, of calibration was performed according the following steps; (1) a conventional void fraction measurement was first done with the single insert only; (2) the test section was then emptied, dried and the insert re-installed; (3) a known theoretical volumetric amount of beads were added to the annulus; (4) in order to verify the theoretical bead voidage, the height of beads in the annulus was returned to a water volume. The annulus was then filled with water until the level of water was equal to the level of beads. The water left was then weighted and the in situ bead voidage calculated (5) a void fraction measurement was then performed. The difference between the void fraction measured with the single insert and the single insert-beads combination was verified by repeating the calibration with an additional cylindrical insert which represented a volumetric fraction equal to the sum of the initial insert-beads combination. (6) the final step in the calibration procedure, for one particular single insert diameter, single insert-bead combination and the additional insert, was taken the void fraction measurement of the latter. Annular flow calibration data obtained from the 127mm pipe was plotted and comparison was made between a theoretical 70mm flow arrangement, solved by using the model derived by [17]. In addition, also other models proposed were solved and plotted for the 127mm pipe [17,18,19]. The results are shown in Figure 2. The data obtained with the new calibration approach shows deviations from the initial calibration points by using the single insert for ideal annular-type flows. The error was determined using Equation 15. This returned the void fraction as theoretically responded by the probes according the calibration curve and thus for an "ideal" annular-type flow regime. These results were plotted against

the experimental G_e^* obtained during calibration with single insert-bead combination. Figure 3 shows the absolute error. It can be noted that this not directly explains the effect of bead diameter. Therefore the relative error between the bead diameters was determined, shown by Table 1.

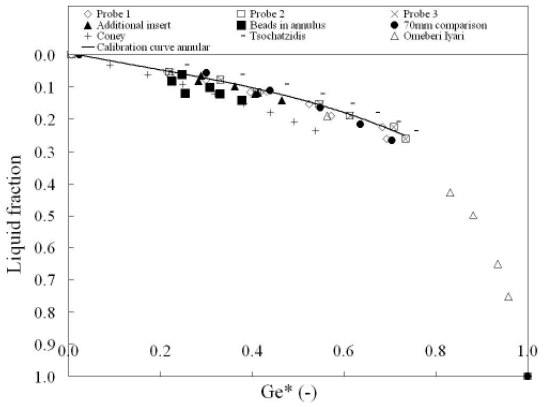

Figure 2. Annular flow calibration curve

Table 1. Relative error between beads

Bead diameter (mm)	Change in bead voidage (%)	Change in Error (%)
3	20	624.9
4	23.2	48.8
6	12.9	3.5

RESULTS AND DISCUSSION

Experiments were carried out at two liquid superficial velocities of 0.014 and 0.04 m/s and gas superficial velocities from 3.8 to 15.8 m/s. The system pressure was set at 2 barg. Figures 4 and 5 show how the film thickness and pressure drop vary with gas superficial velocity.

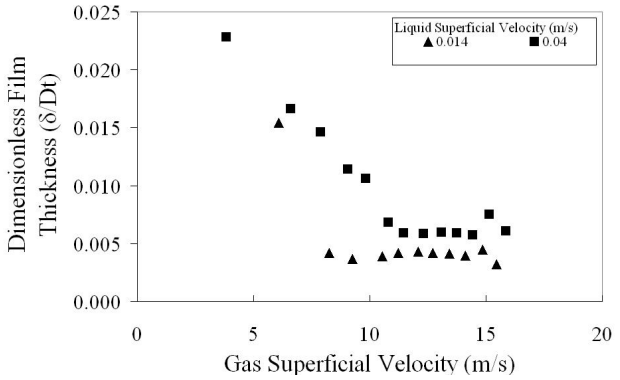

Figure 4. Dimensionless film thickness as function of superficial gas velocity.

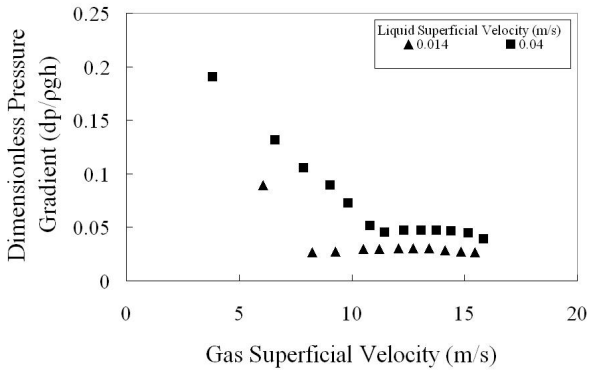

Figure 5. Dimensionless pressure gradient as function of superficial gas velocity.

From Figures 4 and 5 it is apparent that there is a very obvious and systematic effect of the superficial gas velocity on the film thickness and the pressure drop. There is a steep decrease of both film thickness and pressure drop over gas velocities of 3.82 to 10.86 m/s and from 6.07 to 8.25 m/s for liquid superficial velocities of 0.04 and 0.014 m/s respectively. At higher gas superficial velocities there is a gradual increase. It is suggested that the change of slope is linked to a transition of flow pattern from churn to annular flow. In contrast to the smaller diameter cases [7], the pressure gradient in annular flow for this larger pipe increases only slowly with gas velocity. Therefore the expected minimum is not very clear. Further statistical analysis of the data was carried out for both the film thickness and pressure drop at a liquid superficial velocity of 0.04 m/s. Three regions of Figures 4 and 5 were of particular interest. These are tentatively identified as being from: the churn flow area, the transition area and the annular flow area. The gas superficial

velocities are 6.6, 10.8 and 15.8 m/s respectively. The analysis employed Probability Density Function, autocorrelation/Power Spectral Density (for most probable frequency) and cross correlation (for time delay and thence structure velocity). The results are shown in Figure 6 and 7. The time series of the film thickness in the churn flow area show clearly the presence of waves, these are believed to result in the larger pressure gradient. However, the waves decrease in amplitude with increasing gas superficial velocity, with correspondingly lower pressure gradient as can be seen from the time series of pressure drop in the annular flow area. The Power Spectral Density curves all show clear peaks which occur in both the film thickness and pressure gradient data with the frequencies at which those peaks occur having equivalent values for both signals. In addition, cross correlation was performed between two successive conductance probe signals. The distance between the first and the third conductance probe is 2.8 pipe diameters. As can be seen from Figure 6, the majority of the time lag for the churn flow area and annular flow area is positive. However, for the transition area, the time lag shows a peak with a negative value. This indicates that at the transition from churn to annular flow in the present study, there are waves which move up and those which move down.

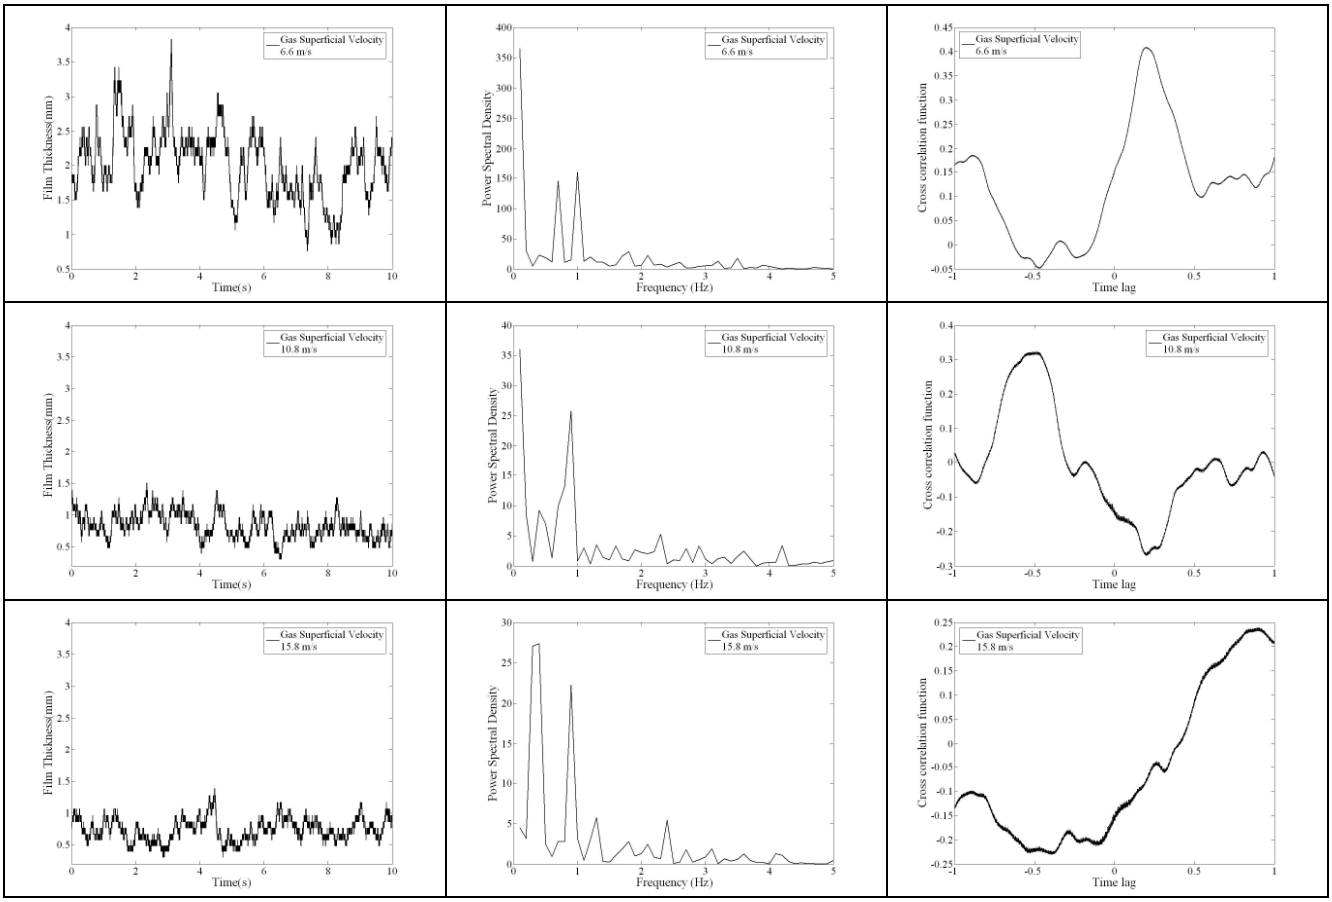

Figure 6. Film thickness time series, Power Spectral Density (PSD) and cross correlation .

CONCLUSION

The results of the present study show that the calibration of conductance ring probes needs to be approached carefully. The performance and accuracy of these probe types is strongly dependant on the calibration procedures. In churn and annular-type gas-liquid flows one may encounter gas bubbles entrained in the liquid film, particularly in the waves. The comparison between the new approaches suggested in the present study for the calibration of conductance probes in annular-type flows to the conventional method shows that the gas bubbles entrained in the liquid film can cause erroneous results. The inappropriate calibration of the conductance probes can lead to an unrealistic view of the phase distributions in annular-type flow and the transition to churn flow. Simultaneous

phase distribution measurements and visual observation (e.g. high speed photography) may therefore reduce the risk of experimental errors. However, it may be concluded that conductance probes, calibrated for a specific flow regime, are producing invalid results when used otherwise. The current experimental results of liquid film thickness and pressure drop show that there are similar trends for each. At lower gas superficial velocity there are larger liquid fractions and the pressure drop decreases significantly. This feature may therefore be directly related to the amplitude of the liquid film thickness and thus the existence of disturbance waves. Three important features in the film thickness and pressure drop can be noted; (1) there is a relatively large shift in the transition region between the two liquid conditions; (2) after a dramatic decrease of pressure drop, there is not a very clear minimum in the pressure drop, as previously reported by various workers for smaller pipe diameters; (3) in the transition region between churn and annular flow, as evidenced by the negative structure velocity obtained from cross correlation, flow reversal is occurring.

PARTICLE- AND FLUID-LIKE BEHAVIORS ON SEDIMENTATION OF A STRATIFIED SUSPENSION

K. Sato[1*], T. Mitsui[1], S. Harada[1,]
[1]Hokkaido University, Sapporo, Japan

ABSTRACT. The sedimentation of partially suspended particles in fluid is studied experimentally. The settling behavior of particles in a stratified suspension, which has both the upper and lower interfaces, is observed in various conditions. We examine whether the macroscopic or the microscopic natures of suspension is dominant during sedimentation, *i.e.*, whether the particles settle as a particle assembly relative to surrounding fluid or as a continuous suspension. The experimental observation shows that the gravity-induced instability of suspension-fluid interface governs the particle motion for high concentration and small particle size. However, the microscopic nature of suspension comes out in case of large particles with low concentration. In this study, the dependency of sedimentation behavior of stratified suspension on concentration and constituent particle size is discussed quantitatively.

Keywords: *Sedimentation, Suspension, Rayleigh-Taylor Instability, Linear Stability Analysis*

INTRODUCTION

Sedimentation of suspended particles in liquid is an important phenomenon in the field of environmental, chemical and material engineering and is related to various processes such as coating, accumulation, separation, filtration of particulate materials. It is already known that the mean settling velocity of particles in a stationary fluid changes with concentration due to their hydrodynamic interactions [1]. The hydrodynamic interaction of suspended particles affects not only the mean settling velocity but also their relative motions. The resultant fluctuating motion brings about the diffusion of settling particles, which is called hydrodynamic diffusion [2]-[8]. Generally, the hydrodynamic interactions between particles are long-ranged under conditions of low particle Reynolds number, since the disturbed flow by the motion of individual particles decays inversely proportional to the interparticle distance [9]. Consequently it is more influential with the settling motion of fine particles in viscous fluid.

The relative motion of particle in suspensions is also caused by macroscopic hydrodynamic effect. In case of sedimentation of homogeneous suspensions, the variation of the concentration evolves almost one-dimensionally in the vertical direction [10]. On the other hand, if the suspension is not uniform and the positive concentration gradient exists against gravity, the lateral variation of concentration will develop during the sedimentation [11]-[15]. This lateral variation of concentration is similar to the gravity-induced instability of pure fluid and can be explained from the viewpoint of continuous fluid.

The purpose of this study is to investigate the hydrodynamic effect on the sedimentation of inhomogeneous suspension. We have investigated the settling of a stratified suspension which has both the upper and lower interfaces of concentration in quasi-two dimensional vessel. We observed the settling behavior of particles in the suspension and measured the settling velocity of particles

near the interfaces. Especially we examine the effect of constituent particle size on the sedimenting suspension in order to know whether the macroscopic or the microscopic natures of suspension is dominant during sedimentation, *i.e.*, the particles settle as a particle assembly relative to surrounding fluid or as a continuous suspension.

EXPERIMENTAL SETUP

Figure 1 shows the schematic diagram of the experimental apparatus. The test cell is quasi-two dimensional vessel with a height L =240mm, a width W =100mm. The vessel depth D is adjustable from 3mm to 12mm. In order to stratify the suspension, we used two slits in back side of vessel so as to put stainless steel blades into them. The thickness of the blade is 0.5mm and the distance between two blades L_s is 19.5mm. The blades divide the test cell into three parts in vertical direction. The lower blade separates the lower pure fluid and suspension, while the upper blade separates the upper fluid-suspension. Therefore the distance between blades L_s corresponds to the initial height of the stratified suspension.

The procedure of our experiment is as follows. At first pure fluid is filled into the lower part of the vessel and then the lower part is closed by the lower blade. Next the suspension is poured into the vessel above the lower blade until the surface reaches the position of the upper blade. Finally the upper blade is put into the vessel and the pure fluid is filled above it. Consequently, stratified suspension is held between the two blades. After these settings, the blades are removed backward simultaneously. The settling behavior of the suspended particles by gravity is recorded by a digital video camera. The suspension contains silicone oil and glass particles with diameter in d_p=30μm and 100μm or polystyrene particles in d_p=550μm and 800μm. Mass density of glass and polystyrene are ρ_p=2500 kg/m^3 and 1050 kg/m^3, respectively. The suspension is mixed by stirring for several hours and is deaerated well in constant temperature (22±1C˚). The silicone oil which has the different property (density ρ_f=970–972 kg/m^3, viscosity μ_f = 971–1944 mPa·s) is used for making suspension. The pure fluid which is used to fill the upper and lower part of the vessel has the same property as the suspension. Therefore the initial condition can be interpreted as *partially suspended particles in a static pure fluid*.

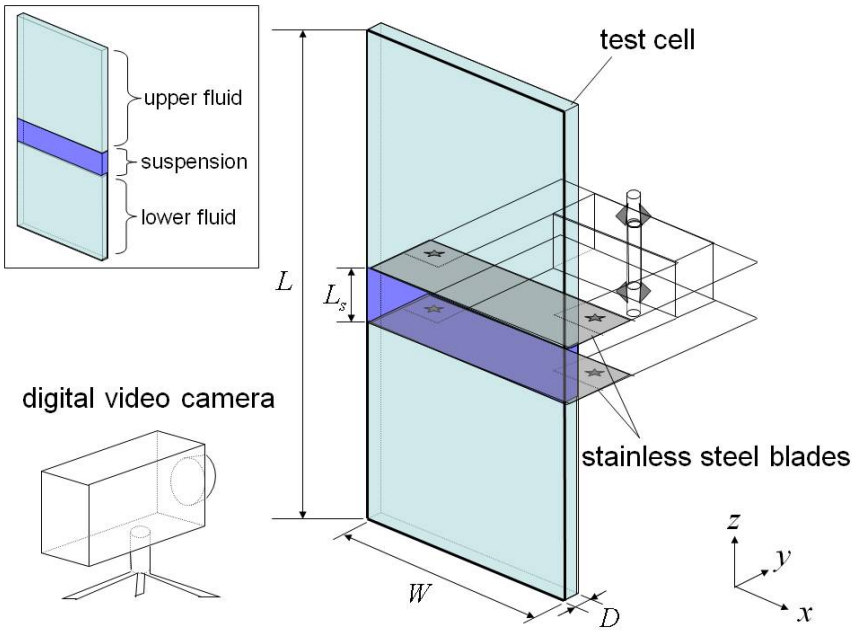

Figure 1. Schematic diagram of experimental system

LINEAR STABILITY ANALYSIS

When two immiscible fluids are separated by a horizontal boundary with positive density gradient in the vertical direction, it is known that the gravity-induced instability occurs at the interface (Rayleigh-Taylor instability). Rayleigh-Taylor instability is caused by the balance between gravity force and interfacial tension, and is influenced by density and viscosity of both fluids. In case of two inviscid fluids, the condition for instability is as follows [16];

$$gk\left[\frac{\overline{\rho}_2-\overline{\rho}_1}{\overline{\rho}_2+\overline{\rho}_1}-\frac{k^2T}{g\left(\overline{\rho}_2+\overline{\rho}_1\right)}\right]>0\,, \tag{1}$$

where $\overline{\rho}_1$ and $\overline{\rho}_2$ are the density of the lower and the upper fluid, k is the wave number of the disturbance and T is the coefficient of interfacial tension. In case of viscous fluids, the equation of instability condition is more complicated and is a function of the viscosity $\overline{\mu}_1$ and $\overline{\mu}_2$.

The similar gravity-induced instability can be observed at the suspension-fluid boundary even though there is no distinct interface between them. Völtz *et al.* [11-13] has been studied systematically the sedimentation of suspension in a vessel which has narrow width. They reported that the instability of a suspension-fluid interface could be predicted from a similar analysis to immiscible viscous fluids on the assumption that the suspension is pure fluid having apparent density ρ_s and viscosity μ_s as;

$$\rho_s=(1-\phi)\rho_f+\phi\rho_p\,, \tag{2}$$

$$\mu_s=(1+2.5\phi)\mu_f\,, \tag{3}$$

where ϕ is the concentration of suspended particles. Equation (3) is known as Einstein's apparent viscosity.

In order to understand the macroscopic nature of sedimenting suspension, we examine Rayleigh-Taylor instability of two viscous fluids in quasi-two dimensional vessel by linear stability analysis. Since most part of analytical procedure is similar to the well-known linear analysis of hydrodynamic stability [16], the different point from three dimensional analysis is described here. On the assumption that the vessel has narrow depth, the velocity in y direction is set to zero and the velocity and density fluctuation has parabolic Poiseuille profiles [12,17].

$$u_i(x,y,z,t)=\hat{u}_i(z)\exp(ikx+nt)\zeta(y)\,, \tag{4}$$

$$\rho(x,y,z,t)=\overline{\rho}(z)+\hat{\rho}(z)\exp(ikx+nt)\zeta(y)\,, \tag{5}$$

where k is the wave number of disturbance in x direction, n is the growth rate of disturbance, and $\zeta(y)$ indicates a parabolic function in y direction defined by

$$\zeta(y)=\frac{6}{D^2}\left(\frac{D^2}{4}-y^2\right), \tag{6}$$

where D is the vessel depth. Substituting equations (4) and (5) to Stokes equation and continuity equation for viscous fluid and averaging over y direction, we finally obtain the relationship between the wave number k and the growth rate n

$$\begin{aligned}&-\left[\frac{gk}{n^2}(\alpha_1-\alpha_2)+\beta_1+\beta_2\right]\left[\beta_2q_1+\beta_1q_2-k(\beta_1+\beta_2)\right]-4k\beta_1\beta_2\\&\quad+\frac{4k^2}{n}(\alpha_1\overline{\nu}_1-\alpha_2\overline{\nu}_2)\left[\beta_2q_1-\beta_1q_2+k(\beta_1-\beta_2)\right]+\frac{4k^3}{n^2}(\alpha_1\overline{\nu}_1-\alpha_2\overline{\nu}_2)^2(q_1-k)(q_2-k)=0,\end{aligned} \tag{7}$$

where $\bar{\nu}$ is kinematic viscosity ($=\bar{\mu}/\bar{\rho}$) and subscripts 1 and 2 indicate the lower and the upper fluid respectively. α, β and q are defined as follows;

$$\alpha_1 = \frac{\bar{\rho}_1}{\bar{\rho}_1 + \bar{\rho}_2}, \qquad \alpha_2 = \frac{\bar{\rho}_2}{\bar{\rho}_1 + \bar{\rho}_2}, \qquad \beta_1 = \alpha_1\left(1 + \frac{\bar{\nu}_1\eta}{n}\right), \qquad \beta_2 = \alpha_2\left(1 + \frac{\bar{\nu}_2\eta}{n}\right),$$

$$q_1 = \sqrt{\frac{n}{\bar{\nu}_1} + k^2 + \eta}, \qquad q_2 = \sqrt{\frac{n}{\bar{\nu}_2} + k^2 + \eta},$$

where $\eta = \partial^2\zeta/\partial y^2 = 12/D^2$.

For stratified suspension, we set $\bar{\rho}_1$, $\bar{\nu}_1$ (lower fluid) to properties of pure fluid ρ_f, ν_f and set $\bar{\rho}_2, \bar{\nu}_2$ (upper fluid) to apparent properties of suspension ρ_s, ν_s which are defined by equations (2) and (3).

RESULTS AND DISCUSSION

Sedimentation behaviour of suspension

Figure 2 shows the observation results of settling behavior of suspension with different particle and fluid. As described in Table 1, We changed the particle density ρ_p, diameter d_p, concentration ϕ, fluid viscosity μ_f and vessel depth D. The Stokes settling velocity for a single particle $U_0 = (\rho_p - \rho_f)gd_p^2/18\mu_f$ is also shown in the Table 1. The corresponding particle Reynolds number $Re_p = \rho_f U_0 d_p/\mu_f$ is less than 0.01 for all conditions.

As shown in Figure 2, while the suspension keeps its upper interface almost flat, a perturbation of the lower interface develops. The flat upper interfaces are due to a self-sharpening effect which results from the dependency of the settling velocity on the local particle concentration [10]. The instability at the lower interface is obviously the gravity-induced instability described in the previous section. For small particles and dense concentration (Figure 2a), the suspension behaves like immiscible fluid, and therefore finger-like perturbation (finger) can be found clearly. It should be emphasized again that the system considered here is *partially suspended particles in a static pure fluid* because the suspension is made of the same fluid as the upper and lower ones. Therefore there is no defined border between the suspension and the fluid. Here we call this settling behavior as *fluid-like settling* of suspension.

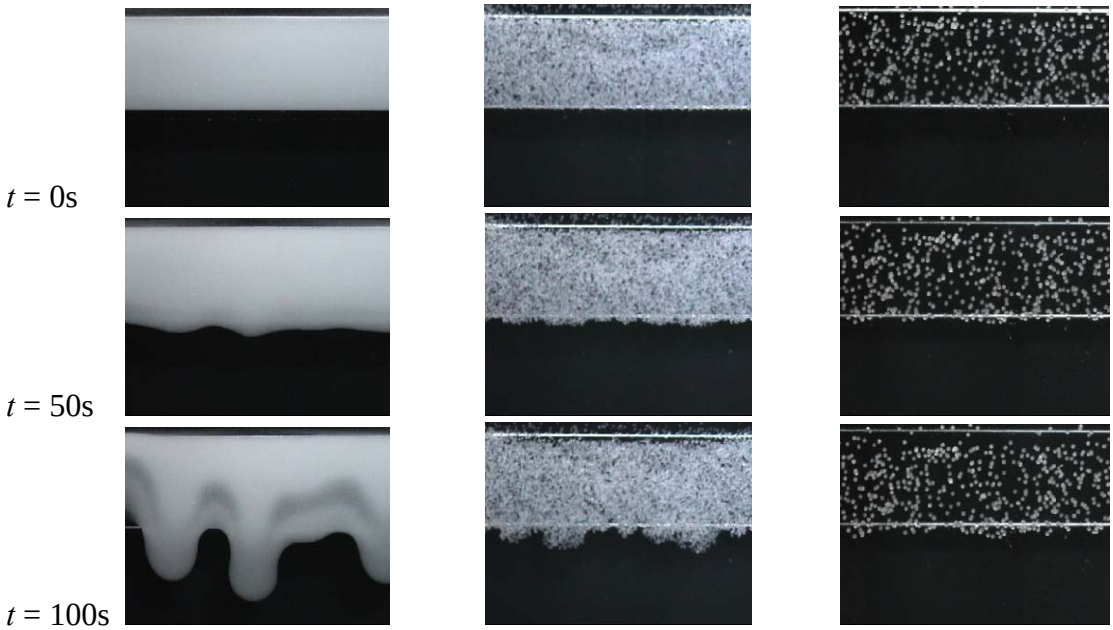
On the other hand, in case of large particle and dilute concentration (Figure 2c), the suspended particles seem to settle individually. For hindered settling of particle in fluid, it is known that the mean velocity of the particles is expressed as $f(\phi)U_0$, where $f(\phi)$ is a decreasing function of the particle volumetric ratio. A well-known empirical relation for $f(\phi)$ is as follows;

$$f(\phi) = (1-\phi)^n, \tag{8}$$

where n is a constant and is generally 5 to 5.5 [1]. Another factor of the settling velocity is the wall effect. The settling velocity of particle is influenced by the presence of the wall and, for our experimental condition, it decreases around ten percent of the Stokes velocity [9]. At all events, if we consider that the particle settles individually, the settling velocity will be the same order of magnitude as the Stokes settling velocity U_0. We call this kind of settling behavior as *particle-like settling*.

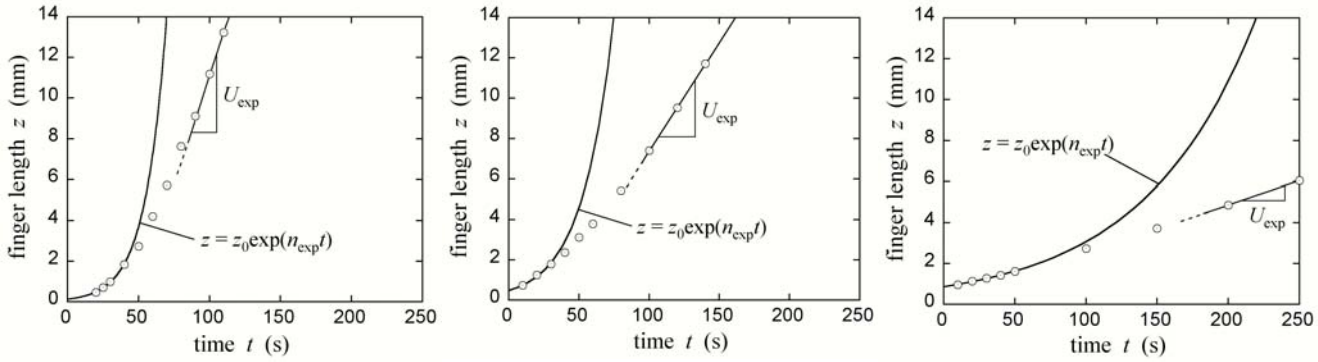
Table 1
Physical properties of particle and fluid

	ρ_p (kg/m^3)	d_p (μm)	ϕ	μ_f (mPa·s)	D (mm)	U_0 (mm/s)
(a) glass particle	2500	30	0.03	1944	8	3.85×10^{-4}
(b) polystyrene particle	1050	550	0.1	971	8	1.34×10^{-2}
(c) polystyrene particle	1050	800	0.01	1944	12	1.40×10^{-2}



(a) d_p=30μm, ϕ=0.03, D=8mm (b) d_p=550μm, ϕ=0.1, D=8mm (c) d_p=800μm, ϕ=0.01, D=12mm

Figure 2. Settling behaviors of stratified suspension



(a) d_p=30μm, ϕ=0.03, D=8mm (b) d_p=550μm, ϕ=0.1, D=8mm (c) d_p=800μm, ϕ=0.01, D=12mm

Figure 3. Change in average length of fingers with time

Figure 3 shows the change in the average length of fingers with time. For all conditions, the fingers grow exponentially at the beginning and then their growth speed becomes constant. The exponential growth of fingers can be seen in the Rayleigh-Taylor instability of immiscible fluids and the finger length z can be calculated by linear stability analysis as the following form,

$$z = z_0 \exp(nt), \tag{9}$$

where n is the growth rate. We define two experimental values which express the settling speed of particles. As shown in Figure 3, we calculated the exponential growth rate n_{exp} and the succeeding settling velocity U_{exp} from experimental results.

If the suspension behavior is perfectly fluid-like, the experimental growth rate n_{exp} will be close to the growth rate calculated by linear stability analysis n_{theo}. On the other hand, if the suspension behavior is perfectly particle-like, the change in the finger length with time will become almost linear and the succeeding growth velocity U_{exp} will be the same order of magnitude as the Stokes settling velocity U_0. Comparing the experimental results from this point of view, we finally found the settling velocity U_{exp} of condition (a) is the largest although it has the smallest Stokes velocity (see Table 1). The detailed comparisons of these values are given later.

Instabilities on Fluid-like Settling of Suspension

In order to understand the fluid-like settling of suspension, the experimental results for small particle are compared to the theoretical results for immiscible fluids. Figure 4 shows the results of the growth rate n for given wave number k calculated by equation 7 under the experimental conditions of d_p = 30μm, ϕ = 0.03, μ_f =1944mPa·s. We set $\overline{\rho}_1$, $\overline{\nu}_1$ (lower fluid) to properties of pure fluid ρ_f, ν_f and set $\overline{\rho}_2$, $\overline{\nu}_2$ (upper fluid) to apparent properties of suspension ρ_s, ν_s which are defined by equations (2) and (3). The theoretical analysis shows that the growth rate of disturbance is larger for larger vessel depth D and the wave number of maximum growth of disturbance k_{max} also depends on D.

Figure 4 (a)-(c) are the experimental pictures for same conditions as theoretical analysis. It is found that the width of finger is larger for larger vessel depth D. Yellow line in each picture indicates the wave length of maximum growth of disturbance λ (=$2\pi/k_{max}$) predicted by theoretical results. They are in quantitative agreement with wave length of disturbance (finger width) observed in experiment. Such perfectly fluid-like behaviors of suspension have been studied by Völtz *et al.* [11-13]. The main purpose of our study is investigating the transition from fluid-like settling to particle-like settling of suspension as explained below.

Transition from Fluid-like to Particle-like Settling

We consider the parameter which describes the transition from fluid-like to particle-like settling of suspension as shown in Figure 2. The parameter would be a function of particle density ρ_p, particle diameter d_p, liquid density ρ_f, liquid viscosity μ_f, particle concentration ϕ and vessel depth D. We propose a new dimensionless parameter $H = H(\rho_p, d_p, \rho_f, \mu_f, \phi, D)$ as follows:

$$H = \frac{l}{\lambda} \tag{10}$$

where l is average distance between particles in suspension and is function of d_p and ϕ. $\lambda = \lambda(\phi, \rho_p, \rho_f, \mu_f, D)$ is the wave length of interfacial perturbation (finger) which can be obtained from the linear stability analysis.

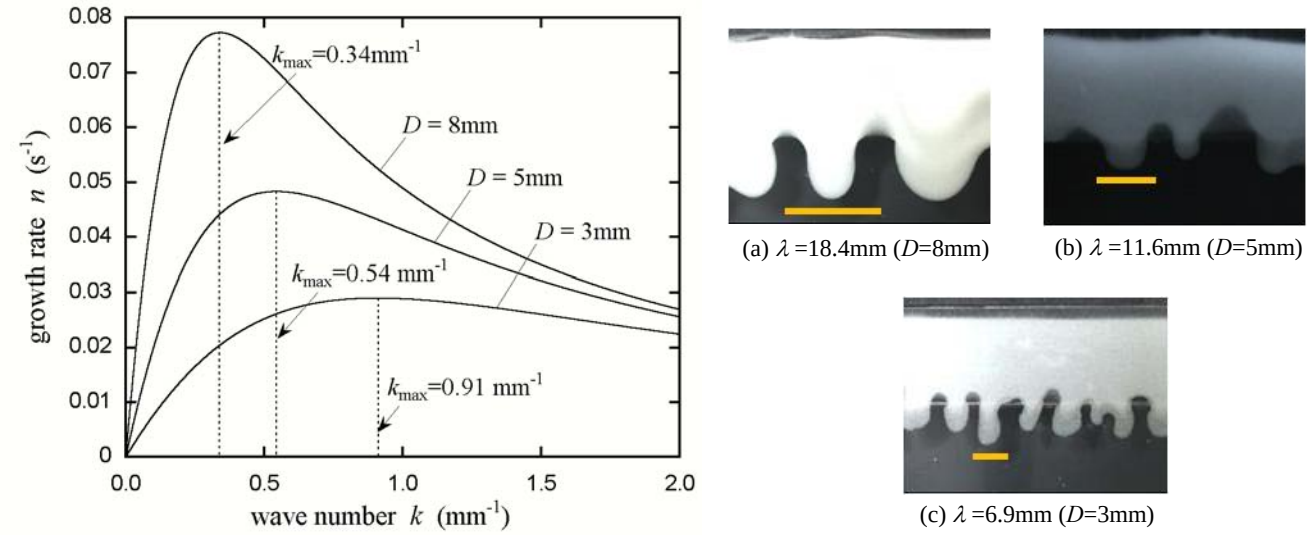


Figure 4. Maximum wave number k_{max} calculated by linear stability analysis and corresponding wave length $\lambda = 2\pi/k_{max}$ for glass particle suspension (d_p = 30μm, ϕ = 0.03, μ_f =1944mPa·s)

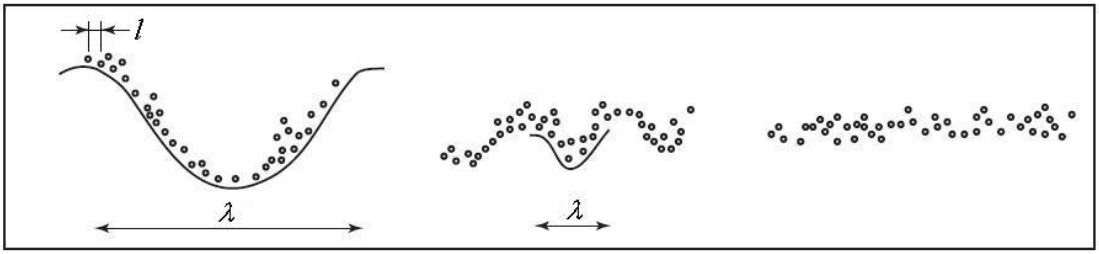
Figure 5 indicates the physical meaning of equation (10). It can be found that the parameter H expresses the border resolution of the density interface. That is, when H is large, the particles in suspension cannot form the finger clearly. By a simple assumption, the average distance between particles is calculated as $l \sim d_p \phi^{-1/3}$ and consequently H is as follows.

$$H = \frac{d_p}{\lambda \phi^{1/3}}. \tag{11}$$

As explained above, if suspension behaves perfectly fluid-like, the growth rate obtained experimentally n_{exp} is close to that by linear stability analysis n_{theo}. On the other hand, if it behaves particle-like, the measured velocity U_{exp} is close to the Stokes settling velocity U_0. Figure 6 shows $n_{\mathrm{exp}}/n_{\mathrm{theo}}$ and U_{exp}/U_0 obtained by 14 experiments with variation in fluid and particle properties and also the vessel depth. The horizontal axis is set to the parameter H given by equation (11). As can be seen in Figure 6, we could classify the settling behaviors of suspension as fluid-like, particle-like settlings and their transition by new parameter H.



(a) $\lambda > l$ (b) $\lambda \sim l$ (c) $\lambda < l$

Figure 5. Relation between wave length of interfacial pertuabation and average distance between particles

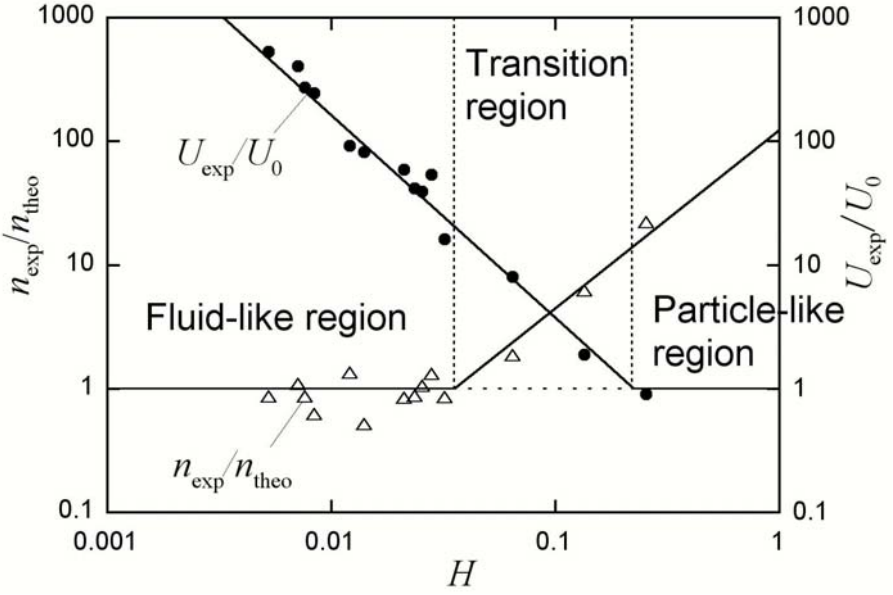


Figure 6 Transition from fluid-like to particle-like behaviors of suspension ($n_{\mathrm{exp}} / n_{\mathrm{theo}}$ and U_{exp} / U_0 represent the index of fluid-like and particle-like settling respectively)

CONCLUSIONS

The sedimentation of inhomogeneous suspensions in quasi two-dimensional vessel was investigated experimentally. We have examined whether the particles behave as a particle assembly (particle-like settling) or as a continuous suspension (fluid-like settling). If the suspended particles are adequately small, the settling behavior is completely fluid-like and the settling velocity is dominated by downstream flow due to the gravity-induced instability. The experimental results showed that the settling velocity of particles is influenced not only by the physical properties of particle and fluid but the size of the vessel. The transition of fluid-like to particle-like behaviors can be predicted quantitatively by a new parameter which expresses the border resolution of the density interface.

ABSTRACT. This study deals with a laminar channel flow interacting with a synthetic jet, with emphasis on low Reynolds numbers. The study is predominantly experimental, with supporting numerical simulations. The experiments were performed with water as the working fluids, and two methods were used: Laser Doppler Vibrometry for measurement of membrane oscillations, and PIV. The experimental and numerical results confirmed that the channel flow can be effectively controlled by means of the synthetic jet. As a result of the synthetic jet propagation through the channel flow, two significant effects were found: an oblique jet impingement and an overall modification on the channel flow more downstream the impingement area. Based on these local and overall effects, a possibility of heat/mass transfer enhancement was deduced. The authors suggest that this technique can be used for desirable augmentation of various applications.

Keywords: *Synthetic jet, flow control, flow visualization, Particle Image Velocimetry*

INTRODUCTION

A synthetic jet (SJ) is generated by the periodic motion of an actuator oscillating membrane. It is synthesized by the interactions within a train of vortices. The time-mean mass flux in SJ orifice is zero; hence the other common expression is zero-net-mass-flux (ZNMF) jet [1–3]. This study focuses on the interaction of a SJ with a laminar channel flow, with emphasis on low Reynolds numbers. This arrangement can be useful in many micro-scale applications, such as cooling of micro-electronics or the detection of various (biological, biomedical or chemical) species. The flow regime in micro-scale is usually laminar with very small Reynolds numbers. Therefore, the transfer processes such as mixing and cooling are typically based on gradient diffusion. Despite the present Reynolds numbers (in order 10^2) are too low for transition to turbulence, an actuation can essentially enhance the transport mixing creating the so-called "quasi-turbulent" flow character [4].

EXPERIMENTAL AND NUMERICAL INVESTIGATION

Problem parameterization

The "stroke length" is defined as $L_0 = U_0 T$, where U_0 is the time-mean orifice velocity relevant to the extrusion stroke [1], T is the time period ($T=1/f$), and f is the frequency. The Reynolds number of SJ is $Re_{SJ} = U_0 D/\nu$, where D is the diameter of the actuator orifice. The Reynolds number of 2D channel flow is $Re_C = U_C(2H)/\nu$, where U_C is the time-mean velocity through the channel, i.e. $U_C = (2/3)U_{max}$, where U_{max} is the maximum velocity and H is the channel width.

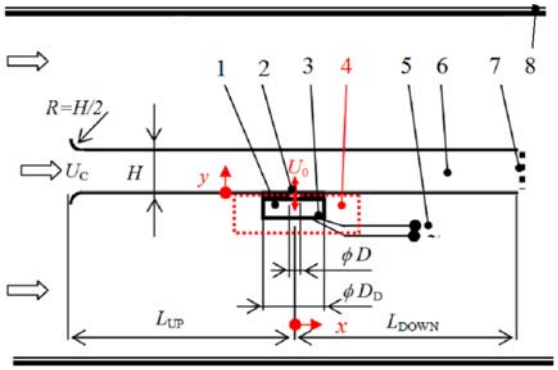

Figure 1. Schematic view of the present configuration. 1 – SJ cavity, 2 – SJ orifice, 3 – SJ membrane, 4 – SJ actuator, 5 – AC supply, 6 – tested channel, 7 – grid, 8 – water channel

Experimental setup and methods

Experimental setup. Figure 1 shows a schematic view of the present configuration - the tested channel inside the closed-loop circulation water channel (at TU Eindhoven). The tested channel was made out of Plexiglas. The inlet was carefully rounded to prevent inlet flow separation, and the outlet was equipped with a grid to control the flow velocity through the channel. The channel length, height and width were L_{UP}+L_{DOWN} = 1020mm, H = 40mm, and B = 200mm, respectively. The SJ-actuator (pos. 4) consists of a sealed cavity with an emitting orifice (diameter D = 3.0mm) and with an actuating piezoelectric membrane (D_D = 36mm). The actuator orifice is oriented vertically upwards to the exposed channel of cross section dimensions *H x width* = 40mm x 200mm.

Laser Doppler Vibrometry measurement. The piezoelectric membrane (piezoceramic transducer - PCT) is composed of two basic layers – a piezoceramic layer and a metallic membrane. Measurement of the oscillating PCT membrane is based on the Doppler effect, and the portable digital vibrometer Ometron VQ-1000-D B&K 8338 was used. The main parameters: frequency range 0.5 Hz ÷ 22 kHz; measurement ranges (full scale (peak-peak)) 20mm/s, 100mm/s, 500mm/s; spurious free dynamic range (SFDR): > 90dB; and best resolution: 0.02 μm/s/Hz$^{0.5}$.

Particle Image Velocimetry experiments (PIV). Seeding particles were polyamide balls of 20μm in diameter (DANTEC). The particles were illuminated by a double pulse laser with maximum 200mJ per 5ns pulse, and repetition rate 2 x 15Hz. A typical delay time 30ms was used. The laser beam was expanded by a cylindrical lens into a light sheet about 1mm in thickness. The image pairs were acquired using a 10 Bit CCD camera Kodac ES 1.0 with a spatial resolution of 1008 x 1018 pixels and the maximum frequency of 30 frames/s. The resulting vector maps were averaged over 54 double pulses in sequence. Velocity vectors were determined by adaptive correlation over interrogation windows 32 x 32 pixels at a 50% overlap and by cross-correlation over interrogation windows 64 x 32 pixels at a 50% overlap, respectively. Adaptive correlation was used on the images which show the SJ flow in the direct vicinity of the actuator, cross correlation was used on the images far from the SJ actuator. Data processing used software FlowManager 4.71 (DANTEC).

Numerical simulation

The flow is assumed to be three-dimensional, laminar, incompressible, and isothermal. Both stationary and non-stationary (periodical) problems are studied. The flow fields are computed with the finite-volume method using the commercial solver FLUENT; two governing equations are the mass and momentum conservations. Discretization of the domain uses hexahedron cells. The SJ cavity and SJ orifice contain a fine grid with hexahedrons of a typical size (0.2–0.5) mm and 0.2 mm, respectively. Further from the SJ, the size of the hexahedrons gradually increases

(the maximum of the aspect ration of cell sides is about 70) up to 2.0 mm. The total number of control volumes is about $2.2 \cdot 10^6$. The length of time step of the unsteady problem was chosen about t/T = 1/120. The computation process was highly time-consuming – a typical time for computation of an unsteady task under 16 CPU computer was 150 hours.

The boundary conditions follow the experimental conditions and the working fluid is water at temperature 20°C and pressure 10^5 Pa. The density and dynamic viscosity of water is $\rho = 998$ kg/m^3 and $\mu = 0{,}977\ 10^{-3}$ kg/(m·s), (i.e., the kinematic viscosity $\nu = \mu/\rho = 0{,}979\ 10^{-6}$ m^2/s). Three tasks were studied: (A) Main laminar channel flow without SJ; the boundary conditions were the uniform velocity profile at the channel inlet ($U_C = 0.006$ m/s) and the static pressure 10^5 Pa at the channel outlet. (B) Single round SJ directing across the channel without the main channel flow; the boundary conditions were the (uniform in space and harmonic in time) velocity profile on the diaphragm, $V = V_{max} \sin(\omega t)$, where the max. diaphragm velocity is V_{max}=0.0013m/s, $\omega = 2\pi f$, and f=15.0Hz. (C) Complex flow field A+B, i.e. an interaction of the main laminar channel flow with the single round SJ.

RESULTS AND DISCUSSION

Experimental results

The actuating frequency of the SJ actuator was chosen f = 15.0Hz – to match the present PIV laser repetition rate. It was near the actuator resonance frequency (about 18Hz, as was found during an auxiliary measurement by using Hot Wire Anemometry). The actuator was fed with sinusoidal current, and the electrical voltage and current were about 48V (peak-peak) and 0.076A (rms).

Laser Doppler Vibrometry measurement. The sampling rate for this measurement was 3000Hz. The period starts in zero position of the driving signal. From the membrane velocity and continuity equation, the velocity in the orifice $u_0(t)$ was evaluated; then the time-mean orifice velocity and Reynolds number were evaluated as U_0=0.059m/s and Re_{SJ}=177.

Figures 2(a) and 2(b) show the comparison of measured and theoretical sinusoidal displacement of the membrane centre in time, and the comparison of measured and theoretical cosinusoidal velocity in time, respectively. The sinusoidal displacement is described as $\Delta y(t)=\Delta y_{max}\sin(2\pi ft)$, and the relevant cosinusoidal velocity as $v(t)=v_{max}\cos(2\pi ft)$. The least squares fitting gives Δy_{max}=0.0274mm – see Figure 2(a). The relevant maximum of the membrane velocity is $v_{max}=2\pi f\Delta y_{max}$ = 0.00255m/s.

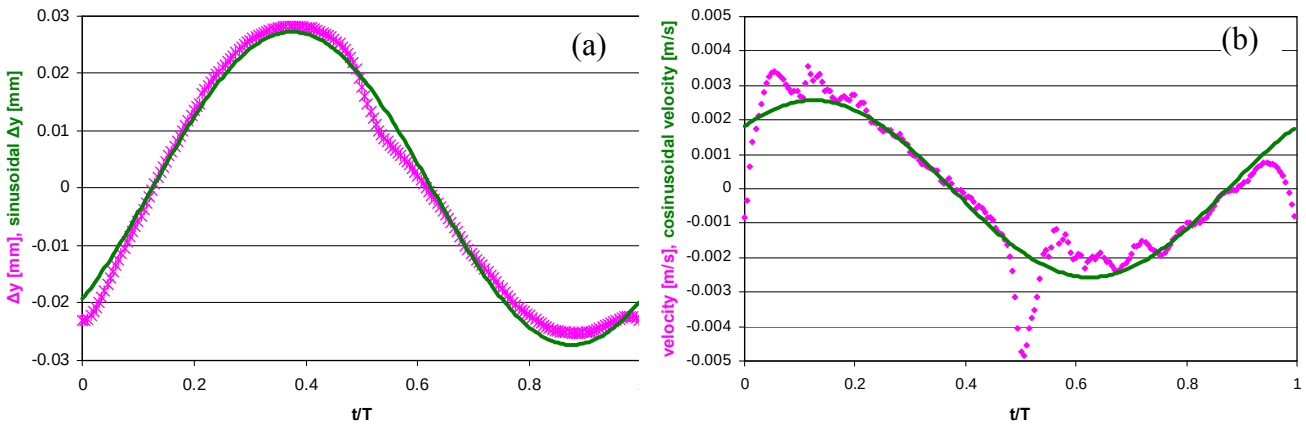

Figure 2. Oscillating membrane: (a) displacement, (b) velocity

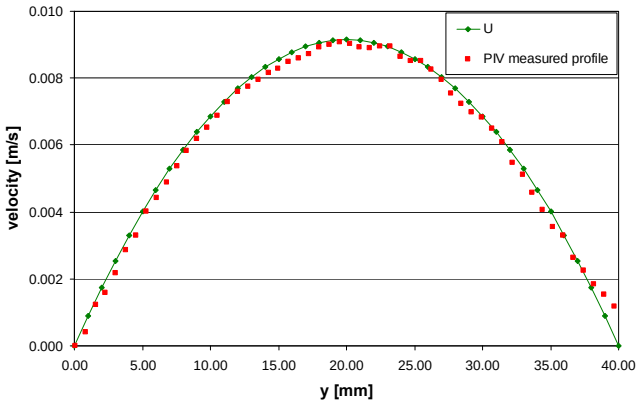

Figure 3. Velocity profile of a channel flow without SJ

Considering continuity, the plug flow model of an extruded fluid column, and the parabolic shape of the membrane deflection, the maximum of the velocity in the actuator orifice can be evaluated as $U_{max}=0.5(D_D/D)^2 v_{max} = 0.183$m/s. Finally, the sinusoidal character gives $U_0=U_{max}/\pi = 0.0583$m/s. Obviously, this sinusoidal approximation of the membrane displacement gives practically the same velocity U_0 as was written above (0.059m/s).

PIV measurement. Figure 3 shows that the time-mean velocity profile for the channel flow without SJ interaction (measured at $x = 0$) compares very well with the parabolic Poiseuille profile (denoted by U): $U = 6\,U_C[y/H–(y/H)^2]$. The time-mean velocity through the channel cross section was evaluated from the parabolic profile (Figure 3), $U_C = 0.006$m/s; the Reynolds number is $Re_C = 480$.

The interaction of the channel flow with a SJ is shown in Figure 4 in a form of contours of time-mean velocity magnitude. This experiment clearly demonstrates the SJ bending and its propagation downstream in the main channel flow. Moreover, SJ reaches the opposite wall (y=40mm), where an oblique jet impingement can be identified (at x = 30–40mm, see the ellipse mark in Figure 4). Obviously, heat/mass transfer enhancement can be expected in the impingement area – this effect is desirable in various applications. Nevertheless, even more important than this local effect could be an overall modification on the channel flow more downstream the impingement area. To explain this effect, the following text discusses profiles of the time-mean velocity at x=12–115mm.

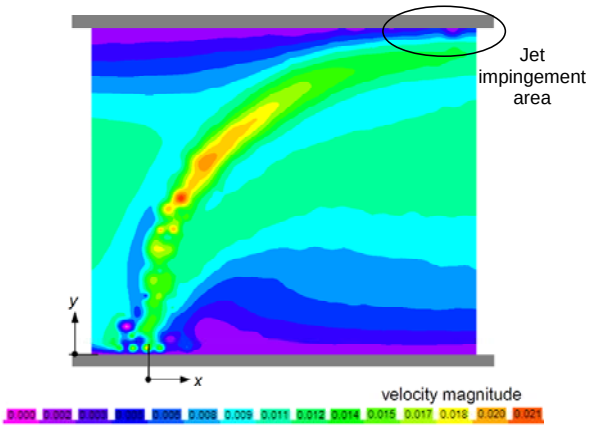

Figure 4. Velocity magnitude of the channel flow interacting with SJ. The presented PIV experiment covers area x from –7mm to 40mm, and y from 0 to 40mm.

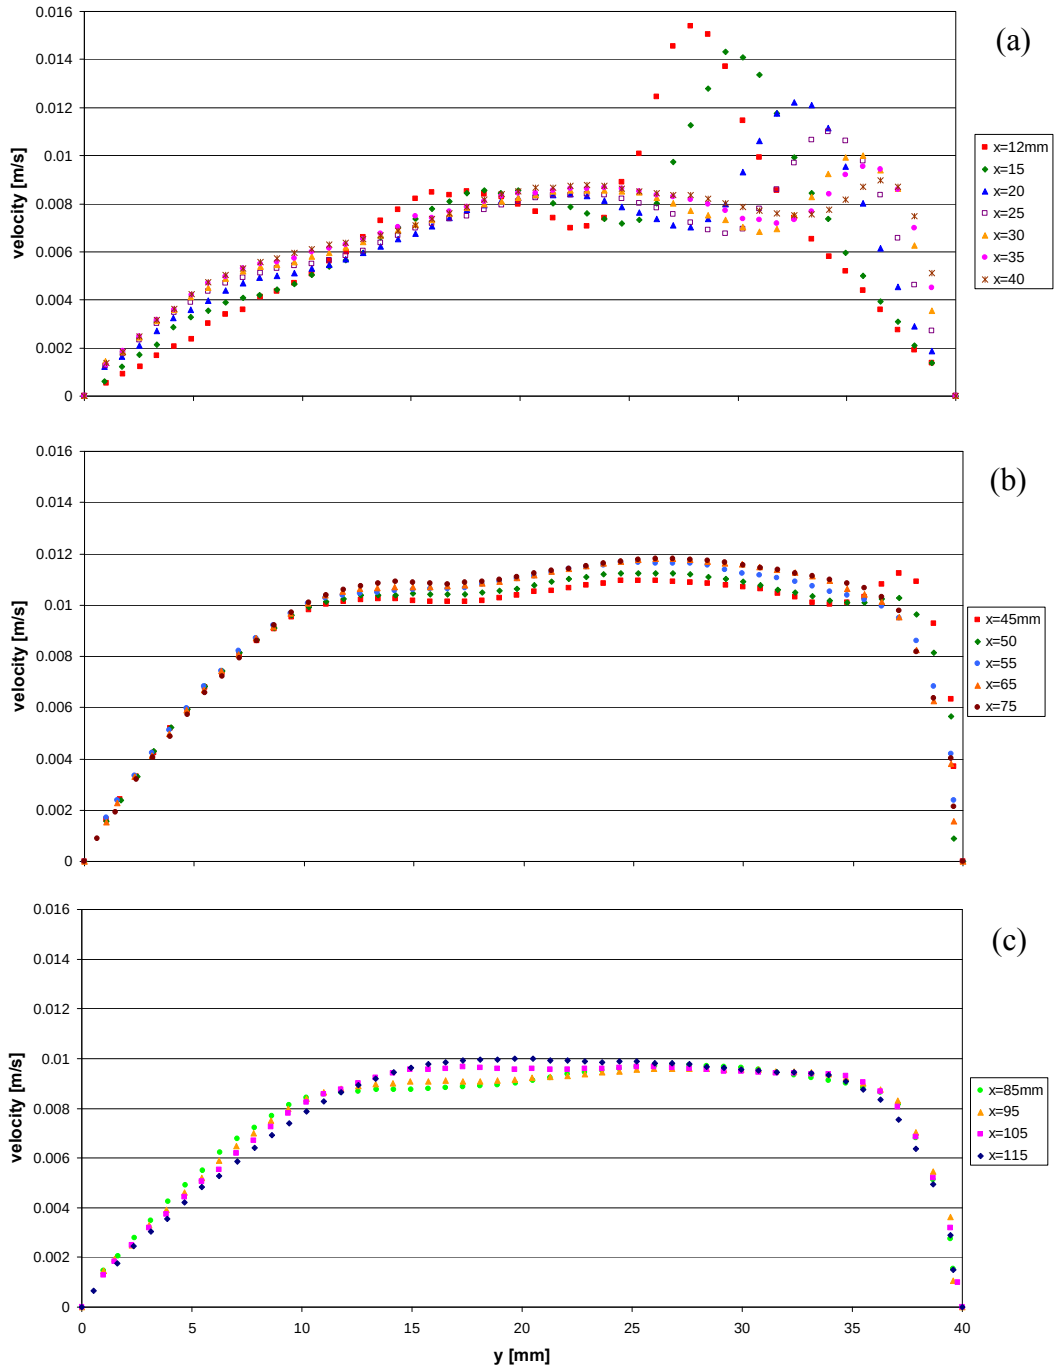

Figure 5. Velocity profile of the channel flow affected with SJ; $t/T = 0.5$

Figure 5 shows results from PIV measurements of the channel flow interacting with a SJ. Figure 5a shows that the velocity profile is influenced first on the top of the channel – i.e. on the wall opposite of the SJ actuator – the velocity there is nearly 0.016m/s. Obviously, it is caused by rather high velocity of SJ – the velocity U_0 was one order higher than U_C, as is evaluated below. More downstream, the flow development is propagated downwards to the bottom channel wall – Figures 5(b and c). The flow profile again redistributes towards a parabolic profile, however at x=115mm this profile is not yet achieved.

Results of numerical simulations

Main laminar channel flow without actuations. Figure 6a shows velocity profiles, which were

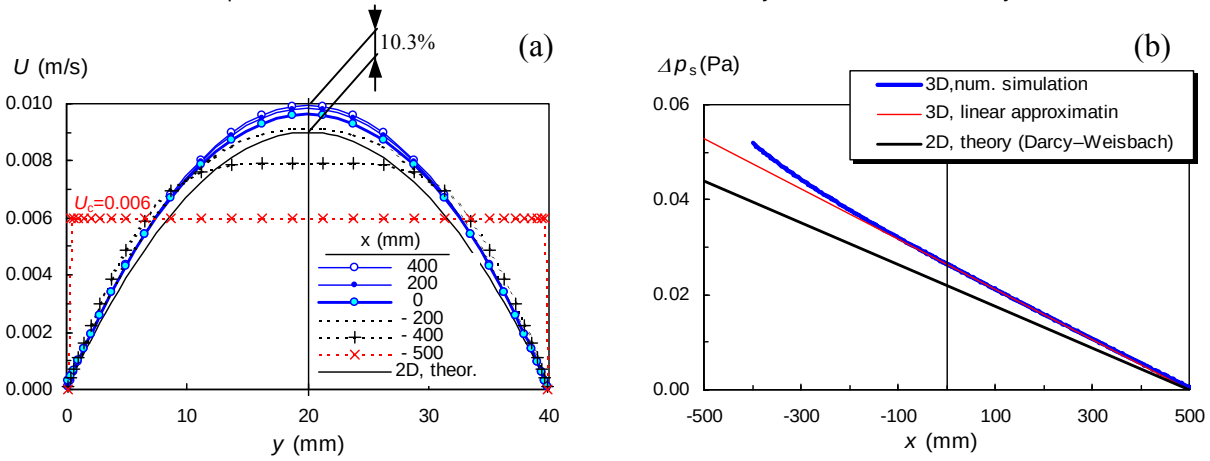

Figure 6. Numerical simulation of the channel flow; (a) velocity profile across the channel, (b) pressure drop along the channel center

computed from the channel inlet $x = -500$mm, where constant velocity $U_C = 0.006$ m/s is prescribed across the channel. According to our expectations, the uniform inlet flow develops into the parabolic channel flow profile, and this process takes place mainly in the first half of the channel (approximately x = from –500mm to -200mm). The increase of the velocity maximum in the second half of the channel ($x > 0$), relating to the final stage of developing is rather small, only 3.7%. For comparison purposes, 2D theoretical laminar parabolic profile of developed channel flow is plotted in Figure 6a, too. Obviously, 2D flow reaches smaller maximum velocity than 3D flow under identical time-mean velocity through channel U_C. This is due to the 3D effect of the boundary layer on the channel side walls $z = \pm B/2$. The difference between velocity profiles of 2D and 3D flows is plotted in Figure 6a, too: 2D flow reaches $U_{max} = 1.5\ U_c$, and the present 3D flow reaches 10.3% higher $U_{max,3D} = 1.654\ U_c$.

It is worthwhile to mention here that consideration of the 3D effect slightly decreases the experimental time-mean channel flow velocity U_c and the Reynolds number Re_c, which was discussed earlier. Taking into account the 3D channel flow character, the velocity and Reynolds number are $U_{c,3D}$ = 0.0054m/s and 435, respectively. Moreover, accounting for the hydraulic diameter of 3D channel, instead of the 2D simplification leads to a decrease of the Reynolds number $Re_{C,3D} = D_h\, U_{C,3D}\, /\nu$, where D_h is the hydraulic diameter of the channel, $D_h = 2H/(1+H/B)$, i.e. $D_h = (5/3)H$ for the present geometry. This 3D evaluation gives the resultant value $Re_{c,3D} = 363$.

Figure 6b shows the static pressure drop computed along the channel center (x = from –500mm to 500mm, $y = H/2$, $z = 0$). For comparison purposes, the pressure drop resulting from the theoretical 2D solution given by the Darcy–Weisbach equation is shown also in Figure 6b. Understandably, the 3D effects from the channel side walls imply that 3D channel flow needs higher pressure drop to reach the same volume flow (i.e. the same channel velocity U_C) as 2D flow. Figure 6b shows, that 2D simplification implies a pressure drop decrease by 17% against the computed 3D flow. The linear approximation of the pressure drop related to the 3D fully developed flow is plotted in Figure 6 too. It well correlates the numerical results in the range from $x = -100$mm to $x = 500$mm. For this approximation, the Darcy–Weisbach friction factor of the present channel was concluded to be $f = 80/Re_{C,3D}$. These characteristics show that the main channel flow is well-captured in these simulations with the set numerical parameters and resolution.

Synthetic jet without channel flow. Figure 7(a) shows the SJ period in a form of contours of velocity magnitude. The images were evaluated at 4 equal time intervals during the actuating period (t/T = 0, 0.25, 0.50 and 0.75). The period origin is defined at the moment of zero velocity in the actuator

orifice, at the beginning of the extrusion stroke. The main visible feature is that the generated SJ crosses the channel width *H*, and it reaches the opposite channel wall where SJ impingement is formed. Moreover, Figure 7(a) for $t/T = 0.75$ shows "the range of the actuator suction" – a spot of small velocity located on the axis at x= approximately $0.35D$; further downstream only the positive orientation of the vertical velocity component exist during the actuation cycle.

An interaction of the channel flow with synthetic jet. Figure 7(b) shows an interaction of the channel flow with SJ in a form of contours of velocity during the actuation period. The numerical simulation shows SJ bending and propagation downstream the main channel flow – cf. Figure 4 showing PIV experiment for the same case. Despite numerical simulation predicts smaller SJ bending (impingement area is predicted at x~15mm in Figure 7(b), and experimental Figure 4 shows x~(30–40)mm) the character of the results is comparable.

Moreover, Figure 7(b) demonstrates another effect: the channel flow exhibits two areas of low velocities at the leading and trailing parts of SJ. This effect is known from steady jets in cross flows, and it resembles front stagnation area and rear separation bubble of bluff bodies in cross flows.

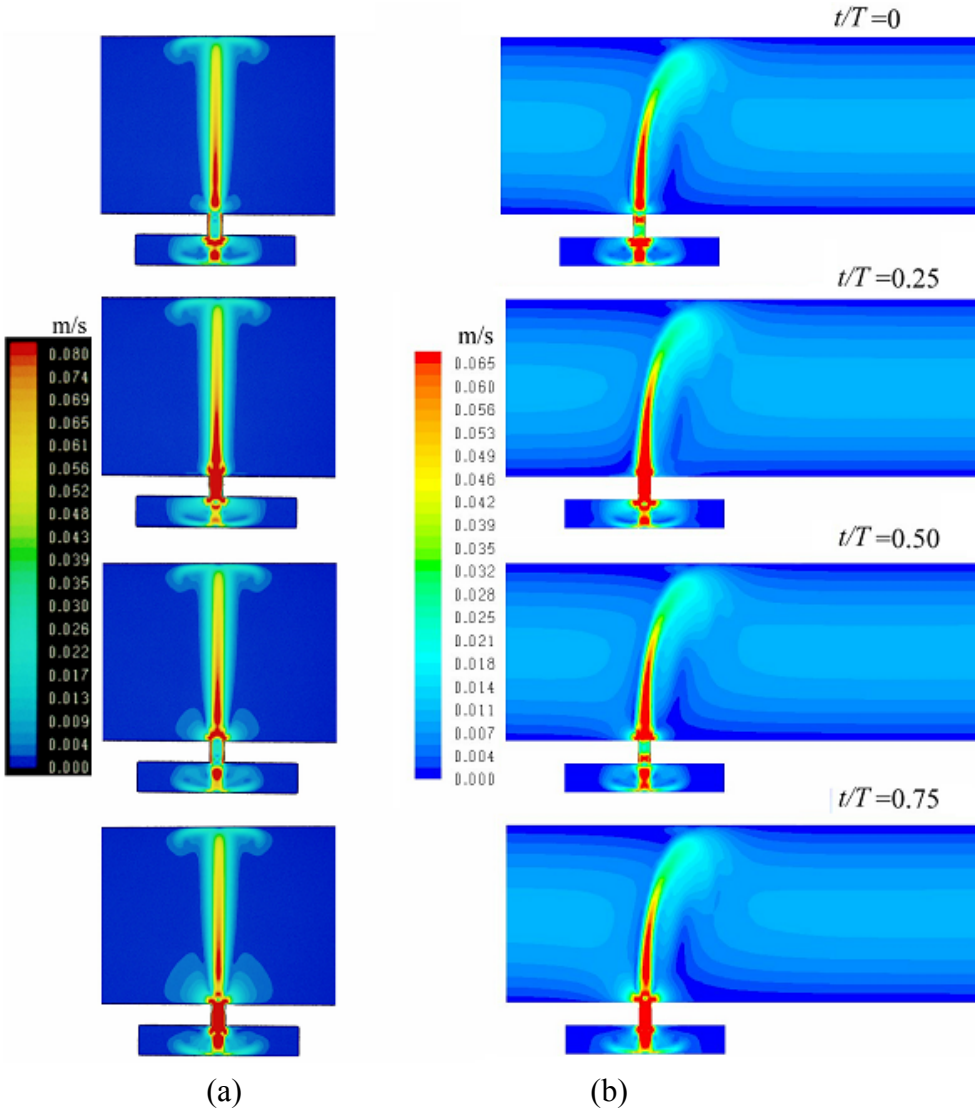

Figure 7. Numerical simulation of SJ period – contours of velocity magnitude during the actuation period; (a) SJ without a channel flow, (b) SJ interacting with the channel flow

CONCLUSIONS

The present study deals with a laminar channel flow interacting with a synthetic jet, with emphasis on low Reynolds numbers. The study consists of experimental and numerical parts. The experimental part of this study used two methods: measurement of oscillations of the actuating membrane using Laser Doppler Vibrometry, and PIV experiment. Laser Doppler Vibrometry evaluated the local displacement and velocity of the membrane. Based on the continuity equation and considering plug flow model of fluid column, data were transformed into the approximation of the orifice velocity in time $u_0(t)$, the time-mean orifice velocity relevant to the extrusion stroke U_0, and the Reynolds number $Re_{SJ} = 177$.

PIV experiment with the channel flow alone (without synthetic jet) confirmed laminar character of flow, and the velocity profile agreed very well with the parabolic Poiseuille profile. The Reynolds number of the channel flow was adjusted $Re_C = 480$. Sequentially, PIV experiment was performed with the same channel flow under the synthetic jet actuation. The experiment demonstrates bending of the synthetic jet and its propagation through the channel flow. The synthetic jet crossed entire channel width, and an oblique jet impingement was identified on the opposite channel wall. An overall modification on the flow more downstream the impingement area was identified too.

Numerical simulations were performed under identical conditions as the experiments. Three tasks were systematically studied: (A) the main laminar channel flow without actuations, (B) the single round synthetic jet directing across the channel in quiescent fluid, (C) an interaction of the main laminar channel flow with the round synthetic jet. The simulation predicted quite well (A) the channel flow development into the parabolic Poiseuille profile, (B) synthetic jet formation, and (C) the character of the synthetic jet propagation into the flow field. A reasonable agreement with experiments was concluded.

The present experiments and numerical simulation confirmed that the laminar channel flow at low Reynolds numbers can be effectively controlled by means of the synthetic jet. An oblique jet impingement and an overall modification on the channel flow more downstream the impingement area was found. Based on these local and overall effects, a possibility of heat/mass transfer enhancement was deduced. The authors suggest that this technique can be used for desirable augmentation of various (typically micro-scale) applications such as cooling of micro-electronics, micro-mixing, and detection of various (biological, biomedical or chemical) matters.

VISUALIZATION TECHNIQUES FOR ESTIMATING THERMAL BOUNDARY LAYERS OF NATURAL CONVECTION FLOWS

Tomasz P. Bednarz*, Feng Xu, Chengwang Lei, John C. Patterson
School of Engineering, James Cook University, Townsville QLD 4811, Australia

ABSTRACT. Particle Image Thermometry (PIT) and shadowgraph methods can be successfully used for estimating thermal boundary layer thickness in transient natural convection flows. PIT is a technique by which temperature fields are extracted by post-processing true-colour photographs of the flow patterns obtained with the application of thermo-chromic liquid crystals added to the working fluid. This is usually done using a calibration curve (hue versus temperature). With such calibration data, every pixel of the colour photograph is transformed to a temperature value, and thus accurate experimental temperature maps can be obtained. In this paper, the general PIT image processing techniques are presented, and new image processing procedures to determine the post-processing window size based on the visible particle size are described.

Shadowgraph is another technique that is used to visualize thermal flow fields. It is known that the intensity variation of shadowgraph images is approximately sensitive to the second derivative of temperature, and a bright strip in a shadowgraph image corresponds to the minima or maxima of the second derivative of temperature in the direction normal to the strip. The present paper describes the advantages and limitations of this technique. Also working examples of the shadowgraph technique used in natural convection flows are presented.

INTRODUCTION

Accurate temperature field data and proper visualization techniques are essential for heat transfer and fluid flow analyses, for example in evaluation of convective heat transfer coefficients in complex geometries or in dynamic fluid flows, as well as for estimating thermal-boundary layers, etc. Traditional temperature sensors such as thermocouples or thermistors can only provide temperature information at discrete points. Moreover, the presence of these sensors in the flow domain may disturb the original flow or physical phenomena. In many thermal flow problems such as the transient growth of thermal boundary layers in natural convection experiments, our interest is mainly in the overall flow field rather than discrete locations in the flow. For this purpose *Particle Image Thermometry* (PIT) and *Shadowgraph* methods can be successfully utilized, as it will be shown in the present work by several examples.

The PIT technique makes use of the special optical properties of TLCs (Thermo-chromic Liquid Crystals), which are widely used in science and engineering to map temperature distributions in fluids or on rigid surfaces. TLCs usually exist in smectic, nematic or cholersteric (also chiral nematic) phases [1, 2]. When a white light source shines on the chiral nematic TLC, light of only one particular wavelength corresponding to the temperature of the TLC is reflected. Thus, this property is used to measure accurately the temperature by observing the reflected wavelengths (or colours). The visible

E-mail address: tomasz.bednarz@jcu.edu.au

colour of TLCs turns from colourless (black against a black background) to red over a certain temperature range. As the temperature increases, the TLCs' colour passes through the visible colour spectrum in sequence (orange, yellow, green, blue, violet) before turning colourless again at a higher temperature [3, 4]. These colour changes are repeatable and reversible, as long as the TLCs are not chemically degraded or physically damaged. TLCs therefore can be calibrated accurately against known temperatures and used as temperature indicators. The response time of TLCs is only 3 ms, which is short enough for typical thermal fluid problems. TLCs are normally clear or slightly milky in appearance and change their colour over a narrow range of temperatures. Their colour-temperature play range depends on the TLC composition prepared during the manufacturing process, and can be selected for bands of about 0.5ºC to 20ºC with working temperatures ranging from -30 ºC to above 100 ºC [5]. The suspension of thermo-chromic liquid crystals can be used not only for temperature visualization but also for concurrent velocity estimations through the method of Particle Image Velocimetry [1, 6], as seen in Figure 1.

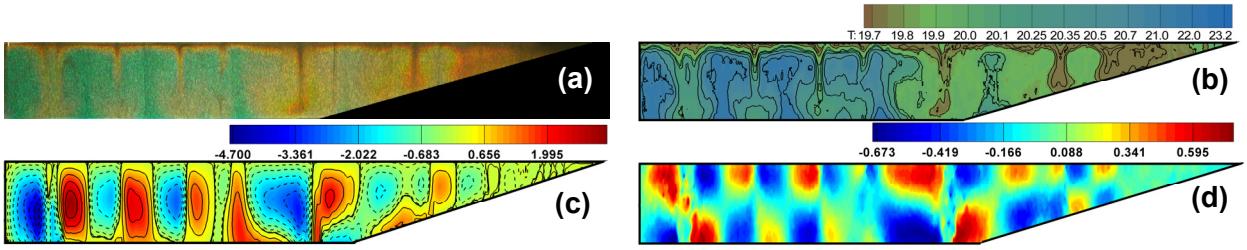

Figure 1. Example of concurrent temperature and velocity extraction in a reservoir model subject to diurnal temperature changes at the water surface [6]; (a) raw image; (b) isotherms extracted through PIT technique; (c) streamline contours and (b) contours of the horizontal velocity extracted using the PIV technique.

Due to its relative simplicity, the shadowgraph technique has also been extensively applied to the observation of various flows. The shadowgraph technique is based on the principle that the refractive index of light depends on the density of the fluid through which it passes; a non uniform temperature field, and therefore density field, will deflect parallel light non-uniformly, and thus an interference pattern will be observed on a distant screen [7]. Therefore, this technique is usually employed to visualize natural convection flows [8, 9]. Various shadowgraph methods can be divided into two categories: direct and focused (see e.g. [10]). The direct shadowgraph means that, in the simplest case, only a bright light source, an object and a suitable surface (on which to cast the shadowgraph image) are required. However, the focused shadowgraph, which will be described in the following section, has been more extensively applied because it enables easy adjustment of the imaging plane through adjusting the camera settings despite that its optical setup is more complex than the direct one.

It is well known that the boundary layer adjacent to a thermal wall has a large temperature gradient in the direction normal to the wall surface, which in turn results in the density variation of the fluid adjacent to the thermal wall. Accordingly, the shadowgraph technique can be used to visualize the transient development of the thermal boundary layer and measure its thickness [11]. In this paper, the shadowgraph technique is employed to estimate the thickness of the thermal boundary layer adjacent to the sidewall of a differentially heated cavity.

PARTICLE IMAGE THERMOMETRY

Calibration

The colour-to-temperature calibration of the liquid crystals was carried out using the experimental model presented in Figure 2. The colour images at a uniform temperature were taken by a digital camera and were digitised in RGB colour space. For calibration purpose, every pixel in the RGB colour space was transformed to another trichromic decomposition called HSI (Hue, Saturation, and

Intensity) according to the methodology presented in [12, 13]. The most important value for colour-to-temperature calibration is the hue value which represents the dominant colour related directly to a specific spectral wavelength. The value of hue is independent of light intensity, so minor variations of the light intensity across the illuminated plane do not affect the calibration. A simple spatial mean filter based on a sliding-window analysis that calculates the mean value of each colour component in the window and replaces the centre pixel value with the calculated mean value was additionally applied. In preliminary tests it was found that the optimal value of the window size is 9×9 pixels, which approximately corresponds to the size of a single particle of the liquid crystal visible in the photograph.

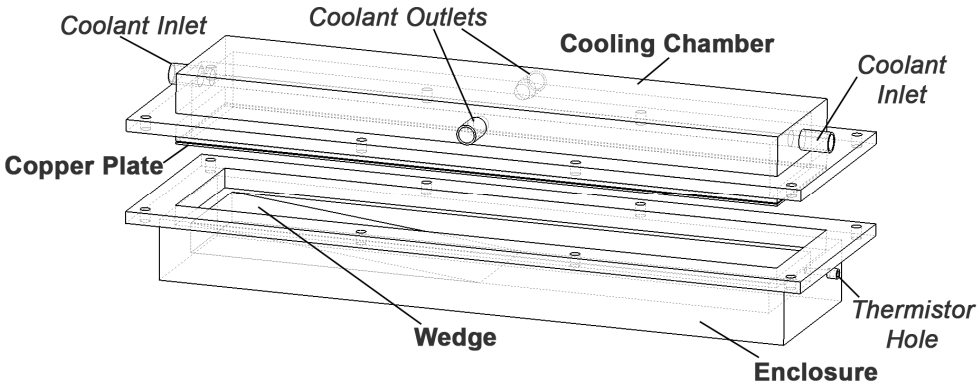

Figure 2. Experimental model of reservoir [6, 13].

For calibration, the water body was cooled to a constant temperature in the range from 24.2ºC to 18.9ºC in 26 steps. At every step, the water was kept at the specified temperature for about 20-25 minutes, and then an experimental photograph was taken (Figure 3a). After that, the temperature was set to the next calibration step, and the above procedure was repeated. In the region with steep increase of the hue value, the number of calibration points was increased since a very small change in the temperature caused a relatively large change in the colour response (hue value). A sixth-order polynomial regression was used to fit the known temperatures with the corresponding hue values calculated from the RGB colour components. The polynomial fit was only applied to points within the monotonic region (i.e. for temperatures between 19.7-23.7ºC in Fig. 3b). Although the nominal temperature indicating range of KWN-20/30 is between 20 and 30ºC, only part of this region (i.e. the monotonic region mentioned above) can be used with confidence for accurate temperature estimation. Above 23.7ºC, the TLCs hue response was almost constant and it was not considered for further analysis. The error bars in Figure 3b represent one standard deviation in the calculated hue from the region of interest within the measured colour bandwidth of the KXN-20/30 liquid crystals used here. As seen in Fig. 3b, there were some variations of the reflected wavelength from the TLC particles at the same temperature. The highest uncertainty occurs at higher temperatures, at which the colour response of the TLCs is entering a transparent regime. The departure of the TLC indicated temperature (obtained using the sixth-order polynomial calibration curve) from the actual temperature (the reference temperature for calibration) is indicated by the coefficient of determination R^2 and the mean absolute error of the linear correlation between the indicated and actual temperatures, which are 0.9953 and 0.059ºC respectively from the present calibration.

Estimation of the Thermal Boundary Layer

Figure 4(a) presents a set of experimental photographs showing the transient response of the thermal boundary layer immediately below the water surface in the initial growth stage in a cooling experiment. The numbers in the lower-left corner of each photograph indicate the relative time measured in seconds after the initiation of cooling. Initially, the fluid was stationary and isothermal, and there was no heat conduction in the enclosure. As soon as the surface cooling started, a thermal boundary layer started to grow downwards underneath the water surface. By comparing the images shown in Figure 4(a), it is seen that a horizontal strip of red/brown colour expanded downwards along

the entire top surface. This red/brown strip met the sloping bottom near the tip. Therefore, a local temperature gradient is created along the sloping bottom in the tip region. This temperature gradient is responsible for the development of a convective flow (to be described later) with relatively colder fluid flowing down along the slope into the deeper regions, resulting in a convective circulation in the enclosure [14].

The presented photographs show clearly the transient growth of the thermal boundary layer and allow an estimation of the boundary layer thickness at different times. Here, the thermal boundary layer thickness can be determined as the distance between the top of the enclosure and the mid height of a very narrow band with distinct colour transition between brown (representing the relatively colder fluid in the thermal boundary layer) and blue colours (representing the relatively warmer fluid in the interior). The lower boundary of the thermal boundary layer is indicated by overdrawn white horizontal lines in Figure 4(a).

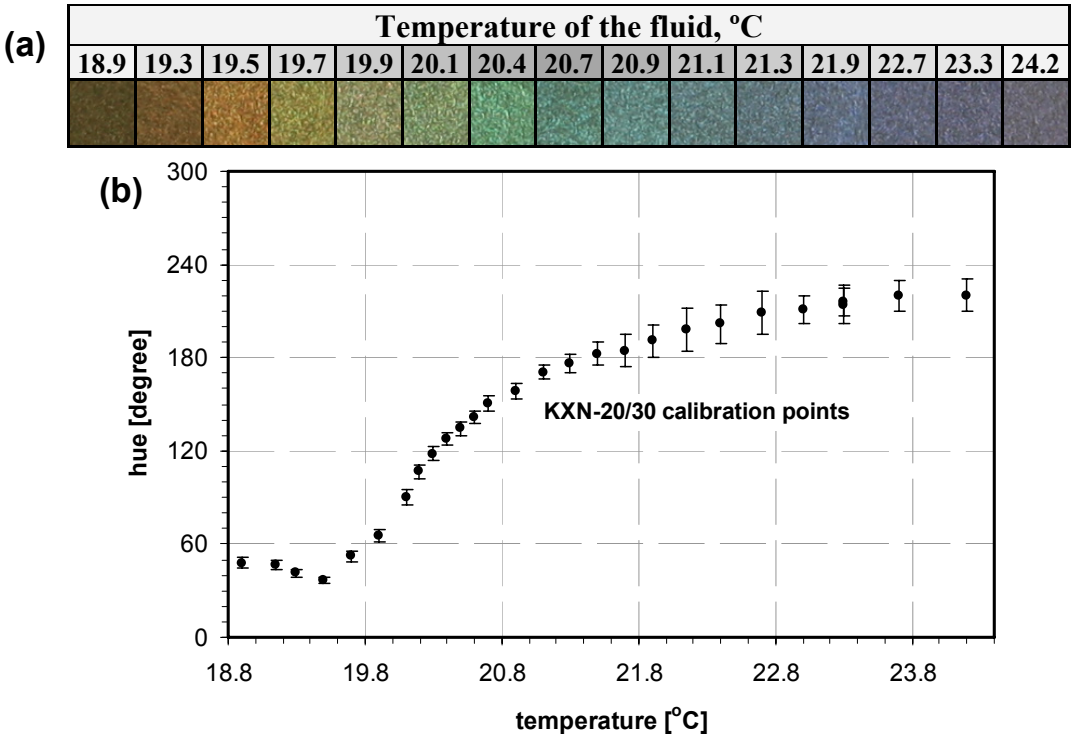

Figure 3. (a) Colour responses of the TLC used in the present experiment. (b) Calibration data points for the KXN-20/30 slurry (temperature versus hue).

Figure 4(b) shows temperature profiles in the thermal boundary layer at three different times in the early stage of the flow development before the convective instabilities were initiated. The profiles are extracted using the PIT technique along a vertical line at a horizontal location of 0.15 m from the tip, and are plotted against the distance below the surface. The figure clearly shows the growth of the thermal boundary layer with time. It is worth noting in Figure 4(b) that the temperature at the water surface is not constant. Instead, it decreases with time. This is a direct result of the present experimental setup, in which a copper plate of a finite thickness is used to conduct heat between the cooling water in the cooling chamber and the water body in the reservoir model. The temperature at the upper surface of the copper plate is maintained approximately constant by the circulating cooling water. In order to maintain a continuous temperature change from the copper plate to the expanding cooling thermal boundary layer under the water surface, a decreasing temperature with time at the lower surface of the copper plate (which is the same as the water surface temperature) is necessary. The result shown in Figure 4(b) implies that the cooling rate at the water surface also decreases with time at this stage.

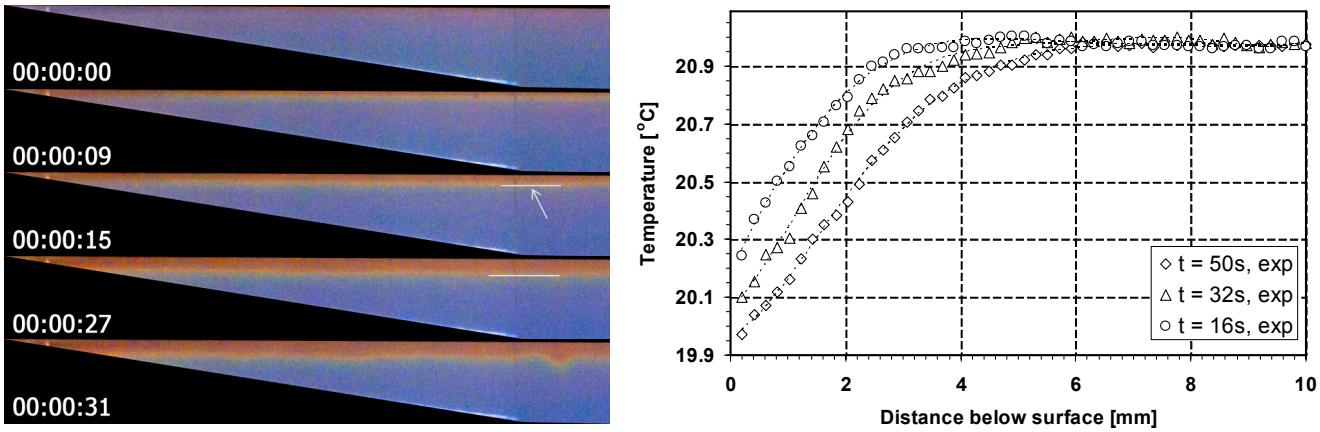

Figure 4. (a) Transient growth of the thermal boundary layer in the initial stage of cooling, (b) temperature profiles in the thermal boundary layer extracted using PIT technique.

A thermal boundary layer started to grow downwards underneath the water surface immediately after the surface cooling started, and the growth of the thickness of the thermal boundary layer with time in the early stage can be described by a simple scaling relation $\delta_T \sim (\kappa t)^{1/2}$ [13-15]. It is worth noting that this scaling law holds only for the initial development of the thermal boundary layer when heat transfer is dominated by conduction. Figure 5 plots the thicknesses of the thermal boundary layer measured in two separate experiments at $Gr = 2.04\times10^4$ and $Pr = 8.05$, in 2 runs and at $Gr = 7.82\times10^3$ and $Pr = 6.91$, against time t during the early growth stage of the thermal boundary layer. The thermal boundary layer thickness was measured at a horizontal location of 0.15 m from the tip, and was determined for the first case as described above, and for the second case where the hue value was 160 (corresponding to a temperature of 20.95 ºC). In Figure 5, the circles, crosses and triangles represent the experimental data, and the dashed lines represent the trend-line fitted to the experimental data. This demonstrates that thermo-chromic liquid crystals can be successfully used for estimating thermal boundary layers in convective flows.

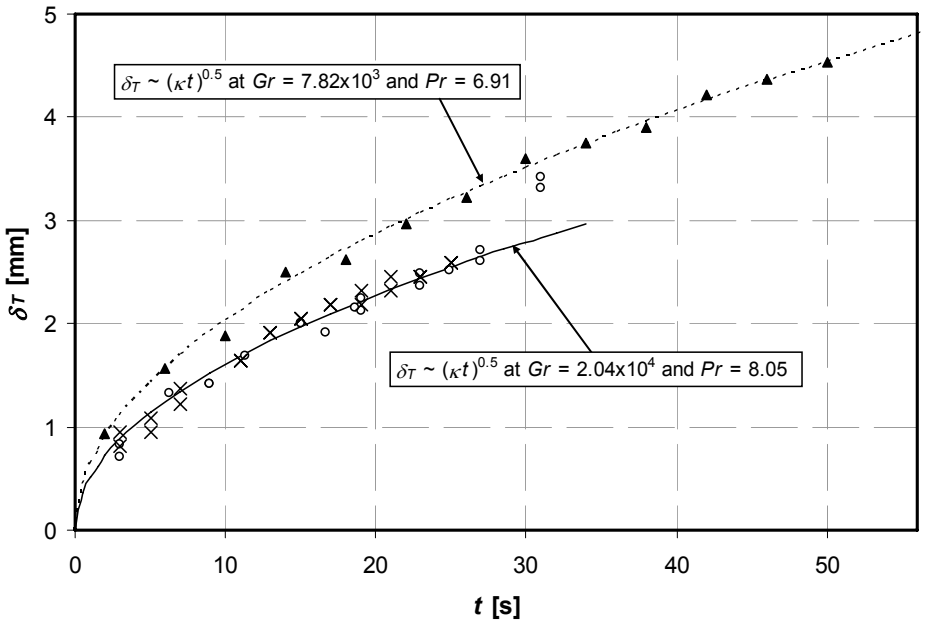

Figure 5. Sample growths of the thickness of thermal boundary layers (TBL is plotted against time). The circles/crosses are the experimental data from two experiments; the solid and dashed lines are scaling predictions.

SHADOWGRAPH

We consider the vertical thermal boundary layer adjacent to the sidewall of a differentially heated cavity. For the purpose of shadowgraph visualization, a Z-shaped focused shadowgraph setup is employed in this paper. Figure 6 sketches a top view of the shadowgraph optical setup, in which a point light source (a 12-W bulb in a small black box with a pin hole covered by a piece of ground glass) is placed at the focal point of a silver-coated spherical mirror with a diameter of 0.3 m and a focal length of 2.4 m. Such an optical setup results in a parallel light beam leaving the spherical mirror. When the parallel light beam passes through the model cavity filled with fluid of non-uniform temperatures, it is deflected by the fluid due to variations of the refractive index of the fluid. In fact, the refractive index depends on the fluid density, and in turn on the temperature. Therefore, a non-uniform pattern with varying light intensity is formed after the originally parallel light beam exits from the cavity. The distance from the mirror to the light-entering sidewall of the cavity is 2.6 m.

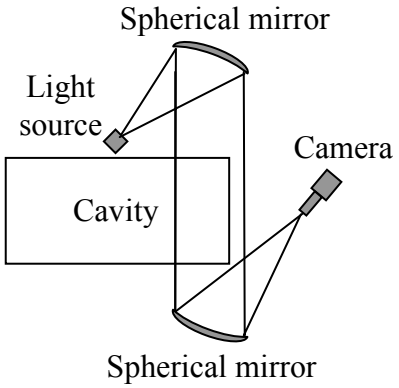

Figure 6. Schematic of the optical setup of the focused shadowgraph.

The exiting light beam is projected onto another identical spherical mirror, and refocused to a black-and-white CCD camera (Pulnix TM-6CN) at the focal point of this mirror. The distance from the light-exiting sidewall to the mirror is 1.8 m, shorter than that on the other side of the cavity (in order to reduce the loss of the intensity of the light beam), but that from the mirror to the camera is still 2.4 m, which is the focal length of the spherical mirror. The CCD camera is connected to a frame-grabber board installed in a computer. As a consequence, a time series of the recorded shadowgraph images displays the development of the temperature field of the fluid adjacent to the sidewall of the cavity.

Figure 7(a) presents a series of shadowgraph images showing the growth of the thermal boundary layer adjacent to the hot sidewall following sudden heating. In the shadowgraph images, the thermal boundary layer is approximately represented by the vertical dark regions, bonded by a clear bright strip. These bright strips are associated with the extrema of the second derivative of the temperature in approximately the horizontal direction. This position may be used as a measure of the boundary layer thickness [11]. It is clear in Figure 7(a) that the thickness of the thermal boundary layer increases from upstream to downstream, and also grows with time. The shadowgraph images in Figure 7(a) have been processed by subtracting a background image recorded immediately before the start of the experiments in order to display more clearly the thickness variations of the thermal boundary layer.

As previously described (also refer to [15]), a scaling relation ($\delta_T \sim (\kappa \cdot t)^{1/2}$) may be used to characterize the thickness growth of the thermal boundary layer with time in the initial stage. Figure 7(b) plots the time series of the thicknesses measured at three different locations along the sidewall. The thickness is determined as the width of the dark strips, typically shown in Figure 7(a), and the measurements have been taken from the full time series of images. The thickness values in Figure

7(b) show step changes with time. This is because the resolution of the imaging system is 0.44 mm per pixel in the present experimental set-up, and any variations of less than 0.44 mm cannot be detected by the imaging system. Note that Figure 7(b) plots the measured thickness of the thermal boundary layer against the scaling prediction, and reveals that the experimental measurements are consistent with the theoretical prediction of $(\kappa t)^{1/2}$ for the initial 10 seconds although the slopes of the fitting lines are not equal to unity. As time increases, the measurements deviate from the scaling (the deviating times at heights -0.052, 0.015 and 0.089 m are about 10 s, 14 s and 20 s, respectively), suggesting that convection effects become important. After approximately 20 seconds, the thickness at the height of 0.089 m starts to fluctuate and eventually approaches a constant value. Indeed, the waves at the height of 0.089 m are caused by the leading edge effect (see [16]).

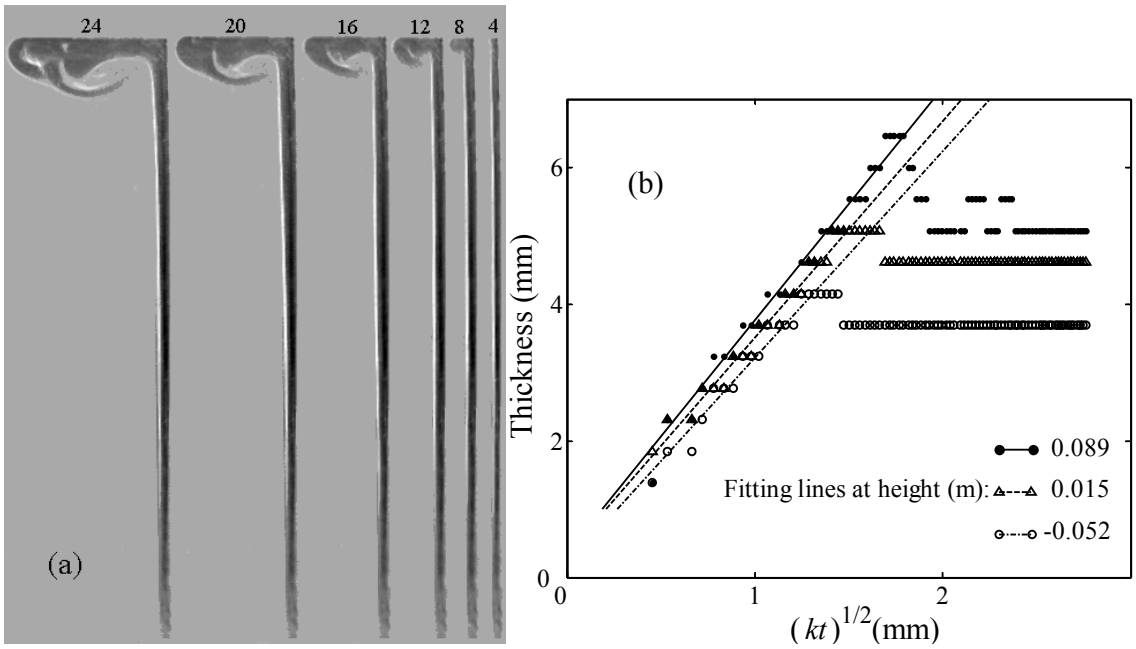

Figure 7. (a) Shadowgraph images of the thermal boundary layer adjacent to the hot sidewall at different times (from 4s to 24s) for $Ra = 3.9 \times 10^9$. (b) Thickness of the thermal boundary layer vs time.

CONCLUSIONS

The present paper has presented examples of application of the PIT and shadowgraph visualization methods for the estimation of thermal boundary layer thickness in natural convection flows.

The first example shows the application of the PIT technique for the estimation of the thermal boundary layer growth carried out in a reservoir model subject to sudden cooling at the water surface. Two equivalent methods of measuring boundary layer thickness were presented, and both produced results consistent with the scaling prediction reported in [15].

The second example shows the application of the shadowgraph technique for measuring the early development of the thermal boundary layer adjacent to the sidewall of a differentially heated cavity following sudden heating. Based on shadowgraph images, the thicknesses of the thermal boundary layer at different heights were measured. The measurements are also consistent with the scaling relation reported in [15].

SPANWISE VORTEX STRUCTURE FROM AN IN-LINE FORCED OSCILLATING CIRCULAR CYLINDER

Y. Yokoi[1, *], K. Hirao[2]
[1]The National Defense Academy, Yokosuka, Japan
[2]Japan Air Self-Defense Force, Kakamigahara, Japan

ABSTRACT. In this study, the flow features of vortex shedding from a circular cylinder oscillating along the direction of the flow were observed by visualizing water flow experiment at the ranges of the frequency ratio f/f_K=0 ~ 5, amplitude ratio $2a/d$ = 0.4 and Reynolds number Re = 1700. As a result of the experiments, the structure of the vortex flow which depends on the frequency ratio was clarified by observing flow from both to the axial direction and the direction of span. In the case of lock-in state f_{VK}/f = 1/1, two kinds of vortex structure were obtained. One of which was three-dimensional on the side of low oscillation frequency, and the other was two-dimensional on the side of high oscillation frequency. In the case of lock-in state f_{VK}/f = 1/2, even if the lock-in had occurred, it was shown that the time difference sometimes occurred to the direction of the span in vortex shedding.

Keywords: *vortex, lock-in, in-line oscillation, flow visualization*

INTRODUCTION

The flow induced vibration problem is very important problem for engineering field so that there are many reports and useful knowledge has been accumulated by many researchers [1]. The 'lock-in' is the phenomenon which the vortex shedding frequency from a cylinder synchronizes with the frequency of cylinder vibration. And it is one of most interesting phenomenon in the field of flow induced vibration. In recent years, the review and the view about the flow-induced vibration including the lock-in phenomenon were reported by Griffin and Hall [2] and Okajima [3] [4]. Although there are many studies about the lock-in and its flow pattern, there are few reports which example to have examined to use a lock-in phenomenon effectively industrially. In order to examine the industrial use of the lock-in phenomenon, the lock-in range and the state of the flow at the time of lock-in must be more widely known in detail. Therefore, the systematically and scrupulous investigation by which the range of oscillation frequency and amplitude expanded becomes necessary, and database which accumulated the results is required. Yokoi and Hirao [5] investigated the effect of cylinder oscillation on vortex shedding and they show the flow pattern distribution in the lock-in region by flow visualization. In general, many of studies that observe the flow pattern from an oscillating cylinder and the range of the lock-in are observed from the plane including the cylinder section and there are few studies which observe from the direction of the cylinder span. It is important to understand the vortex structure with a three-dimensional aspect to understand the flow induced vibration problem. In this study, the flow features of vortex shedding from a circular cylinder oscillating along the direction of the flow were investigated from the direction of cylinder span by visualizing water flow experiment.

EXPERIMENTAL APPARATUS AND METHOD

Experimental apparatus

The experimental apparatus consists of a closed circuit water channel, a cylinder oscillator, a set of visual apparatus and set of data record equipment. Figure 1 shows the cover shot and the drawing of the closed circuit water channel. The closed circuit water channel is a vertical circulation type of 5.8m in length, 1.2m in width, and 2.5m in height, and the volume of water is 4 tons. The water channel is consisted of water flow generation equipment (2 axial flow type pumps), rectification device, test section and 4 corner parts with guide vanes. The test section is 2m in length, 0.8m in width, 0.4m in depth, and the flume structure with the surface of the water. In the test section, the window made of the glass of 1.5m in length and 0.4m in width has been installed in the both sides wall and the bottom for the observation. The velocity distribution in the test section was ±1.5% against main flow velocity 0.4m/s from depth 50mm-350mm and the test section center in the direction of width within the range of ±300mm. There is a set of rail orbit on the flume flange and a carriage is set up. The oscillator which installed CCD (charge-coupled device) camera and circular

cylinder, the visualization apparatus are loaded into the carriage. Figure 2 shows the schematic diagram of the cylinder oscillator. The cylinder oscillator is using a Scotch-yoke mechanism and the oscillator consists of a small-sized variable DC motor with a controller, a turn disk and a connecting rod. The amplitude of oscillation is set by changing the rotation radius of connecting edge on the turn disk, while the frequency of oscillation is controlled by changing the revolution speed of the turn disk.

Test circular cylinder and flow visualization method

The test circular cylinder is made from acrylic resin with 20mm of outside diameter, 16mm caliber, 440mm length. As shown in Figure 3, dye ooze ports (φ1mm) for the flow visual observation are arranged from a front stagnation point to the position of ±60° on the surface of the circular cylinder by two rows, and 50 and 51 ports are made respectively at intervals of 4mm. The row of the dye port becomes independent respectively, and can use the color of the tracer properly. An acrylic disk of 200mm in the diameter with 30° sharp edge is set up respectively at both ends of the circular

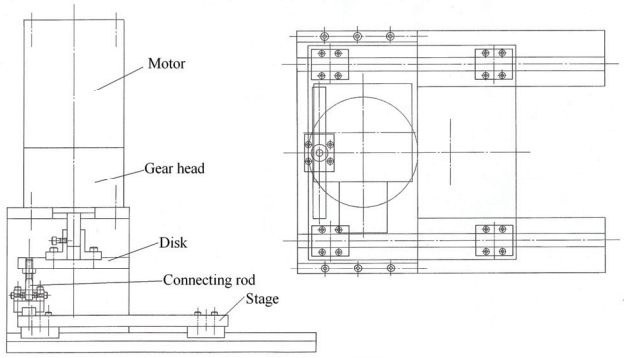

Fig. 2 Schematic diagram of the cylinder oscillator

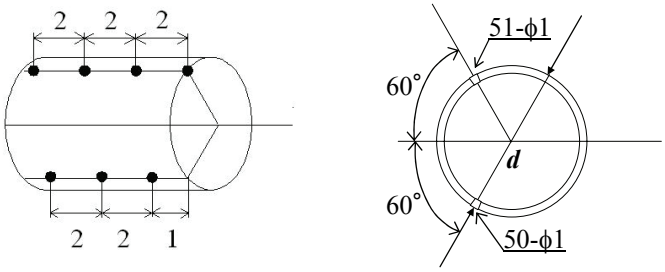

Fig. 3 Arrangement of dye ports on a surface of circular cylinder

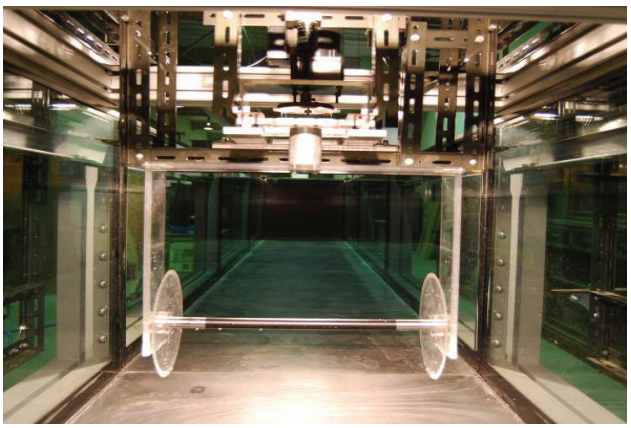

Fig. 4 Circular cylinder installation situation

cylinder span 400mm. As shown in Figure 4, the circular cylinder is installed in the oscillator by the horizontal posture through the holder arm to become 250mm under the surface of the water when the water level in the test section of closed circuit water channel is assumed to be 400mm, and oscillates periodically to the direction of the flow.

The flow visualization was performed with the aid of dye injection method. The tracer inks of two colors that the specific gravity is adjusted ('Color-fan': turquoise and fluorescent pink) are oozed from the dye ports on the surface of cylinder. Two halogen lamps (white light 500W) were used for the lighting, and it was applied from the observation window of both sides of the test section of water channel. Two CCD video cameras were used to take a picture of the aspect of the flow. One was set up to look about the direction of the span, and other one was set up as seen axially. The visualized flow patterns were monitored by the CCD video cameras and recorded on video tapes

Experimental parameters

The main experimental parameters given by the oscillation frequency ratio f/f_K (the ratio of circular cylinder oscillation frequency f to natural Karman vortex's frequency f_K), the amplitude ratio $2a/d$ (the ratio of half amplitude of cylinder motion a to the outside diameter of cylinder d) and the mean flow velocity U in the test section. The mean flow velocity U was 0.085 m/s which correspond to Reynolds number Re about 1700 ($Re=Ud/v$, where v is the kinematic viscosity of water. The amplitude ratio $2a/d$ was set 0.4, and the oscillation frequency ratio f/f_K was varied from 0.0 to 5.0.

Experimental procedure

The experiment was performed by the following procedures. The flow velocity of the test section is set by inputting the operating frequency to the operating control board. The oscillation amplitude of the circular cylinder is set with the cylinder oscillator. And, circular cylinder oscillation frequency f is gradually set based on the natural Karman vortex shedding frequency f_K which is shed from stationary cylinder. Two kinds of tracer ink for the flow visualization are oozed from the surface of the oscillating circular cylinder. The arrangement of colors of the tracer inks is assumed that the surface of the water side is fluorescent pink, and the bottom of the water side is a turquoise (blue). The visualized flow features were monitored with two CCD video cameras, and recorded in video tapes. Here, in this experiment, the observation point of vortex shedding frequency was $2.5d$ and $5.5d$ behind the cylinder. The vortex shedding frequency was obtained from the number and the measurement time of past vortex at the observation point. The cylinder oscillation frequency was measured by frequency analyzer.

EXPERIMENTAL RESULTS AND DISCUSSION

The visualized flow experiment that observed the direction of the circular cylinder span was performed based on a previous experimental result [5]. The variation of mean vortex shedding frequency ratio f_{VK}/f_K with oscillation ratio f/f_K is shown in Figure 5, in which the abscissa is the oscillation frequency ratio f/f_K and the ordinate is the vortex shedding frequency ratio f_{VK}/f_K. Two solid lines in the figure have the ratio of the vortex shedding frequency in case of the cylinder oscillation f_{VK} and the circular cylinder oscillating frequency f and mean the 'lock-in' status. Therefore, the occurrence of lock-in can be assumed when experimental data are shown on the line. It is noteworthy that if the vortex shedding frequency ratio f_{VK}/f_K is close to unity, the effect of the circular cylinder oscillation frequency on the vortex shedding frequency seems to be small. If there is no difference between f_{VK} and f_K, it means that the vortex shedding frequency f_{VK} is independent of the oscillation frequency f. It is shown to begin to receive the influence of the cylinder oscillation as the oscillation frequency increases, to enter the state of the lock-in of $f_{VK}/f=1/1$, the state of the lock-in of $f_{VK}/f=1/2$, and the state of the lock-in of $f_{VK}/f=1/1$, and to come off from the state of the lock-in. Here, the symbols from "A" to "H" in the figure show the observation points in this experiment.

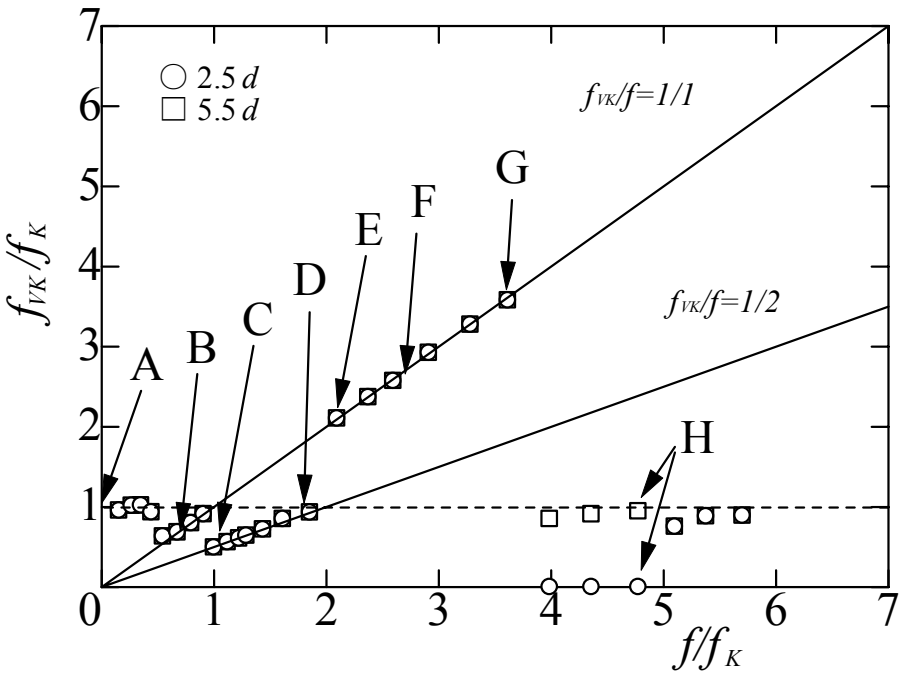

Fig. 5 Variation of mean vortex shedding frequency ratio f_{VK}/f_K with oscillation frequency ratio f/f_K

Figure 6 shows the flow visualization photographs of the vortex flow around a stationary or oscillating circular cylinder seen from the direction of the span. In order to facilitate the visual understanding of the vortex structure, the flow pattern seen from the direction of the cylinder axis is shown together in figure. Figure 6(a) shows the feature of the vortex shedding from a stationary circular cylinder in the direction of the span. The flow seems two dimensional when seeing axially because the vortex is alternately shed and Karman vortex street is formed. However, the tracer streak line swings when the flow feature is seen from the direction of the span. Therefore, it is surmisable that the flow around stationary circular cylinder is a three-dimensional flow. The characteristic of a three-dimensional separation flow on a stationary circular cylinder is reported by references [6] and [7]. It is one of the most interesting experiments of this study to examine how the characteristic of a three-dimensional separation flow on the oscillating circular cylinder changes.

Figure 6(b) shows the flow feature of the low frequency side of the f_{VK}/f=1/1 lock-in. The vortex structure of the direction of the span is three-dimensional though vortices are shed simultaneously from both sides of the circular cylinder.

Figures 6(c) and 6(d) show the flow feature of the f_{VK}/f=1/2 lock-in state. Figure 6(c) shows the flow feature on the low frequency side of the f_{VK}/f=1/2 lock-in. Although vortices are shed simultaneously from both sides of the circular cylinder, an alternate vortex street is formed because the direction of vortex shedding has changed. A complex flow feature can be seen by seeing from the direction of the span. As for the roll of the separated shear layer, it is seen not two dimensional because there is locally a time difference. The direction of the vortex shedding will change in an arbitrary circular cylinder section because the roll of the lower side separated shear layer that a blue tracer shows and the roll of the upper side separated shear layer that a pink tracer shows exist simultaneously attended with the time difference. When the cylinder oscillation frequency f is increased further, the vortex of the mushroom section shape is formed as shown in

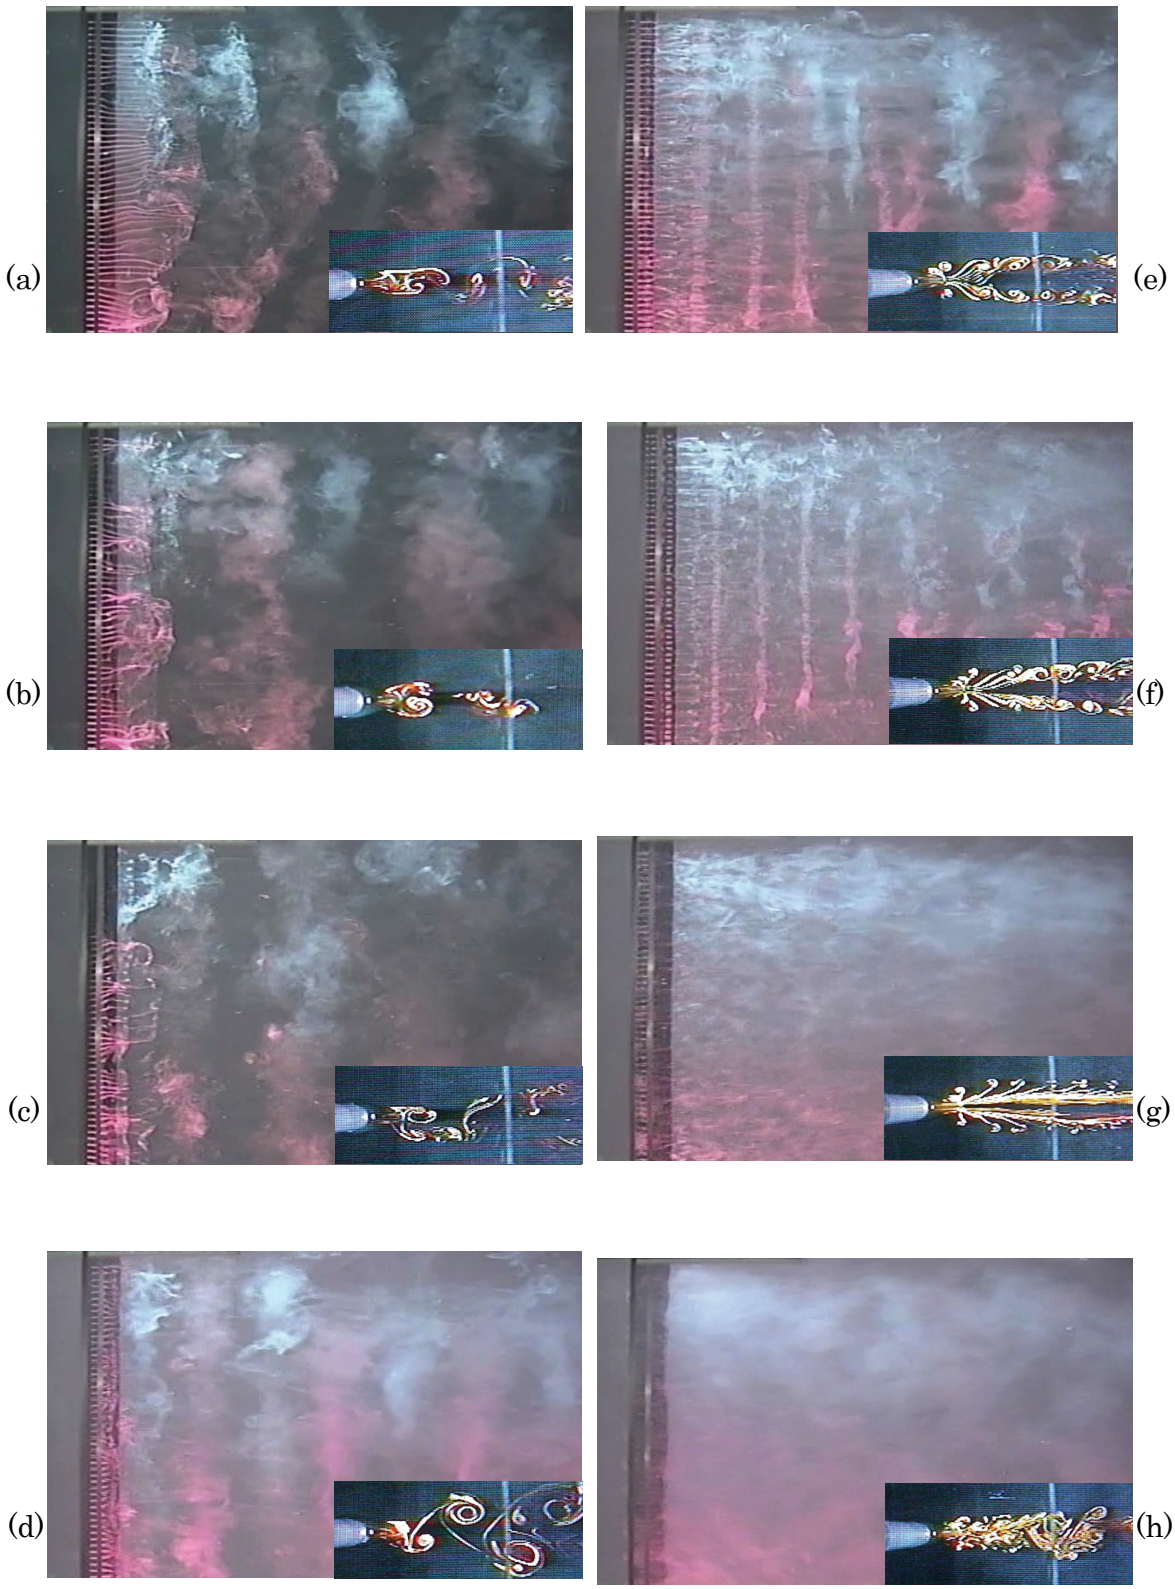

Fig. 6 Representative flow patterns, (every points correspond to Fig. 5)
(a) f/f_K=0.00, (b) f/f_K=0.71, (c) f/f_K=1.09,
(d) f/f_K=1.94, (e) f/f_K=2.06, (f) f/f_K=2.85,
(g) f/f_K=3.59, (h) f/f_K=4.85,

Figure 6(d). It shows the flow feature on the high frequency side of the f_{VK}/f=1/2 lock-in. It was observed to become a two dimensional vortex structure though there was no time difference in the roll of the separated shear layer in the direction of the span in such a case. It was obtained that the structure of the vortex flow was different because of the existence of the time difference of the roll of the vortex in the direction of the span even if it was the same state of the f_{VK}/f=1/2 lock-in.

It becomes the lock-in of f_{VK}/f=1/1 on the high frequency side when the vibration frequency is increased, and the symmetry vortex street is formed as shown in Figure 6(e). In this case, the roll of the vortex in the direction of the span is two dimensional, and it is understood that the union of the vortex in the same direction of the rotation is shown in the cylinder wake. Vortices of the mushroom section shape are shed as shown in Figure 6(f) when the cylinder oscillation frequency f is further increased and the stagnation area where an unstable wave like as Kelvin-Helmholtz's instability was accompanied is formed. In this case, the vortex structure of the direction of the span seems to be two dimensional, and it is observed that the character is kept long. Figure 6(g) shows the flow feature when the oscillation frequency is increased more than the state of Figure 6(f). Small vortices of the mushroom section shape are shed from both sides of the circular cylinder and a long stagnation area is formed. However, remarkable horizontal vortexes are not seen in this case in the vortex structure of the direction of the span.

Figure 6(h) shows the flow feature in the state of non lock-in. It is shown that the discharge of the vortex becomes massive, unites some of that, and forms the oscillation flow. However, the vortex structure of the direction of the span cannot be clearly captured by this flow visualization technique.

These photographs show that the discharged vortex structure depends on a three dimensional character in the direction of the span. In order to clarify such a correlation, the simultaneous observation from axially and the direction of the span becomes important. And, it is likely to become a research topic in the future. In the vortex shedding from the circular cylinder that oscillating in the direction of the flow, it was clarified that the vortex structure was different depending on the oscillation frequency ratio f/f_K in the same state of the lock-in as a result of investigating the span-wise vortex structure. For the case of f_{VK}/f=1/1 lock-in, there are two lock-in areas. Figure 6(b) shows the state of the lock-in caused on the low frequency side, and the span-wise characteristic is not two dimensional. On the other hand, Figures 6(e) and 6(f) show the state of the lock-in caused on the high frequency side, and the span-wise characteristic is two dimensional. Moreover, for the lock-in of f_{VK}/f=1/2, the characteristic is different because it depends on the oscillation frequency ratio f/f_K in the lock-in area though the lock-in area is one. As shown in Figures 6(c) and 6(d), it has been understood that there is the time difference (time delay) is in the roll of the vortex in the direction of the span on the low frequency side and there is no time difference on the high frequency side.

CONCLUSIONS

Focusing on the appearance of the three-dimensional instability in separated flow, a flow visualization study on features of boundary layer separation over an oscillating circular cylinder was performed. The following conclusions were obtained.

(1) In the vortex shedding from an oscillating circular cylinder in the direction of the flow, the appearance of the flow feature of the direction of the span corresponding to the flow pattern of the vortex flow seen axially was obtained.

(2) As for the same state of the f_{VK}/f=1/1 lock-in, the structure of the direction of the span was observed to differ on the low frequency side and the high frequency side. Two kinds of vortex

structure were obtained. One of which was three dimensional on the side of low oscillation frequency, and the other was two dimensional on the side of high oscillation frequency.

(3) In the case of lock-in state f_{VK}/f=1/2, even if the lock-in had occurred, it was shown that the time delay sometimes occurred to the direction of the span in time of vortex shedding. It has been understood that the time delay decides the characteristic of the flow. That is, when there is no time difference in the direction of cylinder span at the roll of the vortex, the characteristic of vortex structure becomes two dimensional, and when there is a time difference in the direction of cylinder span at the roll of the vortex, the characteristic of vortex structure becomes three dimensional.

VELOCITY AND CONCENTRATION FIELD OF DISCHARGE FROM A BOAT PROPELLER

R. Situ*, R. J. Brown, A. Loberto
School of Engineering Systems, Queensland University of Technology, Brisbane, Australia

ABSTRACT. Two-stroke outboard boat engines using total loss lubrication deposit a significant proportion of their lubricant and fuel directly into the water. The purpose of this work is to document the velocity and concentration field characteristics of a submerged swirling water jet emanating from a propeller in order to provide information on its fundamental characteristics. Measurements of the velocity and concentration field were performed in a turbulent jet generated by a model boat propeller (0.02 m diameter) operating at 1500 rpm and 3000 rpm. The measurements were carried out in the Zone of Established Flow up to 50 propeller diameters downstream of the propeller. Both the mean axial velocity profile and the mean concentration profile showed self-similarity. Further, the stand deviation growth curve was linear. The effects of propeller speed and dye release location were also investigated.

Keywords: *propeller, swirl jet, turbulence, concentration field, self-similarity*

INTRODUCTION

Boats and ships release approximately 1.0 million tonnes of oil into the marine environment worldwide each year [1]. In addition, significant quantities of unburned fuel, toxic combustion by-products and well over 14 million tonnes of antifouling agents (tri-butyl tin) are directly released into the water and dispersed by the vessels' propeller annular. In all situations, propellers create considerable turbulence, which thoroughly mixes pollutants and chemicals into the water. While there has been considerable research on propellers for ship propulsion, very little research has been done on the dispersing action of the propeller. Nevertheless, to estimate the effective contaminant concentrations emitted by vessels, it is of great importance to quantify flow field in the jet region.

Turbulent jet flow issued from an orifice has been investigated for more than fifty years. Albertson [2] classified the jet diffusion into two zones: the Zone of Flow Establishment (ZFE), and the Zone of Established Flow (ZEF). The ZFE starts from the outlet of the orifice and ends where mixing with surrounding fluid reaches the centreline of the jet. In the follow-up ZEF, the cross-sectional mean axial velocity profiles exhibit a Gaussian normal distribution and dynamic self-similarity. Furthermore, the velocity profile is independent of the details of the generating source of the jet [3]. Hence, this self-similarity can also be found in a swirling jet and an impeller jet. A swirling jet is characterised by the presence of the centrifugal effect that produces transverse and longitudinal pressure gradients. It is widely used in different technological processes and in engineering. The swirling flow may be generated by: i) mixing of tangential flow with axial through-flow [4, 5]; ii) rotating long pipe [6–8], and iii) vanes for turbines, compressors, or propellers [3, 9, and 10].

Although many investigations have been attempted on air swirling jets, only a few workers have studied the limited range of a water jet emanating from a propeller [11]. The purpose of this paper is to document the velocity and scalar field characteristics of a water swirling jet, and to provide information on the fundamental characteristics of such a jet far enough downstream to make it relevant to the eventual modelling of this mixing problem.

EXPERIMENTAL FACILITY AND PROCEDURES

The experimental setup comprised a three-bladed propeller, powered by a variable speed electric motor with flexible cable transmission, held in space by an aerofoil-shaped frame where the long axis coincides with direction of flow. A schematic showing the major experimental spatial parameters can be seen in Figure 1. The axial coordinate referred to throughout this paper is the *x*-axis shown, while the tangential coordinate is perpendicular to the page in Figure 1 as it is tangential to the propeller blade rotational plane. The source of the jet used in this experiment was a commercialised scale-model boat propeller made of three brass blades. The propeller tip diameter, D_p, was 20 mm. Dye was released at a constant volume flow rate for each profile from two point locations, namely: i) upstream of the propeller by 4 mm along the centreline and 8 mm above the axis of rotation, ii) downstream, symmetric in the *x-y* plane with above. The internal diameter of the injection pipe was 1 mm. The flow of dye was constant maintained by a syringe pump driven from a feed screw running at a constant rotational speed.

The tests were conducted in the closed loop flume at the Department of Mechanical Engineering at Kyoto University, Japan. The flume had dimensions of 12 m (L) × 0.4 m (W) × 0.2 m (H). The water level and also the volume flow rate in the flume were controlled with a straight edged weir at the exit and a header tank. The water level was held at 150 mm for all experiments. The Reynolds numbers for the jet flow in these experiments were 1.4×10^4 and 6.2×10^4 respectively, corresponding to propeller speeds of 1500 rpm and 3000 rpm. The ambient velocity and characteristic length for the flume is 0.04 m/s and 0.086 m respectively. The maximum error in the alignment of the test rig was less than 0.25%. The error in velocity measurements was mainly due to refractive index fluctuations, and was estimated to be 0.3%.

Instantaneous stream-wise and vertical water velocities were simultaneously measured by using a two-colour laser-Doppler velocimeter (LDV, DANTEC 55X) [12]. The turbulent intensity and Reynolds stress were also measured. The mean and fluctuations in the concentration were measured with a Komori concentration probe, held in place by an adjustable frame. The Komori probe has a frequency response of up to 100 Hz sampled at rate of 1 kHz. The average maximum variation in back to back mean concentration measurements across a vertical array of data was found to be around 300% [12].

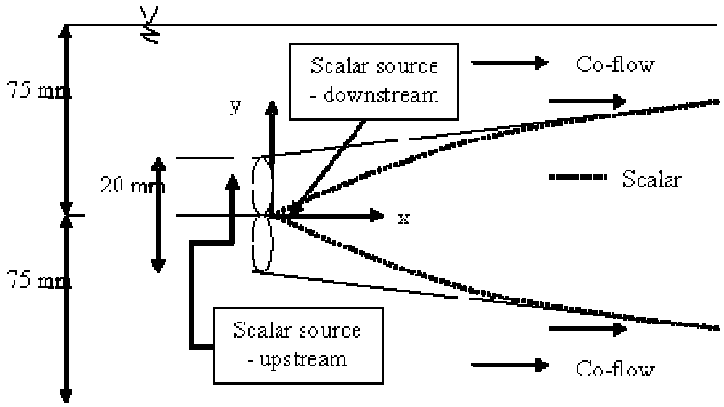

Figure 1. Schematic diagram of experimental setup.

EXPERIMENTAL RESULTS AND DISCUSSIONS

Radial profile of velocity distribution

In current study, velocity measurements were taken from $2.5D_p$ downstream. This means that the jet flow was already established and measurements in the ZFE were not possible. It has been shown in experiments with similar experimental conditions that the mean velocity profiles for a propeller becomes self-similar between approximately $2D_p$ and $3D_p$ [3] and thus the measurements were taken in the ZEF. The practical outcome of this is that from this point further downstream the radial distribution of the mean axial velocity will take on the shape of a Gaussian profile [11].

Mean axial velocity. The full radial fields of mean axial velocity data are displayed for two propeller speeds, N, 1500 rpm and 3000 rpm in Figure 2. The normalisation constant is the tangential tip velocity of the propeller, $U_p = 2\pi NR_p$. Each figure contains five series, representing different axial downstream locations from $2.5D_p$ to $50D_p$. Both figures illustrate the tendency for a slight drift toward the free surface at both speeds. At $x/D_p = 2.5$, within the radial band of $+/-1D_p$, there is some evidence of the local peak velocities from the blades still remaining with the peak velocities occurring either side of the centreline. Inside the ZFE, the axial velocity will vary with radial position along the blade. The position of maximum velocity coincides with the position of maximum thrust and this is taken to be located between $0.5R$ to $0.7R$ [3, 10, 11]. The results here appear to lie approximately in this zone, and they are similar to those described by Petersson et al. [10] where a three-bladed mixer operated in weak co-flow at 1800 rpm. His particular experiment showed a peak of 0.19 at about $r/D_p = 0.25$ at $x/D_p = 2$, whereas here a peak of about 0.35 at around $-0.5D_p$ from the axis at $x/D_p = 2.5$ was observed. Both 1500 rpm and 3000 rpm results show very similar peak magnitudes and location and asymmetric pattern, with good internal consistency. Also, note the small areas of low amplitude negative velocity around $y/D_p = -1$ to -3 at this close proximity to the propeller due to recirculation flow.

Between $x/D_p = 4$ and 6 the peak normalised axial velocity was 0.13–0.10 and the off-axis peak eroded away [10]. Figure 2(a) shows a centred peak of 0.25 at 1500 rpm, while Figure 2(b) shows a broad peak around 1.5 D_p wide (radial) with a magnitude of about 0.21 (both were at $x/D_p = 5$). At $x/D_p = 10$, Figures 2(a) and 2(b) both exhibit a peak of 0.17 while the result of Petersson et al. [10] was approximately 0.08. Their result at $x/D_p = 12$ is similar and those results cease at that point. At $x/D_p = 20$, both figures show similar peaks and distribution, although both are becoming less consistent by this stage. Further downstream at $x/D_p = 50$, both jets are degraded badly and, interestingly, 3000 rpm has half the relative velocity of 1500 rpm. In general, the experiment with

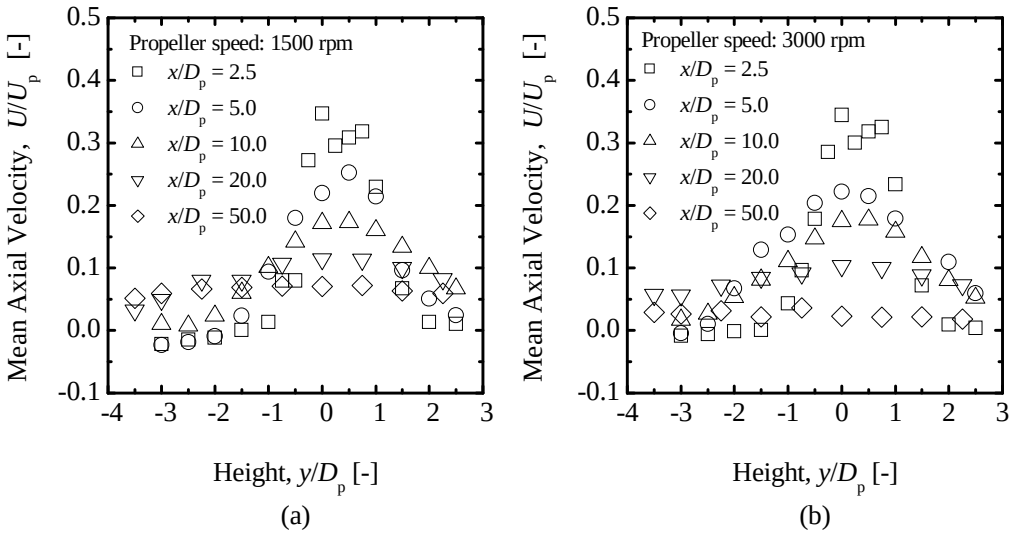

Figure 2. Mean axial velocity profiles.

the small propeller showed relative velocities greater than 1.5–2.0 times those of the three-bladed mixer of Petersson et al. [10], possibly due to the blade profile variations and the emphasis on thrust versus mixing in the case of the smaller 20 mm propeller.

Self-similarity. The mean axial velocities shown in Figure 2 are normalised in Figure 3 with the fitting Gaussian function expressed as:

$$U = U_{\mathrm{m}} \exp\left[-\frac{1}{2}\left(\frac{y-\delta}{\sigma} \right)^2 \right] \tag{1}$$

where U_{m}, δ, σ are local maximum mean axial velocity, vertical offset, and standard deviation, respectively. The vertical offset is determined as the vertical position of the jet maximum velocity relative to the geometric centreline. Since the jet is fully developed into the ZEF by the first measuring position, the evidence of local maximum velocities along the blade vanished and the jet only displays a single maximum. This equation was used by Brown and Bilger [13] for the study of reactive plumes. In contrast to other forms, such as that used by Petersson [10], all the key parameters of magnitude, width, and position are stated explicitly and thus can be exclusively fitted to record physically meaningful statistics about the flow. Figure 3 shows that the data is self-similar at 1500 rpm for all measured locations from $2.5D_{\mathrm{p}}$ to $50D_{\mathrm{p}}$. However, at 3000 rpm the $50D_{\mathrm{p}}$ location failed to allow for a Gaussian profile to be fitted. At this condition the relative mean axial velocity was consistently half what it was at 1500 rpm, right across the whole radial distribution.

Mean tangential velocity. Figure 4 shows the mean tangential velocity distribution at 1500 rpm and 3000 rpm. At both speeds there is a common pronounced peak near the radial position of y/D_{p} = 0.5; this indicates a solid body rotation of water that quickly dissipates downstream [10]. Only at the 3000 rpm condition this structure is maintained to $5D_{\mathrm{p}}$ downstream. This peak at $5D_{\mathrm{p}}$ also moves radially outward from the propeller axis as the swirling jet begins to spread.

A tangential velocity plot where all the data series tend to zero at the axis would indicate good alignment of the measuring apparatus and experimental rig. There is evidence of this trend in Figure 4, but it is not as strong as that exhibited in other similar experiments [10]. Along with a lack of symmetry, this might also be due to the misalignment, which may have even contributed to the far field collapse of the jet at the 3000 rpm condition since the jet edges were being affected by the boundaries and the tolerance for misalignment would be low in these circumstances.

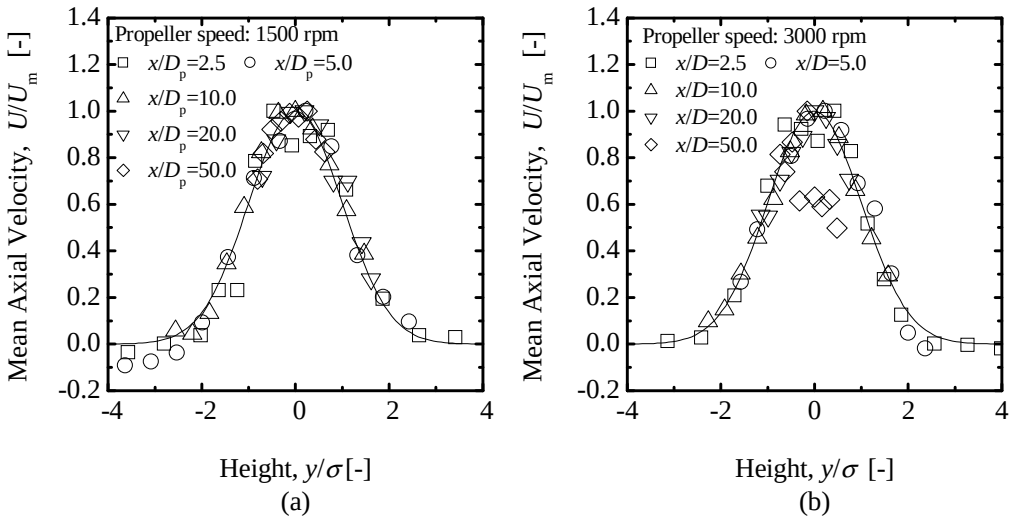

Figure 3. Normalised mean velocity profiles.

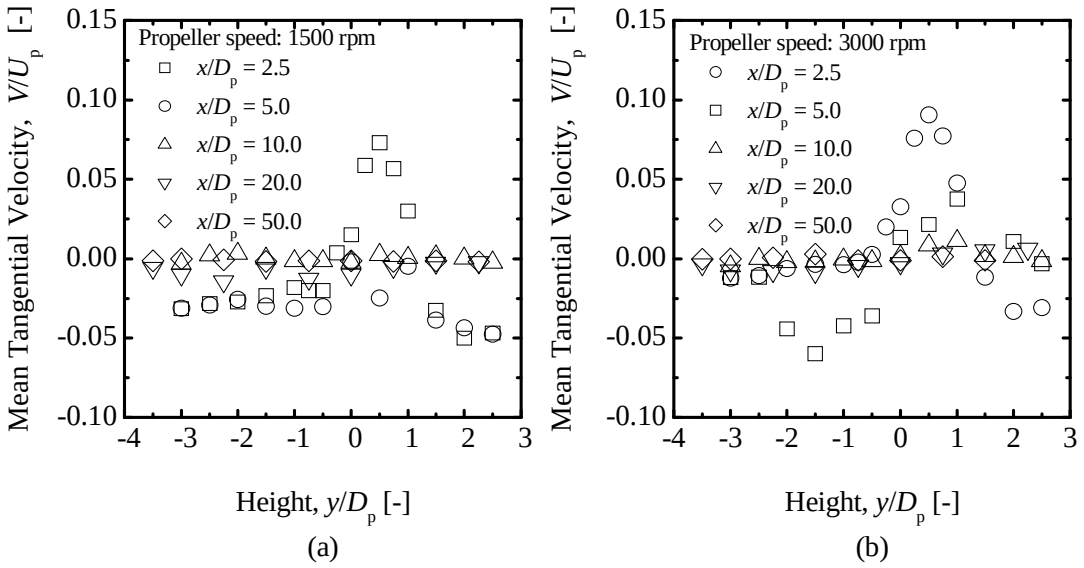

Figure 4. Mean tangential velocity profiles.

Mean axial flow field

Standard deviation growth. As explained earlier, the flow structure in the ZEF shows self-similarity, and the standard deviation of the fitted Gaussian function grows along the flow. Figure 5(a) displays the growth trend of the standard deviation of the water swirling jets for the current study and Petersson et al.'s study [10]. Both datasets displays linear growth with the axial direction. The similar growth trend of standard deviation for air jets are shown in Figure 5(b), where D_0 is the diameter of the orifice or nozzle from which air is issued. The degree of swirling jet is described by a dimensionless swirl number [4] as:

$$S \equiv G_\theta / RG_x = 2\pi\rho \int_{r=0}^{\infty} r^2 UV dr \Big/ R \cdot 2\pi\rho \int_{r=0}^{\infty} r\left(U^2 - \frac{V^2}{2}\right) dr \qquad (2)$$

where R is the radius of the orifice or nozzle, and ρ is fluid density. According to this definition, the swirl numbers for the current study are 0.23 for 1500 rpm and 0.33 for 3000 rpm, respectively.

Volume flux and entrainment. The volume flux, Q, was calculated by integrating the mean velocity profile at each downstream station as:

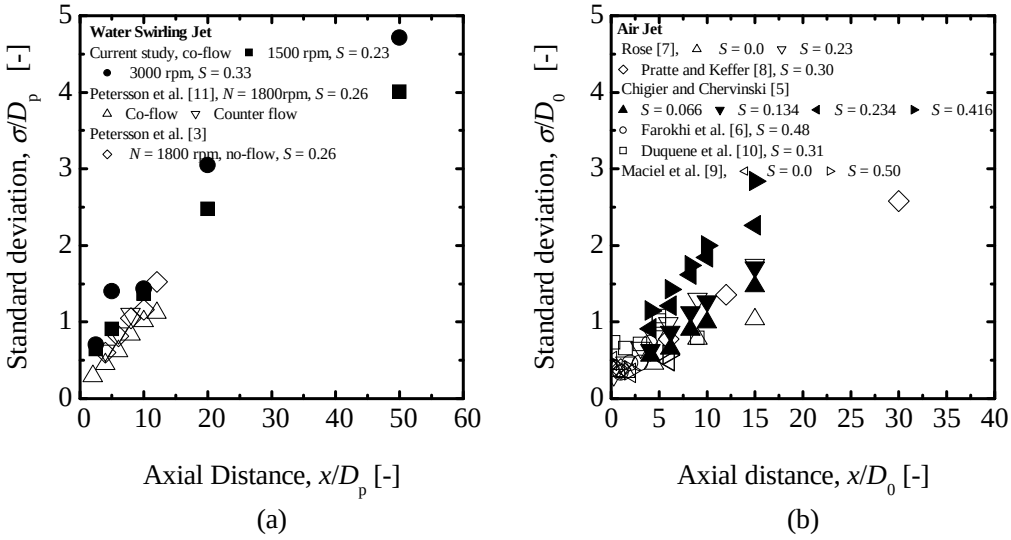

Figure 5. Standard deviation of the mean velocity profile.

$$Q = 2\pi \int_{r=0}^{\infty} rUdr \tag{3}$$

and is normalised against the source momentum $Q_0 = \pi R^2 U_p$. The normalised volume fluxes for both water and air jets display a growth trend along the axial distance in Figure 6. The volume flux at $x = 50D_p$ is not shown for two reasons. First, the self-similarity breaks down most downstream from the propeller, and the flow is more dependent on the ambient flow. Second, the walls of the flume are seemingly affecting the entrainment; this was also pointed out by Petersson et al. [3].

Figure 6 (a) shows that the normalised volume flux of the current data is about four times higher than those obtained by Petersson et al. [10]. The standard deviations of the two datasets are similar, as shown in Figure 6(a). This large difference is mostly due to the difference in the amplitudes of axial velocity. Figure 6(b) plots the normalised volume flux for air jets by Rose [6] and Chigier and Chervinsky [4]. It clearly shows that in an unconstrained jet one would expect to see continual steady growth with increasing distance downstream. Furthermore, the volume flux increases with increasing swirl number, which tends to entrain more ambient fluid into the jet. In addition, the correlation proposed by Albertson [2] agrees well with the data for non-swirl flow ($S = 0$).

Concentration field

Mean concentration field. The mean concentration field was recorded at five measuring stations, i.e., $x/D_p = 2.0$, 2.5, 5, 10, and 20, with the source both upstream and downstream of the propeller. The downstream source experiment was only conducted at a propeller speed of 3000 rpm, and the upstream experiment was conducted at both 1500 rpm and 3000 rpm. The collection of data sets is collapsed using self-similarity as shown in Figure 7 The full suite of data is displayed in subsequent sections relating to the individual parametric trends of C_{max}, r' and σ. Comparison between upstream release data, shown in Figure 7(a) and 7(b) indicated that the plume takes longer to establish self-similar behaviour at 3000 rpm. The data points at measuring stations closer to the source tend to fit less well to a best-fit Gaussian curve. On the other hand, the effect of dye release location can be found by examining Figure 7(b) and 7(c). The figures show that placing the scalar source upstream of the propeller would superimpose a more complex and varied mixing regime.

Mean concentration plume standard deviation growth. The rate of spread of the plume was similar in general for all three experimental conditions. This is shown in Figure 8(a): the standard

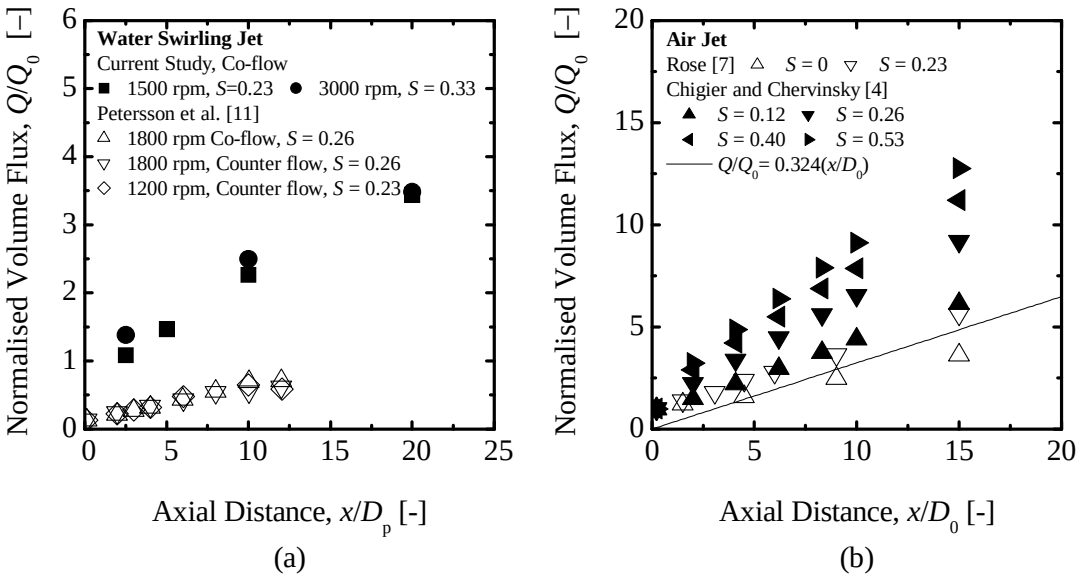

Figure 6. Nomalised volume flux development for water and air jets.

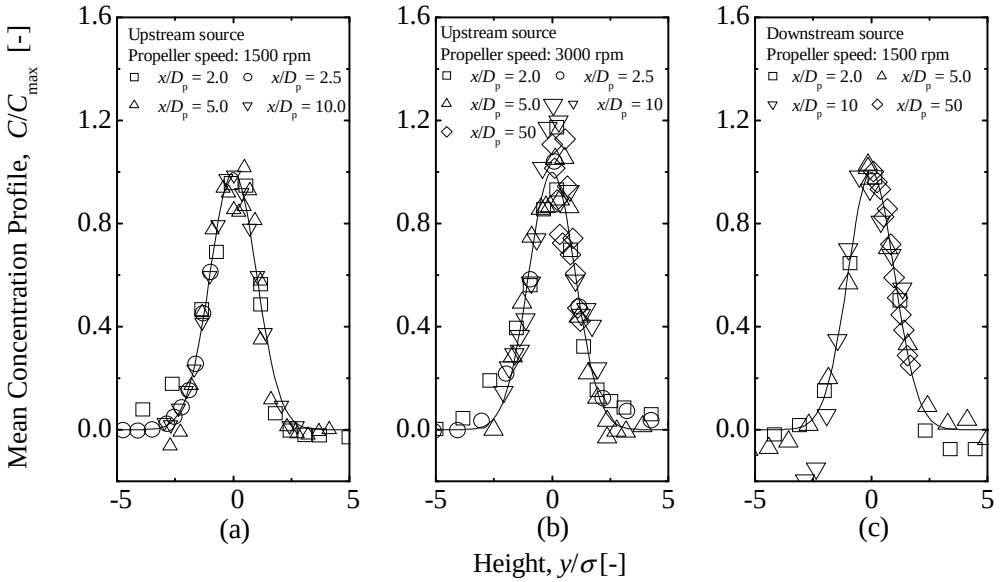

Figure 7. Normalised mean concentration profiles.

deviation of the mean concentration profile. Comparison between these three conditions shows that higher propeller speeds push the virtual origin further upstream (from 2.1 D_p for 1500 rpm to 3.6D_p for 3000 rpm; both for upstream release), and upstream source produces a higher concentration flux spread (7.2° for 3000rpm) than for a downstream source (5.6°).

Concentration Flux Integral. A concentration flux can be calculated in the same way that the velocity field was integrated to calculate volume fluxes:

$$F = \pi \int_{r=0}^{\infty} rUCdr \tag{4}$$

Equation (4) shows that this calculation integrates the products of the instantaneous mean velocity and concentration to give a quantity in the units: ppm.m^{3}s^{-1}. This integral flux trend is displayed in Figure 8(b), normalised against the known source flux, F_s. Figure 8(b) indicates that concentration flux was mainly preserved up to 50 D_p downstream, and the source location has a larger affect than rpm. The decay of mean Gaussian concentrations were dependent on velocity but the radial spreading was dependent on the source condition. The concentration flux integral should be affected to some extent by both of those phenomena because they collectively define the radial concentration

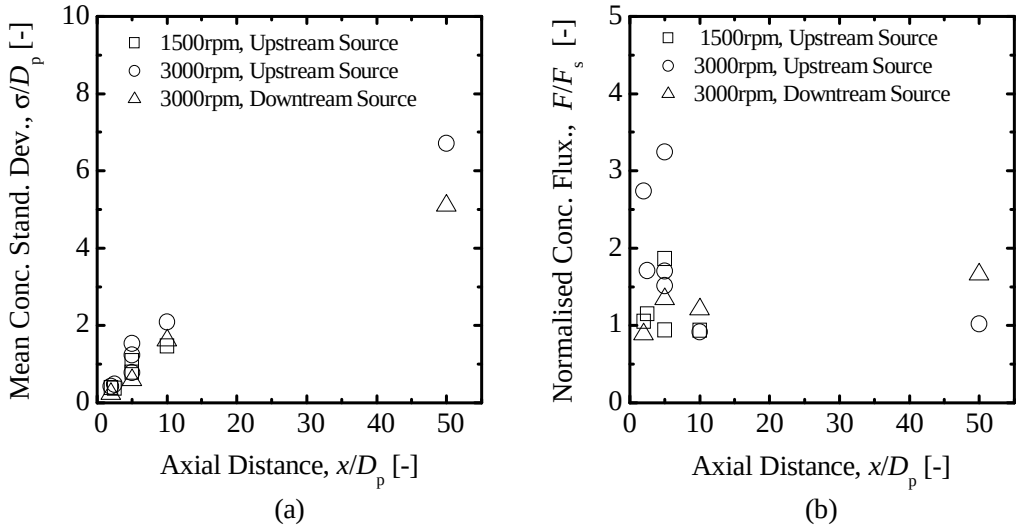

Figure 8. Axial concentration profiles.

profile that has been integrated here. However, at two different speeds, the two upstream source experiments exhibit a similar integral trend, decaying to 10 D_p then settling at a normalised flux of unity. The downstream sourced integral starts around unity and climbs toward 1.5 by $50D_p$.

CONCLUSIONS

Two-stroke outboard boat engines using total loss lubrication deposit a significant proportion of their lubricant and fuel directly into the water. Emissions of outboard motors are largely unaddressed in the literature and could be critical because the exhaust of most outboard engines is released below the water and mixed by the action of the propeller. The purpose of this work is to document the velocity and concentration field characteristics of a submerged swirling jet emanating from a propeller. Measurements of the velocity field (axial and tangential) and concentration field were performed in a turbulent jet generated by a model boat propeller (0.02 m diameter) operating at 1500 rpm and 3000 rpm in a weak co-flow of 0.04 m/s. The measurements were carried out in the ZEF up to 50 propeller diameters downstream of the propeller that was placed in a glass-walled flume, 0.4 m wide with a free surface depth of 0.15 m. Mean velocity and concentration distribution results are presented. Self-similarity of the mean axial velocity and concentration is preserved up to 20 propeller diameters from the propeller. The standard deviation of the fitting Gaussion profile of mean axial velocity and mean concentration shows linear growth along the axial distance. Furthermore, the volume flux shows linear growth while axial momentum flux is mainly preserved for the current data. The effects of propeller speed and dye release location on the velocity and scalar field were also investigated.

THERMAL AND HYDRODYNAMIC STUDY OF A FLAT PLATE HEAT PIPE

S. Lips, F. Lefèvre [*], J. Bonjour
Université de Lyon, CNRS
INSA-Lyon, CETHIL, UMR5008, F-69621, Villeurbanne, France

ABSTRACT. An experimental study of a flat plate heat pipe having a capillary structure made of rectangular grooves is presented. Its thermal performance and hydrodynamic behaviour is analysed for two different filling ratios and for different heat fluxes. A confocal microscope is used to determine the shape of the liquid-vapour interface, and particularly, the value of the meniscus curvature radius along the grooves. The uncertainties associated to this experimental method are discussed. The importance of coupling both thermal performance and pressure drop determination in order to validate numerical models is shown. A good agreement is found between numerical and experimental results.

Keywords: *Flat heat pipe, meniscus curvature, thermal resistance, micro-grooves, confocal microscope*

INTRODUCTION

Flat plate heat pipes (FPHP) are micro-fluidic devices that are usually designed for thermal management of electronic components [1]. They can also be used in others applications, such as the cooling of proton exchange membrane fuel cells [2]. They are used for their heat transfer capacity as well as their capacity of homogenizing the temperature of the heat source.
A FPHP is a cavity of small thickness filled with a two-phase working fluid. Heat sources and heat sinks are located anywhere on the cavity with the other parts being insulated. Heat is transported from heat sources to heat sinks by vaporization of the liquid and condensation of the vapour. The parts of the system where evaporation and condensation occur are the evaporator and the condenser, respectively. The liquid returns from the evaporator to the condenser through a capillary structure made of micro-grooves, meshes or sintered powder wicks.
A lot of works have been published on flat heat pipes and several numerical models have been proposed in order to predict the thermal performance and/or the capillary limit of FPHP or micro heat pipes [2-10]. These models are based on hydrodynamic and thermal governing equations for fluid flow that are solved numerically or analytically. Hydrodynamic and thermal behaviours of a FPHP are highly correlated to the liquid/vapour interfacial shape, and especially the meniscus curvature radius. The major part of the heat flux is transferred through thin films at both the evaporator and condenser locations. Thus, heat transfer phenomena are highly linked to hydrodynamic parameters and to interfacial properties. Although a lot of works have been published on flat plate heat pipes, the literature is poor in experimental papers. Furthermore, the provided measurements are not sufficient to describe the behaviour of these systems, but only to estimate their overall thermal performance. The physical phenomena that drive a heat pipe are complex and cannot be understood only with temperature sensors. Indeed, measurements of the location and the shape of liquid films

inside a heat pipe are required in association with temperature measurements to understand the physical mechanisms that drive the system.
In this communication, we present an experimental study of the thermal and hydrodynamic behaviour of a FPHP with micro-grooved as its capillary structure. A confocal microscope is used to measure the meniscus curvature radii in the grooves. The uncertainties due to this experimental method are discussed. The importance of coupling both thermal and hydrodynamic measurements is shown.

EXPERIMENTAL SET-UP

The flat plate heat pipe test apparatus

The flat heat pipe under investigation is shown in figure 1. Its capillary structure, of dimensions 70×90 mm², is made of 88 longitudinal micro-grooves machined in a copper plate. Each groove has a rectangular cross-section of height and width equal to 400 µm. The distance between two grooves is equal to 400 µm. The wall thickness under the grooves and the vapour space are equal to 3 mm and 2 mm respectively. The FPHP is hermetically sealed on its upper face with a transparent plate, which allows the liquid-vapour meniscus observation in the grooves. A filling copper pipe closed by a valve is sealed on the grooved plate at the extremity of the condenser. The heat source is located on the copper wall (Figure 2). It is a heated copper block of dimensions 70 × 20 mm^2 supplied by a 0 - 220 V AC power supply. Electric power is obtained by measuring the voltage drop across the heating resistor and the current, thanks to a calibrated resistance. The heat sink is a water heat exchanger of dimensions 30 × 70 mm^2. The water flow rate is constant and the inlet temperature is controlled by means of a thermostatic bath in order to have a constant working temperature when the heat input increases. The heat source and the heat sink are separated by an adiabatic area of length equal to 40 mm. Two series of nine calibrated thermistors are located symmetrically along the FPHP wall. They are fixed thanks to silver lacquer in small grooves that were machined in the wall in order to reduce the contact resistance (figure 1). The value of their resistance is recorded by a Keithley 2700 multimeter. The working temperature of the FPHP is the saturation temperature T_{sat}, which is determined as the mean temperature of the six thermistors located in the middle of the adiabatic zone. The FPHP is thermally insulated during the thermal tests. Before the thermal tests, the FPHP is degassed and filled carefully [2].

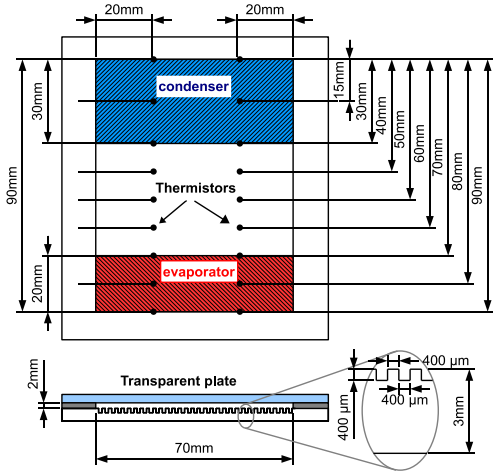

Figure 1: Schematic of the FPHP

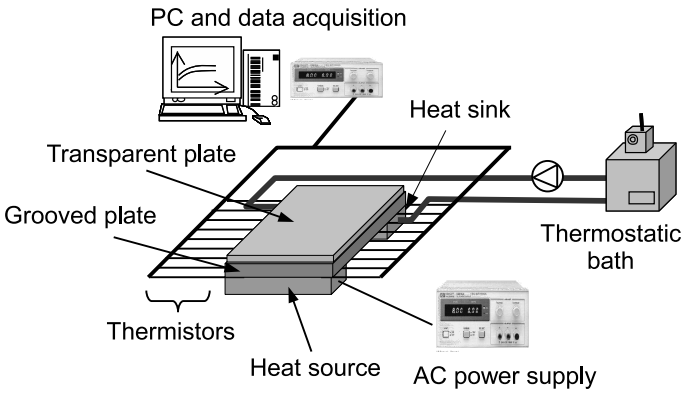

Figure 2: Schematic of the flat heat pipe test apparatus

Confocal microscopy

Measurements of hydrodynamic parameters in a FPHP are difficult: most of non intrusive standard methods are not useful in such an application. For example, the process of insemination used in micro PIV is not appropriate. Indeed, particles introduced in the liquid would be blocked at the evaporator because of their non evaporative properties. Measurements by means of a camera or image-analyzing interferometry through a transparent system are not feasible. Indeed heat sources and heat sinks have to be located on the system, which prevents any optical system to pass through the FPHP. As a result, the liquid film has to be measured from above and not from under. Furthermore, the experimental bench should sustain high pressure variations that occur in working conditions. Among non intrusive methods, confocal microscopy is well adapted to characterization of the liquid/vapour interfacial shape in the capillary structure. The FPHP must be tightly sealed thanks to a transparent plate in order to realize measurements in saturated atmosphere.
Optical principles of confocal microscopy are described in figure 3. A white light point source is decomposed by a chromatic aberration lens into a series of monochromatic point images in the measurement space. The reflected light passes back through the lens and is directed towards a spectral detector by a semi-transparent beam. The spectral analysis of the collected lights that are separated by a spatial filter allows the location of the surface to be measured. The monochromatic light having the highest intensity corresponds to the surface to be measured.
The confocal microscope is a STIL Micromesure 2 system. The chromatic aberration lens is fixed on a motorized system in the *z* direction. The optical sensor has a nominal measuring range of 350 µm and the working distance is about 13 mm. The diameter of the spot is equal to 3 µm. As the measurement is punctual, the FPHP is fixed on a micrometric motorized table in *x* and *y* directions, which allows to achieve profile and surface measurements. The uncertainty in z direction is equal to 60 nm. The optical system has been calibrated to take into account the characteristics of the transparent sealing plate.
The visualisation of profiles or surfaces is limited to steady state configurations. Indeed, the scanning time can vary from few seconds for a small profile to several hours for a surface measurement in high resolution. As a result, the use of confocal microscopy for the study of transient phenomena is difficult and is limited to punctual measurements or to small profile measurements.

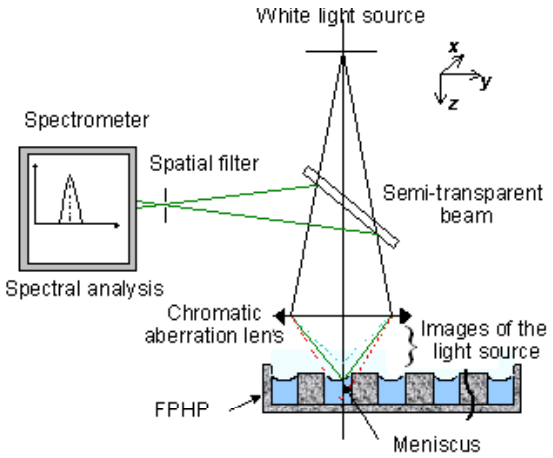

Figure 3: Confocal microscopy principles

EXPERIMENTAL RESULTS

Measurement of the meniscus curvature radius

The thermal and hydrodynamic performance of the FPHP has been characterized for different heat fluxes from 0 W to 88 W and for two different filling ratios f_r. For higher heat fluxes, measurements by confocal microscopy are not possible because of boiling phenomena at the evaporator [11]. Figure 4 presents an example of two profiles obtained at the condenser and at the evaporator of the FPHP. The menisci and the top of the fins are visible. At the evaporator, the junction between the menisci and the top of the fins can not be measured because the slope of the liquid/vapour interface is too stiff and thus, the light is reflected out of the measurement space. However, circles fitting at best the experimental data show that menisci are circular and always attached to the fins top even for small curvature radii. Figure 5 (a) and (b) present the mean curvature radii along the FPHP for different heat fluxes and for filling ratios of 9% and 13%, respectively. The standard deviation of the measurements is indicated for each point under the form of a vertical bar. This uncertainty is not due to the confocal microscope, but to the dispersion of the curvature radius measurements in different grooves at the same position along the FPHP. As a consequence, the radius of curvature has been measured in several grooves and the mean value is retained. The level of meniscus curvature radii increases with the increase of the filling ratio. In non working conditions, the meniscus curvature radius is about 1.5 mm for f_r = 9% and it reaches 2.5 mm for f_r = 13%. Thus, the filling ratio has to be taken into account to model meniscus curvature variations along the grooves and the resulting temperature field. For a fixed filling ratio, it appears that there is a location in the FPHP where the meniscus curvature radius is constant whatever the heat flux. This particular position is closed to the middle of the condenser in this experiment. In [2], Rulliere *et al.* found a similar particular position that was located in the adiabatic zone.

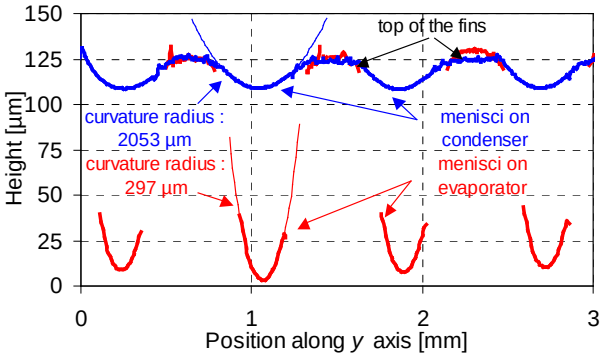

Figure 4: Menisci visualization at the condenser and the evaporator

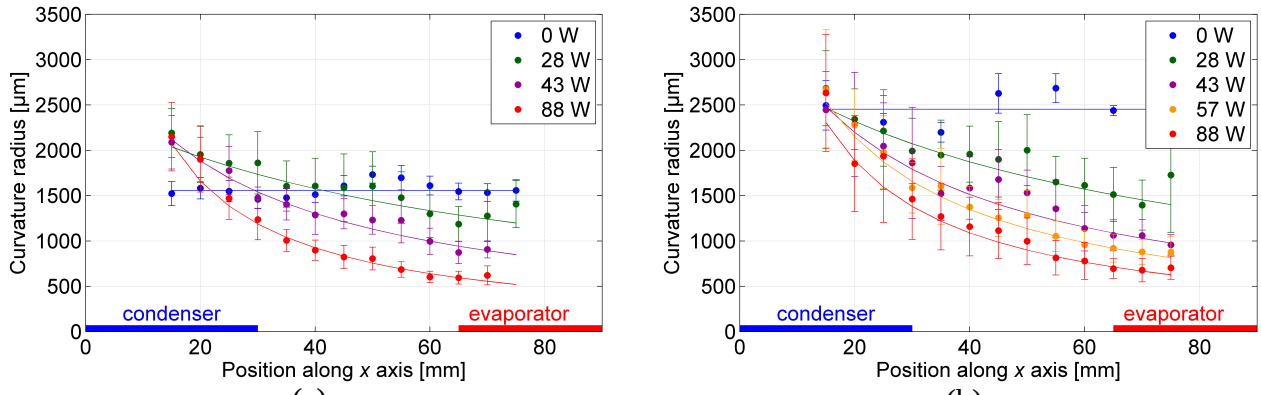

Figure 5: Meniscus curvature radius along the FPHP (f_r = 9% (a) and f_r = 13 % (b))

Pressure drop measurements in the FPHP

The meniscus curvature radius is directly linked to the capillary pressure (i.e. the difference between vapour pressure and liquid pressure) by the Laplace-Young law:

$$P_{cap} = P_v - P_l = \frac{\sigma}{r} \tag{1}$$

The capillary pressure along the FPHP for different heat fluxes and for two filling ratios is presented in figure 6 (a) and (b). Assuming that the capillary pressure is linear with the position along the grooves in the adiabatic zone, it is possible to determine the mean total pressure drop (i.e. the sum of the mean liquid and vapour pressure drops) along the FPHP by measuring the slope of the fitting line. A particular attention is given to the uncertainty of this mean total pressure drop. Figure 7 presents the capillary pressure along the FPHP in several grooves for Q = 88 W and f_r = 13%. Although the measurement dispersion in different grooves is important, the slopes of the fitting lines are close one to the other. Thus, the mean pressure drop in the FPHP and its standard deviation is the mean of the fitting line slopes in each groove and their corresponding standard deviation. In that example, the mean pressure drop is equal to 266 Pa/m and its standard deviation is equal to 52 Pa/m.
These measurements are compared to numerical results in next sections. However, the mass flow in the grooves has to be estimated to calculate the induced pressure drop. Indeed, one part of the heat flux is directly transferred by heat conduction in the wall from the heat source to the heat sink.

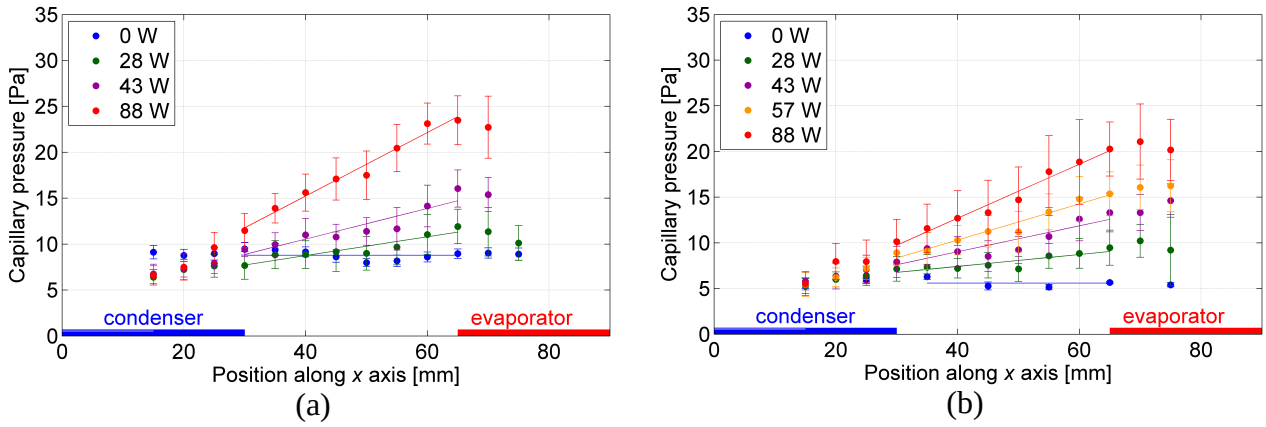

Figure 6: Capillary pressure along the FPHP (f_r = 9% (a) and f_r = 13% (b))

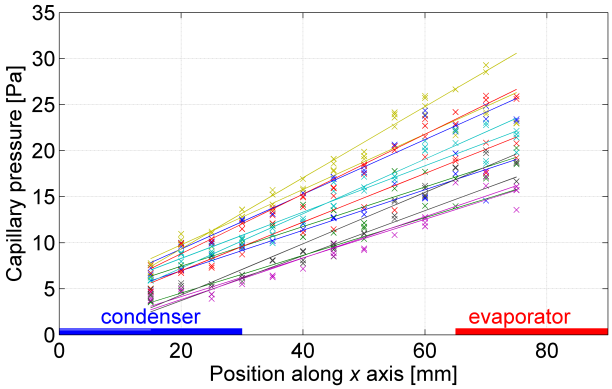

Figure 7: Capillary pressure dispersion in the grooves (Q = 88 W ; f_r = 13 %)

Estimation of the mass flow in the grooves

Liquid and vapour pressure drops depend on geometric parameters of the FPHP (width and height of the grooves, vapour space height, etc.), on thermophysical properties (viscosity, latent heat of vaporization, …) and on hydrodynamic parameters (interfacial shear stress, effect of the phase change on streamlines, effect of the meniscus on the fluid flows, etc.), but it depends primarily on the mass flow in the grooves and in the vapour space. Indeed, for laminar flows, pressure drops are proportional to the fluid velocity and hence to the mass flow in the channel. In a FPHP, the heat flux imposed at the heat source is transferred to the condenser by both heat conduction and phase change.
The mass flow in the grooves in the adiabatic zone is equal to:

$$\dot{m}_{l,v} = \alpha \frac{Q_{tot}}{h_{lv}} \quad \text{with} \quad \alpha = \frac{Q_{\text{phase change}}}{Q_{tot}} \tag{2}$$

Experimentally, it is possible to estimate α by considering both the total thermal resistance R_{tot} and the conduction thermal resistance R_{cond} of the FPHP:

$$\alpha = 1 - \frac{R_{tot}}{R_{cond}} \tag{3}$$

R_{tot} can be calculated with the temperatures measured for a given fluid charge in working conditions and R_{cond} is the thermal resistance calculated when the FPHP is empty:

$$R_{tot} = \frac{T_{\max} - T_{\min}}{Q_{tot}} \quad ; \quad R_{cond} = \left(\frac{T_{\max} - T_{\min}}{Q_{tot}} \right)_{FPHP\ \ empty} \tag{4}$$

Figure 8 presents the temperature profile along the FPHP for different heat fluxes and for two filling ratios. The thermal resistance of the FPHP as a function of the heat flux is plotted in figure 9 for filling ratios of 0%, 9% and 13%. Thermal resistances obtained for filling ratios of 9% and 13% are sensibly equal. Moreover, thermal resistances are almost constant with the heat flux. Thus, the part α of heat fluxed transferred by phase change is hence almost constant with the heat flux too. For filling ratios of 9% and 13%, α is equal to 45 +/- 5% of the total heat flux imposed at the heat source.

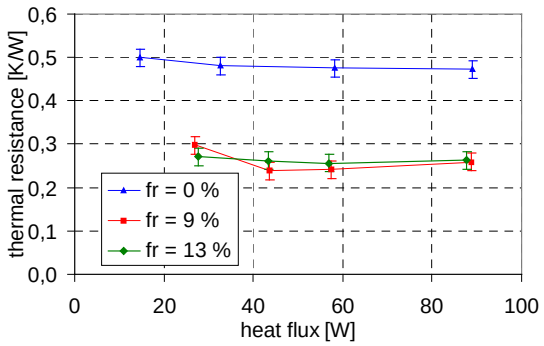

Figure 9: Thermal resistance of the FPHP

Comparison with numerical model

A hydrodynamic model has been developed under the finite elements based commercial software Comsol Multiphysics. Liquid and vapour flows in a groove section and in the vapour space have been simulated assuming laminar flow. The geometrical characteristics are those presented in figure 1 and the meniscus curvature radius is imposed. The liquid-vapour interface has been taken into account assuming the continuity of the shear stress at the liquid-vapour interface. A non-slip boundary condition is imposed at the walls. The mass flow in the channels is calculated with equation (2). Figure 10 summarizes the boundary conditions of the model and figure 11 presents the velocity fields in the channels for Q = 88 W and r = 0.5 mm.

The mean pressure drop in the grooves is presented in figure 12 as a function of the heat flux. Experimental results are presented for two filling ratios (f_r = 9% and f_r = 13%) and numerical results (in solid lines) are presented for three different meniscus curvature radii. As α is constant in the experiments, the mass flow in the grooves is proportional to the heat flux. Hence, pressure drops vary linearly with the imposed heat flux. Pressure drops are smaller for a filling ratio of 13 % than for a filling ratio of 9%. This difference can be explained by the reduction of the liquid cross section when the filling ratio decreases. Indeed, a decrease of the filling ratio induces a decrease of the meniscus curvature radius in the grooves, as seen in figure 5 (a) and (b). The influence of the curvature radius on pressure drops is shown by numerical results. The measurements obtained by confocal microscopy are in good agreement with the calculated pressure drops.

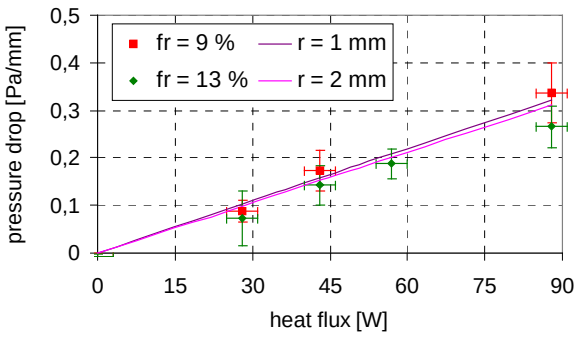

Figure 12: Experimental and numerical mean pressure drop

CONCLUSION

The physical phenomena that drive a heat pipe are complex and cannot be understood only with temperature sensors. Measurements of the location and the shape of liquid films inside the system are required in association with temperature measurements to understand the physical mechanisms that drive a heat pipe. Thermal data are available in the literature, but hydrodynamic data are rare. In this study, a confocal microscope was used to measure the meniscus curvature radii in the grooves of a FPHP. Temperature measurements are used to calculate the part of the heat flux transferred from the evaporator to the condenser by phase change. Both measurements are necessary to compare theoretical and experimental pressure drops.

ABSTRACT. A major goal of fuel assembly design for nuclear power plants is a reliable prediction of the critical heat flux. Development and validation of computational fluid dynamics (CFD) methods for predicting two-phase flows and critical heat flux (CHF) conditions is subject of ongoing research at AREVA-NP. This paper deals with numerical modelling of subcooled flow boiling of water in pipes and subchannels at flow conditions corresponding to the range of pressurized water reactor operation conditions. As simulation tool the commercial CFD software Star-CD is used in conjunction with its Extended Boiling Framework (EBF), a software package providing modelling tools for two-phase flow boiling. Substantial progress towards a CFD prediction of thermal hydraulic phenomena relevant for fuel assembly design could be achieved. In the future, modelling will be needed to be complemented by experimental validation data with sufficient local resolution, to validate CFD models for high pressure thermal hydraulic operating conditions.

Keywords: *Two-phase flow, CFD, validation experiments, nuclear power plant, fuel assembly*

INTRODUCTION

The thermal-hydraulic design of fuel assemblies for nuclear power plants nowadays relies strongly on theoretical and numerical design tools. A fuel assembly contains a bundle of several fuel rods containing the nuclear fuel, see sketch in Figure 1 (a). The heat released in the fuel rods by nuclear fission is transferred to water flowing parallel to the rods in the interstices, the so called subchannels. Heat transfer is enhanced by spacer grids, which generate fluid mixing and give additional mechanical stability. In order to improve the performance of fuel assemblies, e.g. by an optimized spacer grid design, numerical simulation of two-phase boiling flows by computational fluid dynamics (CFD) becomes increasingly important to assess geometric variants prior to costly experiments. An important goal for modelling is finally the prediction of critical heat flux (CHF), which poses an operating limit for the fuel assembly. To provide an efficient heat transfer from the fuel rods to the coolant, the fuel element requires an optimized design, with appropriately shaped mixing devices, as e.g. vanes, at the spacer grids. When the heat flux reaches a critical value at given flow conditions, the vapor generation at the rod surface prevents sufficient cooling. As a consequence of the reduced heat removal, the rod temperature rises rapidly and the rod may become jeopardized. The onset of this critical heat flux depends on the flow conditions (flow rate, subcooling, pressure) and the geometry.

While single phase flow CFD is meanwhile an established tool in industrial design, numerical modelling of two-phase flows coupled with phase change (boiling/condensation) is still subject of ongoing research efforts worldwide see [1],[2] for a review. For modelling and validation, experimental data on two-phase flows are particularly important.

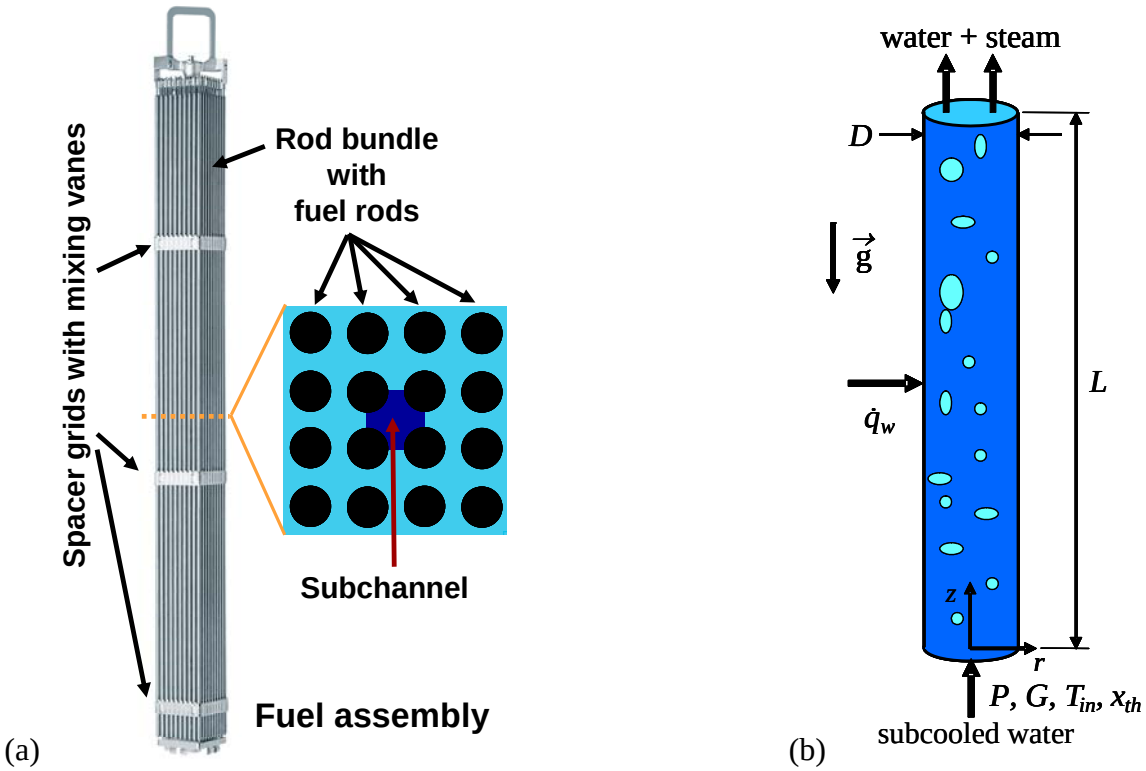

Figure 1. (a) Sketch of a fuel assembly for nuclear power plants. Enlarged bundle cross section: fuel rod array with subchannels for coolant flow. (b) Sketch of a laboratory scale flow boiling experiment for generating CFD validation data in simple geometries (here: circular pipe).

A requirement for application in nuclear industry is the availability of experimental validation data for CFD under realistic thermal hydraulic conditions occurring in boiling and pressurized water reactors (BWR and PWR, resp.), in a pressure range up to 200 bar. A comprehensive review of the available literature on experimental validation data for local flow boiling models for CFD software revealed gaps in this range of operating conditions, see e.g. [1]. There is a need in nuclear industry to close these gaps by appropriate experiments using advanced experimental techniques, such as fast X-ray tomography, digital image analysis, etc., to obtain *local* data of void fraction, liquid and vapour velocities [3]. This data is needed to get a fundamental insight into two-phase flow physics and to validate numerical models. Although integral measurements (e.g. average axial void fraction or CHF determination) provide a base to evaluate plausibility and quantitative results, they do not in general allow conclusive distinguishing between CFD flow boiling models, giving e.g. different local void distribution but same average. Model fluid experiments at low pressure, like refrigerants, are useful for fundamental studies, but accurate scaling to realistic thermal-hydraulic conditions is a matter of ongoing scientific debate. The particular challenge for two-phase flow experiments is the limited access of the flow domain at pressure occurring in thermal hydraulics applications.

For modelling two-phase flow on the scale of sub-channels and fuel assemblies, the Eulerian two-fluid approach is most common [1],[2],[4],[5] where the two phases are treated as interpenetrating continua, with conservation equations obtained by an averaging procedure. This approach requires appropriate closure equations for describing the inter-phase mass, momentum and energy transport. Setting up such closure models requires both a thorough theoretical background and detailed experimental data to describe inter-phase transfer. For developing such models, simple flow geometries as sketched in Figure 1 (b), like pipes, channels or annuli, proved to be convenient test cases to obtain experimental data on the flow configuration, such as local temperatures or void fraction [6],[7], and to tune models and validate numerical codes cf. e.g. [1],[5],[8]. The application

of two-phase CFD to sub-channels and to fuel assemblies has been tackled by numerous groups in the past, see e.g. [7],[9],[10],[11]. Recently, intense research has been also devoted to flows near or at CHF conditions [11],[12],[13]. Although the main physical phenomena could be reproduced, an improvement of the physical models underlying the two-phase CFD software is necessary and also improved experiments to provide local validation data for CFD are required, in order to clarify the complex interplay of the underlying physical submodels.

The present paper deals with numerical modelling of subcooled flow boiling of water in circular pipes and subchannels of fuel assemblies. As simulation tool the commercial CFD software Star-CD is used in conjunction with its Extended Boiling Framework (EBF), a software package providing tools (user routines) for modelling Eulerian two-phase flows with boiling in the bubbly flow regime. The package has been applied to reference experiments on flow boiling for conditions near or at critical heat flux from literature, such as e.g. [6]. In the framework of this paper the status of ongoing research and development work towards a more reliable prediction of critical heat flux is presented, but also the demands for experimental validation data are expressed.

NUMERICAL MODEL

Governing Equations

Subcooled flow boiling in pipes is described in the frame of an Eulerian approach, where the two phases are treated as interpenetrating continua which coexist in the flow domain. Each phase has its own physical properties and its own velocity and temperature fields, $\vec{u}_k$ and T_k, respectively, with $k=l,v$ denoting the liquid and vapour phase, respectively. The local fraction of a phase is characterized by its void fraction ε_k, for which $\varepsilon_l + \varepsilon_v = 1$ holds by definition. Both phases are assumed to have the same pressure field p. The governing equations of the flow problem are mass, momentum and enthalpy balances for each phase k, resulting in the classical six-equation two-fluid model. The interaction between the two phases is described by inter-phase transfer terms which enter the transport equations as source or sink terms. Following [4], the governing equations implemented in Star-CD are given as

- mass balances

$$\frac{\partial}{\partial t}\left(\varepsilon_k \rho_k\right) + \nabla \cdot \left(\varepsilon_k \rho_k \vec{u}_k\right) = \dot{m}_k \,, \tag{1}$$

- momentum balances

$$\begin{aligned} \frac{\partial}{\partial t}\left(\varepsilon_k \rho_k \vec{u}_k\right) + \nabla \cdot \left(\varepsilon_k \rho_k \vec{u}_k \vec{u}_k\right) = \\ -\varepsilon_k \nabla p + \nabla \cdot \left(\varepsilon_k \left(\tau_k + \tau_k^t\right)\right) + \varepsilon_k \rho_k \vec{g} + \vec{F}_k \end{aligned} \,, \tag{2}$$

- enthalpy balances

$$\begin{aligned} \frac{\partial}{\partial t}\left(\varepsilon_k \rho_k \hat{H}_k\right) + \nabla \cdot \left(\varepsilon_k \rho_k \vec{u}_k \hat{H}_k\right) = \\ \nabla \cdot \left(\varepsilon_k \lambda_k \nabla T_k + \frac{\mu_k^t}{\sigma_h^t} \nabla \hat{H}_k \right) + Q_k \end{aligned} \,. \tag{3}$$

In equations (1)-(3), $\hat{H}_k = \hat{H}_k(T_k, P)$ denotes the enthalpy at system pressure P, ρ_k is the density, μ_k viscosity, λ_k thermal conductivity and σ_h^t the turbulent thermal diffusion Prandtl number. For the mass, momentum and energy inter-phase terms conservation requires $\mathrm{I}_v = -\mathrm{I}_l$, with $\mathrm{I}_k = \dot{m}_k, \vec{F}_k,$ and Q_k, respectively. In order to calculate the turbulent stresses τ^t for the liquid and vapour phase in Equation (3) above, an extended k-ε turbulence model is used, containing extra

source terms which account for the effect of the vapour phase on the turbulence field, cf. [4] for details.

Interfacial forces

Due to the averaging process for the two-fluid formulation, inter-phase interaction terms between the two phases occur for which appropriate models have to be provided to close the system of equations. Between the two phases, drag, lift, virtual mass, turbulent drag, wall lubrication and convective momentum transfer act as interfacial forces [4]:

$$\vec{F}_v = \vec{F}_D + \vec{F}_L + \vec{F}_M + \vec{F}_T + \vec{F}_W + \left(\dot{m}_{vl}\vec{u}_v - \dot{m}_{lv}\vec{u}_l\right). \quad (4)$$

Bulk boiling model

The heat and mass transfer between the liquid and the vapour phase for bubbly flow is described in the frame of an energy balance as described in [4]. Liquid and vapour side heat fluxes to the interface are modelled using heat transfer coefficients, the mass flux through the interface then results from the difference between the liquid and gas side heat fluxes, divided by the latent heat. The local bubble diameter is assumed for simplicity to be a function of the local subcooling in the fluid, using an empirical model of Kurul and Podowski [4].

Wall heat partitioning model

The total heat flux through the wall q''_w is split up into several parts, determined by a wall heat partitioning model [4], extended in the spirit of [11],[12],[13] for modelling CHF. In subcooled flow heat is transferred in part directly to the liquid and the vapour which are in contact with the heated surface by convective transfer, using single phase heat transfer coefficients (convective part). Evaporation starts from nucleation sites at the heated surface, creating bubbles adjacent to the wall, which leave the surface when reaching their departure diameter (evaporative part). The nucleation site density and the departure diameter determine the fraction of the wall area covered by nucleation sites, empirical models are adopted here, cf. [4]. After bubble detachment, cooler water replenishes the space occupied by the bubble, which has to be heated again (quenching part).

PROBLEM DESCRIPTION

In order to investigate subcooled flow boiling, two-phase flow through uniformly heated vertical circular pipes of diameter D and length L is considered in the present work. Figure 1 (b) shows a sketch of the problem under consideration. Subcooled water enters the pipe with inlet temperature T_{in}, thermodynamic quality $x_{th,in}$, and mass flow rate density G. The water is heated by a uniform wall heat flux q''_w at the wall. For this configuration, experimental data on flow, temperature and average void fraction is available in the literature, cf. e.g. [6] and also databases on CHF experiments for circular pipes, cf. e.g. [14]. For circular pipes, steady, axisymmetric flow configurations are considered for the numerical computations. A fully 3D CFD simulation has been carried out for subchannel geometries.

NUMERICAL RESULTS

Two-phase flow under CHF conditions were investigated at PWR conditions, using parameters derived from an experimental set of Weatherhead (1963), see [14], with P=138 bar, G=940-2650 kg/m^{2}s and outlet qualities $x_{th,o}$= -0.05 in a pipe with L=0.457 m and D=7.7 mm. As flow regime, bubbly flow with the liquid phase being the continuous phase is assumed, in addition allowing for a regime change in the wall layer at high void fraction. Lift and wall lubrication forces are switched off. Profiles of void fraction, liquid and vapour temperatures are shown in Figure 2 for illustration, for a particular set of parameters. The heat flux was increased, until the wall temperature T_w

increase reached outlet region of the experiment (at $z \approx 0.45$ m), where CHF is observed. The computational domain has been chosen longer to get more detailed insight into the flow behaviour. The contour plot of the void fraction (Figure 2, left) shows a rather pronounced layer of high void content near the wall.

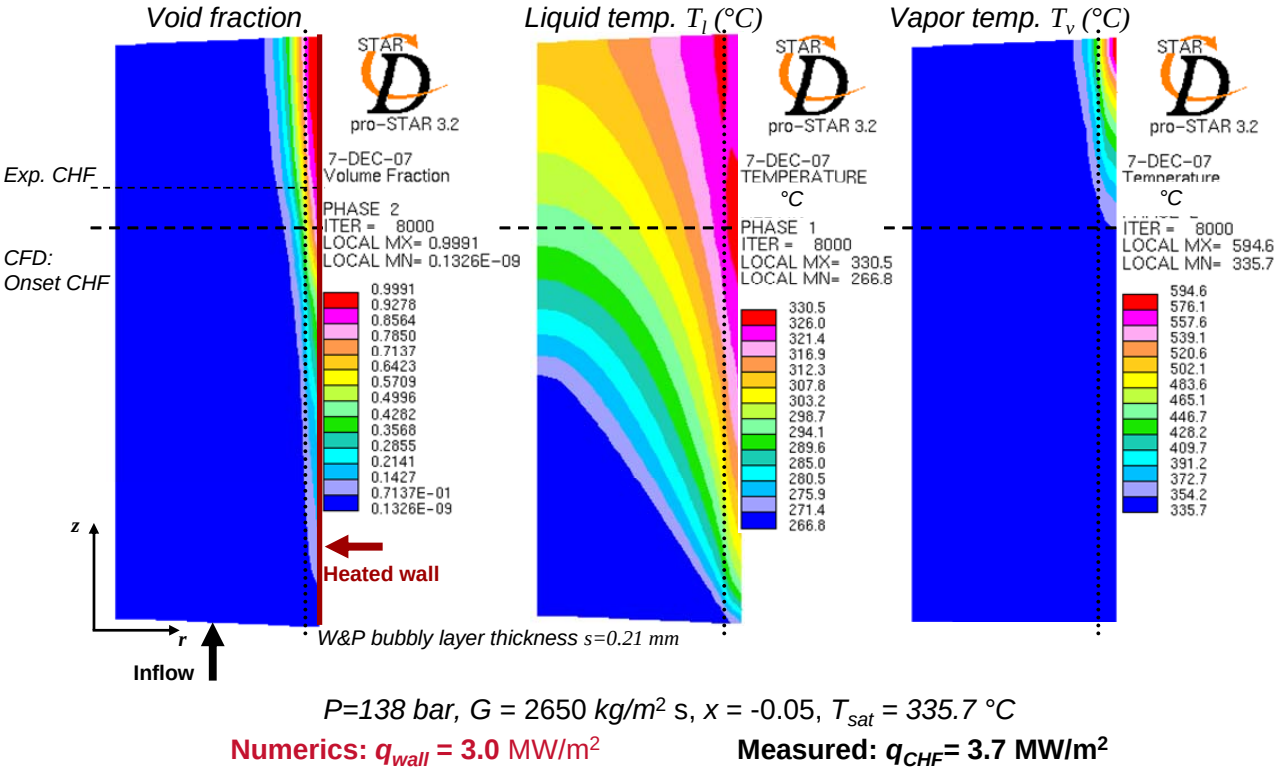

Figure 2. Numerical computation of critical heat flux for the Weatherhead experiment.

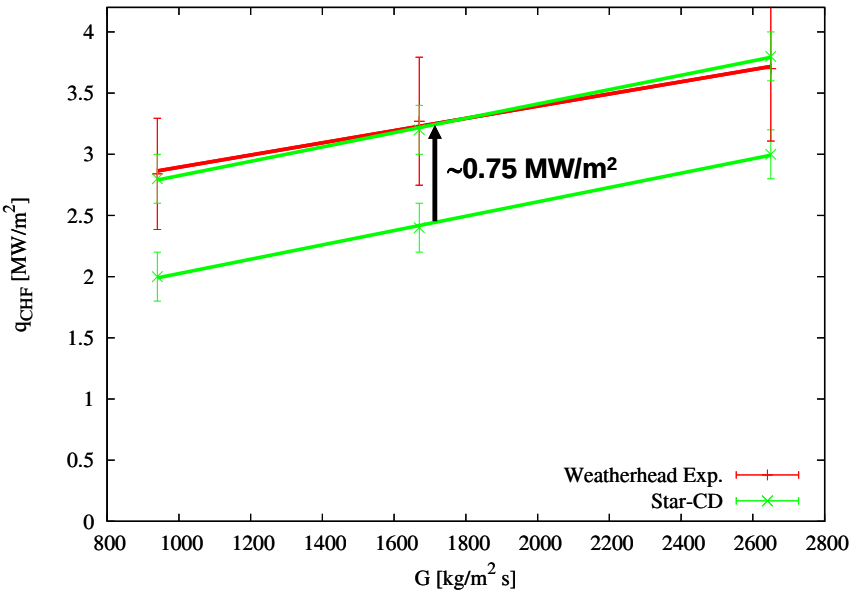

Figure 3. Comparison of computed CHF values with Weatherhead experiments (before and after shifting by a single additive constant).

The thickness of the layer with $\varepsilon >> 0.7$ matches qualitatively well with the prediction of the Weisman-Pei one-dimensional correlation (vertical dotted line) [15]. The CHF results obtained by using the modified heat partitioning model are summarized in their dependence on the mass flux

in Figure 3. It is interesting to note that the qualitative dependence of the CHF value on mass flux is very well captured by the model, however, the critical heat flux is under-predicted. Shifting the values by a *single* additive constant allows matching of CFD and experimental results very well.

Subchannel with vaned spacers – Influence of swirl on CHF

Results for two-phase flow simulations in a subchannel with vanes are presented for a generic spacer configuration with a four-fold symmetry, allowing to exploit the symmetry and to reduce the size of the computational domain to a ¼ subchannel with cyclic boundary conditions. In Figure 4 results for void distribution and lateral velocity components are shown in two horizontal sections at different distances from the vane tips.

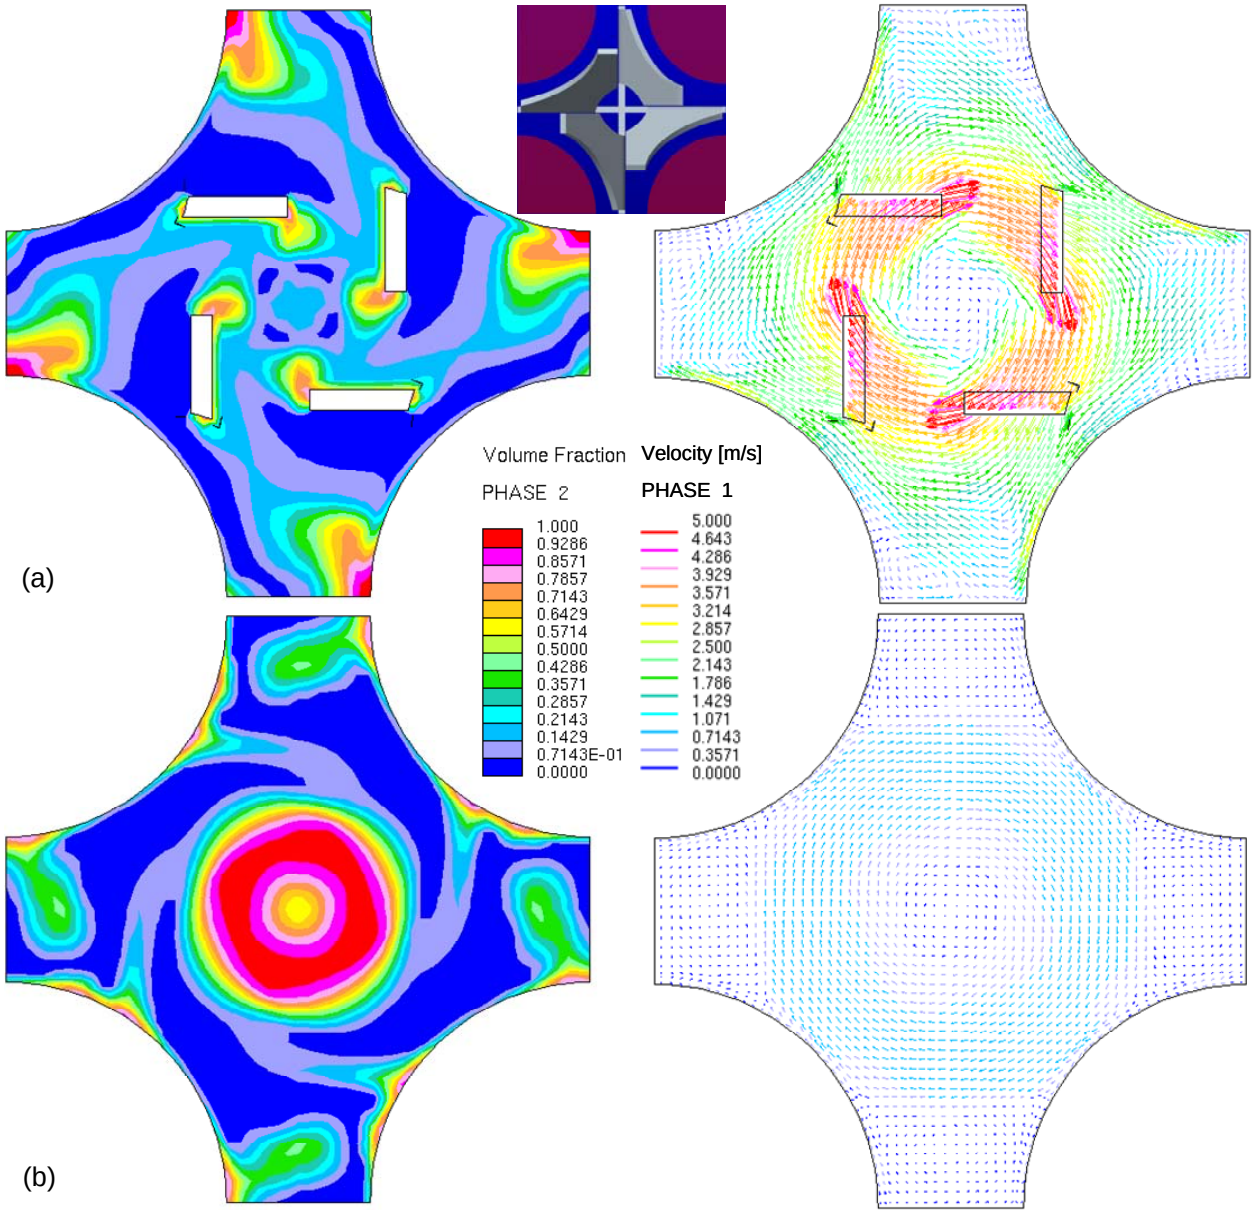

Figure 4. Subchannel geometry with vanes: Horizontal cuts, void fraction (left), horizontal components of velocity (right), (a) 1 mm before vane tip, (b) 150 mm downstream of vane tip.

The vanes generate swirl and cause a redistribution of the void fraction, with liquid gathering preferentially on the lower side of the vane (low void, blue colour) due to local centrifugal forces resulting from the local curvature of stream lines, while on the upper side vapour is accumulating, cf. Figure 4 (a). The centrifugal forces in the swirl flow are dominant downstream of the vanes and

cause a separation of the vapour and the liquid, with a vapour core developing in the centre of the channel, see Figure 4 (b). Bubble pockets with high void fraction develop on the rod surface, which may cause the onset of CHF. In a next step, the investigation of the influence of swirl has been extended towards the development of CHF in a subchannel section with several spacer spans 4-vane grids. In order to reduce the complexity of the model and to speed up computation time, only two spans of the subchannel, with inlet and outlet sections, are considered.

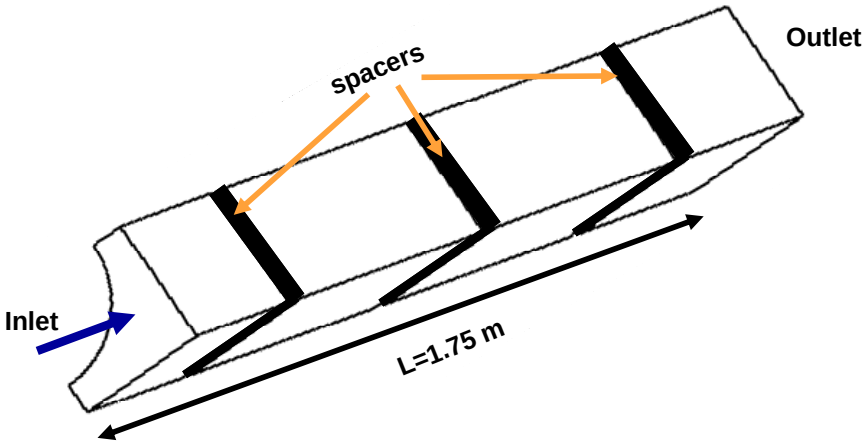

Figure 5. Sketch of the computational domain (one quarter of channel, exploiting symmetries) of the subchannel section with three spacers.

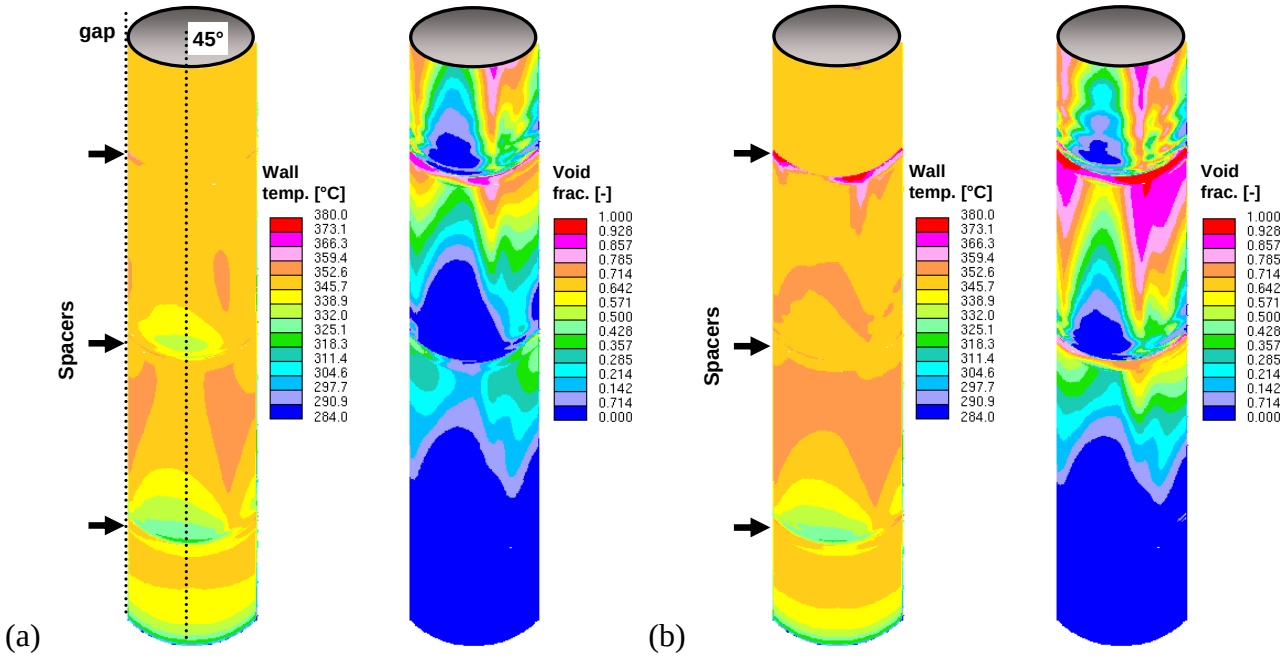

Figure 6. Rod temperature T_w (left) and void fraction ε near rod surface (right) for (a) q''_w=2.0 MW/m^2 and (b) q''_w=2.1 MW/m^2 (plotted on one quarter of rod surface).

Figure 5 shows a sketch of the configuration. The operation conditions investigated here correspond to G=3000 kg/m^2 s and T_{in} = 195 °C. In Figure 6 contour plots of the wall temperature T_w (surface temperature of the rod) and for the void fraction ε adjacent to the rod surface are plotted for a wall heat flux q''_w = 2.0 MW/m^2 (a) and for q''_w = 2.1 MW/m^2 (b). For the lower heat flux, a wall temperature increase, causing CHF, was already observed in the outlet section of the subchannel *without spacers*, which was computed for comparison. Figure 6 (a) shows, that due to the swirl generated by the spacer vanes, the rod surface is significantly cooled even below saturation temperature (T_{sat} =339.5°C) downstream of the first and second spacer, in an area around the 45°

position. The effect of the spacers on the wall temperature becomes clear in Figure 7, where the wall temperature along the 45° line and along the gap is plotted for both the subchannel *with spacers* and *without spacers*. The improved heat transfer by the swirling motion causes a steep drop of the wall temperature along the 45° line downstream of the first two spacers (red line in Figure 7). The wall temperature increases and reaches the level of the subchannel *without spacers* (green line in Figure 7) just before the next spacer, in the last third of the span. The effect of the third spacer on T_w appears much less pronounced, apparently due the higher void content of the flow towards end of heated length, the wall temperature downstream of the third spacer is hardly influenced. Along the gap of the subchannel, the effect of the spacers on T_w is also significantly smaller. Figure 6 shows also contour plots of the local void fraction adjacent to the rod surface. Significant void production sets in the first span (before the second spacer), up to this point the flow is essentially single phase. The swirl generated by the second spacer causes a redistribution of the void, especially before the 3rd spacer and in the outlet section the formation of bubble pockets appear, which may lead to CHF, cf. Figure 6 (b). It should be noted here, that the increase of the CHF value by the action of vanes is in the range observed by measurements.

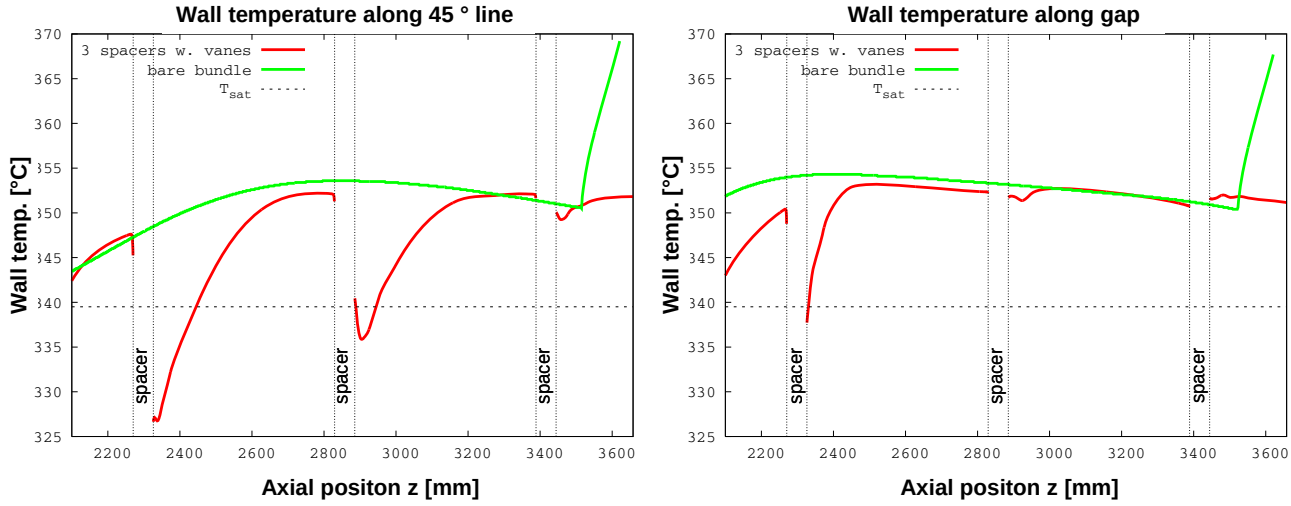

Figure 7. Rod temperature at 45° position (left) and in the bundle gap (right) for $q"_w$=2.0 MW/m^2. Comparison between vaned spacer (red line) and subchannel *without spacers* (‘bare bundle’) (green line).

CONCLUSIONS

In this paper numerical modelling of subcooled flow boiling at CHF conditions has been investigated using the software package Star-CD with its extended boiling framework (EBF). Goal of the ongoing research is to use two-phase CFD methods for the prediction of critical heat flux (CHF) in subchannels of fuel assemblies. The numerical results show for the investigated parameters, that the two-phase CFD model is capable to produce quantitative results, which reproduce trends of the parameter dependence very well. In addition, two-phase CFD provides a valuable qualitative insight into regions in the subchannel, which are otherwise not accessible by experimental methods. Still, deeper insight into the underlying physical mechanisms of two-phase boiling flows at high pressures is required, to significantly improve the accuracy of the models. Experimental data on void, velocity and temperature distribution with a high spatial, down to the sub-millimetre scale as the results presented in Figure 2 and Figure 4 imply, are desirable. The development of non-intrusive measurement methods, for instance, is considered an attractive prospective for obtaining validation data in the future.

The authors would like to thank J. Bigot, F. Burtak, M. Leberig, T. Kehely, T. Salnikova, and J.-P. Simoneau for fruitful discussions.

PREDICTION OF ASYMMETRIC AIR BUBBLE OSCILLATIONS

C. W.M. van der Geld*, J.G.M. Kuerten
Eindhoven University of Technology, Eindhoven, The Netherlans

ABSTRACT. Production of sound by asymmetric air bubble oscillations in water is enhanced when the parameter $\{p_L R_0 / \sigma\}$ approaches a resonance value that depends on $\gamma = c_p/c_v$. With an Euler-Lagrange approach a new, extended Rayleigh-Plesset equation is derived that takes account of arbitrary axisymmetric interface deformation. A solution of this equation for the isotropic 'breathing mode' is presented that is shown to predict the amplitude well over long periods of time. This breathing mode causes monopole emission of sound. The solution behaves properly also at resonance. The parameters p_L and σ have been varied in a broad range and in all cases the dimensionless equation (15) was found to be valid. The radian frequency ω_3 defined by equation (9) is found to change gradually in time. This is related to the well-known experience [5] that ω_3 appears to depend on initial amplitude β for nonlinear deformation of bubbles and spheres of liquid. At resonance, the fluid properties and the pressure are such that energy is quickly converted from the driving anisotropic deformation mode to the breathing mode. But also far from resonance, each deforming air bubble produces sound, be it with smaller amplitude.

Keywords: *bubble deformation, large amplitude oscillation, resonance, sound production*

INTRODUCTION

Sound in water can be produced by a water surface ruffled by the wind, by jets impinging at a free surface, by air bubbles emerging from an underwater nozzle and by imploding steam bubbles (cavitation). Fully nonlinear theories for sound production by bubble pulsations were given by many researchers but merely for cavitation phenomena. See the review of Plesset & Prosperetti [1]. However, sound is also produced by air bubbles, as partly explained by Minnaert [2] who showed that the frequency of the sound is close to that of the radial mode of isotropic bubble oscillation, the so-called 'breathing mode'. A nonlinear theory for air bubbles was given by Longuet-Higgins [3]. He performed a perturbation analysis of three sets of parameters (velocity potential, interface, pressure) simultaneously with an equation of state that pertains to air bubbles:

$$p_b V^{\gamma} \equiv \text{constant}, \tag{1}$$

with $\gamma = c_p/c_v$, V the bubble volume and p_b the pressure in the bubble. Let P_n denote the n^{th}-Legendre polynomials. Longuet-Higgins showed that each oscillation with amplitude β at the frequency of the linear fundamental mode corresponding to P_n produces oscillations that behave at a distance just as those of the breathing mode, but at twice the frequency of the fundamental mode (ω_n) and with an amplitude proportional to β^2. Longuet-Higgins derived a $\cos(2\omega_n t)$-component in solving his equation (6.23) with a velocity potential Φ given by $Z R_0 \sin(2\omega_n t)/r$. Here R_0 denotes the initial bubble radius, ω_n the frequency of a normal mode with order n, t is time and r the radial distance from the

bubble. This leads to amplitude of the breathing mode, b_1, that is inversely proportional to $\{\omega_{RP}^2 - 4\omega_n^2\}$, with

$$\omega_{RP}^2 = 3\,\gamma p_L/(\rho_L R_0^2) + (3\gamma - 1)2\sigma/(\rho_L R_0^3). \tag{2}$$

Selecting ω_{RP}^2 close to $4\omega_n^2$ obviously causes large amplitudes which enhances the generation of sound. However, this solution leaves the questions unanswered what precisely will happen close to resonance, how the full analytical solution of the breathing mode amplitude reads and what the level of accuracy is of the truncated expressions at time scales that are a multitude of $2\pi/\omega_n$. These are the questions addressed in this paper. It will be shown that next to the above potential $Z\,R_0 \sin(2\omega_n t)\,/r$ a second solution, $Q\,R_0 \cos(2\omega_n t)\,/r$, of the Laplace equation exists that needs to be taken into account in order to predict the breathing mode well.

APPROACH

Consider an axisymmetric, freely deforming air bubble in an ideal, infinite liquid for which $p_b V^\gamma$ is constant. Viscous effects are neglected. Our approach is threefold. The first method is based on the Euler-Lagrange approach in which the coefficients $b_m(t)$ in the expansion of the function $R(\theta,t)$ that describes the interface:

$$R(\theta,t) = \sum_m b_m(t)\, P_{m-1}(\cos\theta) \tag{3}$$

are generalized coordinates. Here θ is polar angle in a spherical coordinate system. An analytical solution for arbitrary axisymmetric deformation of convex shapes is obtained that needs to be integrated in time, the only numerical step. This method, named BEL for sake of convenience, is compared with boundary element method (BEM) solutions for validation purposes. These are the full solutions that coincide if sufficient coordinates (BEL) and sufficient wall point (BEM) are employed. Without loss of generality only initial shapes will be considered for which b_1 and b_3 are nonzero. For excitation of normal modes other than b_3 similar results hold since the extended Rayleigh-Plesset equation that accounts for general deformation reads [4]

$$2\psi_{11}\mathrm{d}^2b_1/\mathrm{d}t^2 + 2\sum_k \psi_{k1}\mathrm{d}^2b_k/\mathrm{d}t^2 = 2\,Q_1/\rho_L - (\mathrm{d}b_1/\mathrm{d}t)^2\,\partial\psi_{11}/\partial b_1 - 2\mathrm{d}b_1/\mathrm{d}t\,\sum_{k=3}\mathrm{d}b_k/\mathrm{d}t\,\partial\psi_{11}/\partial b_k$$
$$+ \sum_{k=3}\mathrm{d}b_k/\mathrm{d}t\;\mathrm{d}b_m/\mathrm{d}t\,\partial\psi_{mk}/\partial b_1 - 2\sum_{k=3}\mathrm{d}b_k/\mathrm{d}t\;\mathrm{d}b_m/\mathrm{d}t\,\partial\psi_{m1}/\partial b_k \tag{4}$$

Here each ψ_{mk} denotes an added mass coefficient that depends on all generalized coordinates. The Q_1 is the generalized force that is given by

$$Q_1 = (p_b - p_L)\,\partial V/\partial b_1 - \sigma\,\partial A/\partial b_1 \tag{5}$$

with A the surface area of the bubble. An equation similar to (4) exists for b_3. Details of this approach are given in a previous paper [4] that also summarizes the main features of the BEM.

The third method is based on the BEL solution and constitutes a perturbation analysis that produces approximate solutions. Note that only a single set of parameters, the generalized coordinates, needs to be perturbed which lead to a consistent and coherent solution of which the accuracy is readily assessed. This approach is explained in the next section.

RESULTS AND ANALYSIS

Let β denote $b_3(t=0)/R_0$, with $R_0 = b_1(t=0)$. A perturbation calculation of b_1 and b_3 simultaneously:

$$b_1 = b_{1,0} + \beta\, b_{1,1} + \beta^2\, b_{1,2} + \ldots; \tag{6}$$

$$b_3 = b_{3,0} + \beta\, b_{3,1} + \beta^2\, b_{3,2} + \ldots \tag{7}$$

yields

$$b_3 = \beta\cos(\omega_L\, t) + \beta^2\, \mathrm{C}\cos(2\,\omega_L\, \mathrm{t}) + \ldots \tag{8}$$

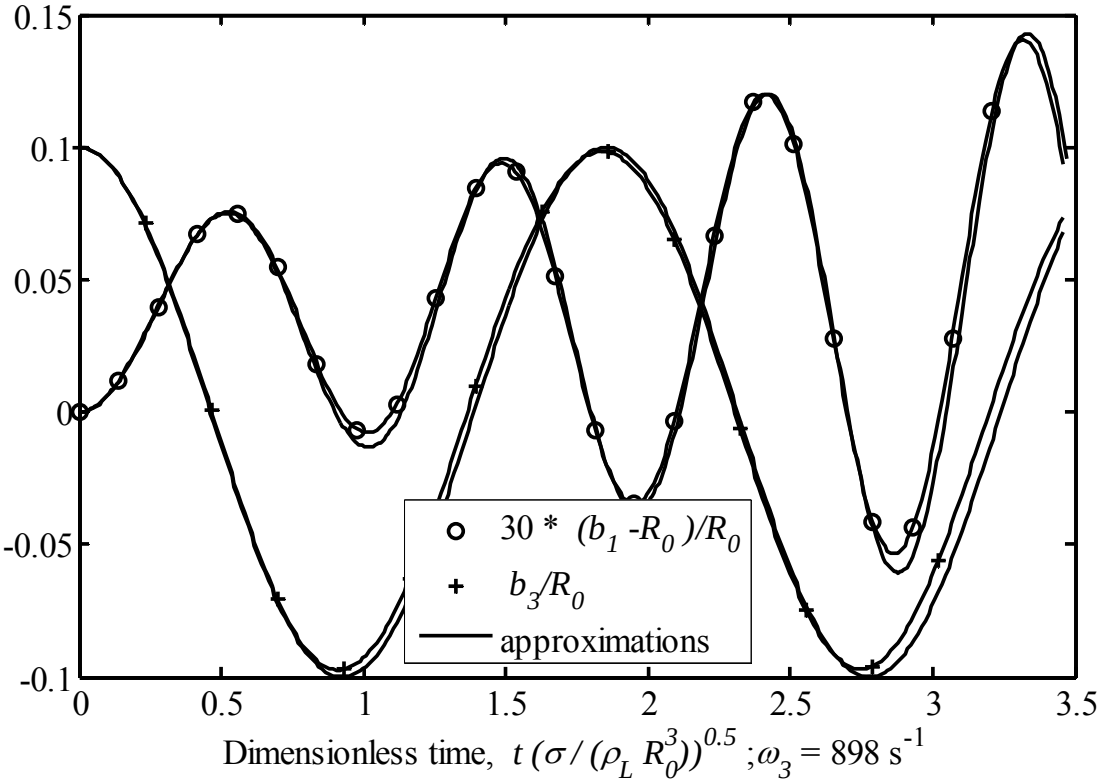

Figure 1 Shape coefficient histories at early times for b_3-excitation with $\beta = 0.1$, $\gamma = 1.4$ and $p_L R_0/\sigma = 10.89$, *i.e.* $k = 1.1$.

with $\omega_L^2 = 12\ \sigma/(\rho_L R_0^3)$ and C a constant. This shows that if b_3 is approximated by

$$b_3 \approx \beta \cos(\omega_3 t), \tag{9}$$

ω_3 becomes dependent on amplitude β. This is in agreement with the findings of both experiments and previous analysis, see the summarizing figure 4 of Tsamopoulos & Brown (1983, page 535). It also explains why the approximation for b_3 given by equation (9) in figure 1 deviates from the full BEL and BEM solutions; the value of ω_3, given in the caption, is obtained by fitting to the first cycle of the full solution of b_3. If ω_L would have been used, the agreement would have been slightly worse.

For the perturbation calculation ω_3 does not exist. In the remainder of this paper, ω_3 is assumed to be equal to ω_L unless specified explicitly otherwise. The symbol ω_3 is kept for reasons that will become clear shortly. The perturbation analysis shows that the breathing mode is described by

$$(b_1 - 1) / R_0 = \mathrm{A}\ \beta^2\ \{\cos(2\ \omega_3 t) - \cos(\omega_{RP} t)\} + \mathrm{B}\ \beta^2 \{\cos(\omega_{RP} t) - 1\} \tag{10}$$

with $\omega_{RP}^2 = 3\ \gamma p_L/(\rho_L R_0^2) + (3\gamma - 1) 2\sigma/(\rho_L R_0^3)$ and

$$\mathrm{A} = 0.2\{\omega_{RP}^2 - (17/6)\omega_3^2\} / (4\omega_3^2 - \omega_{RP}^2)\ ; \quad \mathrm{B} = -0.2\{\omega_{RP}^2 + \omega_3^2/2 + \omega_L^2/3\} / \omega_3^2 \tag{11}$$

The occurrence of the term with ω_L in B stems from the initial condition of the pressure in the bubble, p_b. Despite the initial deformation, prescribed by $\beta = 0.1$, the initial value of p_b has been chosen to be $p_L + 2\sigma/R_0$, *i.e.* the equilibrium value of a sphere with radius R_0. The actual equilibrium pressure, minus p_L, is given by 2σ divided by the radius of the volume-equivalent sphere of the initial bubble. Since this radius is larger, the mean value of b_1/R_0 is found to exceed 1, see figure 1. The physics of an initial offset in pressure leads to an extra ω_L-term in the generalized b_1-force, Q_1:

$$Q_1/(4\pi\,\rho_L\,\beta^2) = -\,\omega_{RP}^2\,b_{1,2} + \omega_{RP}^2\,0.2\,\sin(\omega_3\,t)^2 + 0.2\,\omega_L^2/6 \qquad (12)$$

Equation (12) is accurate up to order β^2. The governing equation of b_1, an extension of the Rayleigh-Plesset equation, reads

$$b_1^3\,\mathrm{d}^2b_1/\mathrm{d}t^2 + b_1^2\,b_3\,\mathrm{d}^2b_3/\mathrm{d}t^2\,((1/3) + (b_3/b_1)/7) + b_1^2\,(\mathrm{d}b_3/\mathrm{d}t)^2\,((7/30) - (b_3/b_1)/105) = Q_1/(4\pi\,\rho_L) \qquad (13)$$

The terms with the ratio (b_3/b_1) in equation (13) are insignificant to the present level of approximation, but contribute to $b_{1,3}$. equations (7), (12) and (13) lead to the solution given by equation (10), and the last term on the RHS of equation (12) for Q_1 leads directly to the ω_L-term in B.

If the solution for b_1 given by equation (10) with $\omega_3 = \omega_L$ would have been drawn in figure 1, the agreement with the full solution would have been slightly worse than the solid line actually drawn for b_1 in figure 1. This latter line has been obtained by fitting ω_3 to the first part of the full solution of b_3 and using the value thus obtained for ω_3 in equation (10). This is formally improper since higher orders of β would need to be taken into account, but it turns out to be an easy way to obtain better agreement between estimations of b_3 based on equation (10) and full solutions for b_3 obtained with BEL and BEM, during a certain interval of time. In the sequel of this paper, this procedure will be named the approximating of b_3 with equation (9) and equation (10). This approximation is the main reason to maintain the symbol ω_3 in the equations. The agreement for b_1 shown in figure 1 is actually quite good considering the b_3-accuracy of the approximation (9), also drawn as a solid line in this figure. Other computations have been performed with $\beta = 0.001$ and smaller, which yielded very good agreement between equation (10), $b_3 = \beta\,\cos(\omega_L\,t)$, and full BEL and BEM solutions. This shows that discrepancies in figure 1 are due to higher order terms in β.

In order to study the characteristics of the breathing mode close to resonance it is advantageous to define λ, k and ψ, as follows, and to rewrite equation (10). Let

$$\lambda \equiv \omega_3/\omega_L,\quad k \equiv \{p_L R_0/\sigma\}/\{16/\gamma - 2 + 2/(3\gamma)\},\quad \psi \equiv (\mathrm{k}-1)(25-3\gamma) + 24 \qquad (14)$$

In the definition of λ, ω_3 stems from fitting and equation (9). With dimensionless time τ given by $t\,\sqrt{\{\sigma/(\rho_L\,R_0^3)\}}$, equation (10) is written as follows:

$$b_1/R_0 = 1 - 0.2\,\beta^2\{1 + 7\lambda^2/(\psi - 24\,\lambda^2)\}\sin(\tau\,\{\sqrt{(\psi/2)} - \lambda\sqrt{12}\})\,\sin(\tau\,\{\sqrt{(\psi/2)} + \lambda\sqrt{12}\}) + -\,0.1\beta^2\,\{1 + 3\,\lambda^2/\psi + 2/\psi\}\,\{\cos(\tau\,\sqrt{(2\psi)}) - 1\} \qquad (15)$$

The amplitude of the double sinus-term in equation (15) clearly increases for ψ approaching 24, which is equivalent to k approaching 1 (equation 14). Full 'resonance' occurs for k equal to $\{1 - 24(1-\lambda^2)/(25 - 3\gamma)\}$, in which case the double sine term changes into a term that increases linearly with dimensionless time τ. The predictive capacity of equation (15) for a time comprising a multitude of cycles with duration $2\pi/\omega_L$ is investigated in figure 2.

Figure 2 shows that the amplitude of the double sinus-prediction of equation (15) is in very good agreement with the full solutions of BEL and BEM. The main radian oscillation frequency of b_3, the fitted ω_3 from (9), is found to be changing continuously with time. If the period of oscillation is made dimensionless as in the definition of t, the dimensionless radian frequency is at early times about 3.4135, which is less than the dimensionless frequency of ω_L, $\sqrt{12} \approx 3.4641$. At later times it decreases even more.

The even coefficients b_2, b_4, …, are zero for reasons of symmetry. The first nonzero coefficient, b_5/R_0, has no contribution to $b_{1,2}$ and $b_{3,1}$ and consequently no influence on the time history of b_1 in figure 2. In each b_3-cycle of duration of about $2\pi/\omega_L$ where the maximum amplitude of b_1 reaches its maximum (at dimensionless times 8 and 23 in figure 2, for example), the maximum amplitude of b_3 is somewhat lower than in other such b_3-cycles. Part of the surface energy of the driving mode, b_3, is apparently

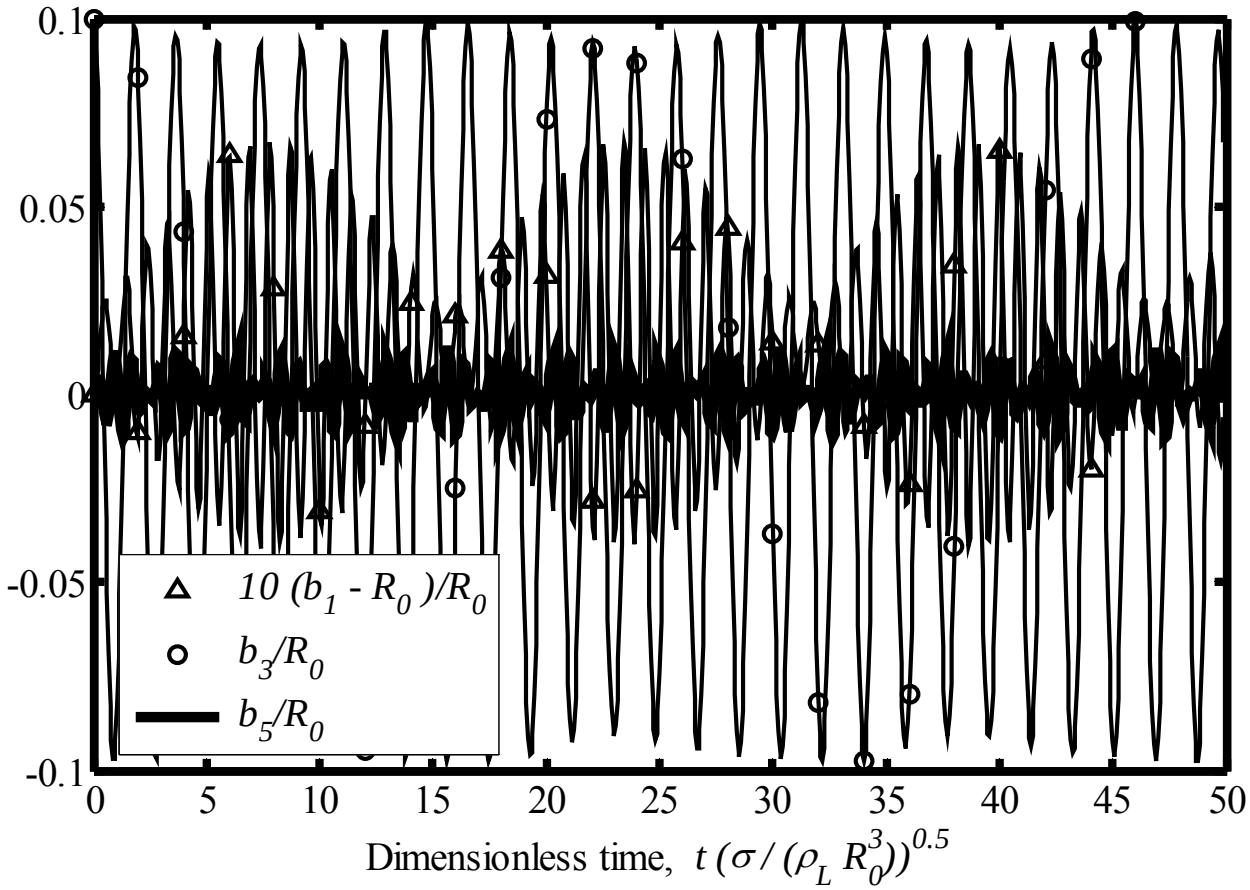

Figure 2. Shape coefficient histories for b_3-excitation with $\beta = 0.1$, $\gamma = 1.4$ and $p_L R_0/\sigma = 10.89$, *i.e.* $k = 1.1$. This condition is for example obtained with water with $\sigma = 0.07$ N/m and $\rho_L = 1000$ kg/m^3 at a pressure of 762.3 Pa, if $R_0 = 1$ mm. Values of $|b_5/b_1|$ are about 0.01 at maximum; values of $(b_1–1)/R_0$ vary between about –0.04 and 0.07.

converted into sound-making isotropic vibrations of the bubble, the so-called breathing mode of b_1. As compared to cases when k is far from 1, the amplitudes this breathing mode attains are quite high. The conditions of figure 2, for k =1.1, are beneficial for sustained generation of sound at a reasonable level at the two frequencies of the sine-terms in equation (15). This condition can be obtained for $R_0 = 1$ mm, as in figure 2, but also for other pressures and surface tension coefficients as long as $p_L R_0/\sigma =$ 10.89 equals 1.1.

The closer to resonance the value of k is chosen, the higher the amplitude of b_1 gets, see figure 3. The corresponding shapes of the bubble are all in the range from spherical to slightly ellipsoidal, still.

The higher the maximum amplitude of b_1 during a period of dimensionless time $\pi/\{\sqrt{(\psi/2)} - \lambda\sqrt{12}\}$, about the time-span shown in figure 3, the lower the corresponding maximum of b_3, as is clearly observed in figure 3. In this case of $k = 1$, the main radian frequency of b_3 (ω_3 from equation 9) hardly varies in time since it is close to $\omega_{RP}/2$.

Although the amplitude of b_1 has been blown up considerably by selecting $k = 1$, and that of b_3 decreased considerably, the periodicity on the time scale $\pi/\{\sqrt{(\psi/2)} - \lambda\sqrt{12}\}$ is not lost for the above cases with initial shape deformation given by $\beta = 0.1$. Shapes remain not far from spherical, and for example b_5 is unimportant for the b_1-history. All this is not true anymore for $\beta = 0.4$, see figure's 4 and 5. The shape changes considerably in this case of $k = 12$, $\sigma = 0.05$ N/m, $\rho_L = 1000$ kg/m^3, $R_0 = 1$ mm, $\gamma = 0.1$, $p_L R_0 / \sigma = 2000$ (resonance value close to 164.7). Other conditions for $\beta = 0.4$ resulted in even stronger deformations. Not only the value of b_5 becomes significant, see figure 5, also the amplitude of

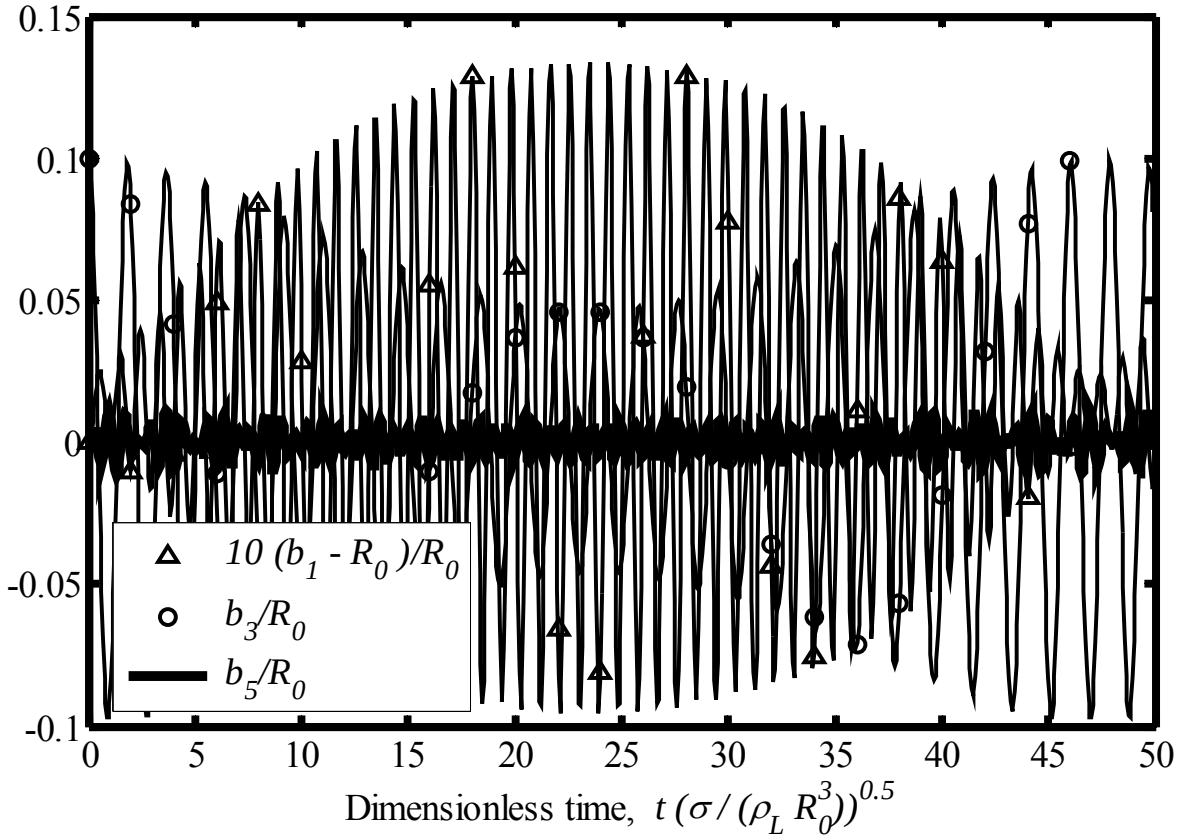

Figure 3. Shape coefficient histories for b_3-excitation with $\beta = 0.1$, $\gamma = 1.4$ and $p_L R_0/\sigma = 9.9048$, *i.e.* $k = 1.0$.

b_1 is not well predicted by equation (15) anymore. The radian frequency ω_3, fitted with equation (9), deviates by as much as 18 % of ω_L already in the first b_3-cycle.

These violent interface deformations are well described by both BEL and BEM, but not by the approximations given in the above. It will be investigated in a future study whether the inclusion of higher order terms in β leads to a better approximation.

CONCLUSIONS

An Euler-Lagrange approach has been followed to derive a new, extended Rayleigh-Plesset equation that takes account of the interaction between a fundamental anisotropic deformation mode and the isotropic expansion-compression mode, the so-called breathing mode. The latter mode is connected to parameter b_1, usually written as R in the context of Rayleigh-Plesset bubble dynamics. As fundamental mode the one related to Legendre polynomial P_3 has been chosen since this constitutes the most important anisotropic deformation mode and since the procedure for higher modes is essentially the same. The amplitude of this mode is given by b_3 and is not restricted to small values, *i.e.* nonlinear interaction has been studied. Deformation of gas bubbles for which the constitutive equation is given by $p_L V^\gamma \equiv$ constant is studied. For moderate deformation with initial amplitude $b_3(t=0) = \beta$ about 0.1 it has been found that the extended Rayleigh-Plesset equation (15), or its equivalent equation (10), yields good predictions of the amplitudes that b_1 attains in the course of time. Comparison has been made with full solutions of the complete Euler-Lagrange equations and with computations with the boundary element method. Interesting features of equation (15) are the occurrence of an amplitude that is inversely proportional to $(4\omega_3^2 - \omega_{RP}^2)$, a finding first derived by Longuet-Higgins [3], a proper behaviour in the limit $(4\omega_3^2 - \omega_{RP}^2)$ going to zero, and the occurrence of a low dimensionless frequency $\{\sqrt{(\psi/2)} - \lambda\sqrt{12}\}$ and the high radian frequency $\{\sqrt{(\psi/2)} + \lambda\sqrt{12}\}$. The latter frequencies are

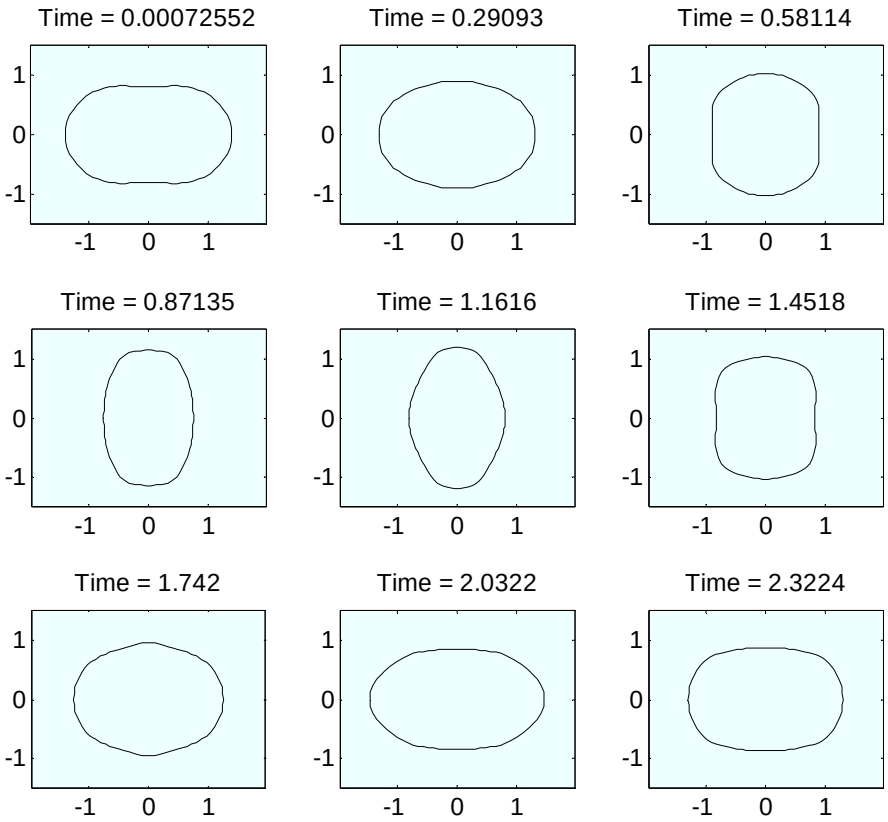

Figure 4. Shapes at various characteristic times, for b_3-excitation with $\beta = 0.1$, $\gamma = 0.1$ and $p_L R_0/\sigma = 2000$, *i.e.* $k = 12$. See figure 5 for corresponding histories of deformation coefficients at corresponding dimensionless times.

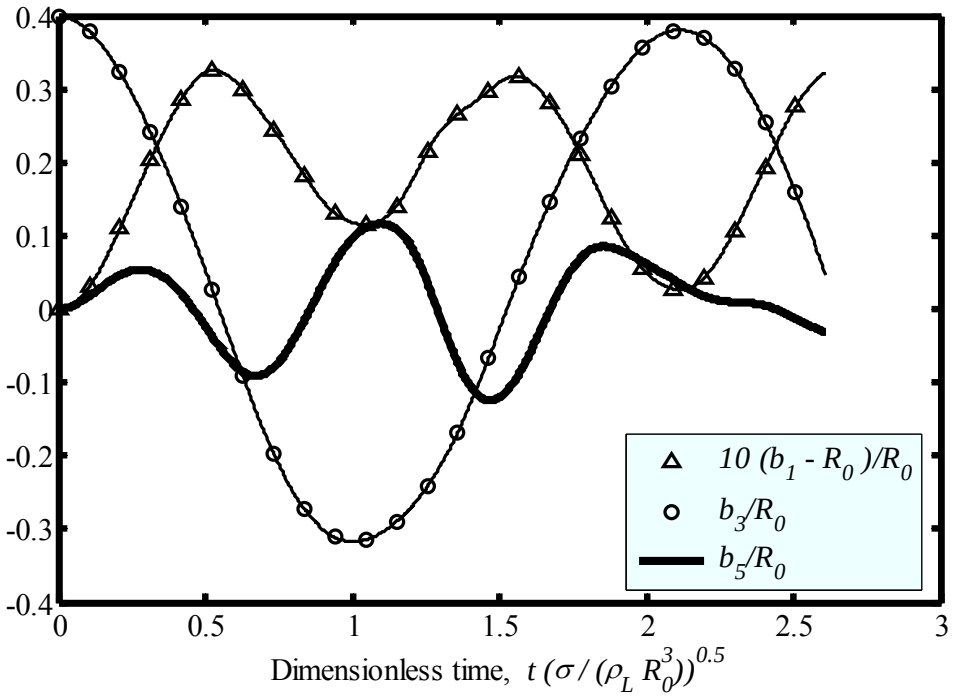

Figure 5. Shape coefficient histories for b_3-excitation with $\beta = 0.4$, $\gamma = 0.1$ and $p_L R_0/\sigma = 2000$, *i.e.* $k = 12$. See figure 4 for corresponding shapes.

clearly observed in actual deformation cases, see for example figure 3. The case of resonance depends on the parameter $\{p_L R_0/\sigma\}$ and the parameter k defined in equation (14); at resonance k is close to 1.

The parameters p_L and σ have been varied in a broad range and in all cases the dimensionless equation (15) was found to hold. The radian frequency ω_3 defined by equation (9) is found to change gradually in the course of time for k-values far from resonance.The reason is that b_3 depends on terms that are second order in β (equation 8) and is only fairly well described by equation (9) during periods of time of about $2\pi/\omega_L$. This explains the well-known experience [5] that ω_3 appears to depend on initial amplitude β for nonlinear deformation of bubbles and spheres of liquid. Practical cases are not close to resonance and ω_3 then changes in time; for times exceeding the dimensionless time $\pi/\{\sqrt{(\psi/2)} - \lambda\sqrt{12}\}$ equation (15) predicts the amplitudes well, but not the times at which the amplitudes are reached. We expect that this will be solved by predicting b_3 more accurately and intend to investigate this in a future study.

For a certain type of fluid a pressure-dependent initial b_1-value, R_0, may exist for which resonance occurs. At resonance, the fluid properties and the pressure are such that energy is quickly converted from the driving fundamental deformation mode to the breathing mode and much sound is produced. Far from resonance, each deforming bubble produces sound, be it with smaller amplitude, since each fundamental mode of oscillation is strongly coupled to the breathing mode (as in equation 13). The nonlinear production of sound by deforming gas-liquid interfaces created by sea waves or underwater nozzles may be better predicted with the results of this paper, in particular with the extended Rayleigh-Plesset equation (13) and its solution (15).

NOMENCLATURE

A	area of bubble surface
k	resonance indicator: $\{p_L R_0/\sigma\}$ / { 16/ γ – 2 + 2/(3γ) }
R_0	initial amplitude of the isotropic breathing mode: $b_1(t = 0)$
Q_1	generalized force, defined by equation 5.
V	bubble volume
β	initial dimensionless amplitude of the anisotropic deformation mode: $b_3(t = 0)/R_0$
γ	ratio of specific heats, c_p/c_v
λ	ratio of observed radian frequency, ω_3 (equation 9), to ω_L: ω_3 / ω_L
ψ	(k – 1)(25 – 3γ) + 24
ω	radian frequency. $\omega_L^2 = 12\ \sigma/(\rho_L R_0^3)$; ω_{RP} is defined in equation 2; ω_3 by equation 9.

EXPERIMENTAL STUDY ON SPACIAL STRUCTURE IN THE DRAG REDUCING CHANNEL FLOW OF VISCOELASTIC FLUID - BEHAVIOUR OF UNSTABLE LAYER

W. Gu[1], A. Saito[2], M. Motozawa[2], D. Wang[1], Y. Kawaguchi[2]*
[1]Shanghai Jiao Tong University, Shanghai, China
[2]Tokyo University of Science, Chiba, Japan

ABSTRACT. In this paper, drag reducing flow of dilute surfactant solution in a two dimensional channel has been investigated. We paid attention to the effects of Reynolds number ranging from 10000 to 40000 and concentration of additives CTAC from 25ppm to 100ppm in the flow. To measure the instantaneous velocity *u*-*v* in *x*-*y* plane, Particle Image Velocimetry (PIV) was employed. Turbulent statistics was calculated from the velocity data of few hundreds of PIV images. As a result of this study, we found that there appeared a train of inclined fluid lumps having high streamwise velocity fluctuation at the fixed *y*-position. We named this region "unstable layer". It was also found that the distribution of turbulent statistics has multiple peaks corresponding to the position where unstable layer exists. This characteristic structure of the drag reducing flow was discussed in the comparison of turbulent intensity and local mean velocity gradient.

Keywords: *Non-Newtonian fluid, Drag-reduction, PIV*

INTRODUCTION

The dilute solution of some kind of surfactant or polymer show obvious drag reduction (DR) comparatively with the water at the high Reynolds number[1]. This characteristic is useful for saving pumping power in a water-circulating device such as a district heating/cooling (DHC) system. For such applications, the surfactant additives are more advantageous than polymers because surfactant has self-repairing ability and as a result less affected to the mechanical degradation caused by the pump in the circulation system. Therefore, research in drag-reducing flow has received great attentions for the past several decades. Because the slight viscoelasticity of solution affects to the energy dissipation process of the flow, the flow with drag reduction exhibits special flow pattern which is different from laminar flow or turbulent one of Newtonian fluid. Therefore it is important to investigate the detailed structure in the drag reducing flow.

Many researches on the drag reducing flow have proceeded. Kawaguchi et al.[2] carried out the investigation of turbulent statistics in a two dimensional channel by LDV or PIV. They found that two components of velocity fluctuation were suppressed and Reynolds shear stress almost disappeared in the drag reducing flow. Li et al.[3] investigated the Reynolds number dependence of the turbulent structures in a drag-reducing flow by using relatively low-resolution PIV. They examined relationship between the dynamic process of the Shear-Induced Structure in the solution and turbulence. Thus the investigation of turbulent statistics and turbulent structures in the drag reducing flow is under the progress in the recent years[4,5].

In this paper, drag reducing flow of dilute surfactant solution in a two dimensional channel has been investigated experimentally by using high resolution CCD camera. We pay attention to the

(a) Flow System (b) PIV Arrangement

Figure 1. Experimental Facility.

effects of surfactant concentration and Reynolds number on the fine turbulent structure near the wall. We employed PIV to measure the instantaneous velocity *u*-*v* in the *x*-*y* plane. The turbulent structure was discussed based on the instantaneous velocity distribution in *x*-*y* plane. Turbulent statistics was calculated from the measured velocity data, and mean velocity profiles, distribution of root mean square (RMS) of velocity fluctuation components *u* and *v*, and Reynolds shear stress were obtained. Based on these measurements, the characteristic turbulent structure in the drag reducing flow was discussed.

EXPERIMENTAL SET-UP

Figure 1 shows (a)flow system and (b)PIV arrangement. Flow system consists of closed-circuit water loop with two dimensional channel test section. The channel was made of transparent acrylic resin having a length of 8m, inner height (*H*) of 0.04m, and spanwise width (*W*) of 0.5m. A honeycomb rectifier with length of 0.15m was set at the channel entrance for removing large eddies. An electromagnetic flow meter with an uncertainty of ±0.01 m^3/min was installed upstream of the channel for measuring flow rate *Q*. Bulk mean velocity U_b can be calculated by this flow rate, it represents $U_b=Q/A$, where *A* is the cross section area in the channel. Storage tank in the flow loop contained a heater and an agitator to adjust a temperature of fluid. The temperature of fluid maintained at 25°C with an uncertainty of ±0.1°C. The wall shear stress was estimated from pressure drop of the channel, which was measured with pressure tabs located on the wall of channel over a distance of 1.5m with an uncertainty of ±0.1Pa.

The PIV system consists of a double-pulsed laser, laser sheet optics, charge-coupled device (CCD) camera, synchronization device, image-sampling computer and image processing software (Dantec Dynamics studio ver. 1.45). The double-pulsed laser (New Wave Research Co. Ltd., MiniLase-Ⅱ /30Hz) is a combination of a pair of Nd-YAG lasers, each having an output of 30mJ/pulse and maximum repetition rate of 30Hz. The synchronization device communicates with the CCD camera and computer, and generates pulses to control the double-pulse laser. The CCD camera used in this experiment has a resolution of 2048×2048 pixels. The laser sheets were aligned at *z*=250mm (*z*=0 at the side-wall) for the *x*-*y* plane measurements. The measurement point is located at 7m downstream from the channel entrance. At the location of the measurements, the channel was equipped with two circular glass windows having a diameter of 0.15m on both sides of the channel. PIV images were acquired for 500 dual frames for all the measurements. The photograph acquisition rate was 4Hz. The picture were taken to cover the full height of the channel (the PIV image covered an area of about 60×60 mm^2). The interrogation area was set to be 64×64 pixels with 75% overlap in each

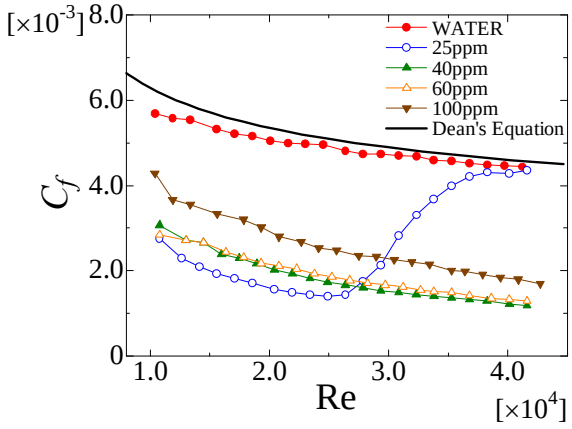

Figure 2. Friction coefficient versus Re.

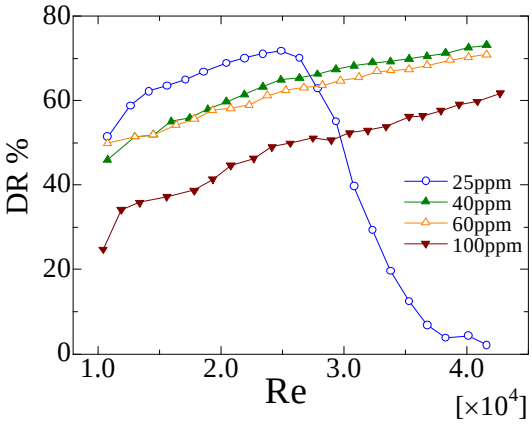

Figure 3. Drag reduction rate versus Re.

direction. The spacing between adjacent vectors in both directions was around 0.45mm. The tracer particles used to seed the flow were acrylic colloid. The particle concentration was adjusted so that on average at least ten particle pairs were observed in an interrogation window for each case.

The surfactant tested in this measurement was the cationic surfactant, cetyltrimethyl ammonium chloride (CTAC : $C_{16}H_{33}N(CH_3)_3Cl$). Local tap water was used as the solvent. Sodium salicylate (NaSal) was added to the solution with the same weight concentration as that of CTAC for providing counterions. The molar ratio of Sodium salicylate to the CTAC was about 2. The CTAC solution with concentration of 25ppm, 40ppm, 60ppm, and 100ppm was selected as drag-reducing fluid. Tap water was also used as the tested fluid for comparison. In this paper, Reynolds number was defined as $\mathrm{Re}=U_bH/v$, where U_b is the bulk mean velocity, H is the height of the channel and v is kinematic viscosity of the solvent. Re was ranged from 10000 to 40000 for each concentration.

RESULTS AND DISCUSSION

In this section, the instantaneous velocity maps and the results of turbulent statistics were analysed in the water and surfactant solution flows based on the PIV measurements in the x-y plane. Turbulent statistics was calculated from the instantaneous velocity data of 500 PIV images for each condition.

Friction coefficient and drag reduction rate

The friction coefficient was obtained from the pressure drop of the channel. Based on this measurement, drag reduction rate (DR) can be calculated. The drag reduction rate was defined as

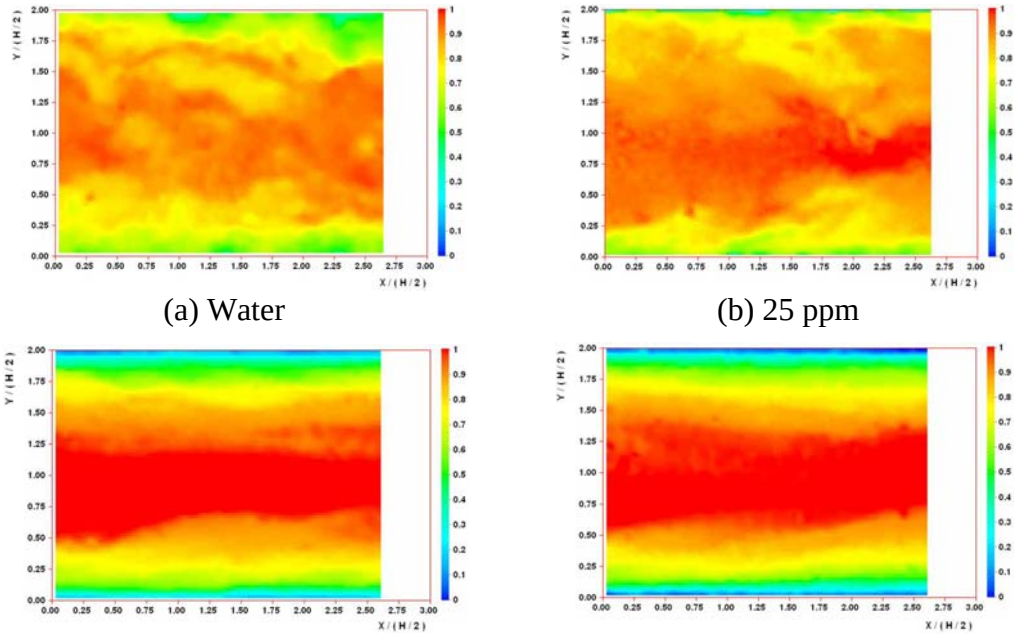
$$\mathrm{DR} = (C_{f,w}-C_{f,s})/C_{f,w} \times 100\ \% \qquad (1)$$

where C_f is the friction coefficient $C_f = \tau_w / (1/2\rho U_b^2)$, and the subscript w and s represent water and surfactant solution, respectively. τ_w is the wall shear stress and ρ is the density of the solvent.

Figures 2 and 3 show the friction coefficient distribution and the DR distribution versus Reynolds number, respectively. The solid line in Figure 2 is the friction coefficient of water flow in a two dimensional channel obtained by Dean[6]. This line represents following equation.

$$\mathrm{Re} = \sqrt{2/C_f}\,\exp[0.41(\sqrt{2/C_f} - 2.4)] \qquad (2)$$

The friction coefficient of drag reducing flow is much smaller than that of water flow. Especially, in case of 40ppm, 60ppm and 100ppm, drag was reduced largely in the wide range of Reynolds number. Maximum DR in this study was about 73%. On the contrary, in case of 25ppm, DR has a maximum at critical Reynolds number, and DR starts to decrease with increasing Reynolds number beyond the critical Reynolds number, and finally disappeared. This seems to be explained that the network structure of micelles is destroyed with high shear rate and viscoelasticity effect of fluid



(a) Water (b) 25 ppm

(c) 40 ppm (d) 60 ppm

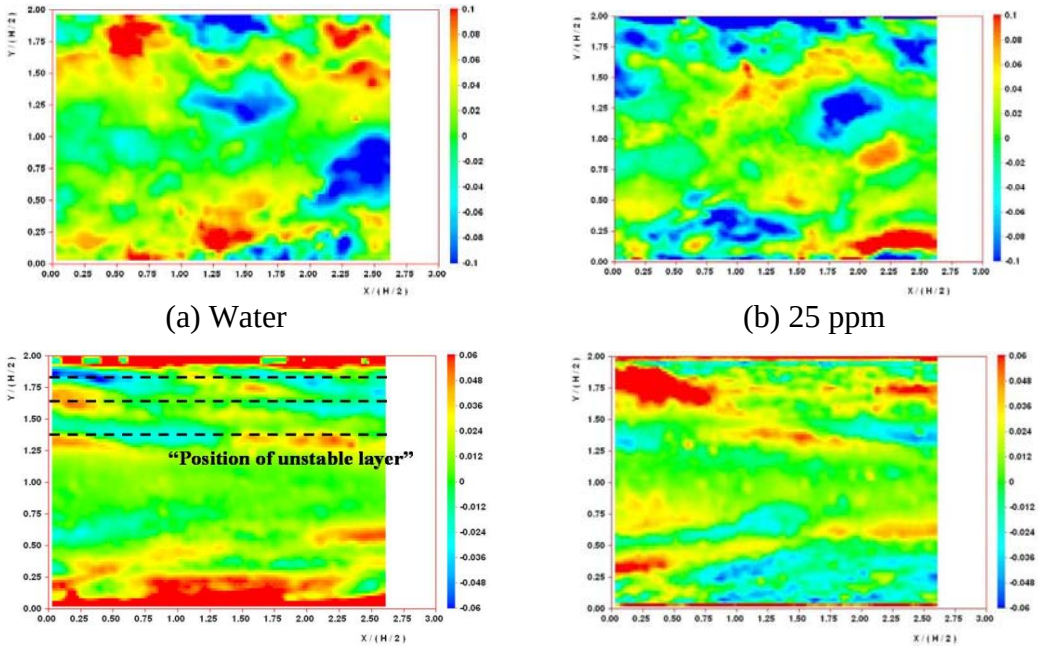
Figure 4. Instantaneous distributions of streamwise velocity (Re=40000).

also disappears. This rheological property depends on the surfactant concentration and temperature of fluid. It is worth noting that the friction coefficient changes according to the Reynolds number at 25ppm but not in the other concentrations. This suggests that in this Reynolds number range, surfactants suppress the turbulence at the concentration of 40ppm. Surplus of surfactant gives no effects to the suppressed turbulence. Under the lower concentration condition such as 25ppm, the drag reduction rate has a complicated relation with Reynolds number. It suggests that the turbulent eddies which have different scale in different Reynolds number are interacting to the turbulent suppression at this concentration range.

Instantaneous distribution of streamwise velocity and velocity fluctuation

Figure 4 shows instantaneous distributions of streamwise velocity u for Re=40000 in the x-y plane. Main flow direction is from left to right. The contour of these maps shows the streamwise velocity. In the water flow, it is seen that there are many eddies with different size and intensity coexists, by this motion, momentum transportation of fluid is occurring actively. This is the common idea for the Newtonian fluid turbulence and was confirmed from the cloud like pattern seen in the present PIV picture. In contrast with water flow, the turbulent structure in the drag reducing flow at high reduction rate is very different as shown in Figure4(c), (d). It is observed that smaller eddies disappears and fluctuation in larger size survives. There remains “wavy structure” along the streamwise direction. The wavy structure seems regular and detailed discussion on this regularity will be given in the next section. This structure is far from the normal turbulence but it is not also the same with the laminar flow of Newtonian fluid. Therefore, the drag reducing flow is not simply the suppression of turbulence.

Figure 5 shows the distributions of instantaneous streamwise velocity fluctuation u' for Re=40000. The velocity fluctuation was defined as the instantaneous local velocity subtracted the local mean velocity averaged by 500 velocity fields from the instantaneous local velocity. As shown in Figure 5, streamwise velocity fluctuation was observed in the drag reducing flow. In the water flow, velocity fluctuation occurs irregularly. However, we found that there appeared a train of inclined fluid lumps having a different velocity at the fixed y-position in the drag reducing flow, as shown Figure5(c), (d). This alternating behaviour relates to the wavy fashion of instantaneous velocity distribution in Figure4(c), (d). When the RMS of turbulent fluctuation is calculated at this position, the value of



(a) Water (b) 25 ppm

(c) 40 ppm (d) 60 ppm

Figure 5. Instantaneous distributions of streamwise velocity fluctuation *u'* (Re=40000).

velocity fluctuation becomes high. Through the detailed investigation of numbers of PIV map, it was observed that this layer spreads to the *x*-direction, parallel to the wall surface and has relatively thin in *y*-direction, but the value of velocity fluctuation is relatively small out of this layer. Therefore, we named this region as "unstable layer". Another interesting characteristic is that the unstable layer can be found in multiple places. This means that the "wavy structure" exists at different y-position which forms a group of waves. Surprisingly, the positions of the unstable layer were almost unchanged for the number of PIV maps. This feature is also very different from normal turbulent fluctuation which spreads in irregular position, frequency and intensity.

Turbulent statistics results

Figure 6 shows the streamwise mean velocity profiles normalized by the friction velocity u_τ which is estimated from the pressure drop of the channel. This figure shows the case of Re=40000. The log-law profiles of streamwise mean velocity for Newtonian turbulent flow and drag-reducing flow are defined as follows,

$$U^+=2.4\ln y^+ +5.5 \quad (3)$$

$$U^+=11.7\ln y^+ -17 \quad (4)$$

Mean velocity profile of water flow is in good agreement with equation (3). In drag reducing flow, mean velocity profiles are upshifted in the log-law layer with a larger gradient compared with that in water flow, and close to equation (4). Equation (4) was suggested by Virk for the ultimate velocity profile of polymer solution flow[7]. This upshift of mean velocity directly indicates the large drag reduction existence in this condition. On the contrary, in case of 25ppm where drag reduction disappeared, mean velocity profile is almost same as that in water flow.

Figure 7 shows the distribution of RMS of streamwise velocity fluctuation *u'* normalized by U_b. Horizontal axis is normalized by the half of the channel height *h* (=*H*/2). Figure 7(a) and (b) show the effects on the surfactant concentration and Reynolds number, respectively. In the drag reducing flow, u_{rms} decreases throughout the channel height than that in water flow. The value of u_{rms} decreases with increasing drag reduction rate. The turbulent fluctuation normalized by the bulk mean velocity is suppressed by drag reduction additives. Although u_{rms} has a peak with low DR as Re=10000 for 40ppm, u_{rms} has multiple peaks in the case with high DR as Re=30000 and 40000 for 40ppm. The position

Figure 7. Distribution of RMS of streamwise velocity fluctuation.

where appeared multiple peaks is the same position where the unstable layer appeared in the instantaneous velocity fluctuation map. The local statistical value at the location of the unstable layer will be summarized in the last part of this chapter. Similar characteristic to these multiple peaks in the drag reducing flow was observed in other studies in turbulent boundary layer[8]. It is interesting that the similar characteristics have been found in the other type of shear flow but detailed discussion will be the task in the future.

Figure 8 shows the distribution of RMS of wall normal velocity fluctuation v' normalized by U_b for Re=40000. In the drag reducing flow, v_{rms} largely decreases throughout the channel height than that in water flow. The amount of decrease of v_{rms} is much higher than that of u_{rms}. This fact suggests that the turbulent energy transport between the different directional components is inhibited by the effect of additives. Therefore, the directional components becomes to anisotropic in the drag reducing flow. In the distribution of v_{rms}, there did not appear the multiple peaks seen in the distribution of u_{rms}.

Figure 9 shows the distribution of Reynolds shear stress uv normalized by $u_\tau{}^2$ for Re=40000. In the turbulent water flow, Reynolds shear stress has the large value near the wall, and this corresponds to the larger frictional drag. In the drag reducing flow, Reynolds shear stress largely decreases and the value is almost zero throughout the channel height. This is the typical characteristics accompanied with high drag reduction. When examining carefully, the value has the multiple peaks at similar position of peaks in the distribution of u_{rms}.

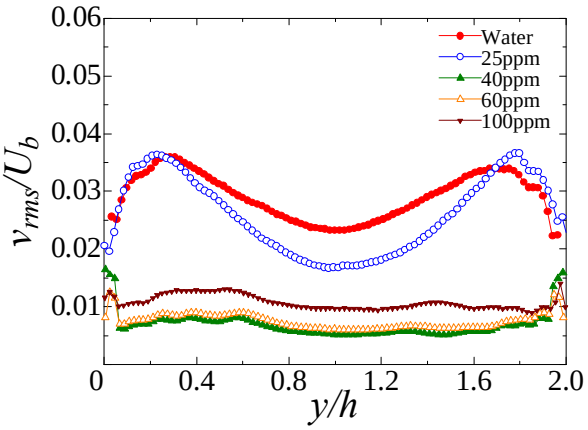

Figure 8. Distribution of RMS of the wall normal velocity fluctuation (Re=40000).

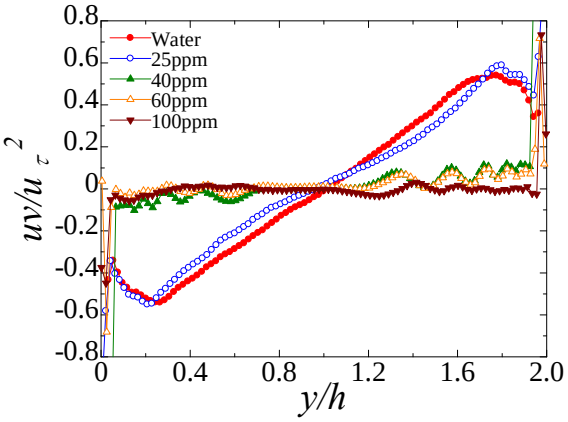

Figure 9. Distribution of Reynolds shear stress (Re=40000).

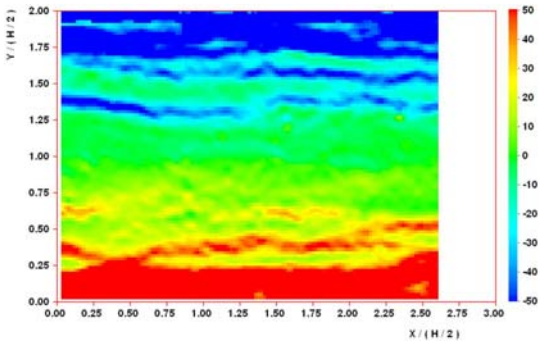

Figure 10. Distribution of instantaneous velocity gradient (40ppm, Re=40000).

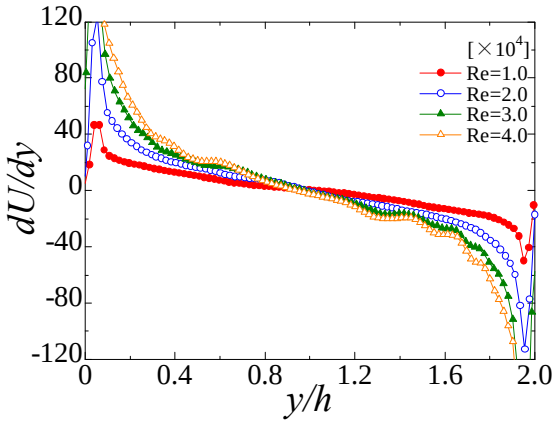

Figure 11. Distribution of mean velocity gradient (40ppm).

To see the relation of unstable layer and local shear rate, examining the instantaneous velocity gradient map is useful. Figure 10 shows the distribution of instantaneous local velocity gradient *du/dy* in the drag reducing flow. It can be seen that the high velocity gradient appears in location of the unstable layer. This coincidence was observed at each of PIV map.

Figure 11 shows the distribution of the mean velocity gradient *dU/dy* for Re=40000. In the case with low DR as Re=10000, the value of *dU/dy* decreases gradually toward to the center of the channel. On the contrary, in the case of Re=40000, the value of *dU/dy* is high in the unstable layer. Because the mean velocity differs for different Reynolds number, the mean velocity gradient also differs for each case. One interesting finding is that even the local value of velocity gradient is different, the unstable layers appear at same y-positions. This fact suggests that the local value of velocity gradient itself does not matter to produce the unstable layer.

Presently, we cannot declare the full mechanism of the unstable layer, but we can summarize the observation in Table 1. From this summary, the unstable layer has “turbulence-like” characteristics. But just outside of this layer, the character disappears. Therefore, the layered structure of “unstable layer” and “stable layer” are locally and temporally stable. The velocity fluctuation found in the unstable layer is regular in space. These characteristics are far from the normal turbulence found in Newtonian fluid. The reason we call the layer as “turbulent-like” comes from this findings.

One possible explanation for existence of the unstable layer may be related to the instability phenomena appearing in the viscoelastic fluid. The fluid has intrinsic time scale and in certain shear condition, the flow becomes unstable. One typical observation in laminar flow is “shear induced

Table 1
Statistical property of at the position of unstable layer

Statistical property	Value
RMS of Streamwise velocity component u_{rms}	Peak
RMS of wall-normal velocity component v_{rms}	Vague peak
Reynolds shear stress	Peak
Mean velocity gradient	Peak

state" which is the formation of large molecular structure under the steady shear. When this phenomenon appears, the cross-talk between the shear and viscosity change occurs and the flow becomes unstable. Presently, we cannot claim the unstable layer is caused by the "shear induced state", further investigation on the idea of viscoelastic instability may be fruitful.

CONCLUSION

The characteristic structure of the drag reducing flow with surfactant additives was investigated experimentally. We employed PIV to measure instantaneous velocity in *x*-*y* plane, instantaneous velocity distribution and turbulent statistics was obtained. As a result of this study, the following conclusions in the drag reducing flow were obtained.

In the instantaneous velocity fluctuation map, there appeared a train of inclined fluid lumps having high velocity fluctuation at the fixed *y*-position. The distributions of u_{rms} and Reynolds shear stress have multiple peaks at this position. The position where unstable layer exists is unaffected by the Reynolds number and the surfactant concentration. Although further analysis is necessary, it is speculated that this ordered motion is taking important role in the momentum transfer in a viscoelastic fluid turbulence.

SYSTEM AIR – GLYCERIN: TOTAL VOLUMETRIC AIR FLOW RATE USING PICTURES OF THE FLOW

M.A.T. Talaia[1 *]
[1]Physics Department, University of Aveiro, Aveiro, Portugal

ABSTRACT. Usually the flow of gas is measured or controlled using a rotameter or a flow measurer.
In this work, for a system air - glycerin the flow of air injected into the base of a vertical and transparent column of quadrangle section, for flow regime with Reynolds number very low (dominate forces of viscosity) produce air bubbles that rise with a spherical geometric shape, can be obtained through pictures.
A theoretical and experimental model was developed based on a dimensional analysis.
The results obtained are very interesting and shows that the model developed predicts, with excellent agreement, the flow of air injected into the base of the column and the number of bubbles of air that arrives to the free surface of the glycerin with Reynolds number from 0.10 to 0.16, terminal velocity from 0.023 m/s to 0.035 m/s and diameter of the bubble air from 0.006 m to 0.007 m.

Keywords: *two phase – flow, gas bubble, terminal velocity, air / glycerin system e, volumetric air flow rate*

INTRODUCTION

Terminal velocity of a single bubble rising through an infinite stagnant liquid is of fundamental importance in the field of gas liquid two phase flow.
As is known, the single isolated gas bubble rising velocity in a liquid large column depends on buoyancy and drag forces. Interactions between forces happen due to surface tension, viscosity, inertia and buoyancy produce a various effects which are quite often evidenced by different bubble shapes and trajectories. Many industrial processes include bubble columns for promoting mass transfer, high pressure evaporators and so on.
The dependence of the velocity on the rising bubble volume for air bubbles in liquid has been determined experimentally by numerous investigators; our team [1-10] and another team [11-23] among the others.
In the present study, for a air - glycerin system the flow of gas injected into the base of a vertical and transparent column of quadrangle section, for flow regime with the Reynolds number very low produce air bubbles that rise with a spherical geometric shape, can be obtained through picture. For a constant flow of air is possible to observe that the air bubbles produced near the injector (centered at the base of the column) rise and when they reach terminal velocity they move maintaining a constant distance between them. If a picture can be obtained it is possible to determinate through its interpretation and of the terminal velocity of the air bubble the total volumetric air flow rate. The velocity of the air bubble will depend on the fluid proprieties, acceleration due gravity and the size of the bubble.

EXPERIMENTAL METHOD

The experimental technique adopted in the present paper to study the behaviour of air bubbles which rise in the interior of a viscid liquid (in this particular case is glycerin), when the volume of injected gas is altered, by an appropriated system placed in the base of a vertical column, is easily understood through the scheme in Figure 1.

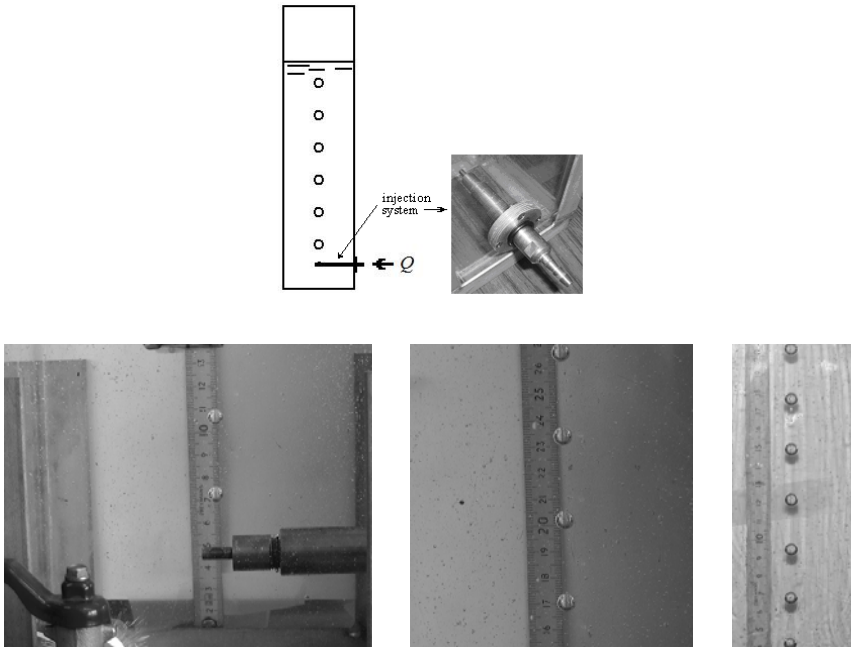

Figure 1 – Schematic of the experimental apparatus; injection system and pictures with the movement of air bubbles

The device used is made of a transparent acrylic glass column, with a height of 1.5 m and a squared section with a 0.15 m ridge. The column is open on the top of the superior part which allows the surface of the liquid to be in contact with the atmosphere.
In the base of the column was installed a tap which allows the exit of the liquid. The height of the liquid determines the pressure of the air bubbles injection and consequently the size of the bubbles, distance between bubbles and terminal velocity of the air bubbles. An injection system is also placed in the base of the column. The exit of the air occurs in the middle (axis longitudinal) to eliminate the wall effects, when the isolated and separated bubbles rise in the interior of the liquid. As the Figure 1 shows, the air exit in the injection system happens through a 0.001 m hole. This can be easily replaced by other exit diameters. The size of the air bubbles depends of the pressure due to the height of the liquid column, the diameter of the injection hole and the superficial tension.
In this work we care about developing experimental techniques of observation and collect of data. Thus, there will be introduced only data referring to the air bubbles which rose with a spherical shape in the glycerin interior. By being a viscid liquid, the glycerin has a great advantage instead of water, in which the techniques are harder to implement and control.
The injection system is connected to the compressed air net. The compressed air passes through a “box / lung” to eliminate the small pressure variations in the alimentation net. A system of air flow measure was installed to control the registered and observed data.
The size of the air bubbles which form inside the glycerin is controlled by one manometer of pressure and by the height of the liquid inside the column.

A tape measure placed in the lateral side of the column allows, by picture and a video system, the determination of the terminal velocity of the air bubbles. Knowing the distance in a certain time and considering the uniform movement (no acceleration) the velocity is easily determined.
The air flow was also measured using two different processes: counting the number of bubbles that get to the surface of the liquid or that pass a level during a determined amount of time and/or collecting the air bubbles in a volume graduated collector during a certain time. To the same air flow, the diameter of the air bubbles was also determined by photo and/or calculation. Also, each bubble was collected in a graduated cylinder at the top of the column in order to determine its volume. In order to minimize the error of the air bubble diameter, and for the same bubble size, the gathered bubbles inside a cylinder graduated were counted. The total volume was divided later by the number of air bubbles gathered
The physical properties of the glycerin (dynamic density and viscosity) were determined.
During the experimental work there was the concern to maintain the constant temperature, because the glycerin viscosity is very much influenced by it.

DEVELOPED MODEL

Pictures of the rising movement of the air bubbles inside the glycerin allowed the development of a simple model to preview the flow of air which is injected in the base of the column.
The air flow was considered to air bubbles that move inside the glycerin with the same terminal velocity, therefore with the same distance between the air bubbles.
As the Figure 2 shows, the volume of the sphere of air of each bubble was considered as a circular column of air between spheres. Therefore, the air bubbles rising system with the same distance between air bubbles is equal to an air column system which moves in the interior of the glycerine, with the same terminal velocity of each isolated air bubble. In this situation the continuity equation was used.
The dimensional analysis allowed the development of two equations which constants are determined by the experimental conditions.

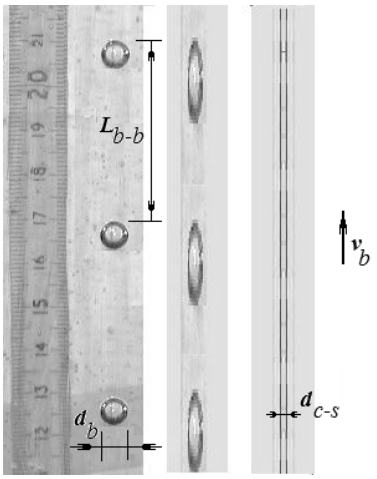

Figure 2 – Theoretical model: air column system

THEORY

In this work we applied dimensional analysis to determine dimensionless groups governing the total volumetric air flow rate of gas bubbles in stagnant liquid, rising in long vertical tubes filled with liquid viscosity.
Physically, we expect the volumetric air flow rate of gas bubbles Q should depend on eight variables

$$Q = Q\left(\rho_l, \Delta\rho, \mu_l, \sigma_{l/g}, g, L_{b-b}, v_b, d_b\right) \tag{1}$$

where ρ_l is the density of liquid, $\Delta\rho = \rho_l - \rho_g$ the apparent density, ρ_g the density of gas, μ_l the dynamic viscosity of liquid, $\rho_{l/g}$ the surface tension of liquid/gas, g the acceleration due gravity, L_{b-b} the distance between gas bubbles, v_b the terminal velocity of one single isolated gas bubble and d_b the equivalent bubble diameter (diameter of a sphere with same volume as the bubble).
The dimensional analysis of equation (1) can be obtained through traditional techniques [24]. The independent variable chosen were g, ρ_l and d_e.
Thus, the six dimensionless groups are:

$$\Pi_1 = \frac{Q}{\sqrt{gd_e^5}} \qquad \Pi_2 = \frac{\Delta\rho}{\rho_l} \tag{2}$$

$$\Pi_3 = \frac{\mu_l}{\sqrt{\rho_l^2 g d_e^3}} \qquad \Pi_4 = \frac{\rho_{l/g}}{\rho_l g d_b^2} \tag{3}$$

$$\Pi_5 = \frac{L_{b-b}}{d_b} \qquad \Pi_6 = \frac{v_b}{\sqrt{gd_e}} \tag{4}$$

Algebraic manipulation leads to

$$Z = \frac{\sigma_{l/g}\Delta\rho}{\rho_l g^{1/2} d_b^{1/2} \mu_l} \tag{5}$$

$$\mathrm{Re}_b = \frac{\rho_l v_b d_b}{\mu_l} \tag{6}$$

For values of $\Pi_1 = \phi\left(\Pi_6\Pi_5^{-1} = \Pi_7\right)$ may be written

$$Q = k\frac{v_b d_b^3}{L_{b-b}} \tag{7}$$

where *k* is a experimental constant.
Also, according Figure 2,

$$\pi\frac{d_{c-s}^2}{4} = \pi\frac{d_b^3}{6L_{b-b}} \qquad d_{c-s} = \left(\frac{2d_b^3}{3L_{b-b}}\right)^{1/2} \tag{8}$$

where d_{c-s} is the gas column with terminal velocity v_b.
Then, also

$$Q = k' d_{c-s}^2 v_b \Leftrightarrow k' d_{c-s}^2 \frac{d}{\Delta t} \tag{9}$$

being $k' = 1{,}5k$.

If we take a time interval $\Delta t\left(=t_f - t_i\right)$, between two marks which define the referential distance d [all measurements were made from the top (nose) of the gas bubble],we can calculate the experimental terminal velocity, being $v_b = \dfrac{d}{\Delta t}$.

By other hand, it is possible to obtain

$$Q = n\frac{\pi d_b^3}{6\Delta t'} \tag{10}$$

where n is a number of gas bubbles considered during a time interval $\Delta t'$.
So,

$$n = \frac{d}{L_{b-b}}\left(\frac{\Delta t'}{\Delta t}\right) \tag{11}$$

RESULTS AND DISCUSSION

The Figure 3 show for the air glycerin system the experimental data, experimental straight line where $k = \left(0.5246 \pm 0.0258\right)$ and theoretical straight line where $k = \pi/6$.
The experimental data allowed the determination of the constants value and its uncertainty or associated error.
So, the experimental equation will be

$$Q = \left(0.5249 \pm 0.0258\right)\frac{v_b d_b^3}{L_{b-b}} \tag{12}$$

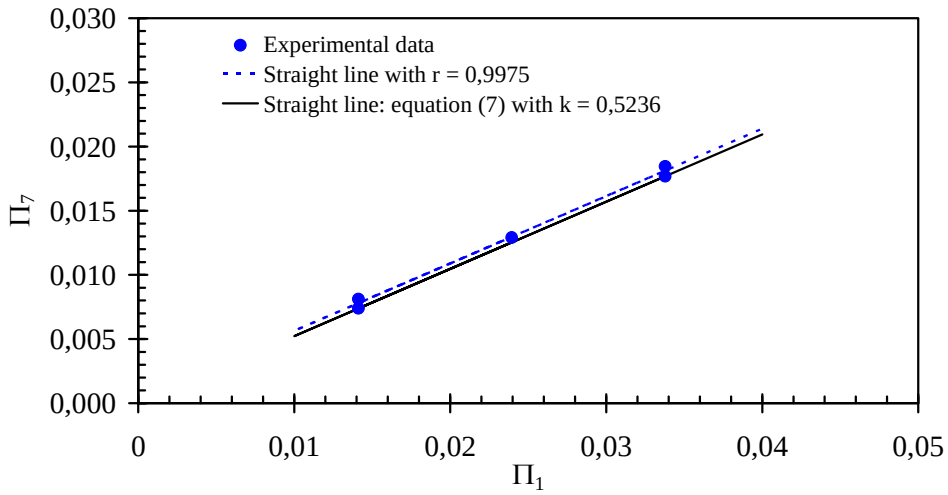

Figure 3 – Experimental data considering $\Pi_1 = \phi\left(\Pi_7\right)$: air glycerin system

So, the equation (12) that can be used to the air / glycerin system with *Z* number from 0.15 to 0.16, terminal velocity from 0.023 m/s to 0.035 m/s and Reynolds number from 0.10 to 0.16.
The results obtained are very interesting and shows that the model developed predicts, with excellent agreement.

with Reynolds number, terminal velocity from and diameter of the bubble air from 0.006 m to 0.007 m.

RESEARCH IN COURSE

It is being studied a injection system which allows the decreasing of the air bubbles size. The superficial tension between fluids (gas / liquid) is important to the formation of the size of the air bubble. At this moment are also being made essays with low viscid liquids, like water. In this stage can be recognized the difficulty of the air / water system in the variables control. The research is in course and it is expected, in a near future, to have an amount of very interesting data. It is being considered the replacement of the picture technique by the use of a transducer differential pressure column.

CONCLUDING REMARKS

During the research, all experiments were carried out at constant temperature.
A method based in the dimensional analysis is presented to preview the air flow by some data read and photograph technique.
Adimensional parameters allowed the presentation of expressions that let preview the constant air flow which is injected in the vase of a column filled with glycerin.
The expression constants were determined by experimental data and the developed and showed expression is in concordance with the theoretical model.
The obtained results are interesting to limit values defined by equivalents air bubbles diameters, terminal velocity of air bubble and where fluids physical properties are known.
Experimental data show that it is possible to work out expression to accurately predict total volumetric air flow rate in air glycerine system.

TRAVELLING WAVES IN A NATURAL CONVECTION BOUNDARY LAYER ADJACENT TO A SIDEWALL OF A DIFFERENTIALLY HEATED CAVITY

F. Xu*, J. Patterson, C. Lei, T. Bednarz
James Cook University, Townsville, QLD 4811, Australia

ABSTRACT Travelling waves in a natural convection boundary layer adjacent to a sidewall of a differentially heated cavity are investigated experimentally. The travelling waves in the transition from an initially isothermal interior fluid ambient to an eventually stratified interior fluid ambient are described based on temperature measurements. The temperature time series at discrete points in the natural convection boundary layer show features consistent with previous visualizations, and the wave features of the fully developed natural convection boundary layer are discussed.

Keywords: *Travelling waves, natural convection boundary layer, differentially heated cavity*

INTRODUCTION

Natural convection induced by a horizontal temperature difference is one of the major flow phenomena of the oceans and atmosphere, and also is of significance in many industrial processes such as electronic cooling systems, heat exchangers, and solar collectors. Accordingly, the study of natural convection flows in a differentially heated cavity was the initial impetus for modelling the above flow phenomena. Considerable studies have revealed important mechanisms of the complex flows in the differentially heated cavity. In particular, the work by Patterson and Imberger [1] characterized the physical features of natural convection flows in the cavity with suddenly heated and cooled sidewalls respectively, and classified them into different flow regimes through detailed scaling analyses. Furthermore, it has also been demonstrated by experimental measurements [2-6] and numerical simulations [7, 8] that a transition of the interior fluid in the cavity from an initially isothermal to finally stratified state occurs.

One of the important flow phenomena in a differentially heated cavity is the evolution of the natural convection boundary layer flow adjacent to the sidewall. Studies (see e.g. [1]) show that when a sidewall of the cavity is abruptly heated or cooled, heat is first transferred in the direction normal to the sidewall surface, resulting in the growth of a natural convection boundary layer with time. Associated with this natural convection boundary layer growth, a one-dimensional (1D) vertical flow driven by buoyancy forces develops. This 1D response lasts only for a short time near a finite length surface. Perturbations from the leading edge effect (hereinafter referred to as LEE) quickly lead to an unstable flow downstream, which eventually develops into a steady two-dimensional (2D) flow [9] as long as the Rayleigh number is sufficiently small. Goldstein and Briggs [10] gave an estimate for this transition time, however, their prediction lagged behind the experimental measurements [11]. Subsequently, Armfield and Patterson [12] suggested that the LEE arrival time is determined from the velocity of the travelling waves triggered by the start-up perturbation, rather than the maximum convection velocity. This suggestion was supported by the experimental

E-mail address: feng.xu@jcu.edu.au

measurements [5]. Indeed, the LEE not only induces the transition from 1D to 2D laminar flows but also is a potential source of turbulence if the Rayleigh number is larger than a critical value.

The horizontal intrusion, discharged from the downstream end of the vertical natural convection boundary layer, is also an important flow phenomenon in a differentially heated cavity. Experiments (e.g. [2-4]) have demonstrated that the separation of the intrusion from the ceiling always appears at the upstream end of the intrusion. The mechanisms responsible for the separation have also been extensively investigated (see e.g. [2, 4, 13]).

Although considerable attention has been paid to the initial transient response of the unsteady natural convection flows in the differentially heated cavity following sudden heating, there have been few investigations of the transition of the natural convection boundary layer to a quasi-steady state except for the visualizations reported in [5, 14]. In order to obtain further understanding of the full transition of the natural convection boundary layer adjacent to the sidewall, particularly the temperature features during the full transition, in this study, thermistors are employed to measure the temperatures of the natural convection boundary layer, and the travelling waves in the natural convection boundary layer are described.

EXPERIMENTAL SETUP

The temperature measurements were carried out near the hot sidewall of a differentially heated cavity sketched in Figure 1, which is similar to that described in [5]. The cavity, containing water as the working fluid, is 1-m long (L), 0.24-m high (H) and 0.5-m wide (W). The cavity walls are made from Perspex sheets except the cooled and heated sidewalls, which are made of 0.00113-m thick gold-coated copper plates.

In the experiments, one sidewall is heated by the hot water in a water bath and the opposing sidewall cooled by the cold water in another water bath. Each water bath, connected to a refrigerated/heating circulator, is initially separated from the sidewall by a pneumatically operated gate with an air gap between the gate and the sidewall. At the start of the experiments, the gates are rapidly lifted, allowing the hot and cold water respectively in the two water baths to flush against the copper sidewalls. This process is completed within a fraction of a second, and thus a close to instantaneous isothermal boundary condition is established at each end of the cavity [5]. During the experiments, the temperatures of the water in the water baths are kept constant by the circulators with a temperature stability of ± 0.01 K.

Thermometrics FP07 thermistors with a time constant of 0.007 s in water are used to measure the temperature of the flows adjacent to the sidewall. The body of the thermistor has a maximum diameter of 2.2 mm and a length of 12.6 mm, and is mounted in an insulated tube in order to minimize thermal disturbances. All four thermistors were placed in the vicinity of the hot sidewall,

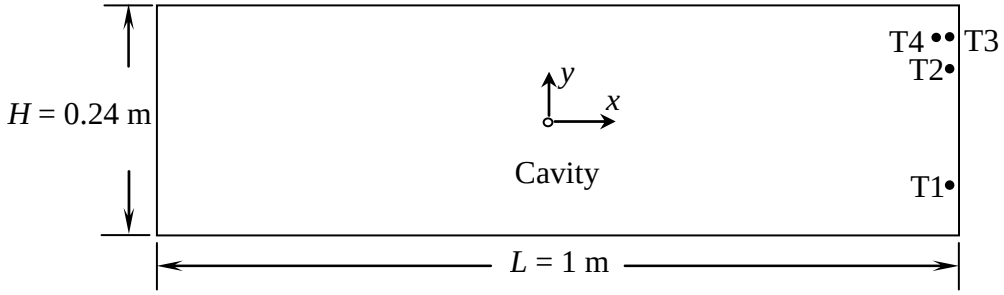

Figure 1. Schematic of the experimental cavity: Points T1 to T4 denote Thermistor locations, which are corresponding to Thermistor 1 (0.4978 m, -0.048 m), Thermistor 2 (0.4974 m, 0.0624 m), Thermistor 3 (0.497 m, 0.0899 m) and Thermistor 4 (0.4869 m, 0.0868 m) respectively.

as seen in Figure 1, three of which (T1 – T3) are close to the sidewall but at different heights with the fourth (T4) located further from the sidewall but at approximately the same height as T3. For the description of physical locations, the origin of the coordinates is at the center of the cavity.

The dimensionless controlling parameters in the experiments are the Rayleigh number (*Ra*), the Prandtl number (*Pr*) and the aspect ratio (*A*), defined respectively as follows,

$$Ra = \frac{g\beta\Delta T H^3}{\nu\alpha} \tag{1}$$

$$Pr = \frac{\nu}{\alpha} \tag{2}$$

$$A = \frac{H}{L} \tag{3}$$

Table 1. Experimental parameters for temperature measurements

Experiment	Initial temperature of water in cavity (T_0, K)	Temperature difference between sidewalls (ΔT, K)	Ra ($\times 10^9$)	Pr
1	294.45	4	0.88	6.83
2	294.45	8	1.75	6.83
3	295.55	16	3.77	6.63
4	294.15	32	6.87	6.81

RESULTS AND DISCUSSION

It is clear that the experimental conditions may be varied by changing the temperature difference between the two sidewalls. Four experiments with temperature differences between the two sidewalls ranging from 4 to 32 K were performed, and the corresponding ranges of *Ra* and *Pr* are $0.877 \sim 6.87 \times 10^9$ and $6.63 \sim 6.83$ respectively. Table 1 lists all experimental parameters. The results of the temperature measurements will be described based on $Ra = 1.75 \times 10^9$ (Experiment 2) in this section unless specified otherwise.

Figure 2 shows the time series of the temperatures measured at the four locations. The temperature fluctuations of the natural convection flows adjacent to the sidewall are clear and the time series of

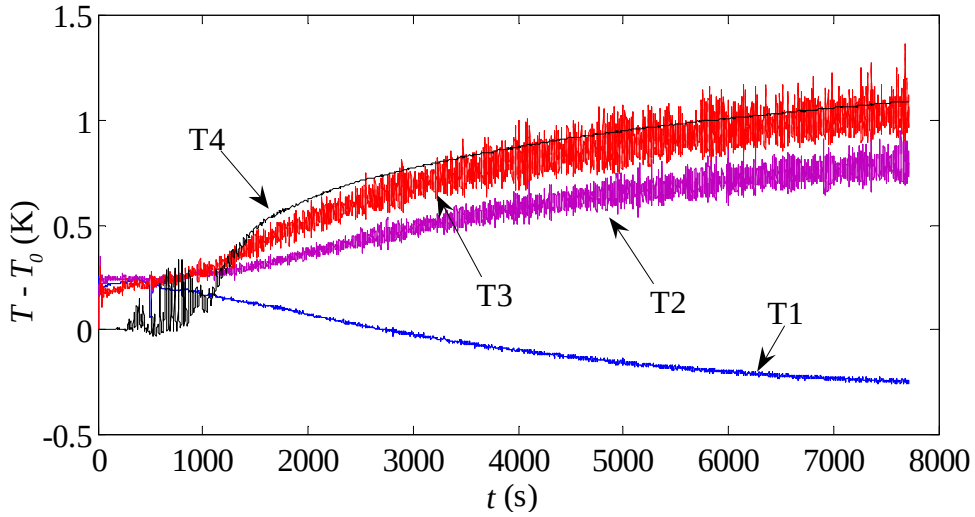

Figure 2. Time series of the temperatures at different locations (shown in Figure 1) for the Rayleigh number of 1.75×10^9.

the temperatures at all the four locations eventually approach quasi-steady states respectively. It is seen in this figure that the temperatures measured by Thermistors 2 - 4 in the upper part of the cavity increase with time and the temperature measured by Thermistor 1 in the lower part of the cavity decreases with time. As a consequence, the difference between the two time series of the temperatures by Thermistors 1 and 3 increases with time. This implies that a stable stratification of the fluid in the cavity is continuously reinforced [15]; that is, the transition of the interior fluid in the cavity from an initially isothermal state to an eventually stratified state occurs.

The transient features of the natural convection boundary layer flow will be demonstrated with a closer examination of these time series, as described in the following sections.

Temperatures in the early stage

Figure 3(a) replots the temperature time series measured by Thermistors 1, 2 and 3 in the early stage (up to 100 s). It is seen in this figure that the features of the LEE are clear, which are characterized by an overshoot (also see [5]) followed by an oscillatory signal. Furthermore, there are distinct differences in the initial temperature growth recorded by Thermistors 1 and 2 and 3; that is, the temperature by Thermistor 1 increases more quickly than those by Thermistors 2 and 3. This is because the location of Thermistor 1 is closer to the hot sidewall than those of Thermisters 2 and 3, as shown in Figure 1.

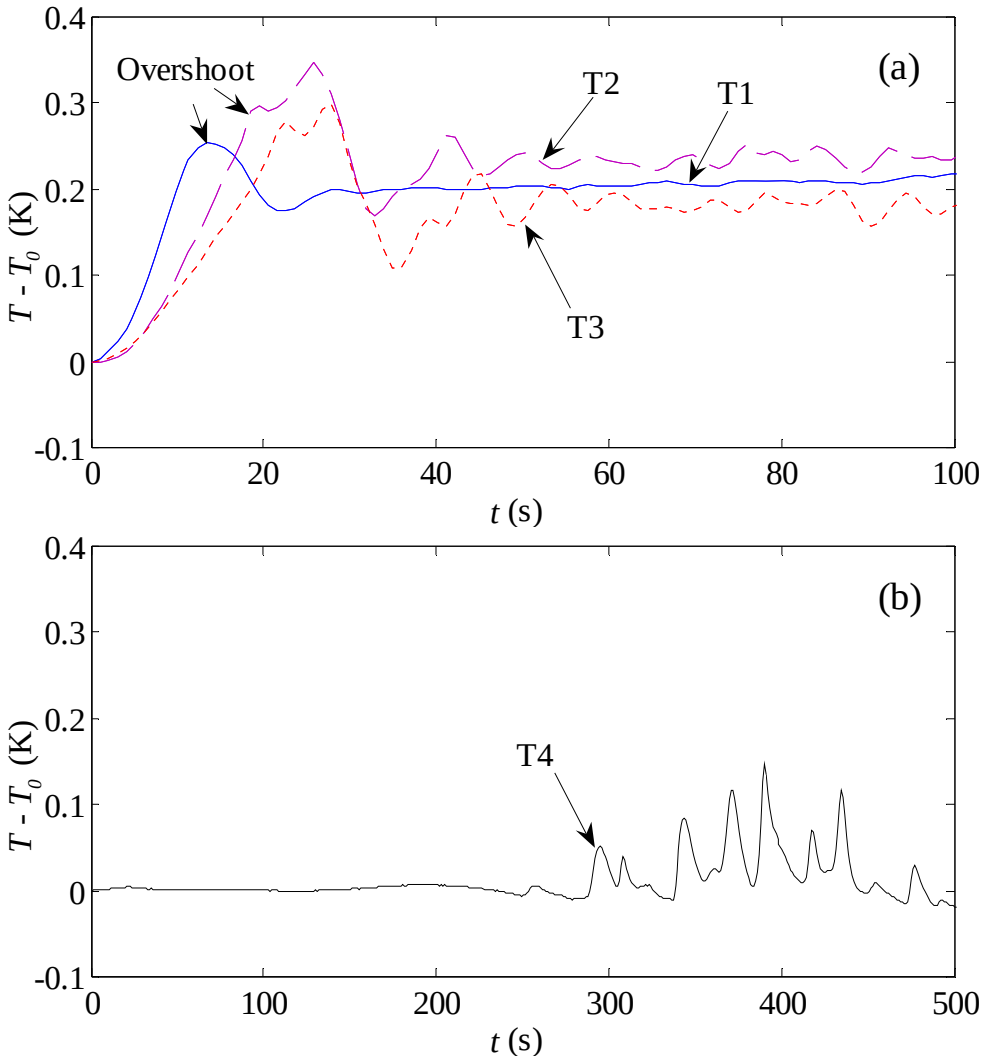

Figure 3. Time series of the temperatures at different locations in the early stage. (a) Temperatures measured by Thermistors 1, 2 and 3. (b) Temperature measured by Thermistor 4.

Figure 3(a) also shows that following the overshoot, the temperature measured by Thermistor 1 approaches an approximate constant, whereas the temperatures measured by Thermistors 2 and 3 remain oscillatory. This means that the travelling waves (convective instabilities [16]) in the natural convection boundary layer grow as they propagate downstream (also see Figure 2).

The temperature in the early stage measured by Thermistor 4 is replotted in Figure 3(b). It is clear that, differently from those measured by Thermistors 1, 2 and 3, the temperature by Thermistor 4 changes little in the early stage (until about 250 s). This is because the location of Thermistor 4 is far from the hot sidewall and the LEE is not recorded by Thermistor 4. However, after approximately 250 s at which time the cold intrusion flow from the opposite sidewall has arrived at the upstream end of the boundary layer and triggered additional waves in the boundary layer (refer to visualizations in [6]), the horizontal intrusion flow, discharged from the end of the natural convection boundary layer, becomes unstable, and thus these waves are recorded by Thermistor 4 located under the horizontal intrusion flow. Furthermore, it is worth noting that the frequency (around 0.05 Hz) of the temperature waves recorded by Thermistor 4 is much lower than those by Thermistors 1, 2 and 3 (around 0.12 Hz). This confirms that this signal is an instability of the intrusion rather than the vertical boundary layer.

The early transient features of the temperature time series are dependent on the Rayleigh number. Figure 4 shows the temperature time series measured by Thermistor 1 for two different Rayleigh numbers, relative to the initial temperature (T_0) in each case. Clearly, as the Rayleigh number increases, the temperature in the natural convection boundary layer grows more rapidly during the early stage and the overshoot is also larger, as seen in Figure 4.

Travelling waves in the quasi-steady stage

Following a slow transitional stage, the amplitudes of the temperature waves recorded by all thermistors approach constant values (refer to Figure 2). In order to display further the wave features of the boundary layer, Figure 5(a) shows the temperature time series from Thermistors 1 to 3 for a short time period in the quasi-steady stage. It is seen in this figure that the amplitude of the temperature waves at this time is strongly dependent on the spatial location but less dependent on time. The temperature time series from Thermistor 1 displays the upstream waves, and those from Thermistors 2 and 3 display the travelling waves in the downstream natural convection boundary layer. Similar to the results in the early stage (see Figure 3a), the travelling waves grow significantly in the quasi-steady stage as they propagate downstream.

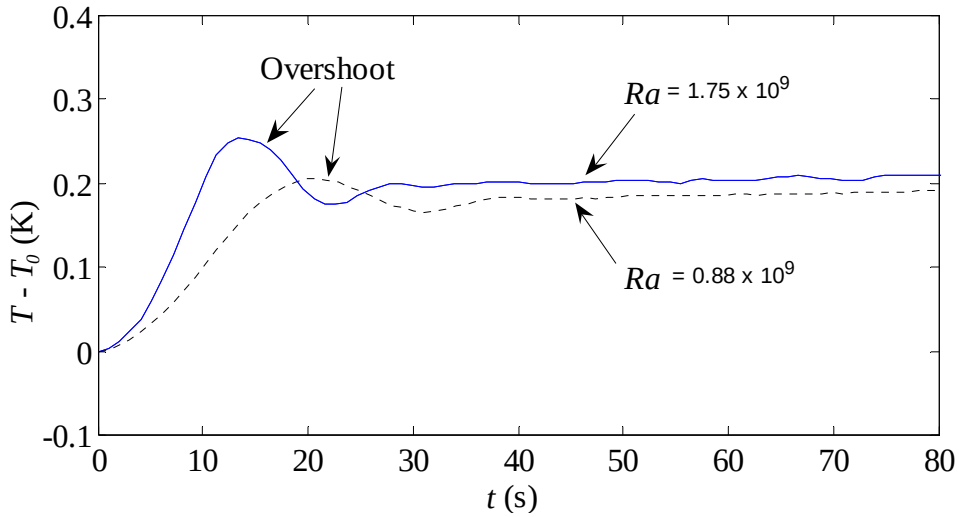

Figure 4. Temperature time series at the point (0.4978, -0.048, Thermister 1) for two different Rayleigh numbers.

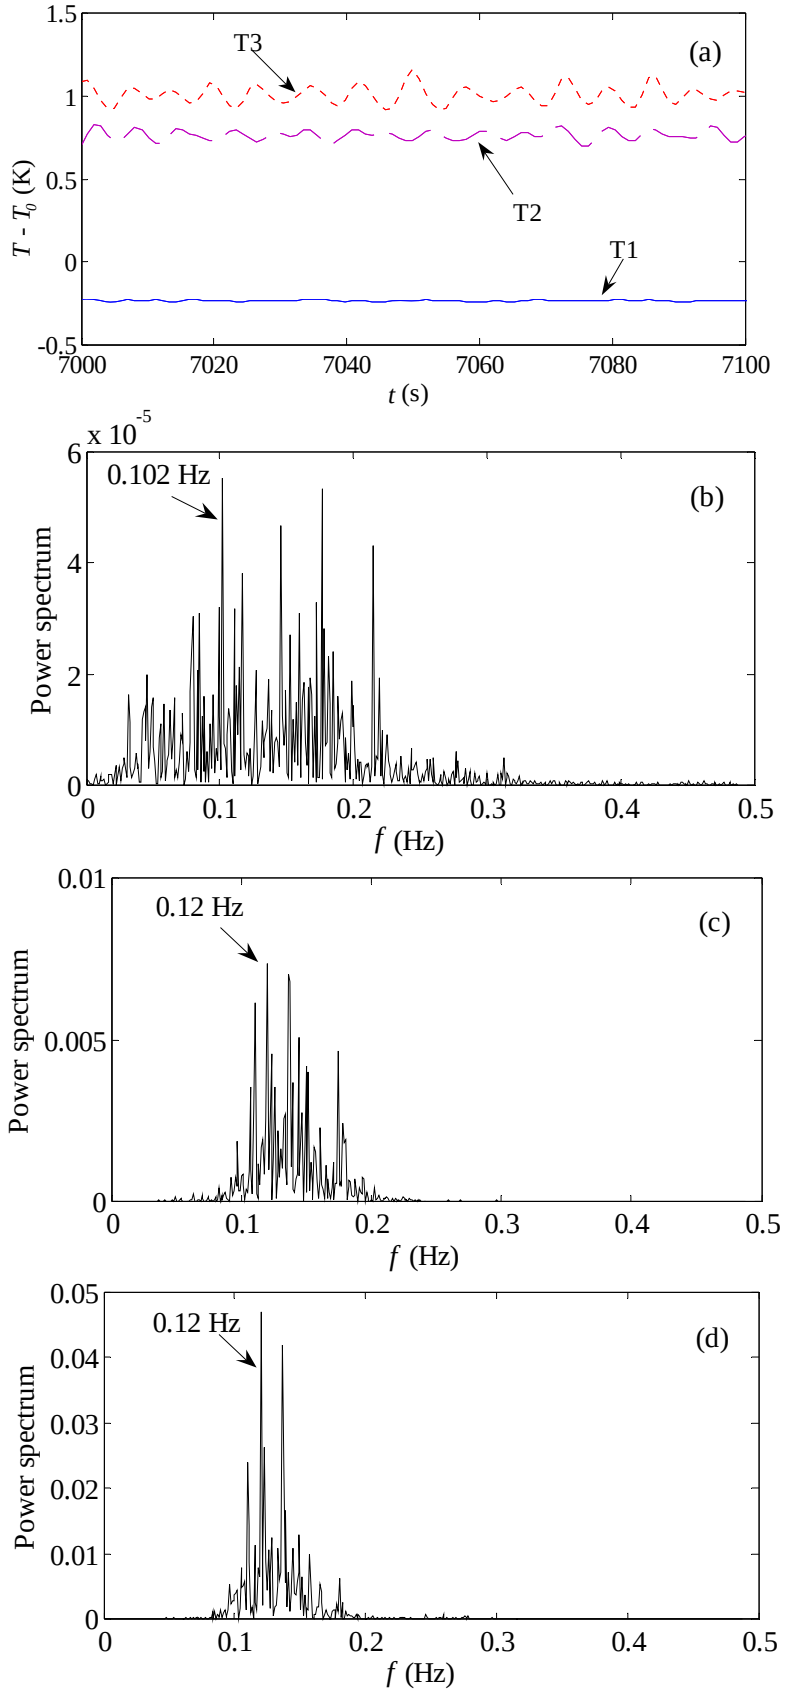

Figure 5. Temperatures and power spectra in the quasi-stage stage. (a) Temperature time series from Thermistors 1 to 3. (b) Spectrum for Thermistor 1. (c) Spectrum for Thermistor 2. (d) Spectrum for Thermistor 3.

The corresponding power spectra of the temperature signals from Thermistors 1, 2 and 3 are shown in Figures 5(b), 5(c) and 5(d), respectively. Clearly, the frequency characteristics of the temperature

waves are different at these locations. For example, at the Thermistor 1 location, the peak of the spectrum is around 0.102 Hz, but the dominant frequencies of the temperature waves at the Thermistors 2 and 3 locations are around 0.12 Hz. That is, the dominant frequencies of the temperature waves change with the locations at which the temperature signals are recorded.

CONCLUSIONS

In this paper, the temperatures of the unsteady natural convection flows adjacent to the sidewall of a differentially heated cavity are measured by fast-response thermistors. The travelling wave features in the natural convection boundary layer are characterized.

The present temperature measurements show features consistent with the flow visualizations in [6]. The temperature time series from thermistors at different locations clearly characterize the LEE and other transient features of the natural convection boundary layer in the transition from an initially isothermal interior fluid ambient to an eventually stratified interior fluid ambient. Furthermore, the spectral analysis of the temperature time series has revealed the dominant frequency of the travelling waves in the natural convection boundary layer. The travelling waves in the natural convection boundary layer are indeed convective instabilities.

ABSTRACT. This work is dedicated to the improvement of effusion cooling efficiency on combustion liners, by using an innovative multiperforation made of shaped holes of elliptical cross-section. Low-temperature experiments provided a spatial characterization of cooling efficiency in a suction-type wind tunnel, whereas discrete measurements were performed in the engine-like conditions of THALIE facility. A RANS computational study was also performed to give a detailed insight on the aerothermodynamics of the complex flow created by effusion holes. Experimental and numerical data confirm the enhancement of effusion cooling by shaped holes, thanks to a better coverage of the first rows of the plate, and a better individual efficiency of each hole.

Keywords: *combustor liner, effusion cooling, adiabatic efficiency, thermochromic liquid crystals*

INTRODUCTION

Due to the increasing need to reduce the emissions of aero-engines, it is necessary to optimize the design and integration of engine components. Among them, the combustion chamber focuses many of the challenges encountered. Indeed, it is the very place at which combustion and thermal phenomena pilot the emissions and efficiency of the engine. Therefore, the combustion liner faces important mechanical and thermal stresses. Moreover, the need for higher engine efficiency leads to increasing combustion temperature and pressure that emphasize stresses on the liner.
This statement points out the importance of an adapted cooling of combustion liners. For this, the use of multiperforation is a common way to create a full-coverage cooling of the liner, which is referred to as effusion cooling. However, this technique requires a significant mass flow of fresh air taken from the compressor. Thus, an adapted design is required so that the air passing through effusion holes does not affect locally the combustion rate and globally the engine efficiency.
In terms of multiperforation design, many aspects of hole geometry can be varied. The spacing, the angle, or the length to diameter ratio can be optimized by simple variation, whereas the shape of the hole itself is much harder to study due to practical difficulties in machining and controlling the shape, for instance. Former studies have pointed out experimentally the influence of the transverse dimension of the holes on cooling efficiency, either with converging slot holes called "consoles" [1] or laterally diffused holes [2]. The common feature of these design solutions is a greater extension of the hole perpendicularly to the flow, inducing a better coverage of the multiperforated wall.
This work focuses on an innovative design of multiperforation, using holes of elliptical cross-section that can be processed through laser drilling. Experiments were carried out on cooled plates to compare the efficiency of shaped to conventional holes. A RANS simulation was also carried out to give a detailed insight on the aerothermodynamics of the complex flow of the jets in crossflow.

EXPERIMENTAL SETUP AND MEASUREMENTS

Experiments were carried out to compare the cooling efficiency of conventional and shaped holes, using two experimental devices. The first one allows a fine spatial characterization of cooling efficiency at low temperature, whereas the second one allows a discrete measurement of cooling efficiency in engine-like conditions. Such experiments aim at quantifying the thermal behaviour of each hole geometry in terms of cooling efficiency. Practically, each hole geometry is studied using flat plates drilled with arrays of holes.

Suction-type wind tunnel

The first experiments consist of low-temperature measurements in a suction type wind tunnel.

Experimental facility. The test rig is an open-loop suction-type wind tunnel allowing the measurement of heat transfer, cooling efficiency and pressure loss on multiperforated plates, by controlling completely the mainstream flow and the coolant flow.
The mainstream air flow, at atmospheric pressure and ambient temperature, passes first through a 24 kW controlled electric heater, where desired temperature is reached and kept constant, before entering the PolyMethyl-MethAcrylate test section depicted in Figure 1, through a setting valve.
The coolant flow temperature is controlled by mixing heated air and cool air. Four rotary vane vacuum pumps (total power installed 59 kW) provide the suction for a maximum mass flow rate of 0.50 kg/s. Both flow rates are set up by guiding the motor speeds between 300 and 1200 rpm, and throttling the remote controlled motorized valves. The air temperature exiting from the heater is controlled by means of a four wire resistance temperature detector (RTD Pt-100).
The rig allows performing measurements on test samples made of adiabatic (stereolithography resin, STL) and conductive material (stainless steel, AISI 321), see Table 1.

Table 1
Geometric features of the multiperforated plates

Multiperforated plate	with circular holes	with shaped holes
Plate thickness (mm)	12.7	12.7
Number of holes	38	28
Number of rows	8	5

Porosity	0.036	0.0375
Angle of the holes (°)	17.0	17.0
Hydraulic diameter of the holes (mm)	2.65	3.385
Length to diameter ratio L/D	16.39	12.8

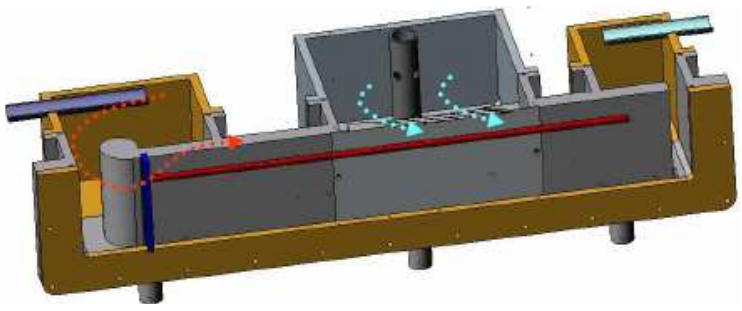

Figure 1. Suction-type wind tunnel

Diagnostics. Tests are run once flow rates, pressures and temperatures have reached steady conditions. Adiabatic and overall cooling efficiencies, denoted resp. as η_{aw} and η_{ov} (see equations (1) and (2)), are evaluated resp. on adiabatic and conductive plate using thermochromic liquid crystals that provide surface temperature T_w. Efficiencies are computed starting from the measured wall temperature values by means of different post-processing procedures accurately described by [3]. The final result of such procedures is the achievement of η_{aw} values once the plate heat loss due to holes heat sink effect is evaluated.

$$\eta_{aw} = \frac{T_{main} - T_{aw}}{T_{main} - T_c} \tag{1}$$

$$\eta_{ov} = \frac{T_{main} - T_w}{T_{main} - T_c} \tag{2}$$

Conditions investigated. All tests have been carried out setting approximately the coolant temperature at 306 K and the mainstream temperature at 317 K and 322 K, resp. for adiabatic and conductive tests. Experimental survey has been performed setting jet Reynolds number at 12500, and imposing three values of blowing ratio close to engine operating conditions (BR = 5–7–9). Blowing ratio is commonly defined from flow momentum in the holes and in the mainstream.

$$BR = \frac{(\rho V)_{hole}}{(\rho V)_{main}} \tag{3}$$

High-temperature wind tunnel THALIE

In the second set of experiments, conductive plates are exposed to realistic engine conditions.

Experimental facility. Experiments are carried out using THALIE, that is a high-temperature wind tunnel designed to study THermal and Aerodynamic features of Experimental Liners, see Figure 2. THALIE generates experimental conditions close to those encountered in the vicinity of combustor liners, in terms of gas velocity, temperature, pressure, and pressure drop across the liner. The test section is equipped with apertures, allowing optical measurements (PIV, LDV, visualization, fluorescence, thermography), as well as intrusive measurements (gas sampling, thermocouples).

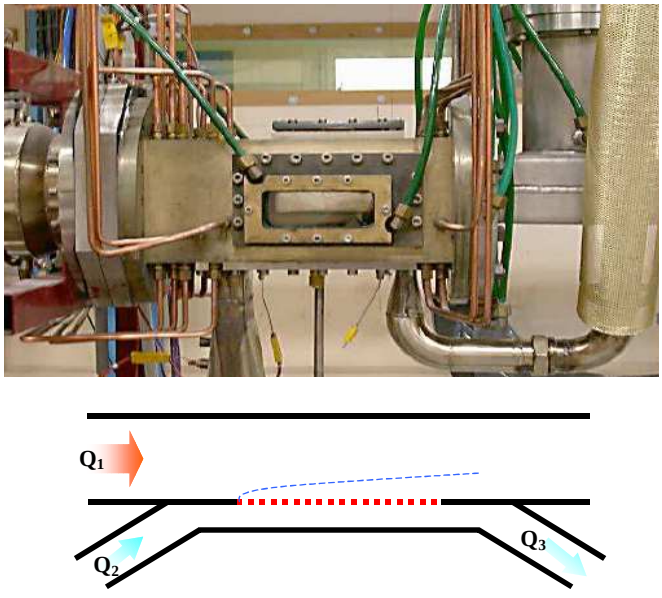

Figure 2. High-temperature wind tunnel THALIE

During an experiment, a multiperforated plate is submitted to a hot gas flow and a coolant flow. The hot flow, Q_1, is made of combustion products supplied by a tubular combustor fuelled with kerosene. The cooling air flow, Q_2, can be heated electrically. The temperatures of both the hot and cooling flows are P.I.D. controlled, ensuring the stability and reliability of experiments. The flow passing through the multiperforated plate, Q_h, is only a fraction of the cooling flow. It is driven by controlling the pressure drop across the plate, ΔP. Q_h is evaluated as the difference between the incoming (Q_2) and outgoing (Q_3) coolant flows. The controlled mass flow rates (Q_1, Q_2 and Q_3) are measured using vortex-type flowmeters. T_1 and T_2 are measured by K-type thermocouples.
Experiments are carried out twice, i.e. once using a plate with conventional holes, and once using a plate with shaped holes. The multiperforated plates are manufactured by AVIO S.p.A. with thermal coating and laser drilling technology (see Table 2). Overall, both plates have similar properties, and similitude rules have been applied to scale the multiperforation. The experimental conditions summarized in Table 3 provide a wide range of blowing ratio, BR = 1–10.

Table 2
Geometric features of the multiperforated plates

Multiperforated plate	with circular holes	with shaped holes
Plate thickness (mm)	2.5	2.5
Number of holes	569	234
Number of rows	17	12
Streamwise to spanwise pitch ratio	2.1	2.0
Total cross-section of the holes (mm²)	149	149
Angle of the holes (°)	18.5	17.3
Hydraulic diameter of the holes (mm)	0.58	0.76
Length to diameter ratio	13.6	11.1

Table 3
Operating conditions of the experiments

	Hot flow	Cooling flow	Hole flow
Subscript	1	2	h
Reynolds number	60,000 – 80,000	10,000 – 100,000	0 – 20,000
Cross-section (mm)	126×72	100×20	
Mass flow rate (kg/s)	0.4	0 – 0.2	
Temperature (K)	1000	288	
Pressure (bar)	3.0	3.0 – 3.5	

Diagnostics. The cooling efficiency of the multiperforated plate is evaluated by means of adiabatic and overall efficiency. Overall efficiency, η_{ov}, takes into account convection as well as conduction and radiation. Evaluating η_{ov} requires the measurement of wall temperature, T_w, see equation (4). Thus, the multiperforated zone is instrumented with K-type thermocouples of diameter 0.5 mm, sheathed with stainless steel. They provide the wall temperature on the cold side of the plate.

$$\eta_{ov} = \frac{T_1 - T_w}{T_1 - T_2} \tag{4}$$

Adiabatic efficiency, η_{ad}, is the cooling efficiency of an equivalent adiabatic plate. It is evaluated by assuming the analogy between heat and mass transfer, which consists of equal molecular and thermal diffusivities, i.e. a unity Lewis number. Measuring adiabatic efficiency requires the local concentration of a reference gaseous species at the wall surface on the hot side, C_w, as well as inside the primary and secondary flows, respectively C_1 and C_2, see equation (5).

$$\eta_{ad} = \frac{C_1 - C_w}{C_1 - C_2} \tag{5}$$

For this, a water-cooled sampling probe of diameter 6.0 mm is set inside the hot flow by the top aperture and fixed to a displacement system driven by a computer. The sampling orifice of diameter 0.7 mm is located at the conical tip of the probe. The reference gaseous species selected for sampling is CO_2, which concentration is constant in the hot flow and null in the cool flow, i.e. C_2=0. CO_2 is probed by an inline gas analyser (COSMA) based on the absorption of infrared radiation.

NUMERICAL SIMULATION

This numerical study was performed using a solver developed into the open-source environment for continuum mechanics analysis named OpenFOAM® [4]. The toolkit implements operator-based implicit and explicit 2nd-order and 4th-order finite volume discretization in 3-dimensional space.
These simulations were run using the steady-state compressible SIMPLE-like solver developed at University of Florence and validated in [5]. The energy equation is solved in terms of total-enthalpy in order to avoid energy losses in high acceleration regions namely the coolant flow into the ducts. The two-layer turbulence model by Rodi was used to model turbulent behavior with Norris and Reynolds closure formulas [6]. Even though the gain compared to standard two-equation eddy viscosity models is considerable in terms of well reproducing near-wall behavior, this model, further referred to as isotropic, suffers the well-known deficiency of the eddy viscosity models to correctly predict the lateral spreading of the jet in crossflow. The same model was thus tested implementing an algebraic correction to increase the lateral diffusion of momentum, energy and turbulence as proposed by [7]. This corrected version is later referred to as the anisotropic model.
For conductive tests, the coupling between solid and fluid was achieved in an explicit manner: at each iteration step a new value of total temperature on the boundary is calculated imposing the continuity of the thermal flux across the interface. A weighted average based on face overlapping area allows the use of non-conformal interfaces between fluid and solid domain. More details on the coupling procedure and the treatment of generic grid interfaces can be found in [8].
The meshes used to perform such calculations finely discretize boundary layer reaching y^+ values up to 1 for all walls of interest, namely the two sides of the plate and the hole ducts. In order to save computational cost all other walls were treated as inviscid wall (symmetry planes) thus avoiding the clustering. Moreover two symmetry planes were inserted at the center of holes, and only one spanwise pitch was simulated in order to save computational cost and to better impose stationary behavior, see Figure 3. The total grid size is around 3 million cells for both the conventional and the shaped geometries. Apart from the different dimensions, the numerical setup to reproduce the two experimental rigs only differs in the boundary conditions for the abduction of coolant. For the suction-type tunnel, constant pressure plenum is simulated imposing no cross-flow and a large low-speed inlet area, see Figure 3. As for THALIE, the same conditions as for the mainstream are applied to the coolant. The boundary conditions were extracted from the experimental ones. For the low-speed wind tunnel, the blowing ratio could be imposed and the pressure drop between plenum and mainstream taken as results. For the THALIE rig, the procedure was inverse, thus it was not possible to investigate numerically the two rig configurations exactly at the same blowing ratio.

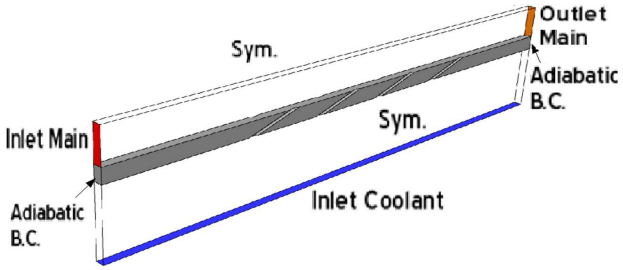

Figure 3. Overview of numerical boundary conditions

RESULTS AND DISCUSSION

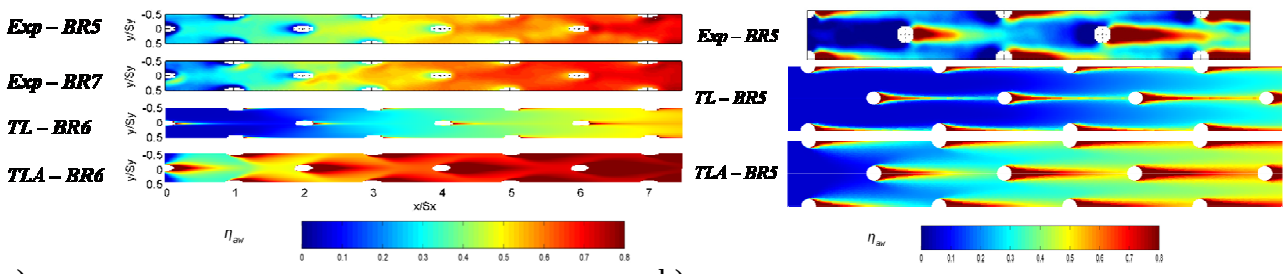
In this section, the results of experiments reported along with the results of numerical simulation are expected to determine whether shaped holes actually improve the efficiency of effusion cooling.

Suction-type wind tunnel

On such rig, the fine resolution of temperature measurements allows investigating the spatial distribution of efficiency. Results are reported in terms of spanwise averaged efficiency. However, efficiency is so uniform for conductive tests that only spanwise averaged profiles are reported.

Adiabatic efficiency maps. In conventional geometry, experimental results at BR=5–7 are reported together with numerical simulations at BR=6, see Figure 4a. Firstly, experimental maps (Exp) exhibit a cold zone upstream of the holes due to the effect of the coolant ducts inside the plate, meaning that the hypothesis of adiabatic behaviour is not completely respected. Secondly, both turbulence models fail in predicting the downstream film development. While the isotropic model (TL) under-predicts the lateral diffusion of jets, the anisotropic correction (TLA) emphasizes this effect too much. In shaped configuration, the shape of coolant wake is better simulated by the anisotropic model, see Figure 4b. By comparing both geometries, the spanwise profile of conventional geometry is obviously more uniform. Shaped geometry should therefore be studied carefully as far as thermal stresses are concerned.

Spanwise averaged efficiency. The profiles of adiabatic and overall efficiency at BR=5 are shown in Figure 5. The anisotropic model simulates well the efficiency of shaped geometry, but overestimates that of conventional geometry. This result is confuting the findings on conventional geometry for higher angles and lower blowing ratios [9]. As for overall efficiency, the conventional plate is better cooled due to a higher heat sink effect connected with a higher L/D. As can be seen comparing experiments with computations, the different modeling of solid plate far form the drilled part modifies strongly the profile of overall efficiency. Although conventional geometry behaves better in terms of cooling performance, this is only related to the specific test conditions. A deeper survey points out that shaped configuration is better performing at higher blowing ratios [10].



a) b)

Figure 5. Spanwise averaged efficiency (BR=5, low temperature) – a) Adiabatic, b) Overall

High temperature wind tunnel THALIE

Measurements of adiabatic and overall cooling efficiency allow the comparison between the two multiperforation geometries, i.e. with conventional or shaped holes.

Adiabatic efficiency quantifies the ability of the plate to perform effusion cooling through the holes, regardless of conduction and radiation phenomena. The streamwise profile of adiabatic efficiency along the plate is presented for experimental and numerical data (see Figure 6a). As usual, adiabatic efficiency increases with increasing blowing ratio. Experimental data show a high uncertainty at low BR, but converge quickly towards an asymptotic curve near BR=5. The experimental and numerical profiles of adiabatic efficiency indicate that cooling is enhanced by shaped holes. The benefit in efficiency decreases along the plate, from 0.08 at 5th row to 0.02 at 10th row. Especially, this benefit exceeds 0.15 at the first two rows due to a strong increase in efficiency in the wake of shaped holes.

The evolution of overall efficiency versus BR is similar to that of adiabatic efficiency, because increasing BR improves effusion cooling (see Figure 6b). Experimental curves confirm that shaped holes enhance overall cooling in the first rows, compared to conventional geometry. Cooling efficiency is similar for both geometries between 3rd and 6th rows. Then, conventional holes have better cooling performance downstream of the 7th row. These results are confirmed by a satisfactory agreement between simulation and experimental data at BR=3.3.

Finally, shaped holes lead to improved wall cooling, even though the higher L/D in conventional geometry enhances the heat sink effect due to a greater inner surface of the conventional holes.

Figure 6. Streamwise profile of cooling efficiency (high temperature) – a) Adiabatic, b) Overall

CONCLUSIONS

Experiments and simulations have been carried out on two geometries of effusion cooling, involving conventional holes and holes of elliptical cross-section. Two configurations have been addressed, providing high blowing ratios in either low-temperature or realistic engine conditions.
This survey points out many features of effusion cooling by shaped holes. Experiments and simulation show that they have a better individual cooling behaviour inducing higher efficiency in the first rows (up to 15%), but conventional holes lead to a better film formation that provides superior thermal protection after several rows of holes. Additionally, this improvement in cooling efficiency is proved to depend strongly on physical conditions, such as blowing ratio and length to diameter ratio [10].
Finally, shaped holes of elliptical cross-section provide a promising way for improving effusion cooling. Indeed, this design recalls not only the shape but also the high thermal efficiency of "consoles" [1]. Further studies should check that such cooling improvement is obtained without penalty to the mechanical strength requirements induced by thermal stresses of combustion liners.

TORNADO-LIKE FLOWS: EXPERIMENTS ON GENESIS, STABILITY AND PREVENTION

A.Y. Varaksin*, M.E. Romash, V.N. Kopeitsev
Joint Institute of High Temperatures, Russian Academy of Sciences, Moscow, Russia

ABSTRACT. The fundamental possibility of physical simulation of wall-free concentrated air vortices (called as tornado-like flows) under laboratory conditions was demonstrated. These vortices were generated over a heated underlying surface due to unstable air stratification. The heating rates of underlying surface and air temporal and spatial temperature shear, which lead to the stable genesis of wall-free vortices have been defined. The influence of operation mode parameters on the characteristics (the time of appearance, the place of appearance, the length of the trajectory, the velocity of travel, the lifetime, the height, the diameter, and others) of generated air vortices was observed. High efficiency of influence of obstacles in the form of vertical grids of different height and cells on vortex characteristics (up to vortex breakdown) was clearly detected. The received fundamental results are useful for the increase of effectiveness of the tornado shelters and for finding the new ways of tornado prevention.

Keywords: *tornado-like flow, wall-free concentrated vortices, unstable air stratification*

INTRODUCTION

Vortex (swirling) flows are widely occurring in nature (atmospheric cyclones, sand storms, air tornadoes, typhoons, forest fires) and find numerous engineering applications (vortex tubes, cyclone separators, centrifugal nozzles, vortex cells, various turbulence simulators, and the like).
So the tornadoes occur frequently in North America and other parts of the world. They destroy everything on its path and lead to the human fatalities [1, 2]. The aim of this paper is to study the characteristic of the wall-free gas-solid concentrated vortices (called here as tornado-like flows) under laboratory conditions.
Vortex flows bounded by the walls are formed by way of tangential nozzle delivery of medium, application of mechanical swirling devices (guide swirl vanes, screws, internal spiral ribbing, and the like), and intensive rotation of body elements of channels (rotating tubes). The thus obtained vortex flows are convenient for detailed experimental description; however, their characteristics may significantly differ from the parameters of real vortex structures observed in the Earth atmosphere.
The study of free (not bounded by the walls) concentrated (the vorticity is localized in space) vortices is complicated by a number of reasons such as spontaneity of formation, space-time instability, practical impossibility of controlling the characteristics and so on. Therefore, even in view of the dynamics of development of direct simulation techniques (DNS method, LES method, and others), the solution of three-dimensional unsteady-state Navier-Stokes equations for a complex hydrodynamic and thermophysical object such as free concentrated vortex may hardly be accomplished in the immediate future because of complexity of formulating the boundary and initial conditions. The difficulties identified above account for the apparent absence of experimental

E-mail address: varaksin_a@mail.ru

studies producing results in stability and dynamics of free concentrated vortices, which could be used for verifying mathematical models (see for example [3, 4]).
There are a number of works where the authors try to measure the parameters of the real tornadoes (for example, [5, 6]).
Therefore, an urgent need appears to exist in the arrangement of dedicated experimental investigations of wall-free concentrated air vortices which are similar to the real air tornadoes. It is important to note, that the most hurricanes are accompanied by the tornadoes, and the hydro-dynamical structure of tornadoes and hurricanes is approximately the same. One can assume that the good result in the tornado studying may be used for human defence from hurricanes. Thus the tornado-like flows research in laboratory conditions is very actual.
The aim of this paper is to study the questions of generation, stability and prevention of the wall-free concentrated vortices (called here as tornado-like flows) in the laboratory conditions.

EXPERIMENTAL SETUP AND PROCEDURE

The experimental setup is schematically shown in Figure 1. It was located in a room with floor *1* 6 by 6 m^2 in area and ceiling *2* 3.3 m high at a distance of 0.5 m from one of walls *3*. The experimental setup included a deck *4* 0.35 m high with three legs *5*. The horizontal surface of the deck *4* was a sheet of aluminum (grade D16AM) 1100 mm in diameter and 1.5 mm thick. The top (underlying) surface of the aluminum sheet was blackened with heat-resistant paint. Placed under the deck was an electrically ignited gas burner *6* of maximal thermal power of 3.5 kW. The diameter of flame *7* of the burner was varied (for different modes of thermal power) from 200 to 300 mm. A liquefied propane-butane mixture required for the operation of the gas burner was placed in a 27-liter vessel *8*.
The experimental setup makes possible the controlled heating of the underlying surface of aluminum sheet, which leads to the generation of unsteady vortex structures *9* as a result of development of unsteady stratification of air [7, 8]. The vortex structures being formed were visualized using tracer particles (micrometer-sized particles of magnesia) which were applied in a thin layer onto the underlying surface prior to experiments.

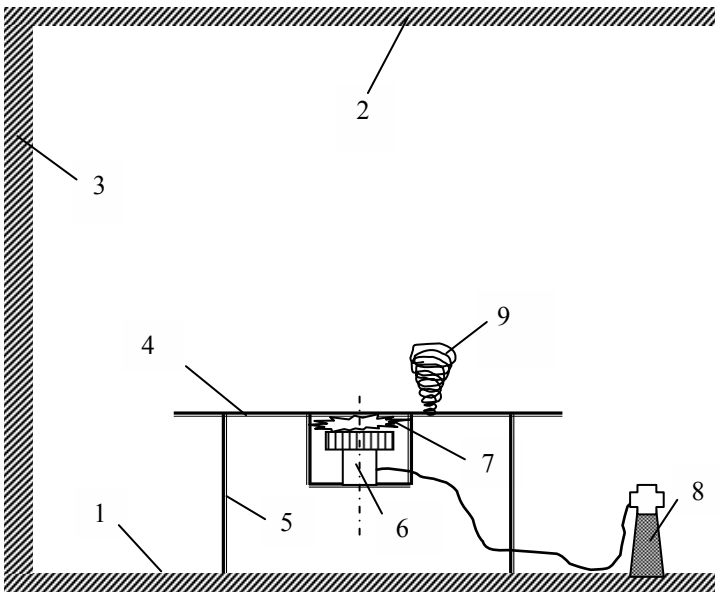

Figure 1. Schematic of the experimental setup

Table 1
Characteristics of the operating (thermal) modes

Mode	Heating	τ_h, s	τ_c, s	$T_{c\max}$, K
1		60	600	420
2	Weak	120	900	470
3		180	1200	500
4		60	600	500
5	Strong	120	900	580
6		180	1200	610

A digital video camera (Sanyo VCC-6572P) was used for video filming of vortices being generated. The wakes of vortex structures were photographed by a camera (Casio Exilim EX-S500). An infrared thermometer (AZ8868) was used for measuring the temperature of the underlying surface of the sheet. The temperature measurements (along the radius) were performed at six points with coordinates r =0, 100, 200, 300, 400 and 500 mm (r is the distance from the sheet centre).
Also monitored in the course of experiments was the air temperature in the room. The initial (prior to experiments) difference between the air temperature on the level of underlying surface T_1 and in the vicinity of the room ceiling T_2 was $\Delta T = T_2 - T_1 \approx 1$ ^{0}C. The maximal increase in the air temperature in the vicinity of the ceiling after a single experiment in one thermal mode (see below) reached a value of ΔT_2 =3-4 ^{0}C. Further experiments were performed after complete "cooling off" of the room to initial values of temperature.
The Table 1 gives the principal parameters of thermal modes employed for generation and study of the characteristics of air vortices. Here τ_h - heating time; τ_c - cooling time; $T_{c\max}$ - maximum temperature of the underlying surface centre. Thus, in the present study we used six different operation modes of underlying surface heating which are characterized by the time of heating (gas burner working time), time of cooling (time after gas burner switching off) and maximum temperature in the centre of underlying surface.

RESULTS AND DISCUSSION

The results concerning tornado genesis, stability and prevention will be discussed below.

Tornado genesis

A stable generation of vortices was observed in all modes except for mode no.1 (see Table 1). The temporal and spatial temperature distributions for the underlying surface and air for all operation modes have been determined. The typical measured temperature distributions for mode no.6 are shown in Figures 2-4.
Figure 2 gives the dependences of temperature of underlying surface centre and air at the point $y = 50$ mm above underlying surface for mode no.6. One can see that this mode is characterized by the following values of maximum temperature: $T_{c\max} = 610$ K (for underlying surface) and $T_{a\max} = 334$ K (for air) at $\tau_h = 180$ s.
The temperature distributions along the radius of underlying surface for mode no.6 under heating for underlying surface and air are given in Figure 3 and Figure 4, respectively. Some decrease in temperature in the central region of underlying surface ($r < 100$ mm), observed for short times of heating ($\tau_h \le 120$ s), is attributed to the structural features of the employed gas burner.

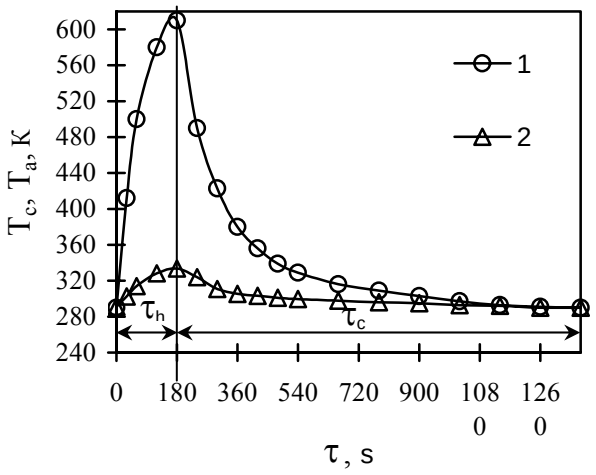

Figure 2. The temperature of underlying surface and air ($y = 50$ mm) as a function of time (mode no.6); $r = 0$: (1) underlying surface, (2) air

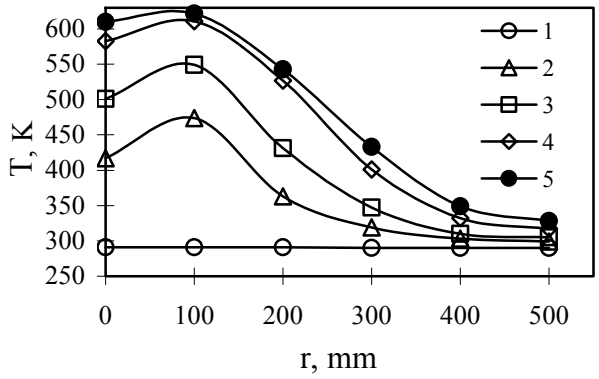

Figure 3. The temperature of underlying surface as a function of the radius and of time under heating (mode no.6): (1) $\tau_h = 0$, (2) 30 s, (3) 60 s, (4) 120 s, (5) 180 s

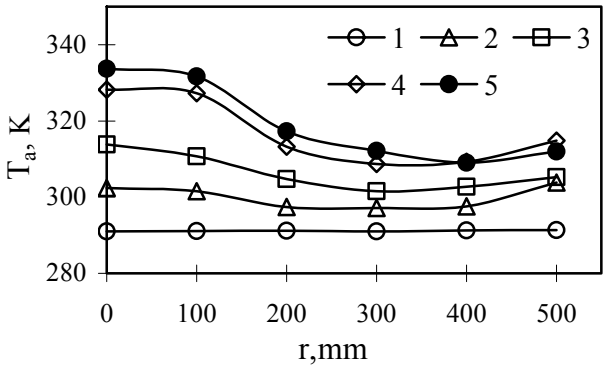

Figure 4. The temperature of air as a function of the radius and of time under heating (mode no.6), $y = 50$ mm: (1) $\tau_h = 0$, (2) 30 s, (3) 60 s, (4) 120 s, (5) 180 s

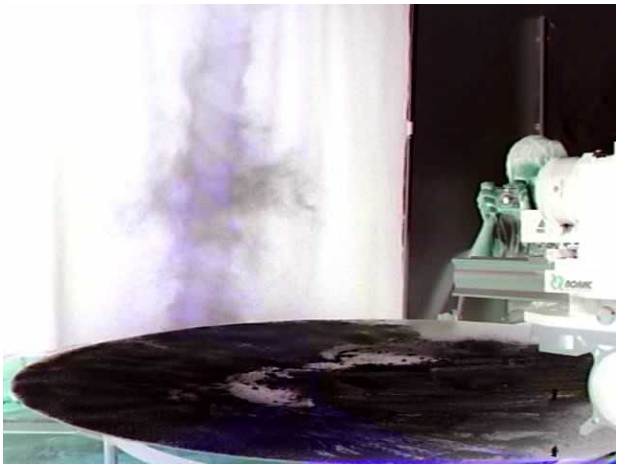

Figure 5. Photograph of tornado-like vortex (negative colours)

The video filming and the use of magnesia particles made it possible to visualize the vortex structures arising above the underlying surface. Frame-by-frame analysis of video records in different thermal modes (see Table 1) enables one to obtain information about the following parameters of the process of generation of vortices and their characteristics: (1) the values of temperature, at which the vortices are generated; (2) the region of underlying surface, where the vortices are generated; (3) the direction of rotation of vortex structure; (4) the number of vortices observed per experiments; (5) the trajectory of travel of the vortex base; (6) the length of the trajectory of the vortex base; (7) the velocity of the vortex base; (8) the lifetime of vortex structure; (9) the height of vortices; (10) the diameter of vortices, and others.

(a) (b)

Figure 6. Photographs of vortex structures: (a) frame with recorded wall-free concentrated vortex (negative colours); (b) air tornado in North America

Repeated experiments in different modes gave rise to the following inferences. Vortex structure began to form in the mode of heating of the underlying surface after the temperature at its centre reached a value of $T_c = 470\,\mathrm{K}$. The largest vortices were generated at temperatures at the surface centre $T_c > 570\,\mathrm{K}$. Vortex structures were largely generated in a circular region (150 mm $< r <$ 250 mm), i.e., in the region of abrupt rise of temperature gradient. The direction of rotation of all vortices being observed was counterclockwise (if the underlying surface is viewed from above). Up to ten vortex structures were observed per experiment. Three types of trajectories (wakes) of motion of vortex base were identified (see below). The maximal length of trajectory of the base of vortex structures was 100-200 cm with the velocity of travel of 5-20 cm/s. The limiting lifetime of observed vortices was about 40 s. The maximal height of generated vortex structures could be 1.5 m, and their maximal diameter – 0.3 m. An example of observed large-scale (visible height about 1.5 m) vortex with long (about 40 s) lifetime is shown in Figure 5.

The example of experimentally observed vortex structure is given on a large scale in Figure 6a for the purpose of detailing its basic parts (vortex core, peripheral region, vortex cascade). Given in Figure 6b for comparison is a photograph of a real air tornado in North America.

Tornado stability

The received distributions of air temperature allowed to find the values of dimensionless number, i.e. Rayleigh number for different thermal modes. This Rayleigh number has the form

$$Ra = \frac{g\,h^3 \beta\,\Delta T}{\nu\,a} \tag{1}$$

Here, g is acceleration of gravity, h is the characteristic distance in vertical direction where the temperature difference exists, β is the coefficient of volume expansion, ΔT is the temperature difference causing the convection, ν is the coefficient of kinematic viscosity, a is the thermal diffusivity.

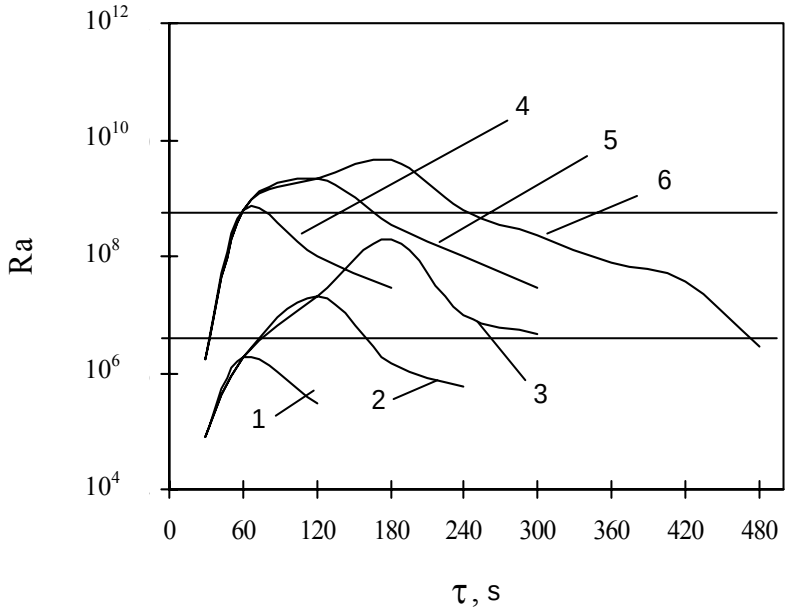

Figure 7. Rayleigh numbers as a function of time for different thermal modes; $r = 0$: (1) mode no.1, (2) no.2, (3) no.3, (4) no.4, (5) no.5, (6) no.6

For the estimations, we take h, as the distance from underlying surface in vertical direction to the place where the air temperature exceeds the surrounding temperature only for 10 K. The values of β, ν and a were taken for parameters of surrounding air.

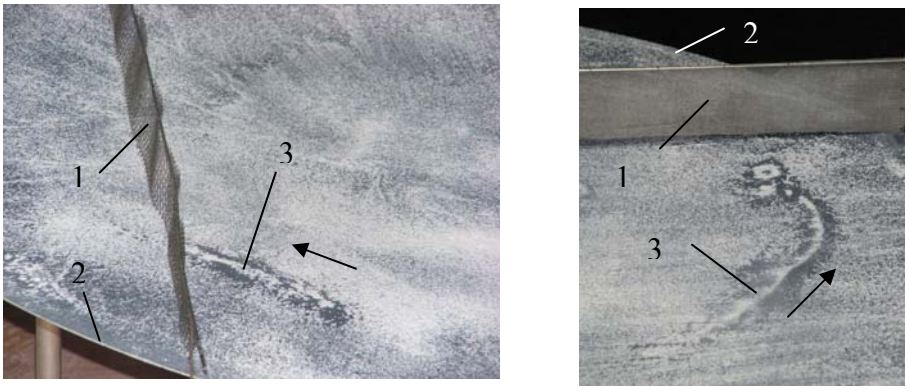
Figure 7 gives the time dependence of Rayleigh number at the centre of underlying surface for all six operating modes. A stable generation of vortices was observed in all modes except for mode no.1. Therefore, the Rayleigh number $Ra \approx 10^7$ may be taken as a minimal value at which the vortex structures began to form. The largest vortices were generated in case of operation in modes no.5 and no.6, which correspond to $Ra \geq 10^9$. There are two horizontal lines in Figure 7, which correspond to $Ra = 10^7$ and $Ra = 10^9$ respectively. By using these lines it is easy to define the time of existence of relatively small ($10^7 < Ra < 10^9$) and large vortices ($Ra > 10^9$) for the different operation modes. Received ranges of Rayleigh number are in good agreement with the experimental data on vortices generation on modes of heating and cooling of underlying surface.

Tornado prevention

In the present work the method of tornado prevention was developed and verified experimentally. The method consists of the creation of obstacles on the vortex path in the form of vertical grids with different height and size of cells. It was supposed, that this method may become an effective means of vortex characteristics control which leads to its weakening and/or destruction. Probably such grid defence constructions will be beyond comparison among another ways of tornado prevention due to simplicity of manufacturing and low price.

The height of grids used in experiments was chosen by realization of geometric similarity between real tornadoes (actual obstacles) and experimental vortices (model grids).

The main six variants of vortex behaviour during its interaction with grid were detected. They are: 1) vortex motion to the grid and its breakdown without grid intersection; 2) vortex destruction in the time of grid crossing (see Figure 8a); 3) vortex deceleration near the grid (up to full stop) and following breakdown (see Figure 8b); 4) change direction of vortex motion near the grid, then motion along the grid with following destruction; 5) vortex breakdown during grid crossing with second generation of vortex after grid; 6) intersection of grid by vortex accompanied of change of motion direction and its characteristics (vortex weakening).



(a) (b)

Digits refer: (1) grid, (2) edge of underlying surface, (3) vortex track.
The arrow shows the direction of vortex motion

Probably, there exist several physical mechanisms of grid-vortex interaction. The generation of small-scale turbulence near the grid which leads to the disturbance of vortex structure symmetry [9], acoustical oscillations generated by grid and running towards to the vortex are among these mechanisms together with some others.

CONCLUSIONS

The fundamental possibility of physical simulation of tornado-like air vortices under laboratory conditions was demonstrated. The influence of operation thermal mode parameters on the characteristics of generated air vortices was observed. The efficiency of the proposed method of tornado prevention was verified under laboratory conditions by means of study of vertical grids influence on behaviour of wall-free vortices with structure which is similar to the structure of real tornadoes. The received fundamental results are useful for the increase of effectiveness of the tornado prevention.

GRANULAR BED LIFTING IN SHOCK WAVE BY THE MECHANISM OF INTRAPHASE INTERACTION OF PARTICLES

S. Poplavski
Cristianovich Institute of Theoretical and Applied Mechanics,
SB RAS, Novosibirsk, Russia

ABSTRACT. Dynamics of lifting of the coal dust bed in the flow behind shock wave is experimentally investigated. On the base of the observations and quantitative data the physical mechanism of the process is suggested which supposes the existence of intermediate state of dust among the dense granular bed and the suspended state. This intermediate stratum is characterized by high concentration and mobility of the particles, and their collisions cause to further lifting. For this mechanism the ballistic model is suggested. In the frames of the model the dependence of vertical velocity and height are found. The comparison of this dependences with the experimental data demonstrate well agreement.

Keywords: *shock waves, multiphase flows*

INTRODUCTION

Mixing behind a shock wave (SW) gliding above a dust layer is an important issue within the framework of the dust explosion problem. There are many experimental and theoretical publications on this topic, but there is no unified model of the process [1]. The available models of bed lifting can be divided into two groups. The first one includes models that take into account the effect of the SW front and the flow behind it on the dust layer. These models consider a granular material as a continuous medium and the interface between the gas and the layer of particles as a contact surface between two fluids. Mostly advanced model in the frames of this approach was represented in the article [2]. Detail consideration of the wave dynamics in granular medium speaks well of this approach. The second group includes models that take into account only the effect of the flow behind the SW and the physical forces acting on the particles from the flow. These are the following forces: 1) the force generated by difference in velocity on the particle scale in the shear flow (Saffman effect) [3, 4]; 2) the force induced by rotation of a sphere in the flow (Magnus effect) [5]. The validity of these models is supported by the fact that bed lifting is also observed in the flows without shock waves.

Each mechanism is realized within its own physical constraints, but they all are possible if the interface between the phases and the particles possess certain mobility. This state of a granular medium, which is conventionally called a fluidized bed, is possible in the case of external energy supply, for instance, from a tangential flow and in the case of intraphase exchange of momentum in the bed through particle collisions. The role of collisions was noted in [5], but this effect was not quantified.

The analysis of the granular bed interaction is not complete without consideration of the papers, which are devoted to some special cases of the particles transition from the state of dense layer to suspended state. First of all these are the investigations of dust lifting behind reflected shock [6, 7].

It is known that behind reflected shock the gas is in the quiescent state and all mentioned mechanisms cease to be actual. However the experiments demonstrate that layer of dust being lifted in the incident shock continues to rise in the reflected wave and in addition - more rapidly [6]. It was shown by numerical simulation that behind the reflected shock propagating over the dust layer the large scale vortex appears in the vertical plane unlike the case of a channel with the smooth wall [7]. Velocity field of the particles confirms the influence of the ascending vortex part on the particles lifting in the reflected shock. The nature of the vortex they explain by the shock front curvature near the dust layer surface. This effect in it's turn connected with the flow non-uniformity in the incident wave because of the losses of the gas flow momentum in two phase mixture above the dense particles layer.

One more paper on the stability of granular bed has to be mentioned, which suggested the important effect far back in 1940 [8]. In the paper the particles takeoff from the bed was considered irrespective of the shock wave but only as a result of flow action just as the Saffman and Magnus effects is connected with the flow behind the shock wave.

However it is need the presence of particle in the flow for the action of Saffman and Magnus forces, but those mechanisms does not explain proper particles takeoff like other effects though. The value of the article is the fact that it experimentally proves and substantiates the quantitative criterions of the particles takeoff solely under the action of the flow sliding above the dusty layer.

In the proposed model the particles on the layer surface were considered untied, but each of them lies in surface irregularities formed with chaotic layout of the particles of lower layer. On average half of midship area of the upper particles is located in the gas flow. On the Figure 1 from paper [8] diagram of the forces is shown which influence on the particle of upper layer in sliding flow.

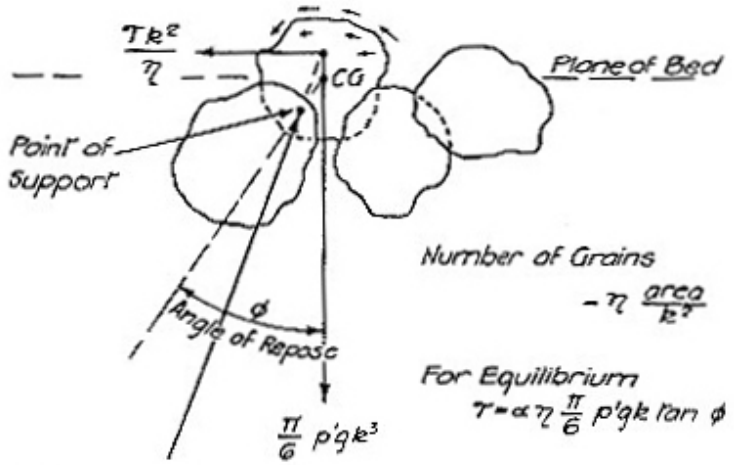

Figure 1. Frame of forces for the upper particle on the granular bed from [8], here k – is average particle size, η - coefficient of bed density, τ- tangential tension.

It is shown in the paper that dusty bed becomes instability when aerodynamics force is enough to "roll out" the particle along inclined trajectory at an angle ("angle of response" φ) on the height of radius. If the aerodynamics force exceeds the particle weight too much then the particles leave the bed at an "angle of response" φ relatively to bed surface. In the proposed model takeoff velocity is not defined, but it can be shown that this velocity is small. In fact at known average acceleration A on the length $\sim d$ particle get velocity $V \sim \sqrt{Ad}$. Acceleration of spherical particle at large Re number can be expressed from the motion equation:

$$A = \frac{s\rho u^2 C_d}{4m} = \frac{3}{8}\frac{\rho}{\rho_p}\frac{u^2 C_d}{d} \quad \text{then} \quad V = u\sqrt{\frac{3}{8}C_d\frac{\rho}{\rho_p}} \cong 10^{-2}u$$

It is clear that initial particles velocity is not large because the critical flow velocity u is small when dusty bed loses stability. According to experimental data [8] angle φ is about 30°- 45° for different types of dust, then the velocity vertical component is ~ 0.5-0.7V. In view of it this mechanism can not provide the lifting of small particles on the big height on the other hand it explains proper appearance of free and moving particles over the dense bed surface. Small thickness of an intermediate stratum between the particles bed and particles suspension is evidence of high concentration of particles inside the stratum. In this state the particles can be lifted by any mechanisms above mentioned.

The existence of such intermediate stratum produces conditions for multiple collisions of the particles with further flight along the ballistic trajectories. In the present paper the lifting of granular bed behind the shock wave is studied. An attempt to study the contribution of the particle collision mechanism to bed lifting behind the SW is made in the present work. The influence of the mechanism is investigated coupled with the particles ballistic flight model.

EXPERIMENTS AND DATA ANALYSIS.

Experiments with single particles

The experiments were performed in the shock tube with the particles of different size and shape, with different type of bed and with individual particles as well. Single particles on the channel floor behind shock wave behave ambiguously. Preliminary tests have shown that individual spherical particle does not lift from the smooth wall at least during observation time up to 0.5 ms. Single particle with an irregular shape is lifted by the flow at the same conditions. On the Figure 2 shadow picture of state of the rear monolayer of the irregular particles is shown after 250 μs of the SW front passing.

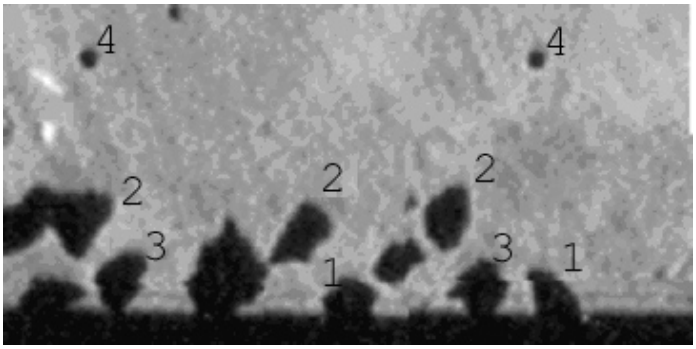

Figure 2. The lifting of the rear monolayer of the irregular particles after 250 μs of the SW front passing; 1 – the particles at rest, 2 – takeoff the particles, 3 – rolling particles, 4 – points of scale on glass window of the shock tube channel (distance 10 mm), particles size 1.5-2 mm.

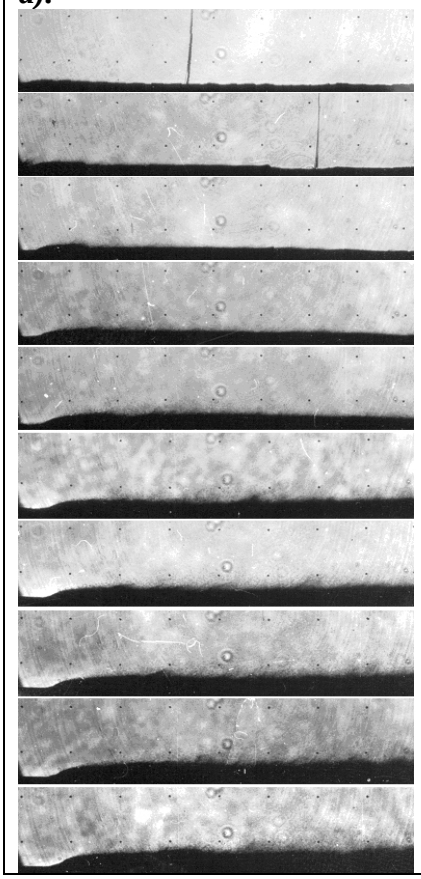
The analysis of such series of the frames shows that the particles is lifted on reaching critical rolling velocity with different delay depending on a peculiarity of shape: the number of verges and the difference between maximum and minimum size. This mechanism, which has not been yet described, to all appearance involves forced vertical oscillations of the center of mass of the particle during its rolling. In the present paper the following criterion of the particles takeoff is suggested by this mechanism. When the acceleration of oscillations is higher than g (constant of gravitation), the particle separates from the wall or from the bed surface. A parametric analysis shows that lifting of

a particle of size d by this mechanism occurs at a rolling velocity $u_x \geq \sqrt{10dg}$, and the initial vertical velocity is $u_0 \approx \sqrt{dg}$. Comparison of those estimations with the experimental observations shows well agreement and the lifting delay is connecting with achievement of the critical velocity u_x. The lifting of the spherical particles from the rough wall or from the bed surface by the flow is explained in a similar way. The velocity u_0 is too small to be responsible for the lifting height observed, but it indicates that there exists an intermediate state between the bed and the suspension, where the particles possess significant mobility at a high concentration. This state of dust more appropriately known as liquefied state.

Experiments with granular bed in shock wave

In the experiments with dusty layers the particles of different size was used and different types of layer location and roughness were investigated. The multiframe shadow method was used for the visualization of dust lifting [5]. Figure 3 shows typical series of shadow pictures obtained in the experiments with the coal dusts for two kind of layer surface. Figure 3***a*** shows dusty bed with natural roughness, and Figure 3***b*** shows the surface with an artificial transverse grooves for addition flow whirl. The height of image darkening over an initial dusty bed surface and further height evolution because of suspended layer appearance were recorded.



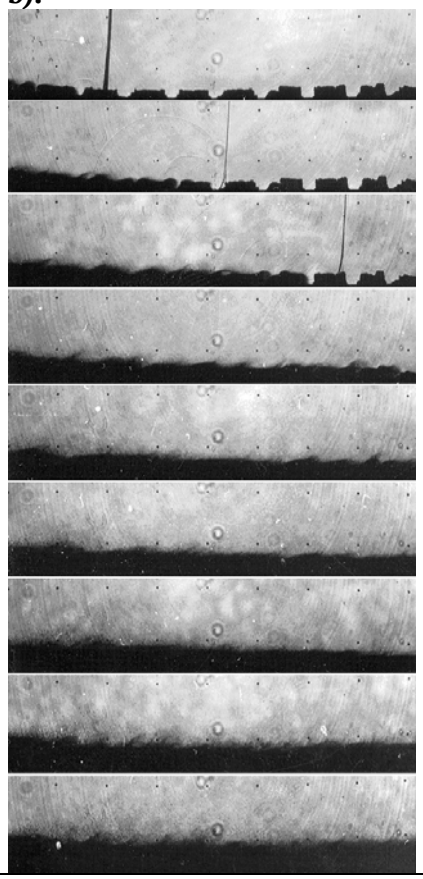


Figure 3.

a). Coal dust layer behind SW; SW Mach number $M_S = 1.54$; gas velocity $u_2 = 258$ m/s; particles size $d < 100$ μm, layer thicness 3-4 mm;

b). Coal dust layer with artificial transverse grooves behind SW; SW Mach number $M_S = 1.35$; gas velocity $u_2 = 175$ m/s; particles size $d < 100$ μm, layer thicness 3-4 mm;

time interval among the frams 50 μs

For the quantitative study the dynamics of a border of absolute darkening of the layer image was chosen. The volume concentration of particles on this border β_{tr}, is estimated at the approach of line optics as

$$\beta_{tr} = \frac{2}{3}\frac{d}{l},$$

here d - an average particles size, l - the optical thickness of tow phase area inside the shock tube channel. For the characteristic value $l \sim 10^{-2}$ m at $d \sim 100$ μm the volume concentration of particles is $\beta_{tr} \approx 10^{-2}$. At such a concentration an average distance among particles is small and comes to

~ 3*d*, but under the border of transparency is even less. In these conditions the collisions of the particles are very probable in view of chaotic component of their velocity because of mutual influence. Figure 4 shows the collision parameters for the case of equal spheres. In the present model it is adopted that collision velocity *V* particles get from the main flow on the length of free path.

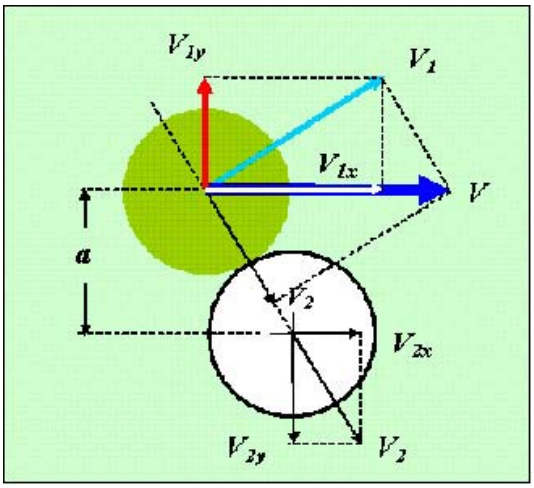

Figure 4. Collision parameters for the case of equal spheres.

Experiencing collisions with each other and with the rough bed surface, they acquire transverse (including vertical) velocity and leave the fluidized bed. In the elementary case of spherical particles of an identical size, their vertical velocity is

$$V_y(\delta,\alpha) = V\delta\sqrt{1-\delta^2}\,\sin\alpha, \quad 0 \le \delta \le 1,\ 0 \le \alpha \le \pi, \tag{1}$$

where *V* is the impact velocity, δ is the impact parameter of the collision *a/d*, and α is the angle of inclination of the impact plane to the bed plane. It is clear that averaging of Eq. (1) with respect to δ and α yields $V_0=V(2k/\pi)$. The impact velocity of particles at the early stage of acceleration can be expressed in terms of the mean free path L_f in the fluidized bed $V \cong u\left(\sqrt{2L_f/\lambda_ч} - 2L_f/\lambda_ч\right)$, where $\lambda_ч = 2\rho_p d/\rho C_x$, $L_f \cong 0.9d/\sqrt[3]{\beta_{tr}}$, $\beta_{tr} \sim d/l$ is the concentration of particles on the visible boundary of the bed. Assuming the particle to be lifted only owing to the momentum induced by the collision, there constructed a mathematical tool that allows predicting the basic parameters of the process, such as the maximum height of particle lifting and the concentration of the suspension.

Hovering of a particle. A process of hovering or a particle deposition in the presence of gravitational forces is not determinant but competitive to the lifting process. However we consider it here in the first place since its parameters are turned to be universal and are used for description of other relaxation processes taking place at a motion of solid particles in gas. We define the hovering as a stage of the particle deposition when the particle has reached a steady vertical velocity, i.e. the gravitational force becomes equal to the aerodynamical one.
We consider quantitatively dynamics of a particle in the gravitation field taking into account drag forces. The particle motion equation is given by

$$\frac{dV_y}{dt} = g - C_x\frac{s}{m}\frac{\rho V_y^{\,2}}{2}, \quad (t=0, \quad V=0). \tag{2}$$

Here the V_y is the vertical component of the particle velocity in coordinate system connected with the gas phase, *s, m,* C_x – midsection area, mass and drag coefficient of the particle, ρ is the gas density, *g* is the gravitational acceleration. It is obvious that behavior of the function V_y has an

asymptotical character, and the asymptote includes all basic physical parameters of the process. Therefore prior to integration of the equation we set the left hand side of the formula equal to zero. So we determine the asymptote as the steady fall velocity at the moment when the forces achieve the balance state. This asymptote value is the hovering velocity evaluated as

$$v = \sqrt{\frac{m}{s}\frac{2g}{C_x \rho}} \ . \tag{3}$$

In particular, a particle of irregular shape (cubic, for instance) with size d and the material density ρ_p has the hovering velocity as following

$$v = \sqrt{2\frac{\rho_p}{\rho}\frac{dg}{C_x}}\ , \text{ and sphere of diameter } d \text{ has } v = \sqrt{\frac{4}{3}\frac{\rho_p}{\rho}\frac{dg}{C_x}}\ .$$

For a coal particle this estimation gives $v \approx 30\sqrt{dg}$ at the gas density 2.2 kg/m^3 for a weak enough SW of Mach number M_s=1.4. Therefore the coal particle of size $d \approx 10$ μm has the hovering velocity of $v \approx 0.3$ m/s, and for $d \approx 1$ μm the velocity is $v \approx 0.1$ m/s. These unexpectedly big values are obtained for the drag coefficient $C_x \sim 1$, which has been chosen from those considerations that the flow regime in vicinity of the particle corresponds to relatively big Reynolds numbers. This regime is determined by the main (lengthwise) stream behind the SW. However in still gas the hovering corresponds to Stokes regime with $C_x \sim 20$ and higher. In this case the hovering velocity is $v \sim 10^{-2}$ m/s and even smaller.

It is obvious that choice of the C_x value depends totally on a level of completeness of the lengthwise velocity relaxation on moment of the hovering balancing achievement. In other words it depends on ratio of lengthwise relaxation time scale to the hovering balancing time. Bit it is correct for cases when scale time of the problem is bigger then both these scales. In other cases the most important parameter influencing the choice of C_x value is the problem time scale.

Besides determining the steady particle fall velocity the hovering velocity is a criterion of the particle lifting in an ascending stream. Indeed if the gas velocity has the vertical component u_y in the laboratory coordinate system and the velocity is higher than the hovering velocity, then according to (2) and (3) the particles within the given coordinate system will elevate with the velocity equal to

$$V_y = u_y - \sqrt{\frac{m}{s}\frac{2g}{C_x \rho}}\ .$$

Then even for weak SWs (M_s=1.4) at the stream velocity ~200 m/s a fluctuation of the velocity vector higher than 0.1% has to evoke lifting of the particles bigger then 10 μm. In angle expression it corresponds to a negligible flow deviation about ~0.06°. Such flow fluctuation can appear first due to weak oblique shocks and in the second place due to surface roughness and even the layer roughness.

The particle lifting height and velocity. In order to validate the model in the frame of experimental data a dependency of thickness of the dust-gas mixture over the layer vs. time of the flow impact has been found taking into account size and density of the particles, collision elasticity and flow parameters. Let us estimate the maximal lifting height of the particle of size d, thrown up with the initial velocity V_0 under the action of gravity and aerodynamical drag. We integrate the equation of motion

$$-\frac{dV}{dt} = g + C_y \frac{s}{m}\frac{\rho V^2}{2} \text{ with the initial condition } V = V_0 \text{ at } t = 0. \tag{4}$$

Using the notations $\Psi = V/v$ and $\theta = t/\tau_y$ determined earlier, where

$$v = \sqrt{\frac{m}{s}\frac{2g}{C_x\rho}} = \sqrt{2\frac{\rho_p}{\rho}\frac{dg}{C_x}}, \qquad \tau_y = \frac{v}{g} = \sqrt{\frac{m}{s}\frac{2}{C_x\rho g}} = \sqrt{2\frac{\rho_p}{\rho}\frac{d}{C_x g}}$$

we rewrite the equation (4) as

$$-\frac{d\Psi}{d\theta} = 1 + \Psi^2 \text{ with initial condition } \Psi = \Psi_0 = V_0/v \text{ for } \theta = 0. \tag{5}$$

The solution of this equation $\Psi(\theta) = tg(\theta^* - \theta)$ includes upper time limit of integration which equals to time period which needs for a particle to be lifted to the maximal height θ^*:

$$\theta^* = \frac{t^*}{\tau} = arctg\left(\frac{V_0}{v}\right) \quad (0 < t^*/\tau < \pi/2), \tag{6}$$

and the solution is given by

$$V(t) = v * tg\left(\frac{t^* - t}{\tau_y}\right) \tag{7}$$

Integrating (7) in the limits defined in (6) we get the required function of the particle lifting height depending on time and the relaxation parameters v and τ_y.

$$H(t) = v\tau_y \ln\frac{\cos\left(\theta^* - t/\tau_y\right)}{\cos\theta^*}. \tag{8}$$

This function is used in the paper for the comparison with the experimental data on dynamics of the layer lifting behind the SW. The value $v\tau_y$ is constant of relaxation length which within the Stokes approach is proportional to Reynolds number:

$$\lambda_y = 2\frac{\rho_p}{\rho}\frac{d}{C_y} = \frac{1}{12}\frac{\rho_p}{\rho}d\,\mathrm{Re} = \frac{1}{12}\frac{\rho_p}{\rho}\frac{d^2 v}{\nu}$$

Therefore we can estimate the maximal particle (layer) lifting height as following

$$H_{\max} = \lambda_y \ln\frac{1}{\cos\left[arctg\left(V_0/v\right)\right]}. \tag{9}$$

At small particle collision velocities when $V_0/v < 1$, the aerodynamical force influence on dynamical process and the height of lifting decreases. So we able to consider only two terms of decomposition one

$$\varphi = arctg\left(V_0/v\right) \cong V_0/v - \left(V_0/v\right)^3 + \ldots \text{, and also } \ln\frac{1}{\cos\varphi} \cong \frac{\varphi^2}{2} + \frac{\varphi^4}{12} + \ldots$$

Finally we get

$$H_{\max} \cong \frac{V_0^2}{2g}\left[1 - \frac{1}{2}\left(V_0/v\right)^2 - \frac{7}{9}\left(V_0/v\right)^4 + \ldots\right]. \tag{10}$$

Dependence (8) was compared with experimental data, and their good agreement was demonstrated (see Fig.6).

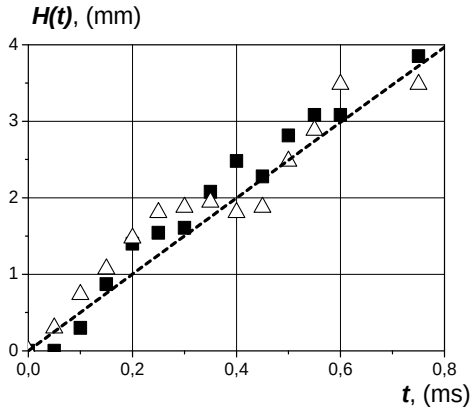

Figure 5. Dynamics of lifting of a coal-dust layer behind a shock wave; the points are the experimental data, and the curve is calculated by Eq. (8).

CONCLUSIONS

Dynamics of lifting of the coal dust bed in the flow behind shock wave is experimentally investigated. On the base of the observations and quantitative data the physical mechanism of the process is suggested which supposes the existence of intermediate state of dust among the dense granular bed and the suspended state. This intermediate stratum is characterized by high concentration and mobility of the particles, and their collisions cause to further lifting. For this mechanism the ballistic model is suggested. In the frames of the model the dependence of vertical velocity and height are found. The comparison of that dependence with the experimental data demonstrates well agreement.

ON THE DROP DYNAMIC AT AN EARLY STAGE OF THE VELOCITY RELAXATION IN SHOCK WAVE

V. Boiko, S. Poplavski
Cristianovich Institute of Theoretical and Applied Mechanics,
SB RAS, Novosibirsk, Russia

ABSTRACT. An experimental study of motion of droplets in the flow behind incident shock waves is presented. The aim of the present work was to investigate the velocity relocation and to measure the aerodynamic drag of drop in wide parameters range in the frames of a unified approach. The drops of water, alcohol, acetone, hexane and tridecane of 2 – 3 mm in diameter were tested in the flow behind shock wave with Mach number M = 0.15-0.55. Special attention was given to an early stage of the velocity relaxation, when the influence of deformation was significant. Data on the drops aerodynamic drag was obtained taking into account deformation and mass erosion. The influence of the drop deformation and mass erosion on the aerodynamic drag C_x was studied. Clear temporal correlation of C_x with the processes of deformation and breakup was shown. The influence of shock wave intensity on the value and dynamic of C_x was shown. These results enable to explain the C_x data dispersion of different authors with differences of time observation and Weber number. The value of real aerodynamic drag for the centre of mass of the drop C_x was found. It was shown that on an early stage of the velocity relaxation C_x for centre of mass is comparable with C_D of solid sphere.

Keywords: *shock waves, gas-drops mixtures, velocity relaxation, aerodynamic drag*

INTRODUCTION

The behavior of fuel drops at sudden penetration in gas flow (in particular in the flow behind shock wave) is important for multiples applications in the chemistry technology, power engineering, aircraft and rocket propulsion engineering [1]. Inert interaction of shock wave with the water drops is of interest from the point of view of the flight of high velocity aircrafts in rainy region.

The problem involves large group of complicated and interrelated processes, which run simultaneously. These are the acceleration of drop as a unit, evolution of the surface wave disturbance, deformation, and breakup. All available knowledge on these processes and determinative parameters by now were found experimentally and are reviewed in a number of articles [1 - 3].

Deformation of the drop and mass erosion are the determinatives in the problem of drop dynamic in the steady flow behind incident shock wave. There are known six modes of the drop behavior at sudden penetration to the gas flow depending on Weber number $We = \rho u^2 d/\sigma$, where $\rho u^2/2$ – is dynamic pressure, d – is the drop diameter, σ - is surface tension. Many authors suggest critical values of the Weber number which correspond to the main modes [1, 3]. So according to [3], following kinds of deformation and breakup (and the corresponding critical Weber number We_{cr}) are mostly typical for the low-viscosity liquids (water, alcohol, kerosene and so on):

1. vibrational breakup We = 8 ÷ 12,
2. bag breakup 12< We < 50,
3. bag-and-stamen breakup 50< We < 100,
4. sheet stripping 100< We < 350 ,
5. wave crest stripping We ≥ 350,
6. catastrophic breakup We ≥ 350.

The first mode is realized in the narrow Weber number range, has a large time delay of breakup and is not practically realized in the shock waves. The second and third modes looks like a soap bubble and are not observed in the experiments with shock waves as in the case of the first mode [4].
Following three modes are observed at large Weber number and cardinally differ from the above mentioned modes [5, 6]. Breakup of the drop at such conditions happens by means mass erosion from the liquid surface with the action of different mechanisms.
First of them is an entrainment of liquid boundary layer from the drop equator (sheet stripping) as a shroud with subsequent fragmentation (mode 4) [6].
The second one is the entrainment of droplets from the crests of micro-waves on the windward side of parental drop (wave crest stripping). This kind of waves is the result of evolution of Kelvin-Helmholtz instability, which is the characteristic feature of the shear streams [7] (mode 5).
One more sort of the instability of liquid surface (Rayleigh-Taylor instability [7]) provokes the drop breakup into several large parts (mode 6). Further breakup of the secondary droplets happens by the mode 4 or 5.
In incident shock waves with the flow velocity behind front u ≥ 50 m/s both stripping mechanisms in general take place, namely - sheet stripping mode and wave crest stripping mode [5, 6]. Our last experiments show that stripping mechanisms of drops breakup are observed in the wide range of Weber number 200 ≤ We ≤ 8000. Change of Weber number of the drop-shock interaction produces only the changes of duration of typical stages of the process. The observation of different stages of the velocity relaxation in the experiments can be reason of large differences of data on the drops aerodynamic drag obtained by various authors. The aim of the present work was to investigate the drops dynamic in incident shock waves and to measure the drop aerodynamic drag in wide range of main parameters in the frames of a unified approach taking into account the deformation and mass erosion.

EXPERIMENTS AND DATA ANALYSIS.

The experimental investigations of the acceleration of drops in the flow behind shock waves are confronted with considerable difficulties. It concerned with the registration of extremely small displacement *S(t)* especially on early stage of the velocity relaxation at $S(t) < d/50$ when the influence of the measurement error is considerably. This procedure requires both perfect diagnostic methods for the maximum spatial and time resolution during registration and modern approaches at the image treating.
The experiments were performed in the shock tube which was outlined in paper [8]. The low pressure channel of the 5 meters length has the square cross section 52x52 mm in the test chamber. Drop generator in the top wall of the channel was equipped by synchronization with the triggering system of the shock tube. It permits to place the descending drop on the centre of test chamber at moment of the shock front arrival.
The shock tube was equipped with fast-acting multi-frame shadowgraph registration on the base of laser stroboscope as a light source. Typical shadow picture of the process is shown on Fig.1. The exposition time ($30 – 50 \times 10^{-9}$ c), number of the frames (15-20) and intervals (10-50 μs) were setting by the laser stroboscope. Spatial separation of the frames was performed by high speed photographic camera with the rotating mirror prism.

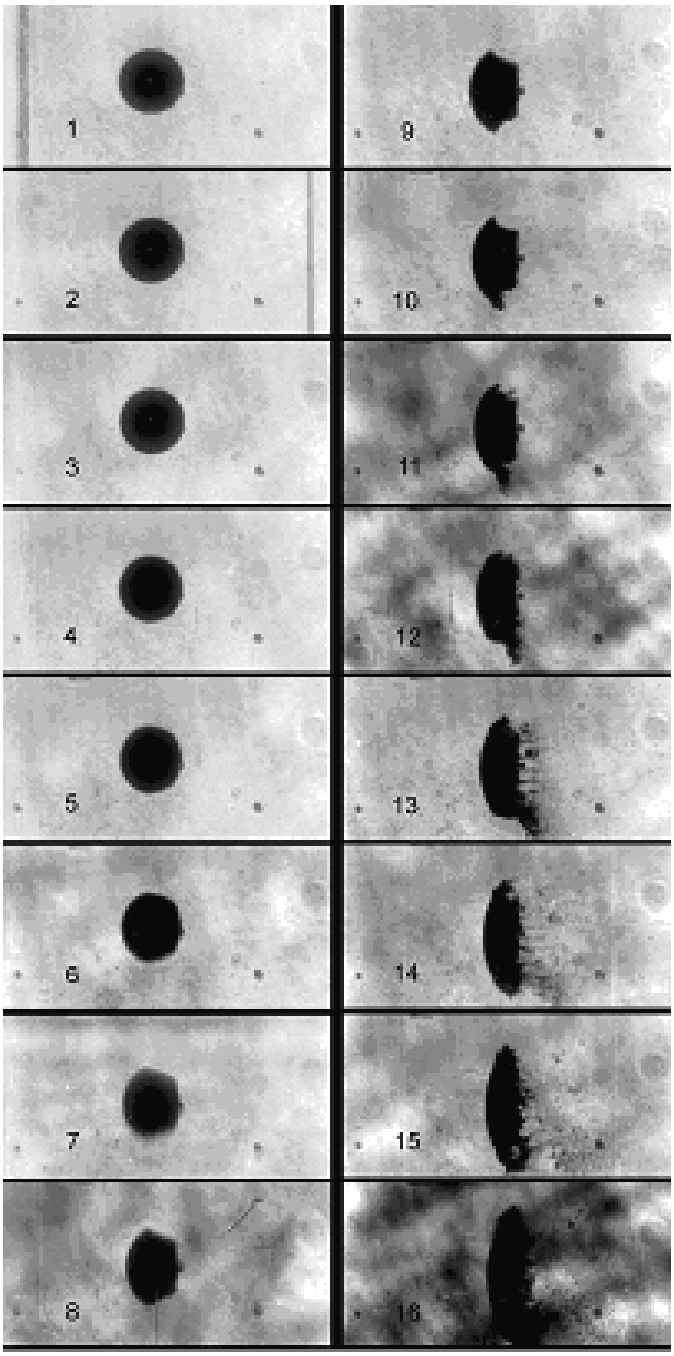

Figure 1. Water drop in the flow behind incident shock wave; M = 0.22; u = 79 м/с; d = 2.8 мм; We = 400; time intervals between the frames $\Delta t = 30 \pm 0.2$ μs

The dimensions of the frame were 18x24 mm and spatial resolution of the optic system was about 20 μm at the subject plane. Precision of time intervals was ~ 0.2 μs. The obtained photos were scanned without loss of the spatial resolution for the further treatment in the digital form.

Series of shadow pictures of the process of drop interaction with shock wave was obtained in every from 50 experiments. Total duration of the series amounts about 600 μs with the interval 30 μs between the frames.

The drops of water, alcohol, acetone, hexane and tridecane of 2 – 3 mm in diameter were tested in the flow behind shock wave with Mach number M = 0.15-0.55. Relatively low shock wave intensity was chosen to provide enough high Weber number We ≥ 300 but extend in time all characteristic effects to study in details.

The influence of deformation on the aerodynamic drag

The measurements of lateral size of the drops have shown that the rate of increase of the midship diameter usually has an unstable mode, but it is close to linear in the time interval at an early stage before mass erosion. Then we can use an empirical value t_{2d} (time of twice increase of the midship diameter) for the dependence of the midship diameter

$$d = d_0\left(1 + t/t_{2d}\right) \tag{1}$$

in the motion equation of the drop in the flow behind shock wave

$$\frac{\pi d_0^3}{6}\rho_l \frac{dV}{dt} = \frac{\pi d_0^2}{4}\left(1 + t/t_{2d}\right)^2 C_D \frac{\rho(u-V)^2}{2} \tag{2}$$

This equation with the initial condition ($t = 0$ then $V = 0$) has the exact solution

$$\frac{V}{u} = 1 - \frac{1}{1 + \frac{t}{\tau}\left[1 + \frac{t}{t_{2d}} + \frac{1}{3}\left(\frac{t}{t_{2d}}\right)^2\right]}, \tag{3}$$

where $\tau = \frac{4}{3}\frac{\rho_l}{\rho}\frac{d_0}{uC_D}$ is the constant of the velocity relaxation, ρ and ρ_l - are the gas and liquid density, d_0 – is the initial drop diameter, u – is the gas velocity, C_D – is aerodynamic drag of a sphere at the same conditions. Comparison of the solution (3) with the velocity function for the solid sphere from [9]

$$\frac{V}{u} = \frac{t/\tau}{1 + t/\tau} = 1 - \frac{1}{1 + \frac{t}{\tau}} \tag{4}$$

shows that these expressions are differ by factor in the square brackets in (3). Introducing new value τ^*

$$\tau^* = \frac{\tau}{1 + \frac{t}{t_{2d}} + \frac{1}{3}\left(\frac{t}{t_{2d}}\right)^2} = \frac{4}{3}\frac{\rho_P}{\rho}\frac{d_0}{uC_X\left[1 + \frac{t}{t_{2d}} + \frac{1}{3}\left(\frac{t}{t_{2d}}\right)^2\right]} = \frac{4}{3}\frac{\rho_P}{\rho}\frac{d_0}{uC^*} \tag{5}$$

where

$$C^*(t) = C_X\left[1 + \frac{t}{t_{2d}} + \frac{1}{3}\left(\frac{t}{t_{2d}}\right)^2\right] \tag{6}$$

we will find usual expression for drop velocity $\frac{V}{u} = 1 - \frac{1}{1 + \frac{t}{\tau^*}}$ similar to (4) with the variable aerodynamic drag (6) in the expression for τ^* (5). From the expression (6) it is evidently that at the moment $t \approx t_{2d}$ (stage of the intense mass erosion), aerodynamic drag of the drop C^* amounts to $\sim 2.3C_X$. This estimation satisfactorily agrees with the experimental measurements from the papers

[1, 2]. The comparison of the expression (3) with the experiment is shown on the Figure 2. Data on drop velocity is obtained by numerical differentiation of measurements of drop displacement depending on time.

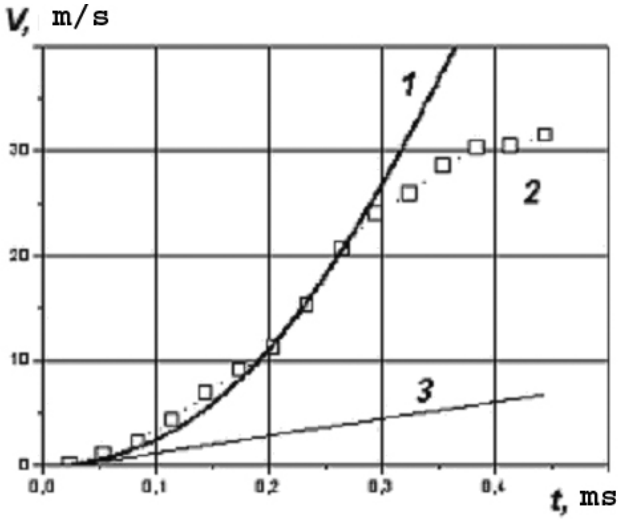

Figure 2. Velocity of the drop (alcohol) in the flow behind shock wave;
the curves: *1* – formula (3), *2* – numerical differentiation of drop displacement depending on time, *3* – velocity of solid sphere according to (4), u = 157 m/s, We = $5*10^3$.

Time delay of drop breakup

The expressions (1)-(6) are very effective for the fast engineering estimations of dynamical parameters of the drop in shock waves and in other cases of sudden acceleration in the flow. But application of them is limited by the time of mass erosion. Time delay of drop breakup was registered on the shadow pictures by appearance of the shroud of micro-droplets in the aerodynamic trail of drop. Figure 3 shows the shape of drop at the moment of mass erosion, place of mass erosion, and delay of the breakup beginning at different Weber number with an example of water.

All investigated liquids reveal the same basic tendencies of the shape evolution before the mass erosion. Distinctive peculiarity of the drop shape is the formation of two sharp curves of the generatrix, which separate tree sort of shape with different geometry. Windward side is part of sphere and is confined by first curves of the generatrix, lateral surface is the truncated cone, and the bottom of the drop is almost flat.

To all appearance the sharp curves of the generatrix are a recall of free liquid surface on the discontinuity of outside pressure distribution of the gas flow at the streamline with the gas flow separation. Outflow of liquid to the low pressure zone of flow separation is the main cause of ring-shaped waves which are observed as sharp curves of the generatrix. From the Figure 3 it is seen that both crests of these waves later will become the mass erosion points as a mostly unstable section of the liquid surface.

Those comprehensive data about the shape of drop in shock wave is found for the first time. This phenomenological picture of drop breakup rather changes the conventional conception of drop breakup by the "sheet stripping" mode. Apparently time delay of drop breakup t_{br} is not determined by delay of boundary layer formation inside the drop but for the most part - by the time of recall of liquid surface on the outside pressure discontinuity.

The experiments show that time delay of drop breakup t_{br} for all investigated liquids well described with hyperbolic expression from Mach number of the flow but more general form is the dependence from Weber number: $t_{br} \approx k \cdot We^{-0.5}$ with moderate change of coefficient k for different liquids. For the water $k = 7.8 \cdot 10^{-3}$ s, for the alcohol $k = 7.7 \cdot 10^{-3}$ s, for the hexane $k = 8{,}1 \cdot 10^{-3}$ s, for the tridecane $k = 8.5 \cdot 10^{-3}$ s, for the acetone $k = 8.8 \cdot 10^{-3}$ s.

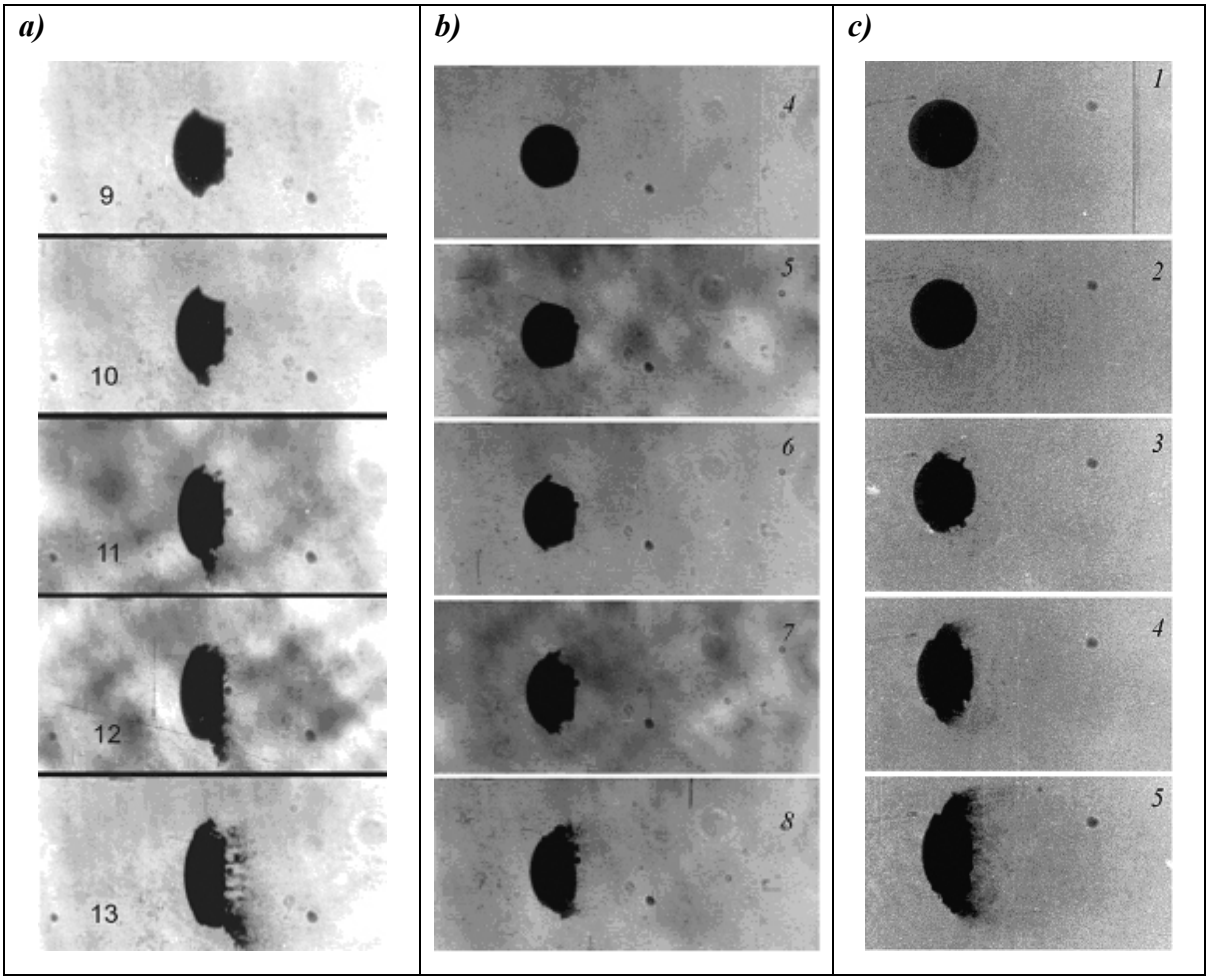

Figure 3. Fragments of shadow series of the water drop evolution by the time of breakup beginning; ***a)*** We = 400, ***b)*** We = 950, ***c)*** We = 2100,

The aerodynamic drag measurement of drop in shock wave

In the present work we follow of the conventional approach when the aerodynamic drag C_x of the drop as a liquid deformable body is calculated from approximation of "x-t" trajectory of the leading edge as for a solid sphere with initial drop diameter d [1]. The approximation can be carried out using the expression (7)

$$X = kT^2,\ X = x/d,\ T = \frac{t}{\tau_d},\ \tau_d = \frac{d}{u}\sqrt{\frac{\rho_p}{\rho}},\ k = const = \frac{3}{8}C_x \qquad (7)$$

Here d and ρ_p are size and density of drop, u and ρ are velocity and density of gas. In the paper [9] it is shown that displacement of solid sphere can be described by expression (8) It is an alternative way to approximate data on the drop displacement with the help of approximate function for solid sphere where for the drop one can use only the first term of the polynomial

$$S(t;u,\tau) \cong \frac{1}{2}\frac{u}{\tau}t^2 - \frac{1}{3}\frac{u}{\tau^2}t^3 + \frac{1}{4}\frac{u}{\tau^3}t^4 - ...; \tau = \frac{4}{3}\frac{\rho_p}{\rho}\frac{d}{C_D u} \tag{8}$$

As it clear from the Fig.1 aerodynamic drag can not be constant in time for such sharp evolution of the drop shape. The aerodynamic drag is not constant even for a free accelerated solid sphere in the flow because of fast change of the streamline mode. Since the measurement of C_x is an averaging on observation time, then one can use a set of data from whole data array.
Procedure of treatment of limited data samples (data sampling) permitted to obtain the quantitative dependence of the drop aerodynamic drag C_x as a function of the observation time of velocity relaxation process at different Weber number We (see Figure. 4). The maximums on curves correspond to the maximum deformation and the mass erosion start. The absence of maximum for large We number just means that mass erosion begins much earlier and prevents considerable increase of lateral droplet size.

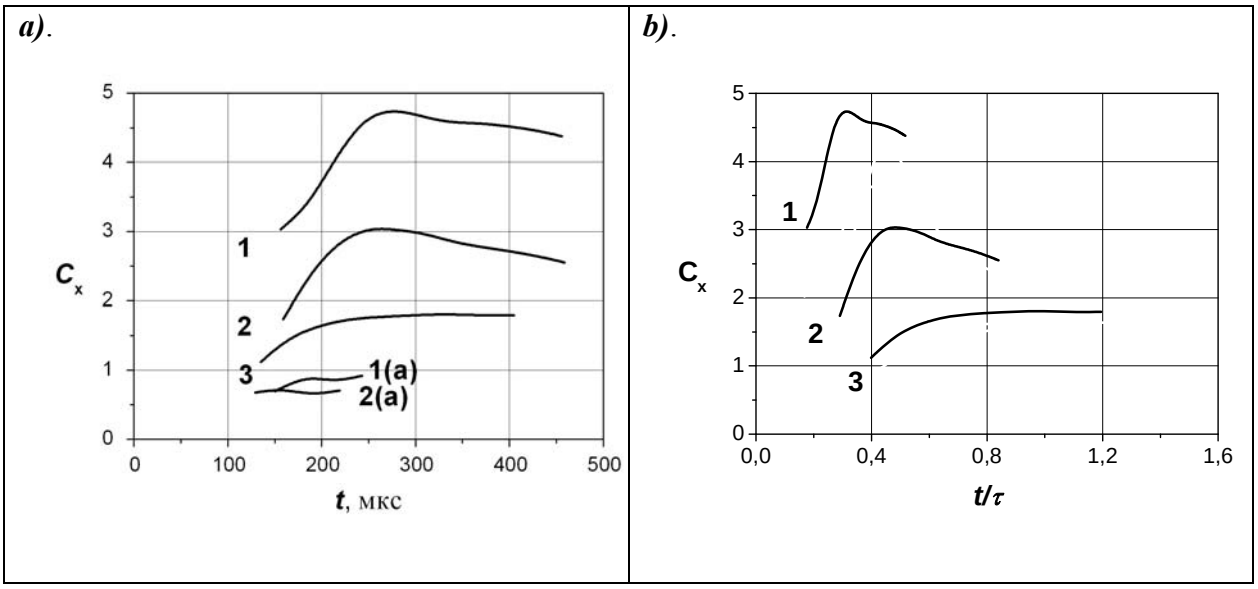

Figure 4. C_x of water drop as a function of the duration of stay in shock wave: a) – from physical time; b) – from nondimensional time; 1 – We = 400, 2 - We = 1010, 3 - We = 2250 for the leading edge; 1(a), 2(a) – for the centre of mass.

Similar dependences were found for othres 4 investigated liquids. It was sugested that nonstationarity of drag at early stage of the velocity relaxation effects on the everaging during larger duration of observation. It coud be reason of large differences of data on the drops aerodynamic drag obtained by various authors.
The measurements of drag for centre of mass were performed for the first time. It was found that the last is considerably less then for leading edge and close to solid sphere drag.

CONCLUSIONS

The drops of water, alcohol, acetone, hexane and tridecane of 2 – 3 mm in diameter were tested in the flow behind shock wave with Mach number M = 0.15-0.55. Data on the drops aerodynamic drag was obtained taking into account the deformation and mass erosion. The influence of the drop deformation and mass erosion on the aerodynamic drag C_x was studied. Clear temporal correlation of C_x with the processes of deformation and breakup was shown. The influence of shock wave intensity on the value and dynamic of C_x was found. These results enable to explain the C_x data dispersion of different authors with differences of time observation and Weber number. The value of real aerodynamic drag for the centre of mass of the drop C_x was measured. It was shown that on an early stage of the velocity relaxation C_x for the centre of mass is comparable with C_D of solid sphere.

This work was supported by the Russian Foundation for Basic Research (Grants No. 04-01-00235, № 07-01-00318).

SIZING OF SAFETY VALVES FOR VERY VISCOUS SHEAR-THINNING LIQUIDS

D. Moncalvo[1,2,*], L. Friedel[2], B. Jörgensen[1]
[1] LESER GmbH & Co. KG, Hamburg, Germany
[2] TU Hamburg-Harburg, Hamburg, Germany

ABSTRACT. The extension of the actual sizing standards for safety valves from Newtonian liquids to shear-thinning polymers is impeded by the lack of measurements. Here, liquid and two-phase flows of aqueous solutions of polyvinylpyrrolidone are discussed on behalf of new experimental data. In liquid flows the mass flow rate is weakly affected by an increment in the polymer weight in the solution. This result suggests that the rate of viscosity increment with the polymer concentration between the seat and the disk is very slow. In support of this theory the distributions of the shear rates and of the viscosities are calculated computationally and that effect is evinced. In two-phase flows the total mass flow rate at constant relieving pressure and quality increases notably with the polymer weight in the liquid. A possible explanation considers both that air entrapment strains shear-thinning liquids to very large shear rates and that a reduction in the void fraction following a redistribution of the phases occurs, when the viscosity of the medium increases.

Keywords: *shear-thinning, non-Newtonian, viscous flow, two-phase flow, safety valve*

INTRODUCTION AND STATE OF THE ART

Safety valves are employed for the protection of reactors and pressurized units from overpressure caused by malfunction, run-away reactions, external fire, etc. If the medium is a very viscous Newtonian liquid the sizing standards ISO 4126 Part 1 [1] and API RP 520 [2] introduce a viscosity correction factor to estimate the reduction in the flow capacity of the safety valve when the viscosity of the liquid is increased. Darby [3] proposed to extend the viscosity correction factor to shear-thinning liquids assuming the power-law rheological model but he could not validate this suggestion, since there are no published measurements on the flows of non-Newtonian media.

The topic of this paper is a description of liquid and two-phase flows of shear-thinning media in safety valves and the final purpose is to find some hints for a future extension of the actual sizing standards.

Table 1
Experimental Test Conditions

Liquids (Single and two-phase flows)	Aqueous solutions of polyvinylpyrrolidone
Gas (Two-phase flows)	Air
Relieving temperature	18 – 25 [°C]
Back pressure	1 [bar]
Liquid flows	
Relieving pressure	1 – 7 [bar]
Mass flow	0.75 – 6 [kg/s]
Two-phase flows	
Relieving pressure	6 and 7 [bar]
Total mass flow	1.0 – 3.2 [kg/s]
Quality	0.01 – 0.10 [--]
Safety valve LESER Type 441 DN 25/40	
Seat diameter	23 [mm]
Disk Lift	2.2 [mm]

EXPERIMENTAL PROGRAM AND SET-UP

Three aqueous solutions of polyvinylpyrrolidone (PVP) K90 with a polymer weight of 4 ± 0.3, 12 ± 0.4 and 16.5 ± 0.6%-weight are the test liquids. In two-phase flows this liquid phase is mixed with dried ambient air.

The experimental conditions of the liquid and the two-phase flows are written in Table 1. The relieving pressure in liquid flows is increased from 1 to 7 bar, while in two-phase flows it is maintained at the constant values of either 6 or 7 bar. The relieving temperature and the back pressure are ambient. The mass flow increases between 0.75 and 6 kg/s in liquid flows and between 1 and 3.2 kg/s in two-phase flows. The quality in two-phase flows changes from 0.01 to 0.10.

The safety valve is a LESER Type 441 DN 25/40 with a seat diameter of 23 mm and a lift of 2.2 mm, which is mounted without the spring load in agreement to the requirements in ISO 4126-1 [1] for the measurement of the flow characteristics.

Description of the test facility and of the sensors

The measurements have been carried out with the facility in Figure 1 at the *Institut für Strömungsmechanik* of the T.U. Hamburg-Harburg [4]. This facility contains a closed loop for the liquid phase and a piping for the injection of dried ambient air. The liquid is pumped from the feeding reservoir into the relief vessel, on whose top the safety valve is mounted. From the valve the medium is discharged into a collection tank, which is connected to the feeding vessel so that the liquid circulates. The collection vessel acts also like an open gravity separator of viscous two-phase mixtures. The mass flow rates of the components determine the relieving condition in the relief vessel. The liquid mass flow rate is adjusted by the user at the pump and eventually with the bypass line, which sends the capacity in excess back into the collection vessel. The mass flow rate of air is manually controlled by a ball valve in position H103 and the exceeding air feed is released to the ambience throughout the butterfly valve in position H101. In two-phase flows both mass flow rates

must be simultaneously regulated in order to record measurements at different qualities but at the same relieving pressure.

The list of the sensors, which have been inserted in this facility, is given in Table 2. This table contains the main product characteristics, the position of the sensors in the test-rig, the measurement range and the calibration errors. Calibration details can be found in Moncalvo and Friedel [4].

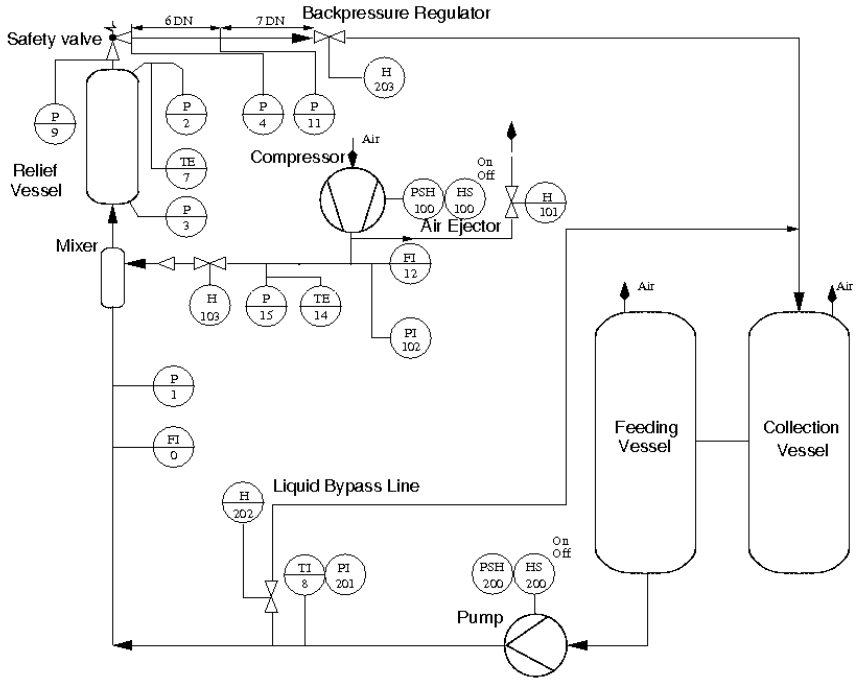

Figure 1. Test facility

Table 2
List of the Sensors installed in the Test Facility of Figure 1

Location	Type	Measuring range	Calibration accuracy
P1, P2, P3, P4 P9, P11, P15	Piezoelectric pressure sensor	1 – 16 bar	0.04 bar
T7 , T8	Temperature sensor Pt 100	15 – 37°C	0.15 °C
T14	Thermocouple NiCr-Ni		1.0°C
FI 0	Electromagnetic flowmeter	0 – 60 m³/h	0.3 m³/h
FI 12	Thermal flowmeter	0 – 2000 Nm³/h	10 Nm³/h

The measurement of the volume flow rates and of the densities determines the mass flow rate of each component, which is necessary to calculate the total mass flow rate of the mixture and the quality, respectively on the base of equation (1) and equation (2).

$$\dot{M}_{TOT} = \dot{M}_G + \dot{M}_L \quad (1)$$

$$\dot{x} = \dot{M}_G / \dot{M}_{TOT} \quad (2)$$

PHYSICAL PROPERTIES

The density, the dynamic viscosity and the surface tension of the aqueous solutions of polyvinyl-pyrrolidone at ambient temperature are listed in Table 3. Own measurements of the density agree with those of Carlfors and Rymdén [5] as well as with those of Renz [6]. The zero-shear viscosity increases remarkably with the polymer concentration from about 0.2 Pa s to 2 Pa s and all the aqueous solutions are clearly shear-thinning, see Figure 2. A shear-thinning behavior is also proven by Bell [6] for the solutions he tested, which had a polymer content above 10 %-weight. This figure shows that the curvature of the flow curves increases with the polymer weight of the liquid, which means that the difference in the viscosity of two solutions at the same temperature remarkably diminishes when the shear rate increases. An analytical expression for the flow curves is the shear-thinning model of Yasuda et al. [8] in equation (3).

$$\mu = \mu_0 + \left(\mu_0 - \mu_\infty\right)\left[1 + \left(\lambda\dot{\gamma}\right)^a\right]^{(n-1)/a} \quad \text{with} \quad 0 \le n \le 1 \tag{3}$$

Pahl et al. [9] reported a simplification of this model under the assumption that the viscosity at very high shear rates, μ_∞, comes close to zero, see equation (4).

$$\mu = \mu_0\left[1 + \lambda\dot{\gamma}\right]^{-c} \quad c = 1 - n \tag{4}$$

Table 3
Physical Properties of the Aqueous Solutions of Polyvinylpyrrolidone at Ambient Temperature

	Density (kg/m³)	Viscosity (Pa s) at shear rate (1/s)				Surface tension with Air (mN/m)

PVP 4 %-weight	1007.1	0.25	0.24	0.23	0.16	72.0
PVP 12 %-weight	1020.9	1.00	0.95	0.73	0.37	69.8
PVP 16 %-weight	1029.7	2.89	2.86	1.88	0.83	70.0

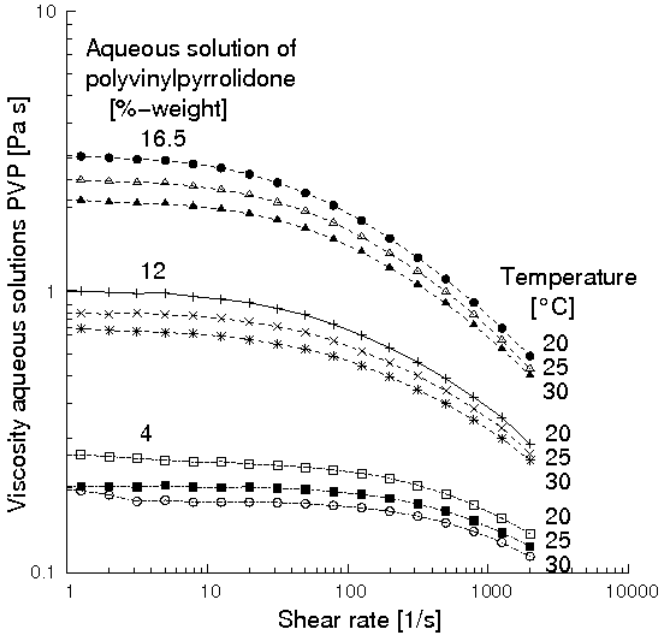

Figure 2. Rheological behavior of the aqueous solutions of polyvinylpyrrolidone

Table 4
Empirical Coefficients for the Viscosity of the Aqueous Solutions of Polyvinylpyrrolidone

	Shear-thinning media - Yasuda model -			Ubbelohde – Walter temperature dependence of μ_0		
	μ_0 (Pa s)	c (--)	λ (s)	υ_0 (mm²/s)	T_* (K)	m (--)
water	0.001	0	0	0.995	230.82	-5.026
PVP 4 %-weight	0.27	0.236	0.00843	268.1	240.69	-6.134
PVP 12 %-weight	1.03	0.386	0.01319	1008.7	252.70	-8.327
PVP 16 %-weight	3.09	0.457	0.01842	3086.6	252.50	-8.086

In equation (4) μ_0 is the zero-shear viscosity , c represents the degree of pseudoplasticity of the solution, which indicates the rate of viscosity reduction with the shear rate and λ is the Carreau time constant. On behalf of Figure 2 the shape of the flow curves is assumed to be unvaried between 20 and 30°C. Therefore, the dependence of the viscosity from temperature is given by that of the zero-shear viscosity, which follows an Ubbelohde-Walther relationship [9], like that in equation (5).

$$\log_{10}\log_{10}(\upsilon/\upsilon_0+1)=m\ \log_{10}(T/T_*) \tag{5}$$

In equation (5) υ_0 and T_* are a fictitious kinematic viscosity and temperature and m is the rate of the logarithmic reduction. The values for these parameters in Table 4 are empirical under the assumption that υ_0 is equal to the zero-shear kinematic viscosity at 20°C.

The surface tension of the aqueous solutions of polyvinylpyrrolidone in Table 3 shows little changes in function of the polymer weight of the solution.

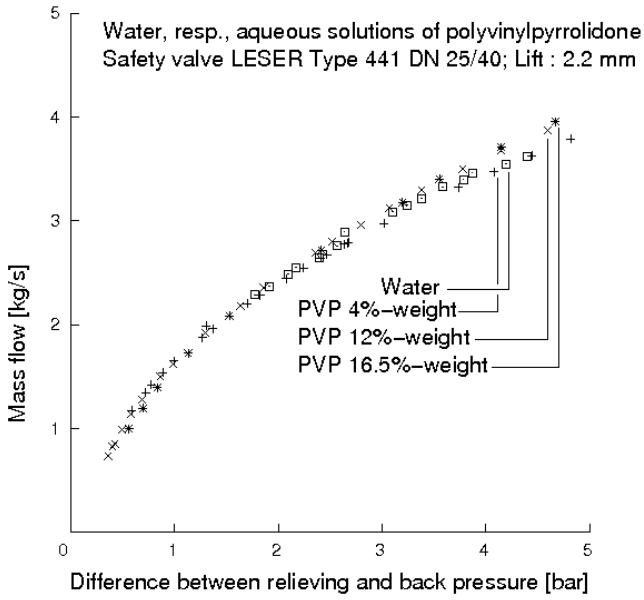

Figure 3. Mass flow rates of the aqueous solutions of polyvinylpyrrolidone for increasing differences between the relieving and the back pressure

RESULTS AND DISCUSSION

The mass flow rates of the aqueous solutions of polyvinylpyrrolidone present small deviations among each other in a wide range of relieving pressures, see Figure 3. This fact suggests that the viscous losses and therefore the viscosities in the region between the seat and the disk, where most of the pressure drop in the safety valve occurs, must increase very weakly with the polymer weight in the aqueous solutions. On behalf of the experienced increase in the pseudoplasticity of the solutions with the polymer weight it seems reasonable that the shear rates in that region must be very large in all aqueous solutions and they must increase with the polymer weight. This explanation sounds a priori plausible, considering that large velocity gradients due to the acceleration of the liquid must be present between the seat and the disk.

In order to support this theory, at least qualitatively, the flow of the aqueous solutions is calculated in the whole range of relieving pressures using the CFD software ANSYS CFX. A grid is generated in the flow volume of the valve, of the relief vessel and of the outlet pipe on the base of the criteria recommended by Moncalvo et al. [10]. The flows are assumed steady-state and adiabatic at the metal walls. Since it is not possible to establish a priori if the flow in the valve is laminar or turbulent for a given reliving scenario, two series of calculations are done, once assuming laminar flows and then using the SST turbulence model. The criterion for the choice between the flow regimes is the minimization of the error in the calculation of the mass flow rate; which ranges for all aqueous solutions between 1 and 8 %. The impact of the different sources of errors on the calculations is currently under study.

The computational distribution of the shear rates and that of the viscosities in the region between the seat and the disk are displayed in Figure 4 for the solution with 16 % polymer weight at a relieving pressure of 2.1 bar (SST). According to this figure the shear rates between the seat and the disk, which are well above one thousand, are the largest in the safety valve and therefore viscosities as low as one tenth of the zero-shear value are evinced for that aqueous solution. No substantially qualitative divergence is found in the distributions, which are calculated using the laminar and the turbulent flow assumption.

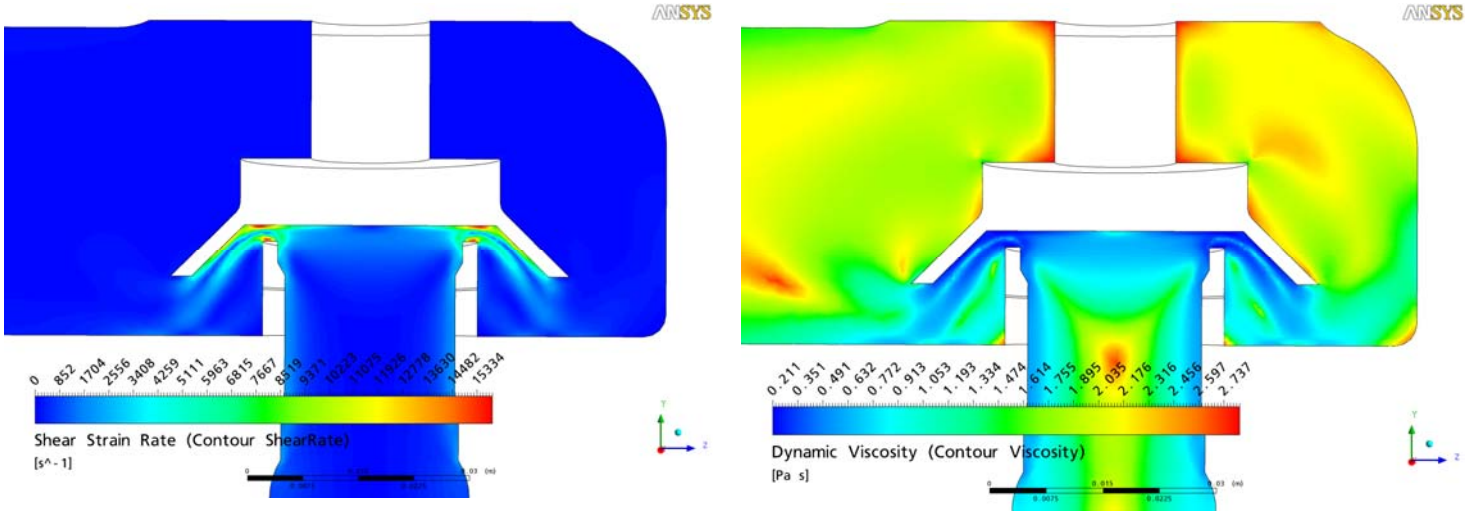

Figure 4. Shear rate and viscosity of the aqueous solution PVP 16 %-weight at the relieving condition of 2.1 bar and 22°C calculated by the software ANSYS CFX with the SST turbulence model

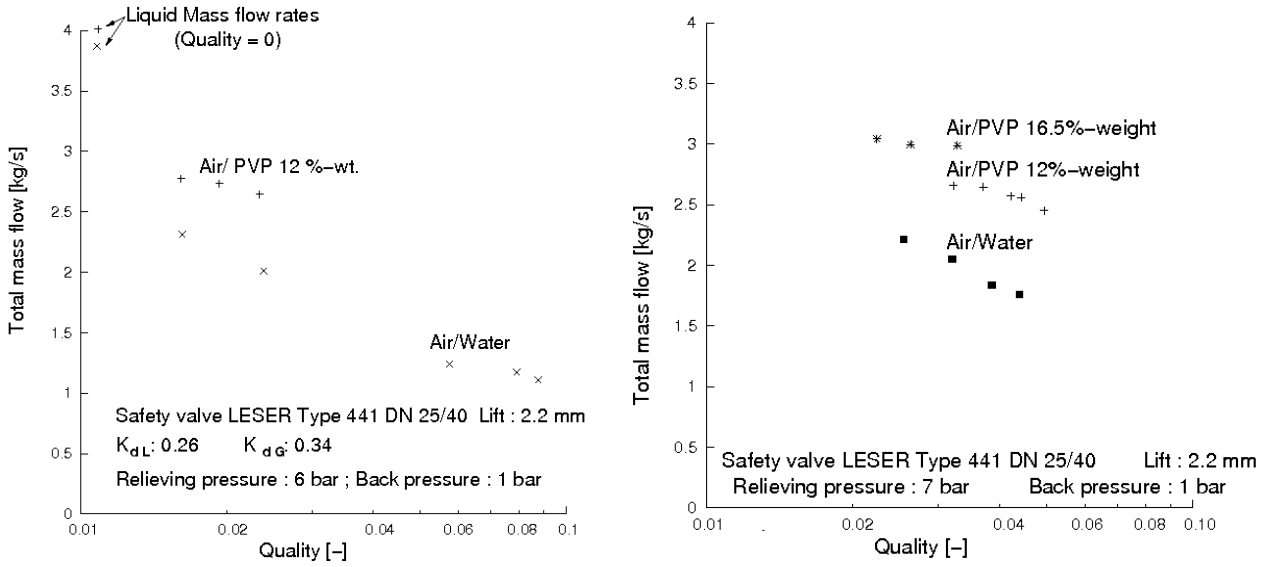

Figure 5. Total mass flow rate of the aqueous solutions of polyvinylpyrrolidone and air in function of quality at the relieving pressure of 6 (left) and 7 bar (right)

For the two-phase flows of air and aqueous solutions of polyvinylpyrrolidone Figure 5 shows that an increment of the polymer weight in the liquid causes an increase in the total mass flow rate of the mixture at constant relieving pressures in the whole range of qualities. A similar behavior was evinced in co-current pipe flows [11, 12]. Shu [13] explained it suggesting that the entrapment of air in the liquid causes large velocity gradients and therefore strains it to very high shear rates.

However, the effect of high shear strains on the reduction of the viscous losses would lead to a far marginal - if any - increment of the total mass flow rate when the polymer weight of the solution is increased. This implies that some additional phenomenon must be considered in order to explain the results. The analogy with co-current pipe flows suggests that the phases redistribute in new structures when the viscosity of the liquid in the safety valve is increased in consequence of the larger liquid drag on the gas. In order to win this resistance, the gas needs to have a higher pressure than the surrounding liquid and therefore it compresses itself, leading to a reduction in the void fraction in the mixture, see Mukherjee [14]. If the total mass flow rate and the quality are unchanged, a reduction of the void fraction leads to a loss in the momentum of the mixture, which determines the pressure in the relief vessel. Since the measurements are here taken at constant relieving pressure at any quality, the total mass flow rate must increase with the polymer weight.

CONCLUSIONS

No reduction in the flow capacity of the safety valves is observed in both liquid and two-phase flows of aqueous solutions of polyvinylpyrrolidone when the polymer content is increased up to 16 %-weight. The authors showed that the pseudoplasticity of these solutions has a paramount role in the reduction of the viscous losses in the region between the seat and the disk of the safety valve. This effect must be accounted for in a possible extension of the viscosity correction factor to this type of media. In fact, the conclusions evinced with polyvinylpyrrolidone are in principle expectable also with other shear-thinning polymers in other types of safety valves for non-cavitating flows.

ABSTRACT. The vortex shedding induced by a solitary wave propagating over a rectangular cavity is studied experimentally, using particle image velocimetry (PIV) and a flow visualization technique. The aspect ratio of rectangular cavity (i.e., ratio of the length to the depth of a cavity, A_r) ranges from 0.33 to infinity in this paper. The ratio of wave height to water depth in the experiment is kept at 0.2. Detailed vortical structures for $A_r = 0.33 \sim \infty$ were observed using particle trajectory photography and measured by PIV. Quantitative characteristics of the primary vortex generated in the cavity, such as trajectories of the jet flow and circulation of the vortex, are investigated in detail.

Keywords: *wave-cavity interaction, solitary waves, aspect ratio, vortices, flow visualization*

INTRODUCTION

The propagation of water waves over a submerged obstacle has received much attention for decades. In physical applications, it relates not only to coastal and ocean engineering problems, but also to the sustainable development for near-shore environment. A submerged obstacle can be regarded as a submerged dike used to prevent coast erosion caused by surging waves. To have a better understanding of the complex flow field generated by wave-obstacle interaction, many researchers used rectangular shape to simplify the geometry of submerged dike.

On the other hand, there is a natural disaster 'tsunami' which has tremendous energy, and may cause huge damage in the near shore region. On December 26, 2004, an earthquake with an intensity of 8.9 on the Richter scale taking place near the Island of Sumatra generated a tsunami which severely impacted the shores of the Indian Ocean, particularly from Indonesia to Sri Lanka. The tsunami washed away long reaches of the coast. In the disaster, the base of American Navy located in the Indian Ocean, Diego Garcia, was not damaged by the tsunami. The reason might be attributed to the coral reef near the base, and the existence of the trench 'Chagos' which is 5,400 km deep, 740 m long outside of the coral reef. Coral reef and Chagos trench may act as an obstruction which decreases the energy of the tsunami. Hence, the topic concerning a tsunami propagating over a trench needs to be further investigated.

Few studies concern about a solitary wave propagating over a cavity. Tang and Chang [1] studied the wave deformation numerically under such a condition. The influences of water depth, cavity number, and aspect ratio of the cavity were discussed. Nakoulima et al. [2] discussed the problem of a solitary wave propagating over periodic cavities. They found that wave dispersion was more obvious with the increase of the cavity length, and the wave amplitude varied suddenly in the location where bottom elevation changed substantially. The cavity also decreased the amplitude of

incident solitary wave, but the topography of the bottom in the downstream side of the cavity determined the final wave height of a solitary wave.

The main concerns of most existing investigations have been focused on the establishment of numerical model and the spatial variation of the wave profile. Therefore, the flow phenomenon while a solitary wave propagating over a cavity has not been investigated experimentally. The objective of this study is to elucidate the characteristics of flow structure induced by a solitary water wave propagating over the rectangular cavity. Flow visualization techniques and particle image velocimetry (PIV) were both used in the study.

EXPERIMENTATION

Experiments are conducted in a glass-walled wave flume located at Hydraulic Laboratory, National Chung Hsing University. A wave maker, equipped with a piston-type wave paddle which is driven by a variable-speed motor, is installed at one end of the wave flume. The wave maker was designed originally for producing monochromatic waves with periods ranging from 0.4 to 2.0 sec and with wave heights (H) up to 3.5 cm. An electromagnetic clutch particularly installed inside the wave maker allows rapid starting and stopping of the piston-type wave paddle. Two capacitance-type wave gauges are used to detect the water surface elevations in the experiments.

A submerged rectangular cavity made of acrylic material is set upon the bottom of the wave flume and has the same spanwise width as the wave flume. The depth of the cavity, D, is 3.0 cm, while the length L varies from 1.0 cm to infinity (see Fig. 1). The aspect ratio of rectangular cavity (i.e., ratio of the length to the depth of a cavity, A_r) ranges from 0.33 to infinity in the present study. The still water depth, h, used in the experiments is 7.0 cm and the wave height of incident solitary wave is kept at about 1.2 cm.

Particle tracing photography is employed to observe the vortex structure generated by a solitary wave propagating over a rectangular cavity. A Phantom camera is used to obtain images at a rate up to 1000 frame/sec. A high-resolution particle image velocimetry (PIV) system is also used to measure the velocity field of the flow structure on the plane of symmetry. The light source for the PIV system is the Continuum Surelite Nd: YAG dual lasers, which contained a crystal harmonic generator to produce the frequency-doubled (532 nm) green light from the original (1064 nm) invisible infrared light. In the experiments, successive frame-pairs were captured in the rate of 10 fps and then analyzed using the TSI Insight 3.0 Software.

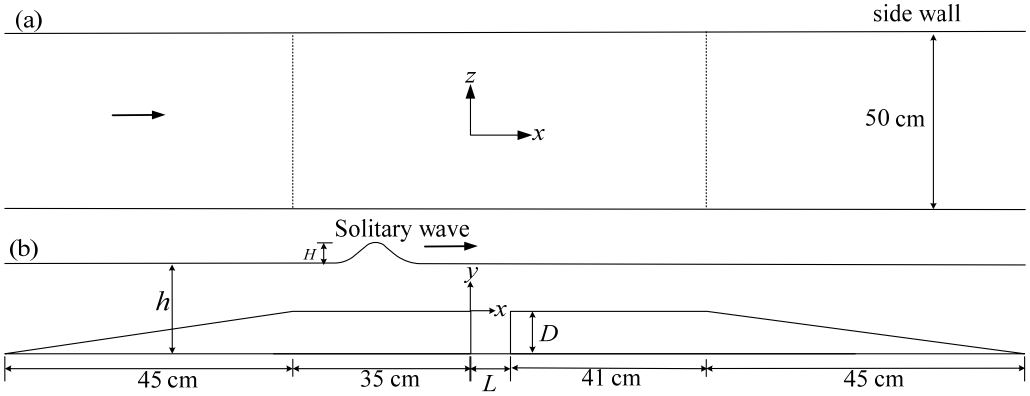

Fig. 1 Diagram of the experimental set up: (a) top view, (b) side view

RESULTS AND CONCLUSIONS

Since the generation of a solitary wave in the present study followed the traditional method, the generated waves may contain certain discrepancies as compared with the theoretical wave form of

$$\eta(x,t) = H \sec h^2 \left[\sqrt{\frac{3H}{4h^3}} (x - ct) \right] \tag{1}$$

where η denotes the free surface elevation, x and t the streamwise direction and time, H the wave height, h the water depth, and c the wave celerity that can be calculated as $c = \sqrt{g(h+H)}$.

Validation for the generated waves was performed by comparing not only the free surface displacement but also the velocity profile along the entire depth as well as the wave celerity. The free surface comparison for the target solitary wave (H = 1.4 cm, h = 7.0 cm) is shown in Fig. 2 Very good agreement is obtained from the comparison. A series of repeatability tests for generating a solitary wave in the flume was also performed. It was found that the generated solitary waves are highly repeatable.

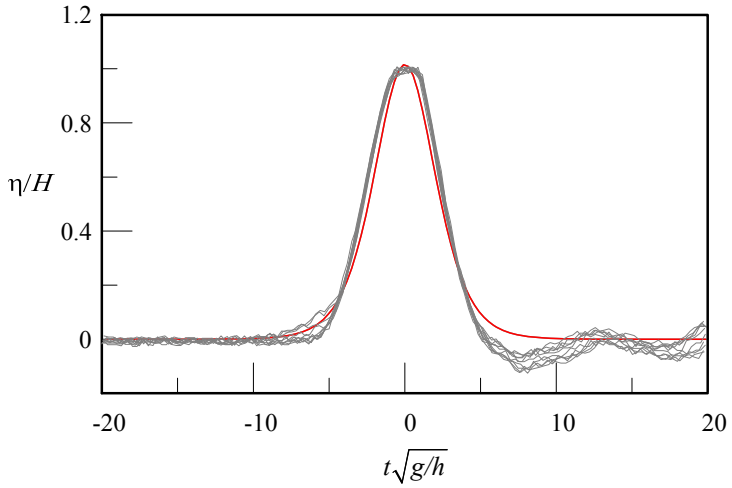

Fig. 2 Free surface elevation of the solitary wave versus non-dimensional time (gray line: experimental data, bold line: theory)

Flow visualization

First, the length of the cavity was first set at infinity. In this case, the condition in the frontal edge of the cavity is similar to the lee side of the rectangular dike (Lin et al. [3]). The flow pattern of this original situation is used to compare with those of cases for A_r = 0.33 ~ 1.0. From the comparisons of qualitative flow visualization pictures and quantitative property of the primary vortex, the influence of A_r can be easily observed.

The images taken using particle trajectory photography are shown in Fig. 3. Note that the frontal edge of the cavity is located at x = 0, and the free surface elevation at each instance can be found in Fig. 2. It shows the beginning of vortex generation process when the wave crest is very close to and just reaches the frontal edge of the cavity. One clockwise vortex is generated at the frontal edge of the cavity due to flow separation. This primary vortex is defined as vortex A_v. The primary vortex grows larger due to formation of the shear layer (Lin et al. [3]) and moves downstream because of the inertia force caused by incident solitary wave. As the wave crest passes, the size of the primary vortex A_v grows in the beginning as shown in Fig. 3(a).

After the passage of the wave crest, the downward velocity of the solitary wave decreases on the lee side of frontal edge of the cavity, thus causing the increase of the upward inertia and in turn forcing the primary vortex to move up rapidly, as demonstrated in Figs. 4(c) and 4(d). In addition, the near-wall upward velocity gradient causes the flow to separate, and in turn creates a counterclockwise vortex near the top of frontal edge (see Fig. 4(c)).

Fig. 5 shows the vortex shedding processes for A_r = 0.75. The vortex starts to shed out when the wave crest just passes the cavity in Fig. 5(a). At the instance, the vortex D_v was generated at the top of the end wall of the cavity. It is relatively small but the number of vortex D_v increases with time. The primary vortex A_v grew larger and rotated continuously, and size of the vortex also increased. The vortex A_v moves toward to the end wall and impinges it (see Fig. 5(a)). At this instance, the vortex D_v separated to two pairs of vorticies. Then a strong adverse velocity is observed to push the group of vortex D_v upstream In Fig. 5(b), The primary vortex A_v touch the end wall of the cavity,

and the vortex E_v and F_v induced by the viscous boundary layer between primary vortex A_v and end wall are discovered. Then primary vortex A_v deformed to an elliptic shape due to the impingement of adverse velocity. In the instance, the minor secondary vortex D_v` induced by the adverse velocity was also formed. Due to the influence of the adverse velocity profile, the direction of the vertical jet skewed to the downstream side. In Fig. 5, the direction of the vertical jet is different from that in the case of $A_r = \infty$, in which vertical jet almost towards to the water surface.

The images for $A_r = 0.33$ and 0.5 are shown in Figs. 6 and 7. Fig. 6(a) shows that the vortex starts to shed out when the wave crest is just close to the cavity. This clockwise vortex is generated at the edge due to flow separation. At the instance, vortex D_v is generated at the top of end wall of the cavity. The size of vortex D_v is relatively tiny. It is smaller than that of the case for $A_r = 1.0$. It may be due to the small separation region caused by small A_r.

The primary vortex A_v grows larger and rotates continuously, but the size of the vortex is confined by the length of the cavity as shown in Fig. 6(b). The vortex A_v touches the end wall and the vortex E_v and F_v are produced (see Fig. 6(c)). They are also secondary vortices caused by the boundary layer between the primary vortex A_v and the end wall. The same result is also observed in the Fig. 7. The size of vortex A_v is smaller than that in the case of $A_r = 0.5$.

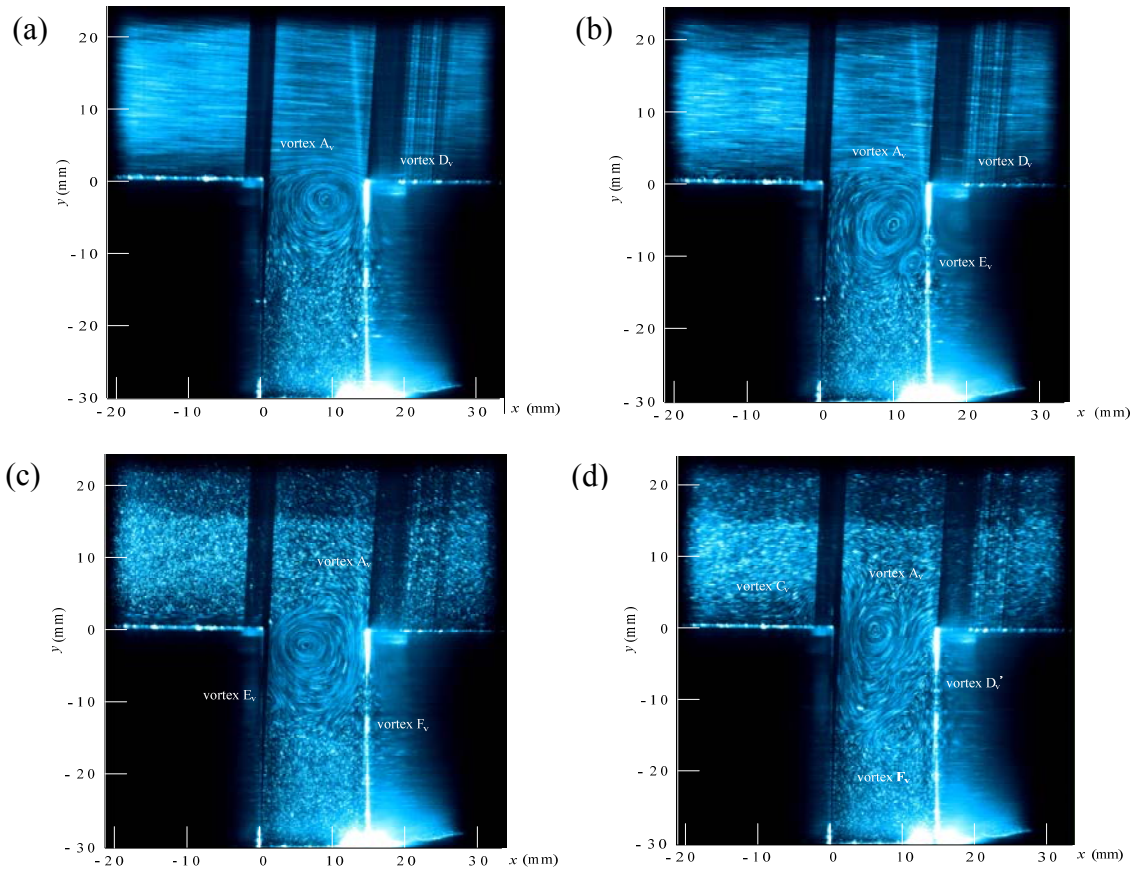

Fig. 6 Images taken using particle trajectory photography at $t\sqrt{g/h}$ = (a) 0, (b) 2, (c) 8, and (d) 12 for $A_r = 0.5$

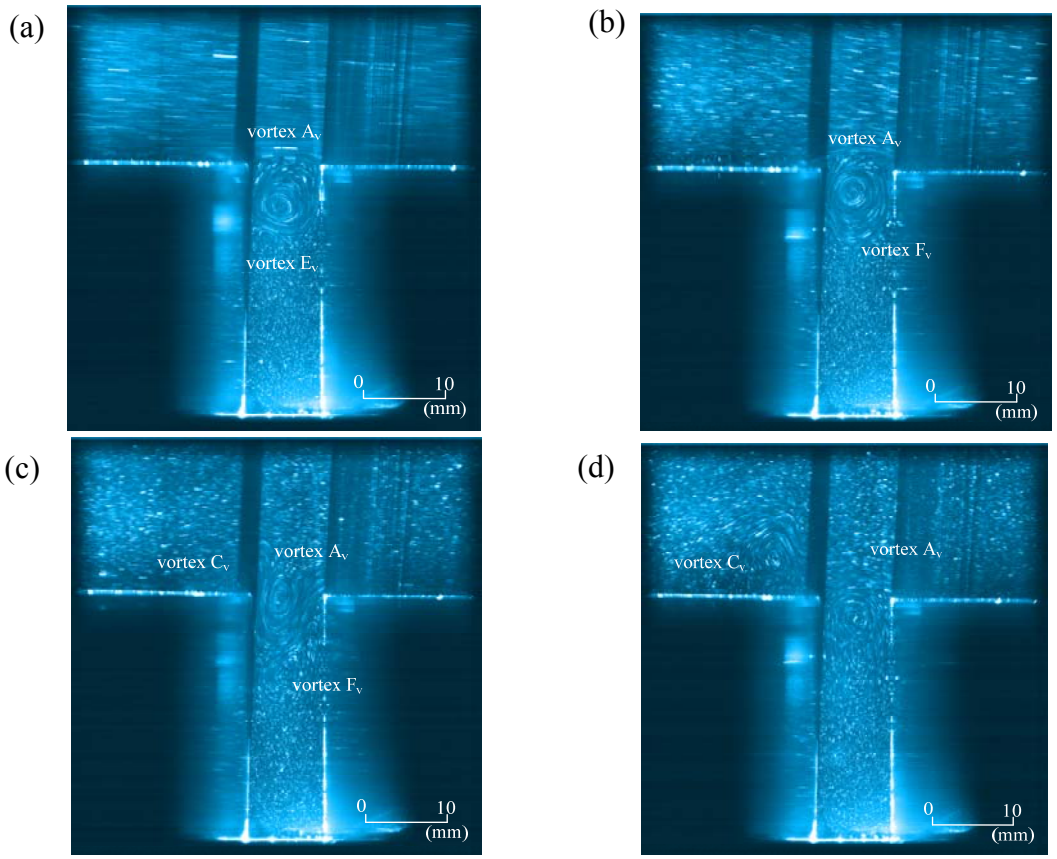

Fig. 7 Images taken using particle trajectory photography at $t\sqrt{g/h}$ = (a) 0, (b) 4, (c) 8, and (d) 12 for $A_r = 0.33$

Characteristics of vortex A_v and jet like flow in the cavity

Fig. 8 demonstrates the trajectory of vertical jet at different A_r. The trajectories were obtained by drawing the path of jet like flow from flow visualization picture. The trajectories are nearly the same for A_r = 2.0 ~ ∞. But the characteristic of jet like flow is quite different at A_r = 0.75 and 1.0. This is because that the primary vortex was pushed by the adverse velocity. The other reason is the scale of the jet is relatively small for A_r < 1.0 due to the size of the primary vortex was confined by length of the cavity.

The circulation of the primary vortex (Γ) can thus be determined using the Stokes theorem shown below to integrate the vorticity of the primary vortex A_v within the region while vorticity (ω) is less than - 2.

$$\Gamma = \oint_c \vec{V} d\vec{s} = \iint_A \omega dA \tag{2}$$

where $\vec{V}$ is the velocity vector ($\vec{V} = u\vec{i} + v\vec{j}$).

As illustrated in Fig. 9, the circulation increases at $t\sqrt{g/h}$ ranging from -4 to 2, and it keeps almost in the same value at $t\sqrt{g/h}$ ranging from 2 to 16. Finally, it decreases because of vortex dissipation at $t\sqrt{g/h}$ ranging from 16 to 40 for aspect ratio varying from 1.0 to ∞. But the circulation does not keep constant for aspect ratio ranging from 0.33 to 0.75 at $t\sqrt{g/h}$ varying from 2 to 16. It decreases obviously while $t\sqrt{g/h}$ varies from 0 to 20. The circulation also decreases with decrease of the aspect ratio at the same non-dimensional time. The circulation of primary vortex highly decreases at low aspect ratio for A_r varying from 0.33 to 0.75 due to the viscous effect of boundary layer induced by the end wall of the cavity. Many vortices such as vortex E_v and F_v are induced by the flow separation, and in turn a part of the kinetic energy of the primary vortex A_v is broken down by these two vortices. The critical aspect ratio of flow pattern can be determined as A_r = 1.0. All the characteristics change obviously while A_r is less than 1.0.

CONCLUSION

The flow pattern of vortex generation process induced by a solitary wave propagating over a cavity has been investigated experimentally. The wave height of the solitary wave is 1.4 cm and water depth is equal to 7 cm. The depth of the cavity is 3 cm for A_r = 0.33 ~ ∞. Particle trajectories photography was used to observe the vortex generation process qualitatively while PIV was used to measure the velocity distribution in the cavity quantitatively.

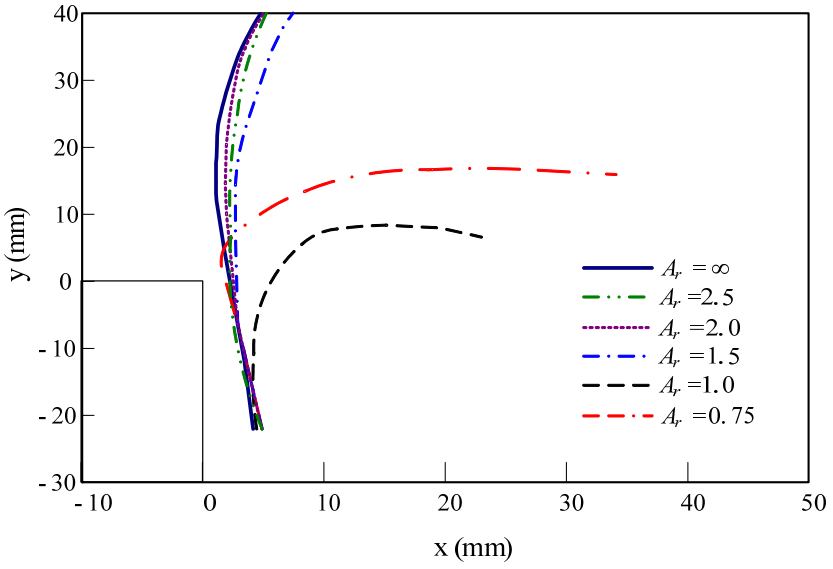

Fig. 8 Trajectory of vertical jet at different A_r

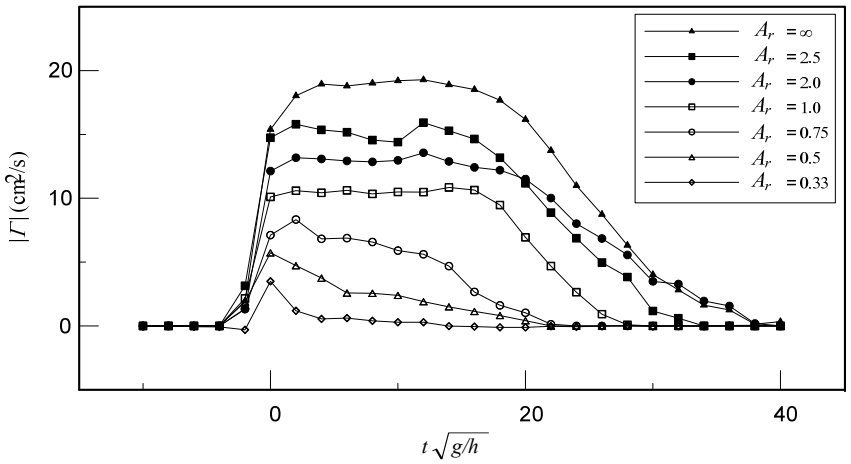

Fig. 9 Variation of the circulation of the primary vortex calculating by a low limit of vorticity equal to -2 (1/s) for different aspect ratios of a cavity

In the case $A_r = \infty$, the result is similar to the flow pattern in the lee side of the rectangular dike while a solitary wave propagates over it. The corresponding figures show a jet-like upward velocity in between the vortex pair that impinged the water surface directly. Due to the influence of the adverse velocity in the case $A_r = 0.75$, the direction of the vertical jet induced by the primary vortex A_v skewed to the downstream side.

In addition, quantitative results are listed as follows: The vorticity increases rapidly at $t\sqrt{g/h}$ ranging from -6 to 2, and then decreases gradually after the solitary wave crest passing at $t\sqrt{g/h}$ ranging from 2 to 40. This indicates that primary vortex A_v obtains the energy from incident solitary wave, and it decays while the solitary wave moves far away.

ABSTRACT. An experimental and numerical investigation was done in order to study the appearance of hydrodynamic instabilities at low bulk axial Reynolds number in the gap between two coaxial cylinders with a diameter ratio of 0.52, 0.8 and 0.9, whose outer cylinders are stationary and inner one is rotating. Skin friction coefficient and wall shear stress have been measured for fully developed laminar flows of water when the inner cylinder rotates at the speed of 0~600 rpm. They point to the existence of a flow instability mechanism. The rotation of the inner cylinder promotes the onset of transition due to the excitation of Taylor vortices.

Keywords: *Wall shear stress, Skin friction coefficient, Vortex flow, Slimhole annulus*

INTRODCUTION

Wall shear stress is of great importance in fluid mechanics research, as it represents the local tangential force by the fluid on a surface in contact with it. By integrating the wall shear stress along the surface, one can compute its contribution to the lift and drag on immersed objects and the pressure drop in pipes and other internal flows.

Rotating flows in annular passages are important, since they have many engineering applications in bearings, rotating-tube heat exchangers and, especially, annulus flows of mud in case of slim hole drilling of oil well.

Shear stresses close to the wall of the borehole can erode it, and cause to cave. This phenomenon can be very dangerous in case of the rotating rods are not supported anymore by the wall and can break. It strongly depends on the velocity gradients. A laminar flow regime induces lower velocity gradients than a turbulent flow and thus lower shear stresses[1].

Vibration and shock data along with torque and weight on bit can be used to modify drilling parameters for increased bit and bottom hole assembly reliability and performance. Successful drilling requires that the drilling fluid pressure stay within a tight mud-weight window defined by the pressure limits for wellbore stability. The lower pressure limit is either the pore pressure in the formation or the limit for avoiding wellbore collapse. The upper pressure limit for the drilling fluid is the minimum that will fracture the formation.

and the stability in a rotating annulus with a bulk flow. Obi *et al*.[3] measured local wall shear stress using the wall velocity gradient in turbulent channel flows. They evaluated the wall shear stress with the fluid viscosity and velocity gradient as Newton's viscosity law.

Dumont *et al*.[4] investigated wall shear stress experimentally in the Taylor-Couette flow at a low Reynolds number. That is, they studied the appearance of hydrodynamic instabilities at a low *Re* in the gap between two coaxial cylinders. Escudier *et al*.[5] carried out numerical and experimental study of fully developed laminar flow of a Newtonian liquid through an eccentric annulus. The results are reported for calculations of the flow field, wall shear stress and friction factor for a range of values of eccentricity and Taylor number.

This paper concerns an experimental and computational study of fully developed laminar flows of a Newtonian fluid through a concentric and eccentric annulus with combined bulk axial flow and inner cylinder rotation. The results are reported for calculations of the flow field, wall shear stress distribution and friction factor for a range of values of eccentricity, radius ratio and Taylor number.

DATA REDUCTION

The skin friction coefficient C_f can be obtained as Eq. (1),

$$C_f = \frac{dp}{dz} \cdot \frac{D_h}{2\rho \bar{v}_z^2} \tag{1}$$

where, the pressure loss dp/dz was measured in experiment, D_h (=2($R_2 - R_1$)) is the hydraulic diameter and ρ is the fluid density. For laminar boundary layers of Newtonian fluids, the wall shear stress τ_w can be determined from the velocity derivative normal to the wall as Eq. (2),

$$\tau_w = \mu \cdot \frac{\partial v_z}{\partial y} \tag{2}$$

where, μ is the fluid viscosity.

EXPERIMENTAL AND MUMERICAL METHODS

Experimental apparatus

The experimental equipment consists of a cylinder part, supporting part, fluid-providing and rotating part and measuring part which measure the flow rate, pressure loss and the temperature. The flow configuration and instrumentation are described detailed by Kim and Hwang[6]. To ensure fully developed flow in the measuring section, the length of straight pipe upstream of the test section is 2.32m, corresponding to 126 hydraulic diameters, in order to produce an artificially thickened boundary layer.

The flow rate has been measured with a magnetic flow meter whose accuracy is within the limit of ± 0.5 %. The temperature of the working fluid has been measured by a digital multi-meter. The inner cylinder may be rotated at any speed up to a maximum of 1000rpm by means of an A.C. motor. The temperature of the fluid within the pipe rig is maintained at 25±0.5°C. The maximum uncertainties are less than ±6 for the flow of water.

Numerical simulation

In a numerical study, a laminar flow of water in an eccentric annulus has been calculated. A control volume based finite volume method is used to solve the equations of motion. The problem reduced to the solution of the conservation of mass and momentum equations along with the appropriate boundary and initial conditions.

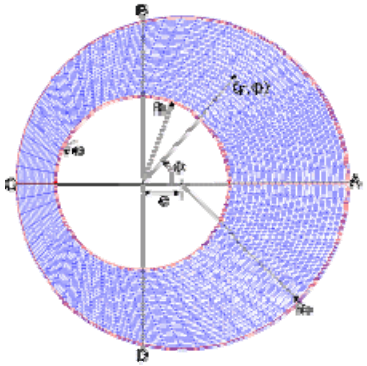

Figure 1**.** Configuration of grid used for numerical calculations.

A typical mesh of the discretised borehole domain in the horizontal plain is shown in Fig. 2. The inner cylinder radius is R_1 =10 mm, the outer cylinder R_2 =19.2 mm (diameter ratio of 0.52) and the eccentricity, e is varied from 0.2 to 0.7.

Since the fully developed flow condition was of concern here, only one row of cell was needed in the axial direction. That is, stream wise fully developed periodic condition is used. The distortions of the axial velocity distribution and the movements of the peak axial velocity are calculated to understand the effect of rotation, eccentricity and flow rate on flow field.

The constant velocity of fluid and the Neumann boundary conditions are imposed on inlet and outlet of an annulus, respectively. No slip boundary conditions are used at the inner and outer cylinders

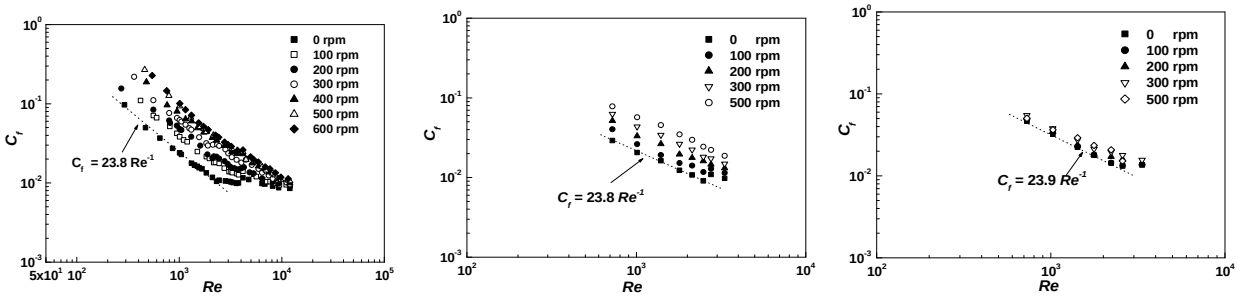
RESULTS AND DISCUSSION

Experimental results

The influence of the inner cylinder rotation for fluids is apparent from the skin friction coefficient versus the Reynolds number. The skin friction coefficient is obtained from pressure loss measurements by using Eq. 2. The skin friction coefficient decreases linearly as the Reynolds number is increased in laminar flow regime. The fact that the skin friction coefficient drops off with increasing the Reynolds number should not mislead us into thinking that shear stress decreases with velocity.

In the case of water as shown in Fig.3, the skin friction coefficient in non-rotating decreases linearly as the Reynolds number is increased and it increases as the radius ratios and the rotational speed of the inner cylinder are increased. The correlation between the skin friction coefficient and the Reynolds number is $C_f = 23.8/Re$ in the radius ratio of 0.52 as shown in Fig. 3(a) and the numerator approaches to 24 as the radius ratio reaches to one.

The effect of axial flow on the skin friction coefficient becomes more prevalent with increasing radius ratios. So the effect of rotation on the skin friction coefficient becomes weak as the radius ratios increase. There is no reliable skin friction coefficient in the transitional flow regime. For turbulent flow of fluid, the skin friction coefficient decreases gradually with the Reynolds number.



(a) η = 0.52 (b) η = 0.8 (c) η = 0.9

Figure 2**.** Skin friction coefficient of water as a function of *Re* at 0~600 rpm.

When the rotational speed of the inner cylinder is increased from 0 rpm to 500 rpm, the increasing rate of the pressure loss is 50%, 45%, and 30% for the radius ratios of 0.52, 0.8, and 0.9, respectively. Also for the same flow rate and rotational speed, the pressure losses are increased up to 80% and 95% when the radius ratios are increased from 0.52 to 0.8 and 0.9, respectively. That is, pressure loss increased significantly with decreasing annular gap.

Numerical results

To obtain a more realistic representation of the drilling operation, the helical flow of water in an eccentric annulus was considered. Numerical calculations have been extended for the case where the inner cylinder rotates about its own axis at a constant rotational speed. Detailed calculations have been carried out for radius ratio of 0.52 covering eccentricities up to 0.7 and Taylor numbers up to 50,000.

Contour of axial velocity for the radius ratio, η = 0.52 and *Ta* = 5,000~25,000 covering eccentricities of 0.2, 0.5 and 0.7 are shown in Fig. 3. The corresponding distributions of the axial and tangential component of the shear stress are shown in Figs. 4~5.

For a fixed rotation speed at low eccentricity (e=0.2) in Fig. 3 (a), the tangential flow around the annulus is slightly reduced by the blockage effect associated with the eccentricity. So the axial velocity peak is moved in the sense of rotation into a narrow gap. As the eccentricity is increased (e=0.5, 0.7), recirculation of the cross flow develops adjacent to the surface of the outer cylinder and the axial velocity peak is roughly centered in the wide gap as shown in Fig. 3 (b). An unexpected feature of the calculations for eccentricity of 0.7, but not seen for e=0.2 and 0.5 is the appearance of a second peak in the axial velocity, located in the narrowing gap, for combinations of very high eccentricities and Taylor number (Fig. 3 (c)).

The distortion of the axial velocity distribution and the movement of the peak axial velocity, due to the combined effects of eccentricity and rotation result in the distributions of the axial component of the surface shear stress shown in Figs. 4~5 for η=0.52 and *Re*=1050. In order to reveal the relative contributions to the skin friction coefficient, the shear stress on the surface of the outer cylinder τ has been weighted by R_2. As shown in Fig. 4 (a), axial component of the shear stress initially has a maximum in the narrowing gap and a minimum in the widening gap. With increasing eccentricity the value of axial shear stress increases apparently as the rotational speed of the inner cylinder increases. However, in the case of ε=0.7 the location of the maximum shear stress is moved according to the change of the maximum axial velocity as shown in Fig. 4(c).

CONCLUSIONS

In this study the effect of the rotational speeds, radius ratio and eccentricity on the skin friction coefficients and wall shear stress in concentric and eccentric annuli has been investigated experimentally and numerically.

The skin friction coefficient in non-rotating decreases linearly as the Reynolds number is increased and it increases as the radius ratios and the rotational speed of the inner cylinder are increased. The effect of axial flow on the skin friction coefficient becomes more prevalent with increasing radius ratios. So the effect of rotation on the skin friction coefficient becomes weak as the radius ratios increase.

A numerical analysis considered mainly the effect of annular eccentricity and inner cylinder rotation. The present analysis has demonstrated the importance of the drill pipe rotation and eccentricity. In eccentricity of 0.7, the flow field is recirculation dominated and unexpected

behavior is observed. For high Taylor number the axial velocity peak is so strongly advected towards the lower side of the inner cylinder that two opposing effects act to create two local peaks of the axial velocity.

HYDRODYNAMIC CHARACTERISTICS OF WEIS-FOGH TYPE SHIP'S PROPULSION MECHANISM HAVING ELASTIC WING

K. D. Ro[1, *], J. T. Park[1] and J. H. Kim[1]
[1]Gyeongsang National University, Tongyeong, Republic of Korea

ABSTRACT. This experiment was conducted in attempt of improving hydrodynamic efficiency of the propulsion mechanism by installing a spring to the wing so that the opening angle of the wing in one stroke can be changed automatically, compared to the existing method of fixed maximum opening angle in Weis-Fogh type ship propulsion mechanism. Average thrust coefficient was almost fixed with all velocity ratio with the prototype, but with the spring type, thrust coefficient increased sharply as velocity ratio increased. Average propulsive efficiency was larger with bigger opening angle in the prototype, but in the spring type, the one with smaller spring coefficient had larger value. In the range over 1.0 in velocity ratio where big thrust can be generated, spring type had more than twice of propulsive efficiency increase compared to the prototype.

INTRODUCTION

The Weis-Fogh mechanism[1,2], which was discovered by the hovering flight of a small bee(Encarsia Formosa), is gathering attention of many scientists studying hydrodynamics for the unique and efficient lift generation mechanism[3~7]. Recently, engineering application of the mechanism is actively attempted as well[8~12]. Some scientists proposed a propulsion model that applied the principle of the mechanism, and conducted experiments on dynamic characteristics and driving test of a model ship, which showed that this propulsion mechanism worked very effectively as a new ship propulsion system[9]. Also, Some scientists visualized the unsteady flow field that was created around the wings when the propulsion mechanism was being operated[13], and verified the time variation of the thrust and the drag on the wing[14]. The weakest point of this mechanism is that while the efficiency of propulsion is high, the range of the velocity ratio that generates maximum propulsive efficiency is narrow, and the velocity ratio is under 1, which means the thrust is relatively small. To put to practical use of this propulsion mechanism, supplementing this weak point is most important. To generate high thrust in the high velocity ratio range, changing the wing of propulsion mechanism from a hard, flat-plate to elastic body would make it possible. In fact, the wings of a small bee and the body of a fish are elastic, and there is enough possibility that elastic body contributes to the improvement in thrust. Therefore, in this study, we will attempt to improve the thrust, drag, and efficiency characteristics of the propulsion mechanism by using an elastic wing with attached spring which automatically adjusts the opening angle in one stroke.

Figure 1. A model of propulsion mechanism

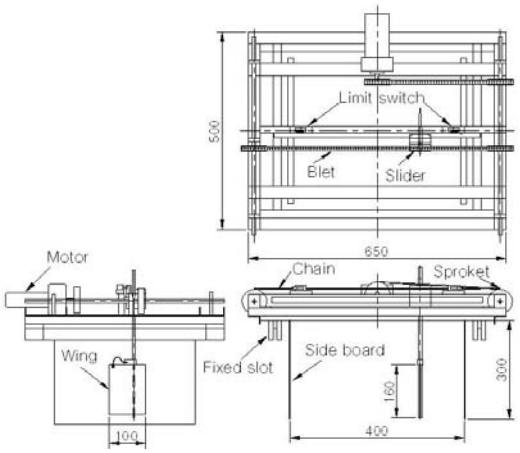

Figure 2. Driving unit of the wing (unit:mm)

EXOERIMENTAL METHOD

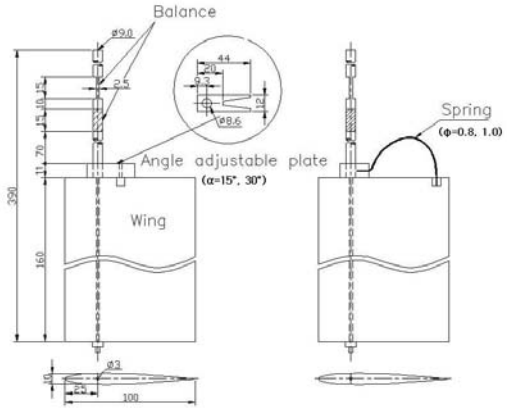
Model of a propulsion mechanism

First, the model of the propulsion mechanism that will be used in this experiment is shown in Figure 1.

The figure shows the model from upper perpendicular side; as one flat-plate wing works in a certain motion in the water channel, thrust is generated toward the left of the figure, which is the direction of the ship. As point P, which corresponds to the center shaft of the wing, oscillates perpendicular to uniform flow U and in the velocity of V, the wing first opens from the lower surface, then maintaining an opening angle of α, it moves translationally in parallel, and finally rotates and closes on the upper surface. Then, the wing repeats the motion by opening at the upper surface in rotation, moves in translation, and finally rotates and closes on the lower surface. Originally in the Weis-Fogh mechanism, one pair of wings open at a certain angle, and while maintaining the angle, each wing moves to the opposite direction of each other. But when seen from the body, the movement of the each wing can be considered as reciprocals. Therefore, by installing channel walls at the symmetrical line and executing the motion with a single wing as in Figure 1, by the mirror effect, the identical effects can be achieved as the Weis-Fogh mechanism.

Measurement of the thrust and drag acting on the wing

The experiment is conducted by making a wing driving system that gives the same wing movement as the propulsion mechanism in Figure 1, which is installed in the circulating water channel where uniform flow runs, and measuring thrust and drag on the wing. The schematic diagram of driving unit of the wing is shown in Figure 2. The main structure of the system is made with acrylic board and aluminum angle bar, and the dimensions are 500mm in length and 650mm in width to fit into the circulating water channel. In the wing driving system, the shaft is fixed onto the slider and the slider is attached to one side of the belt so that when the motor(DC 30W) spins forth or backwards, the wing moves in an oscillating motion. The front and back spin of the motor is operated by a limit switch and a relay circuit installed at the ends of the slider rail, and the velocity of the wing movement is controlled with adjusting the spin speed of the motor. The wing used in this experiment was made in the shape of NACA0010; as shown in Figure 3, the size of the wing is chord C=100mm, and its span 160mm. The shaft was penetrated at the point of 0.75C away from trailing edge of the wing through a hole of 3mm in diameter.



(a) Prototype wing (b) Spring type wing

Figure 3. Structure of the wing and shaft (unit:mm)

Table 1
The Spring coefficients of each elastic wing

The diameter of spring (ø)	ø =0.8mm	ø =1.0mm
Spring coefficient (N·m/rad)	0.0884	0.1185

The shaft was made with a titanium bar, 9mm in diameter. The wing is inserted in the shaft of the wing so that when the slider moves in a reciprocating motion, a momentum around the shaft works toward the wing to open it, and in the closing stage, the leading edge of the wing collides with the side board, forcing it to close. In this experiment, two types of wings were used as shown in Figure 3 (a) and (b). Maximum opening angle α is fixed in (a), and α=15°, 30° angle adjustment plate was made. (b) was made so that opening angle α was automatically adjusted by the water resistance applied on the wing when it moved; in other words, two kinds of steel line, diameter of ø =0.8, 1.0, were bent to function as springs as shown in Figure 3 (b). The ultimate point of this experiment is to improve propulsive efficiency by adjusting opening angle with the water resistance, instead of prototype's fixed opening angle in Weis-Fogh type propulsion mechanism. The measurement of the spring coefficient of each spring is shown in Table 1.

Thrust and drag was measured by cutting the balance, or top of the shaft, evenly in front, back, right and left, as shown in Figure 3, and by attaching 4 strain gauges, thrust and drag was measured by deformation of these gauges. In other words, the voltage waveforms from the strain gauge comes out as the value of thrust and drag by pre-compensated coefficient on a personal computer, through a bridge circuit, strain amplifier and A/D converter in each channel(2 channels in total).

The experiment fixed maximum opening angle α at 15° and 30°, changed uniform flow U(U=0.049~ 0.349m/s) and wing movement velocity V(V=0.055~ 0.246m/s) at regular intervals to prototype wing and spring type which automatically adjusts opening angle, measured the time variation of thrust and drag, and yielded average thrust coefficient, average drag coefficient, and average propulsive efficiency by averaging the values in one cycle. The range of Reynolds number is Re=7.2×10^3~3.9×10^4 when wing chord was fixed as unit length and yielded by uniform flow U.

Definition of the characteristic coefficients

Each coefficient that shows the hydrodynamic characteristic of this propulsion mechanism, that is, thrust coefficient C_T and drag coefficient C_D is defined as follows, by wing movement velocity V.

$$C_T = \frac{T}{\frac{1}{2}\rho V^2 S} \tag{1}$$

$$C_D = \frac{D}{\frac{1}{2}\rho V^2 S} \tag{2}$$

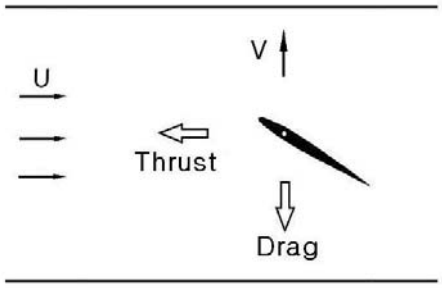


Figure 4. Definitions of thrust and drag

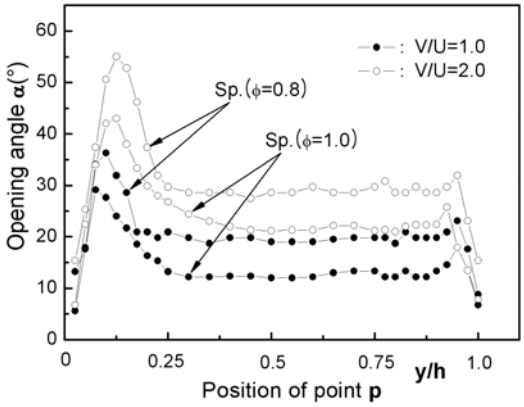

Figure 5. Variations for opening angle according to the wing position in a stroke for each spring type elastic wing

T represents thrust, D for drag, ρ for the density of the fluid, and S for the wing area below the water surface. As defined in Figure 4, thrust T is in the direction of the progress of the ship, which is the opposite direction of uniform flow U. Drag D is the opposite direction of wing movement velocity V.

Also, the average propulsive efficiency of the mechanism $\bar{\eta}$ is the power applied to the wing, namely the percentage of the net output generated from the wing to input, and is calculated as follows.

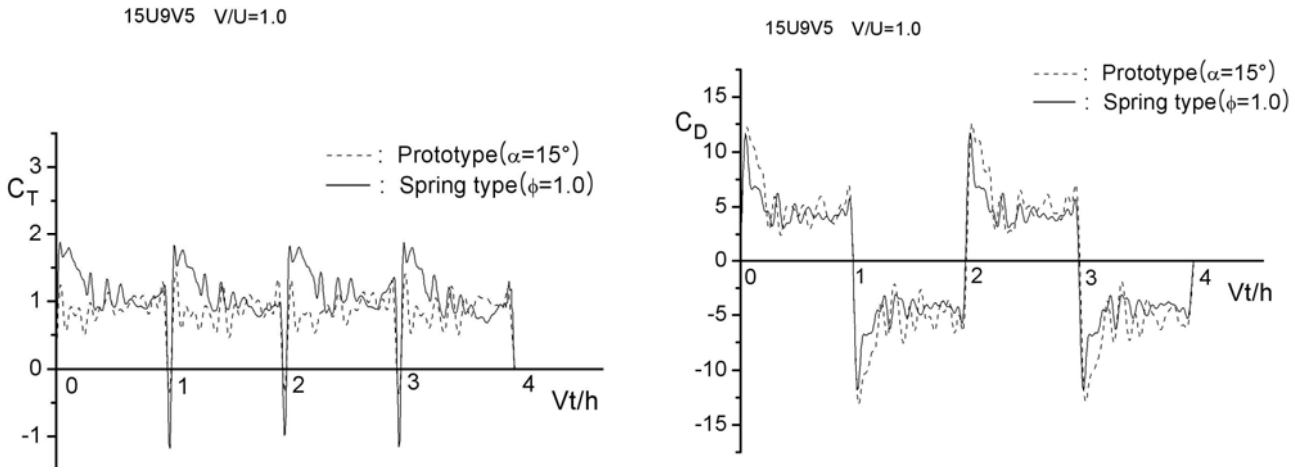
$$\bar{\eta} = \frac{\int_0^{T_C} C_T U dt}{\int_0^{T_C} C_D V dt} \times 100 \tag{3}$$

Here T_C represents the period of one cycle of wing movement.

RESULTS AND DISCUSSIONS

First, in one stroke of each spring type elastic wing illustrated in Table 1, the change of opening angle according to wing position change is shown in Figure 5. Here, x-axis expresses the dimensionless value of wing moving distance y to the width of the channel h; as shown in the figure, although there are some differences according to the velocity ratio V/U and the spring coefficient, the change of opening angle according to the wing position change in the channel is very big when the wing leaves from the channel surface, then the opening angle decreases until it comes to a certain angle where it stabilizes and moves translationally, then finally, when the wing approaches the other side of the channel, it opens up a little bit before it closes. The change of thrust coefficient C_T and drag coefficient C_D over 2 reciprocating movements of the wing at velocity ratio V/U=1.0 is shown in Figure 6.

The dotted line in the figure expresses the prototype flat-plate wing with maximum fixed angle at α=15°, and the solid line expresses the spring type elastic wing that adjusts opening angle by using steel line of ø =1.0 used as spring. In the figure, the x-axis expresses the traveling distance of wing shaft normalized by the channel width; this value means the number of strokes. First, looking at the



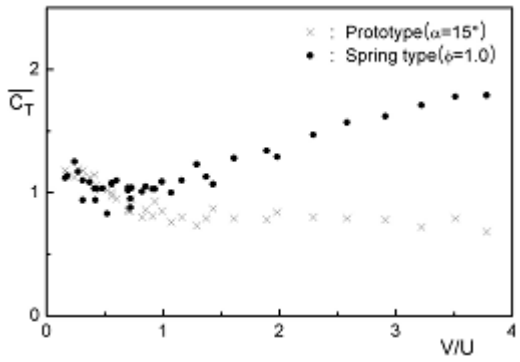
(a) Thrust coefficients (b) Drag coefficients

Figure 6. Time variations for thrust and drag coefficients(V/U=1.0)

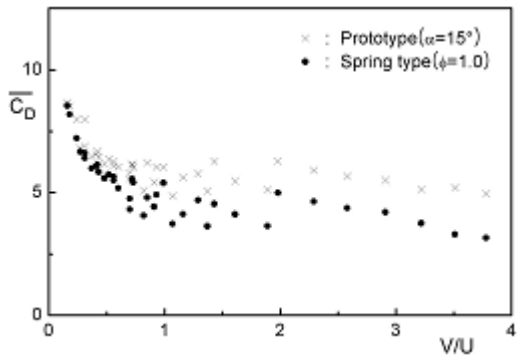
change of thrust coefficient, the value is + through the whole stroke except for the opening stages, which means regardless of the wing's reciprocating motion, thrust occurs toward the direction of the progress of the ship. However, when comparing the dotted and solid lines, in dotted line, there are some fluctuations but have relatively constant value, whereas solid line decreases after having a large value at the beginning of the stroke. This is because when the wing moves from opening stage to translational stage, during opening, the negative pressure side of the wing, that is, the wing takes off from the wall where the pressure between the wing and the channel wall is much lower than the pressure toward the moving direction. As a result, a vortex is released from the trailing edge of the wing. In fact, in the prototype case, during the opening in visualization experiment [13] of the flow field, fluid is inhaled because of the negative pressure between the wing and the wall, and through numerical calculation [14], we confirmed that vortex was released from the trailing edge of the wing in translational stage. But in the spring type case, a momentum is applied because of the spring; therefore before it takes off, the wing has to open up to a larger angle as the trailing edge of the wing touches the wall, which we can assume that right before take off, the pressure difference of both sides of the wing should be smaller than in the prototype. Therefore in the spring type case, the wing can shift over to translational stage with effective Weis-Fogh mechanism.

Meanwhile, when looking at the change of drag coefficient (b), in each stroke, the value is reversed with x-axis; this is because each stroke of wing movement is in opposite direction. Solid line of the drag coefficient is smaller than dotted line, but the difference is very small. This is because with elastic wing, the opening angle increases little bit because of water resistance during wing movement. Especially water resistance increases in the closing stage, but as shown in Figure 5, opening angle opens automatically by spring, which prevents decrease of propulsive efficiency that occur with drag increase.

(a) Average thrust coefficient and (b) Average drag coefficient with the change in velocity ratio V/U of prototype wing with the maximum opening angle of α=15° and spring type elastic wing with ø =1.0 spring is shown in Figure 7. Each point in (a) and (b) in the figure corresponds with the average value of 1 cycle in Figure 6 of (a) and (b). First, when looking at the distribution of average thrust coefficient, with the prototype(α=15°), the values are almost constant regardless of the velocity ratio. Compared to this, with spring type(ø =1.0), the value increases sharply as the velocity ratio increases. In the former type, the opening angle does not change even though the velocity ratio increases; but in the latter, as explained before in Figure 6, as velocity ratio increases, the opening angle right before the translational stage increases sharply as shown in Figure 5 to have impressive Weis-Fogh effect. Also, when looking at the distribution of average drag coefficient,

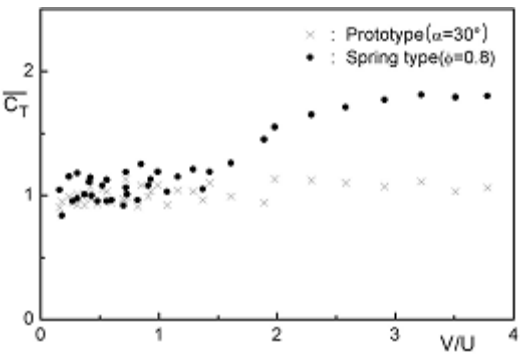


(a) Average thrust coefficients

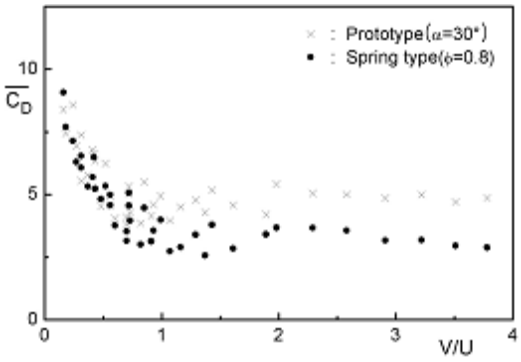


(b) Average drag coefficients

Figure 7. Average thrust and drag coefficients with velocity



(a) Average thrust coefficients



(b) Average drag coefficients

Figure 8. Average thrust and drag coefficients with velocity ratio

over velocity ratio of 1, the differences between the values are increasing little bit as velocity ratio increases; this is because in the spring type case, opening angle increases as velocity ratio increases, which led to decrease in average drag. On the other hand, where the velocity ratio is small, especially under 0.5, as velocity ratio decreases, average thrust coefficient is similar in both types, whereas the average drag coefficient increases in both. This is because in this range, water resistance is small which makes the opening angle to be small.

(a) Average thrust coefficient and (b) Average drag coefficient with the change in velocity ratio V/U of prototype wing with the maximum opening angle of α=30° and spring type elastic wing with ø =0.8 spring is shown in Figure 8. The spring coefficient is smaller than the one in Figure 7; therefore at the same velocity ratio, even if the opening angle is big, the tendency in change of average thrust coefficient and average drag coefficient according to the velocity ratio is same. The average thrust coefficient of prototype(α=30°) is 1.0, which is constant regardless of the velocity ratio. However, with the spring type(ø =0.8), the value increases sharply as the velocity ratio increases. Only it did not increase in a straight line because the spring coefficient was too small, so that the increase in opening angle with velocity ratio exceeded the range of elasticity. Meanwhile, the distribution of the average drag coefficient was both similar in tendency with velocity ratio as Figure 7, but the absolute value was smaller in the spring type than the prototype. This is because in the spring type, as velocity ratio increases, the opening angle increased also, which led to the decrease of average drag.

Average propulsive efficiency of various types of wings with the change in velocity ratio V/U is shown in Figure 9. When the velocity ratio is over 1, with the prototype where the maximum opening angle is constant, the one with big opening angle has larger average propulsive efficiency; with the spring type where the opening angle changes, the one with small spring coefficient has

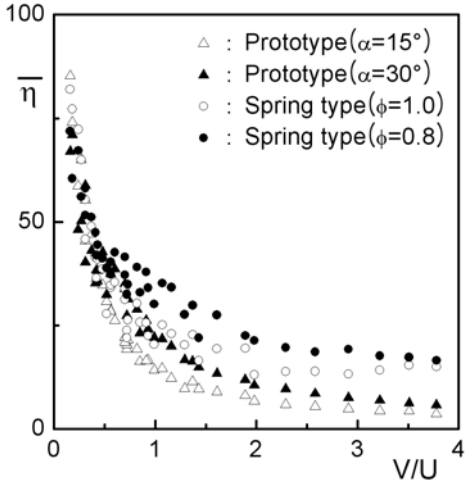


Figure 9. Average propulsive efficiency with velocity ratio for wings of various type

larger value. Especially over the velocity ratio of 1.5 where large thrust can be generated, by automatically adjusting the opening angle with a spring, propulsive efficiency can be increased over twice of the existing fixed angle type. Therefore, practical application of the propulsion mechanism is anticipated, which can greatly complement the weakness of low propulsive efficiency of the prototype in the large velocity ratio range.

CONCLUSIONS

This study was conducted in attempt of improving hydrodynamic efficiency of the propulsion mechanism by installing a spring to the wing so that the opening angle of the wing in one stroke can be changed automatically, compared to the existing method of fixed maximum opening angle in Weis-Fogh type ship propulsion mechanism. There were 2 prototypes of wing with the maximum opening angle of α=15° and α=30°, and 2 types of elastic wing with different spring coefficients. By changing the velocity ratio V/U, thrust, drag, and propulsive efficiency were examined experimentally. The summaries of results are as follows:

(1) With the spring type, the opening angle has large value when moving from opening stage to the translational stage, and moving from translational stage to closing stage.

(2) Average thrust coefficient was constant with the prototype with all velocity ratio, but it increased sharply with the spring type as velocity ratio increased.

(3) Average drag coefficient with velocity ratio was similar in the tendency with each other, but the absolute value was smaller in the spring type than the prototype.

(4) Average propulsive efficiency was larger with the bigger opening angle of the prototype, and with the smaller spring coefficient of the spring type.

(5) In the range of velocity ratio over 1.5 where large thrust can be generated, the spring type showed over twice of the propulsive efficiency than the prototype.

ABSTRACT. An investigation is conducted to study a 2-phase vertically upward hydraulic transport of solid particles in slim hole concentric annulus with rotation of the inner cylinder. Lift forces acting on a fluidized particle plays a central role in many importance applications, such as the removal of drill cuttings in horizontal drill holes, sand transport in fractured reservoirs, sediment transport and cleaning of particles from surfaces. In this study a clear acrylic pipe was used in order to observe the movement of solid particles. Annular velocities varied from 0.3 m/s to 2.0 m/s. Main parameters considered in the study were inner-pipe rotary speed, fluid flow regime and particle injection rate. Pressure drops and average flow rates were measured in the Reynolds number range of $10^2 < Re < 10^4$. For both water and CMC solutions, the higher the concentration of the solid particles is, the larger the pressure gradients become.

INTRODUCTION

Rotating flows in annular passages are important, since they have many engineering applications in bearings, rotating-tube heat exchangers and, especially, annulus flows of mud in case of slim hole drilling of oil well.

When an oil well is drilled, it is necessary to transport the cuttings up to the surface. To this end, fluid is pumped through the center of drill pipe and back up to the surface through the annular gap between the drill pipe and the drilled hole. The fluid is viscous, non-Newtonian, and will typically have gel strength. The flow up to the annulus might be laminar or it might be turbulent, depending on the situation.

Therefore, numerous mathematical and empirical models for the prediction of cuttings transport in horizontal and directional wells have been developed by several researchers. A detailed reveals that the cuttings transport characteristics change with an increase in wellbore angle. Tomren et al. [1] and Ford et al. [2] carried out experimental study on cuttings transport in inclined annulus and observed the existence of different layers that might occur during the mud flow and cuttings in an annulus.

Interest has been growing in the interaction between particle and local flow structure in particulate two-phase flow. Pigott [3] discussed the application of Stoke's law for laminar flow and Rittinger's formula for turbulent flow to drilled particle settling velocity calculation. He concluded that high fluid viscosity was not necessary and suggested that laminar flow in the annulus would lead to more efficient

cleaning. For trouble-free operation, he also recommended that the volumetric cuttings concentration in the annulus be kept less than 5%.

Sifferman et al. [4] found that annular velocity and fluid rheological properties are the most important factors influencing the transport ability of a fluid. Other variables such as particle size, drill pipe rotation, drill pipe eccentricity have only moderate effects on carrying capacity in their study.

Sellgren [5] and Ozbelge et al. [6] discussed the pressure drop and the choice of operating velocities in the vertical upward pipe flows of solid-liquid mixtures. He reported that additional turbulence was created due to the relative velocity between the solid and fluid phases.

This paper concerns an experimental and numerical study of fully developed solid-liquid mixture flow of Newtonian fluid, water and non-Newtonian fluid, CMC solutions through concentric and eccentric annuli with combined bulk axial flow and inner cylinder rotation.

The flow characteristics of solid-liquid mixtures, flowing upward through a vertical annulus in a closed loop system, is determined by measuring the concentration profiles of solids and the axial pressure drops in the test section. It is expected that the results of this study will be useful to explain the effect of solids on solid-liquid mixture transport phenomena in the annular geometry.

EXPERIMENTAL METHOD

The objective of the solid-liquid mixture flow experiments was to provide high quality data on the effects of pipe rotation, flow regime, fluid properties, solid concentration on pressure loss in slim hole annuli. The set-up used in the experiments is a closed-loop system consisting of a centrifugal slurry pump with a by-pass line, a vertical annulus and a feed slurry tank as shown in Fig. 1(a). The flow configuration and instrumentation are described by Kim and Hwang [7].

The outside diameter of the inner pipe (D_i) and the inside diameter of the outer pipe (D_o) being 30 mm and 44 mm, respectively, yield a radius ratio of 0.7 for the annulus. To ensure fully developed flow in the measuring section, the length of straight pipe upstream of the test section is 1.8 m, corresponding to 126 hydraulic diameters, in order to produce an artificially thickened boundary layer.

A cylindrical head tank was used for the preparation of the feed particles. The tank having a conical bottom in order to avoid the settling of the solids and it is connected from its bottom to a centrifugal pump with a vertical pipe.

Pressure drops and averaged flow rates were measured in the Reynolds number ranger of $500 < Re < 3000$. The flow rate has been measured with a magnetic flow meter whose accuracy is within the limit of $\pm$ 0.5 percent. The inner cylinder may be rotated at any speed up to a maximum of 600rpm by means of an A.C. motor. And the axial velocity of solid particle was measured by using high speed camera installed outside of the cylinder. The outer cylinder was made of transparent acryl pipe.

Static pressures are measured with holes of 0.5 mm diameter distributed longitudinally in the outer cylinder. 2 static pressure taps are installed along the flow direction in measuring part. The static pressures are read from a calibrated manometer bank with 1 mm resolution. The specific gravity of the manometer fluid CCl_4 is 1.88, and it gives a height in the range of 20~600 mm.

The head tank was filled with water up to a marked level and the pump was started. Particles, at a desired feed solid concentration were prepared in the head tank by adding the uniformly sized sand

Figure 1. Experimental set-up and computational grid

particle. The mixture flow rate was adjusted manually by the by-pass valve installed after the outlet of the pump. When the mixture flow reaches steady state, the axial pressure drops and velocity of solid particle were measured simultaneously. The mean diameter of particles was 0.1 cm and a material density of 2.55 g/cm^3 were used in the experiments.

NUMERICAL METHOD

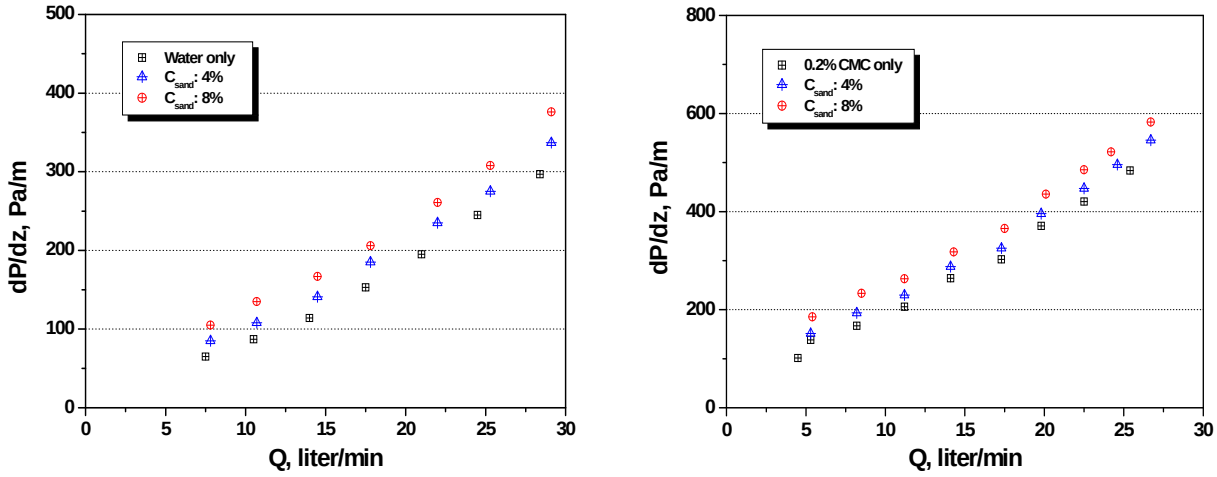
Traditionally, the annulus between drill pipe and the borehole has been represented as a concentric annulus as shown in Fig. 1(b). There are two main approaches to modeling multi phase flows that account for the interaction between the phases. These are the Eulerian-Eulerian and the Eulerian-Lagrangian approaches. The former is based on the concept of interpenetrating continua, for which all the phases are treated as continuous media with properties analogous to those of a fluid. The Eulerian-Lagrangian approach adopts a continuum description for the liquid phase and tracks the discrete phases using Lagrangian particle trajectory analysis.

In the numerical study, the Eulerian-Eulerian approach for granular flow is used that allows the determination of the pressure and viscosity of the solids phase instead of empirical correlations.

In a numerical study of solid-liquid mixture, a laminar flow of water in an eccentric annulus has been calculated. A control volume based finite volume method is used to solve the equations of motion. The problem reduced to the solution of the conservation of mass and momentum equations along with the appropriate boundary and initial conditions.

The governing set of partial differential equations was discretized using a finite volume technique. The discretized equations along with the initial and boundary conditions were solved using FLUENT. Particle-particle interactions via friction were also included.

The solids volume fraction in a domain of known volume was specified at the beginning of each simulation to correspond to the desired solids loading. The particles used in the simulation were solid spheres with a density of 2.55 g/cm^3. Values of the coefficient of restitution and the friction coefficients for these particles were assumed to be 0.9 and 0.09, respectively. The same coefficient of friction was also assumed for interactions between the walls and the particles.



(a) Water (b) 0.2% CMC solution

Figure 2. Pressure drop as a function of fluid velocity and solid concentration

No-slip boundary conditions are imposed on all the solid surfaces for the continuous phase. The same conditions are also applied to the discrete phase and imposed in the corresponding momentum equations. The inlet liquid velocity and the outlet pressure were specified. No-slip boundary conditions were assumed at the walls for the liquid phase. Interactions of particles with the walls were modeled with the same formulation used for solids pressure and granular viscosity for the particle-particle interactions.

RESULT AND DISCUSSION

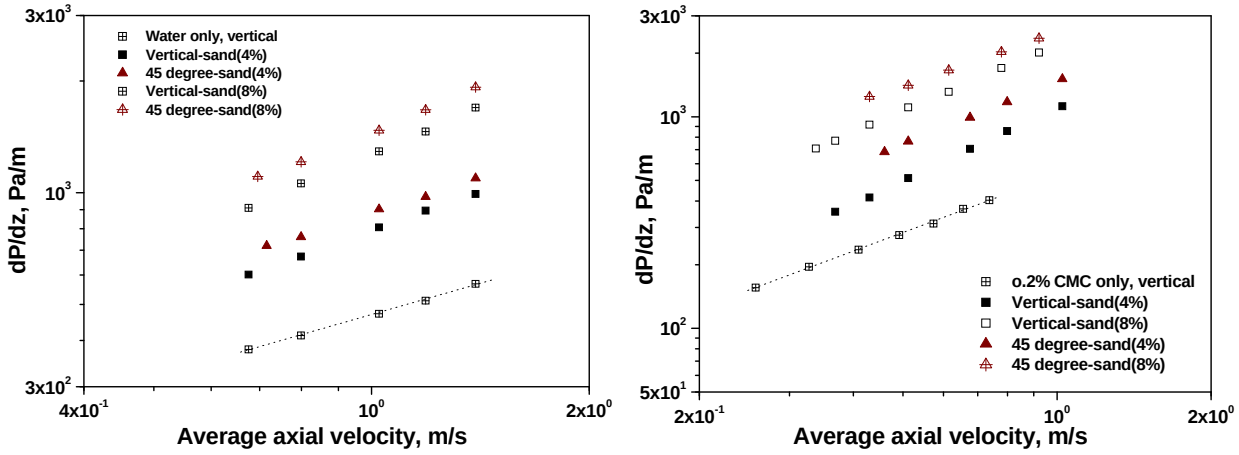
Hydrodynamic characteristics of single phase flows are known well, but the same is not valid for solid-liquid mixture and multi phase flows. In this study, the flow characteristics of solid-liquid mixture flows are investigated experimentally at different operating conditions.

For solid-liquid mixture flows at different operating conditions, the experimental and numerical parameters are the feed solid concentration, mixture velocity in the annulus, rotational speed of inner cylinder, inclination of annulus, and eccentricity of inner cylinder. The important characteristics of solid-liquid flows are the pressure drop versus mixture velocity relationship and solid particle transport velocity.

The pressure drop versus mixture velocity and annular inclination are shown in Fig. 2, for the mean particle size of 0.1 cm. In Fig. 2(a), the total pressure drop increases with along the increase of volume concentration of solid particles and mixture velocity. For higher volume fraction, the hydraulic pressure drop of two-phase mixture increases due to the friction between the wall and solids or among solids. Results of experiments and numerical simulation shows good agreement, but numerical results are slightly lower than experimental values.

The pressure drop versus mixture velocity and annular inclination are shown in Fig. 3 (a), for the mean particle size of 0.2 cm and sand volume fraction of 4% and 8%. The carrier fluids are water. The pressure drop increases along the increase of annulus inclination. Also, the pressure drop of solid-liquid mixture flow is largely increased compared to the single phase fluid flow. The pressure drop of solid-liquid mixture flow increases due to the friction between the wall and solids or among solids.

As shown in Fig. 3 (b). the total pressure drop increases with along the increase of volume concentration of solid particles and mixture velocity. For higher volume fraction, the hydraulic

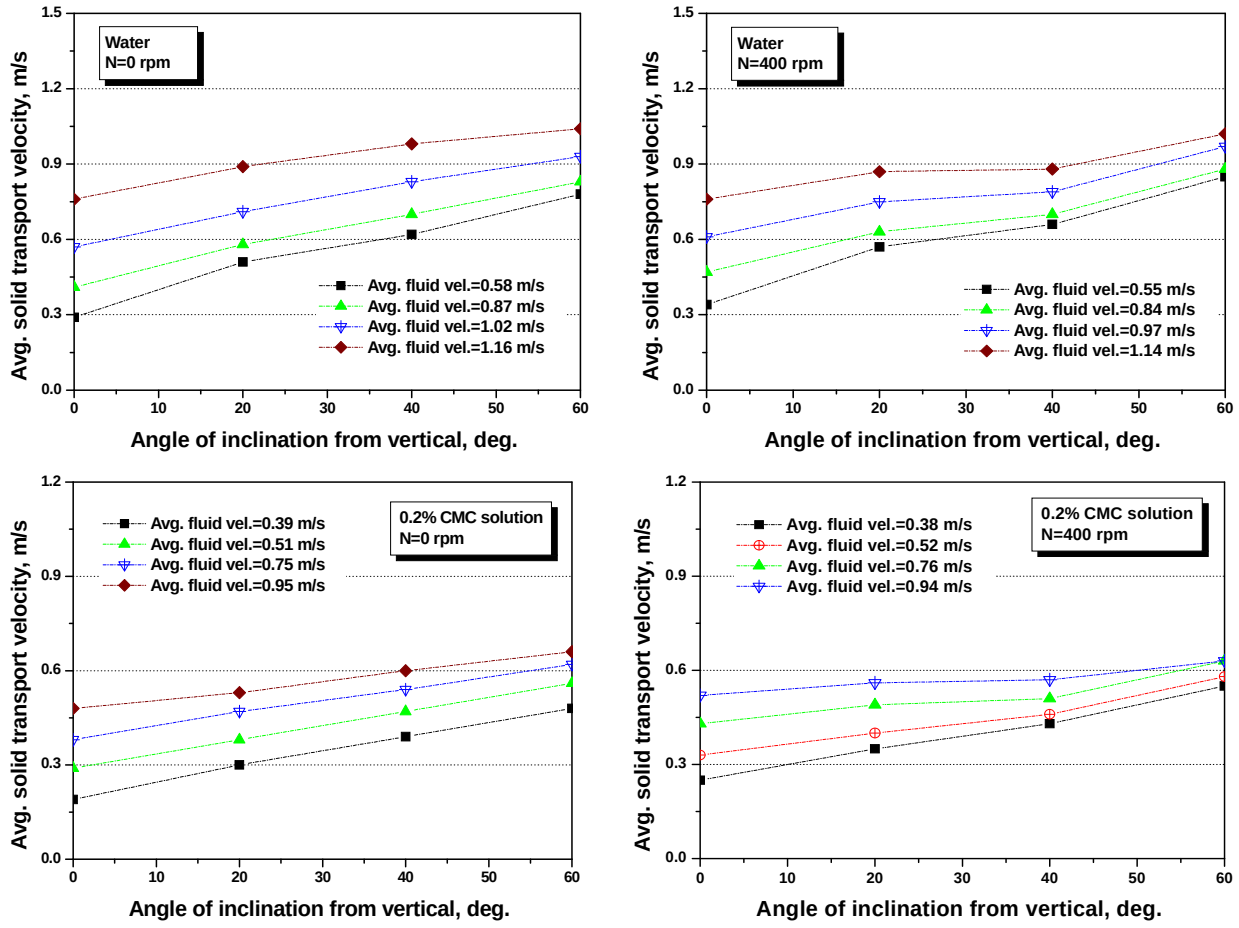


(a) Water (b) 0.2% CMC solution

Figure 3. Comparison of pressure loss in fluid with sand concentration at 0 rpm.

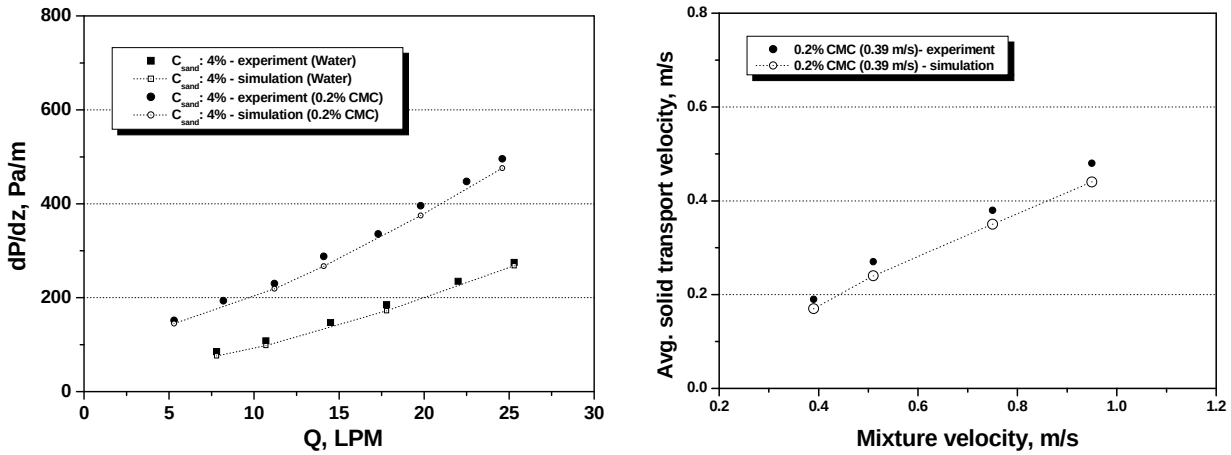
pressure drop of two-phase mixture increases due to the friction between the wall and solids or among solids.

Averaged velocity of solid particles with mixture velocity, rotational speed of inner cylinder, and inclination of annulus is shown in Figs. 4 (a) and (b). At very low mixture velocities, some of the particles may settle down in the annulus. The velocity of solid particles is gradually increased with the



(a) Solid velocity (0 rpm) (b) Solid velocity (400 rpm)

Figure 4. Solid transport velocity as a function of fluid velocity and inclination of annulus



(a) Pressure drop (b) Solid transport velocity

Figure 5**.** Comparison of pressure drop and solid velocity with mixture flow rate in vertical annulus

increasing mixture velocity and inclination of annuls form the vertical. As a result, the amount of solids carried to the annulus is also gradually increased. Rotation of the inner cylinder generally improves the transport of solid particles and it is more pronounced at lower mixture velocities and appears to be negligible at high rotational speeds of 300 rpm. One explanation for this may be that at high flow rate, the mixture velocity is the dominating factor on the particle transportation, with rotational speed having marginal effects.

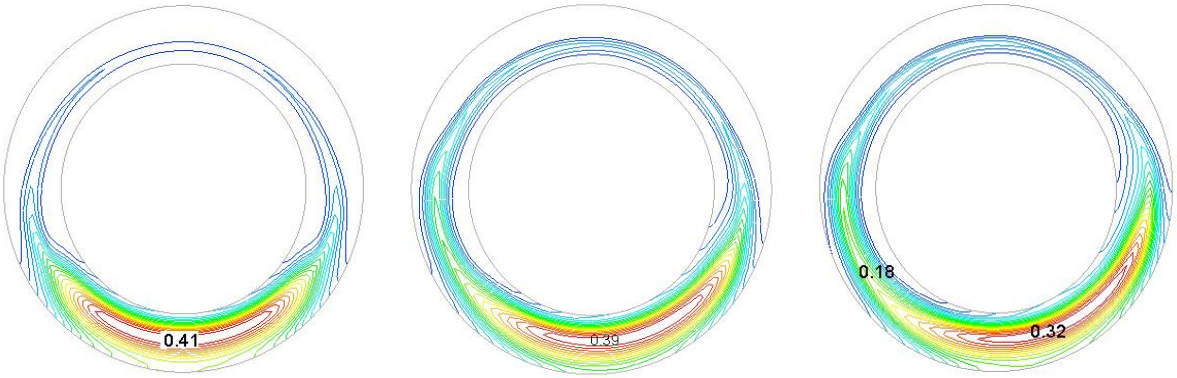
Viscoelastic fluids have been observed to provide better capability to mobilize and transport particles. As shown in Fig. 2, 0.2% CMC solution transports solid particles at lower mixture velocities compared with water. The effective viscosity of 0.2% CMC solution shows a shear-thinning behavior. The repeated experiments show that ±3% error in the solid particle velocity measurements and ±3.5% error in the pressure drop measurements.

To obtain a more realistic representation of the drilling operation, the solid-liquid mixture flow in concentric and eccentric annuli for a Newtonian fluid and then for a power law fluid was considered. Numerical calculations have been extended for the case where the inner cylinder rotates about its own axis at a constant rotational speed. Detailed calculations have been carried out for radius ratio of 0.7 covering eccentricities up to 0.2 and rotational speed of the inner cylinder up to 100 rpm.

The computational domain consists of 15, 96, and 500 nodes in the radial, azimuthal and axial directions respectively. And the calculation results were compared with experimental data in terms of pressure drop.

Calculation results were compared to experimental data in order to validate from the numerical model results. The calculation results showed a good agreement with experimental data for the pressure drop and particle transport velocity in solid-liquid mixture flow as shown in Fig. 5. Results of experiments and numerical simulation shows good agreement, but numerical results are slightly lower than experimental values.

Volume fraction contours of solid particle in the z-section for 30° inclined concentric annulus are shown in Fig. 6. The carrier fluid water and the fluid velocity is 0.6 m/s. So the flow regime is turbulent. The annulus is inclined 30 degree from vertical. In the case of non-rotation in Fig. 6(a), the profile of particle volume fraction is axisymmetric and the particles are located in the bottom side of annulus because of the gravitational effect. The particle volume fraction is decreased as the rotational speed of inner cylinder is increased up to 400 rpm as shown in Figs. 6(b) and (c). From the Fig. 6,



(a) 0 rpm (b) 200 rpm (c) 400 rpm

Figure 6. Contour of solid volume fraction in 30° inclined annulus (water velocity=0.6 m/s, initial C_{VT}=8%)

rotation of the inner cylinder disturbs the formation of bed. Generally this effect is profitable for the cuttings transport in an inclined annulus.

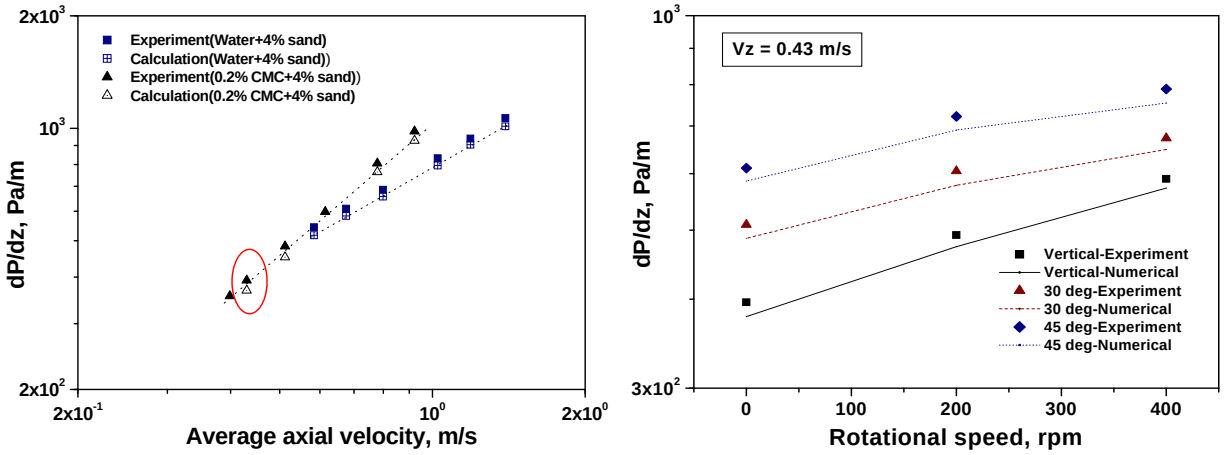
Calculation results were compared to experimental data in order to validate from the numerical model results. The calculation results showed a good agreement with experimental data for the pressure drop and particle transport velocity in solid-liquid mixture flow as shown in Fig. 7.

CONCLUSION

In this study the steady laminar and turbulent upward flows of solid-liquid mixtures through a concentric annulus has been investigated experimental and numerical methods.

The two-phase pressure drop increases with the feed concentration and the flow rate. For higher volume fraction, the hydraulic pressure drop of two-phase mixture increases due to the friction between the wall and solids or among solids.

Generally, 0.2% CMC solution is observed to provide better transport than water. The main reason for this is uniform velocity profile of shear-thinning fluid. And Rotation of the inner cylinder generally improves the transport of solid particles and it is more pronounced at lower mixture velocities and appears to be weakened at high flow rate.



(a) 0rpm (b) 0.2% CMC +4% Sand

Figure 7. Comparison of pressure loss in water and 0.2% CMC solution as a function of flow rate.

Numerical calculations were run for 0.2% CMC solution as carrier fluid and the calculation results showed a good agreement with experimental data for the pressure drop, but numerical results are slightly lower than experimental values.

For small excursions from a concentric annulus, the axial pressure drop falls with the increase of eccentricity as the shear-thinning effects will have ample opportunity to dominate inertial effects.

Numerical calculation predicted that almost all sand particles settle down to the lower part of the annulus and some particles were suspended in the upper part of the annulus. As the hole inclination is increased from vertical, the volume fraction of sand is increased.

FLOW AROUND A CYLINDER SWIMMING IN A QUIESCENT FLUID

M. Nazarinia*, D. Lo Jacono, M. C. Thompson and J. Sheridan
Department of Mechanical & Aerospace Engineering, Monash University, Australia

ABSTRACT. The flow structures around a circular cylinder undergoing combined oscillatory translation and rotation in a quiescent fluid have been investigated experimentally and numerically. Experiments were performed for the set of parameters that was shown previously to result in a net thrust i.e. the *swimming cylinder* case. The range of Reynolds number covered in this study was $141 \leq Re \leq 628$. The velocity fields were measured in multiple planes using particle image velocimetry. The experimental setup was such that the cylinder was mounted vertically to an actuator to create the horizontal translation. The circular cylinder used has an outer diameter of 20mm and length of 800mm. Experimental results confirmed that at certain phase differences between the two motions, i.e. out-of-phase or in phase, the cylinder is capable of generating thrust in a perpendicular direction to the translational oscillation. Experiments were also undertaken to investigate the three-dimensional nature of the flow. Additional analysis on the stability of such flow has been carried out with numerical simulation and confirmed the experimental measurements.

Keywords: *wake, cylinder, quiescent, instability*

INTRODUCTION

A circular cylinder undergoing a combination of translation and rotation oscillatory motions in quiescent fluid has not received much attention until now. It is well known that when a bluff body is oscillating translationally in a quiescent fluid, secondary streaming is generated around the body owing to the influence of nonlinear effects [1]. However, the combination of the two oscillatory forcing mechanisms can, under specific conditions, result in a net thrust being experienced by the circular cylinder in a direction normal to the translational axis [2]. The cylinder experiencing thrust and undergoing a series of pitch and plunge motions has been labeled the *swimming cylinder*. Numerous studies of flow over bodies undergoing pure oscillatory motions exist in the literature. These oscillatory motions include pure translation [3-8] and pure rotation [9-11].

So far, to the best knowledge of the authors, only the investigation by Blackburn et al. [2] and several more recent ones [12-14] have been reported on the combined oscillatory motion. However, the work by Blackburn et al. [2] is the only one on the swimming cylinder (e.g. the quiescent case) and to date no experiments have confirmed this phenomenon. A number of interesting features have been shown to occur as a result of combining the two motions. Blackburn et al. [2] found out that a jet flow will be produced by the cylinder when the two imposed motions are in phase or of opposite phases, i.e. $\Phi = (0, \pi)$. The propulsive force produced by the cylinder caused it to accelerate until eventually reaching a terminal speed of 33% of the peak translational speed.

The purpose of the present study is to investigate not only the near wake structures arising from this combination of forcing mechanisms, but also their associated three-dimensional nature, which has not received attention so far. The present study incorporates experimental and numerical results. To characterise the experiments, the authors employed particle image velocimetry (PIV) technique. A direct numerical simulation and Floquet analysis are also used to support and extend the present investigation. After defining the problem and the methods and techniques used, the results and discussion will be presented below.

PROBLEM DEFINITION

The flow over a cylinder undergoing combined translation and rotation oscillations depends on five independent parameters. The equations of the forcing motions are defined as:

$$y(t) = A_t \sin(2\pi f_t t), \tag{1}$$

$$\theta(t) = A_\theta \sin(2\pi f_\theta t + \Phi), \tag{2}$$

where A_t (A_θ) is the amplitude of translational (rotational) motion, f_t (f_θ) is the frequency of translational (rotational) oscillation, and Φ is the phase difference between rotational and translational motions ***(refer to Figure 1)***. The five independent parameters can be written as translational and rotational Keulegan-Carpenter numbers:

$$KC_{[t,\theta]} = \frac{U_{\max_{[t,\theta]}}}{f_{[t,\theta]} D} = \frac{2\pi A_{[t,\theta]}}{D} \tag{3}$$

and as the translational and rotational Stokes number:

$$\beta_{[t,\theta]} = \frac{f_{[t,\theta]} D^2}{\nu} \tag{4}$$

where D is the diameter of the cylinder, U_{maxt} ($U_{max\theta}$) is the maximum translational (rotational) velocity of the cylinder motion and ν is the kinematic viscosity of the fluid. A Reynolds number can also be defined as a combination of two of the above dimensionless parameters. The associated translational Reynolds number, Re_t, is then:

$$Re_t = \frac{U_{\max} D}{\nu} = KC_t \beta_t. \tag{5}$$

METHODS AND TECHNIQUES

Experimental setup

The experiments were conducted in the FLAIR free-surface closed-loop water channel at the Department of Mechanical and Aerospace Engineering, Monash University. The model used for these experiments was a ***rigid*** hollow carbon fibre circular cylinder with a length of 800mm and outer diameter of 20mm, giving an aspect ratio of 40. The cylinder was suspended vertically from an actuator that was controlled by a micro-stepping stepper motor. The cylinder was fitted with an end plate to reduce the end effects. The end plate was designed following recommendations by Stansby [15], and consisted of a circular plate with a diameter of 9D. The Cartesian coordinate system in use is defined such that the origin is located at the centre of the circular cylinder (at $t = 0$) at the window shown in Figure 1 with x, y and z representing the streamwise, transverse, and spanwise directions, respectively. ***The window is located at a depth of 620mm under the water surface.*** The cylinder was

also oscillated rotationally by using another high-resolution stepper motor. The stepper motors were controlled using a two-axis indexer and two high-resolution drivers (running at 50800 steps/rev). A pure sinusoidal profile, as defined in equations (1) and (2), was used throughout the experiments. During each set of experiments the fluid was *initially* at rest, i.e. quiescent flow. Special care was always taken to ensure the quiescency of the flow. Prior to each set of experiment a honeycomb device was used to break large-scale structures into small-scale, minimising the background noise. Typically, the amplitude of the background noise, measured with the norm of velocity magnitude, was kept below 1.41% of the U_{maxt}, for β = 45. Experiments were performed for a particular set of parameters which has been shown previously to be that of a swimming cylinder [2]: the frequency ratios were held the same $\beta_t = \beta_\theta = \beta$, the amplitude of rotational motion $A_\theta = 1$ radian and the phase difference between the two motions $\Phi = \pi$. With these values the associated translational and rotational Keulegan-Carpenter number are $KC_t = KC_\theta = \pi$. The nondimensional frequency chosen ranged from $45 < \beta < 200$, consequently the range of Re_t covered $141 < Re_t < 628$.

Experimental technique: particle image velocimetry (PIV)

The PIV technique was used to measure the flow fields around the combined oscillating circular cylinder. The PIV set-up, illustrated in Figure 1, was based on that originally described by Adrian [16]. For this purpose, the flow was seeded with spherical polyamide particles having a mean diameter of 20 μm and specific gravity of 1.016. In this system, the particles were illuminated using two miniature Nd:YAG laser sources. The planes of interest for these experiments were the *yz*- and *xy*-plane, being the spanwise and streamwise perpendicular to the cylinder planes respectively, as shown in Figure 1. Pairs of images were captured on a high resolution CCD camera system with a maximum resolution of 4008×2672 pixels. The camera was equipped with a 105mm lens and was triggered by a TTL-signal, which was delivered from the stepper motor. At a particular phase in the oscillation cycle, a number of image pairs over successive cycles were stored for further processing, ***producing phase-locked velocity fields.***

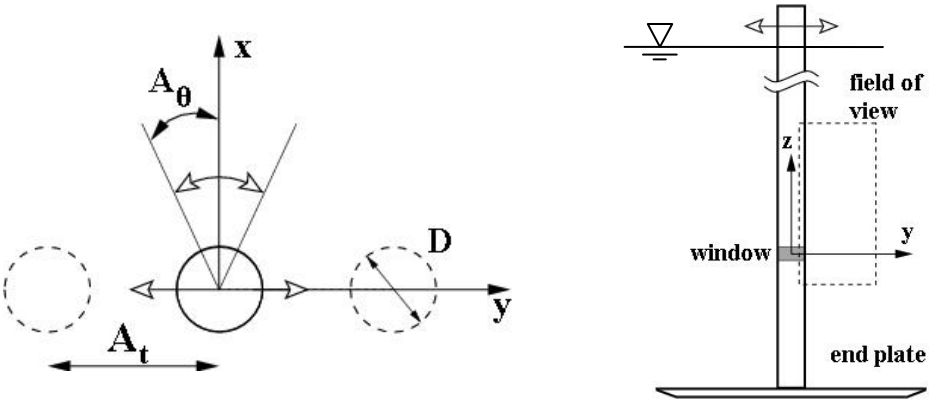

Figure 1. Schematic showing the problem geometry and important parameters relevant to the combined forced oscillation and the circular cylinder model. The green lines show the laser sheet in the streamwise plane (left) and spanwise plane (right).

Each image pair was processed using in-house PIV software ([17, 18]). This software uses a double-frame, cross-correlation multi-window algorithm to extract a grid of displacement vectors from the PIV images. An interrogation window of 32×32 (with an initial window size of 64×64) pixels was found to give satisfactory results with 50% overlap. More than 98% of the vectors were valid for all experiments. This window size corresponds to an average interrogation window of $0.064D \times 0.064D$ and measurement resolution of 249×166 (total of 41334) vectors in each field of view. The overall field of view was $8.0D \times 5.3D$. The displacement fields from these analyses are

presented using phase-averaged vorticity and velocity fields, where the phase-averages were calculated from 30 or more instantaneous velocity fields.

Numerical formulation

The base flows for the present study were calculated by solving the incompressible, time-dependent Navier-Stokes equations. The discretisation method employed was a spectral-element method, using seventh-order Lagrange polynomials associated with Gauss-Lobatto-Legendre quadrature points. A three-step time-splitting scheme is employed [19-21]. A computational domain extending $30D \times 30D$ was split into 518 elements, the majority of which were concentrated in the boundary layer. The resolution, element distribution and domain size are consistent with those used successfully in previous similar studies [20, 22 , 23]. At the cylinder surface, a time-dependent Dirichlet condition was utilized that varied sinusoidally in time according to the driven translational and rotational oscillation. The code employed a power method to resolve the most dominant Floquet mode (and the magnitude of the largest Floquet multiplier). Further details of the method in general can be found in [19], and details of the implementation used here in [20]; the formulation of Floquet stability analysis can also be found elsewhere [24].

RESULTS AND DISCUSSION

Figure 2 shows a comparison of the velocity at y/D=0.6 behind a purely translational oscillating circular cylinder in a quiescent flow. The measurements are taken at KC_t=5 and β=20, similar to previous numerical and experimental results of Dütsch et al. [8]. Figure 2 shows that the present experiment and the numerical simulations match the experimental results of Dütsch et al. [8] very closely. As can be seen, the present experimental results match more closely to the numerical results compared with the experimental results of Dütsch et al. [8]. Also excellent agreement was found with the results of Dütsch et al. [8] at different locations behind the cylinder which further validates our experimental setup.

Figure 3 shows the agreement between the present numerical simulation and the experiments for the ω_z vorticity contours around the cylinder undergoing combined translational and rotational oscillation at $KC=\Phi=\pi$ and $\beta=90$. On the left the present phase averaged experimental results are shown while on the right are the numerical simulations. The cylinder is at the middle of the oscillation cycle starting the motion towards the top of the page, in the vertical direction and rotating clockwise in the negative direction at the instant shown. These experiments confirm the earlier results of the numerical simulations of Blackburn et al. [2]. Figure 3 clearly shows the vorticity transport to one side of the cylinder as well as comparing the same flow between the present experimental and numerical investigation. Figure 3 also shows the excellent qualitative agreement between the experimental and numerical results.

Figure 4 shows the sequence of one complete cycle of translational and rotational oscillations in eight different consecutive snapshots, from t=0 to t=7T/8, where T is the period of oscillations. The cylinder, based on equations (1) and (2), starts the motion from the centre to the top of the page, the positive direction of y, and at the same time starts rotating clockwise, the negative direction of rotation angle, θ. Figure 4c shows the instant where the cylinder is at its maximum vertical position and the most negative angular displacement. As the oscillations are 180° out-of-phase, the maximum surface-tangential component of cylinder acceleration is located on the left hand side of the cylinder, i.e. it is where the accelerations are additive rather than in opposition. Morton [25] has shown that this combination of accelerations will result in the generation of vorticity on that side of the cylinder while the cancellation of accelerations on the other side results in a cross-annihilation of vorticity. The direction of rotation of the vortices will result in their being stretched and directed to only one side of the cylinder and perpendicular to its translation axis will necessarily result in thrust generation in this direction. Only in certain cases does the motion of the cylinder thus act to

produce vorticity more strongly from one side of the cylinder while retaining an overall zero production of vorticity from the cylinder. As reported by Blackburn at al. [2], for this to occur a threshold amplitude of oscillation is required. The phase angle between the motions seems to influence the degree to which cross-annihilation of vorticity occurs and the distance from the cylinder at which vorticity persists.

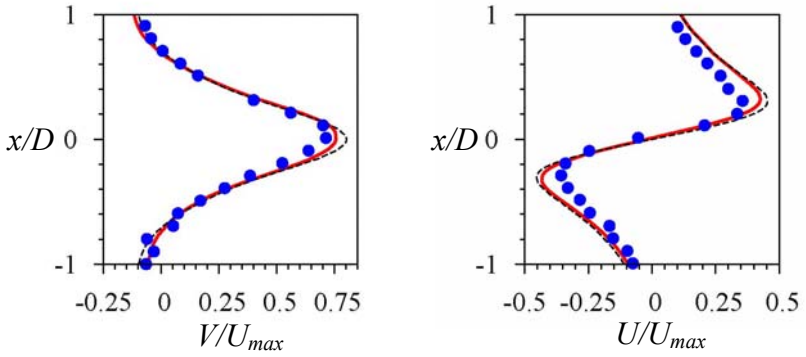

Figure 2. Comparison of the velocity components at y/D=0.6 behind the purely translationally oscillating cylinder in a quiescent flow (at KC_t=5 and β=20). solid (red) lines: present experiment; the dashed (black) lines: present numerical simulation; filled circle (blue) points: the experimental results of [8].

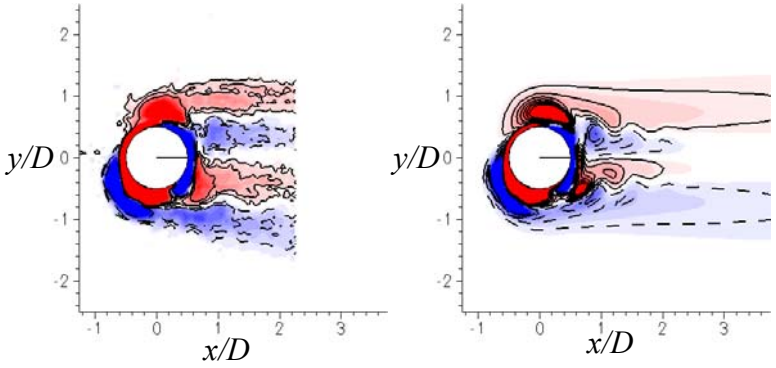

Figure 3. Vorticity contours, ω_z, around the cylinder undergoing combined translational and rotational oscillation at KC=Φ=π and β=90. The dashed lines (blue) are showing the clockwise direction of vorticities, negative, where the solid lines (red) are showing the counter-clockwise direction, positive. Left: present experiments; Right: numerical simulations.

Experiments were also undertaken to investigate the three-dimensional nature of the flow. The onset of three-dimensionality was measured and calculated to occur at β_c=32. Figure 5 shows the spanwise distribution of ω_x vorticity. Figure 5a shows the two-dimensionality of the flow for $\beta < \beta_c$ while at the higher β values shown in Figure 5b and c the flow displays a characteristic spanwise wavelength λ. The wavelength of the spanwise structures was found to be in the range $1.8 < \lambda/D < 2.0$. Numerical simulations with Floquet analysis have been performed and confirmed this wavelength; the comparison is shown in Figure 6.

CONCLUSIONS

The research reported here extends the study of Blackburn et al. [2] both experimentally and numerically. The study is restricted to the case with the phase angle set to Φ=π, and large amplitude oscillations-corresponding to a *swimming cylinder*. For the first time flow around a cylinder

undergoing a combined translation and rotation oscillatory motion has been measured experimentally. The development of wake three-dimensionality has also been examined experimentally. The stability of the wake to the growth of three-dimensional flow through Floquet stability analysis has also been determined. In particular, the experimental results along with our numerical simulations show and confirm how a cylinder at certain phase difference between the combined motions can generate thrust. Because of the phase difference, the oscillation velocities at the cylinder surface cancel on one side and reinforce on the other. This leads to preferential vorticity generation and transport on one side, and the cylinder rotational motion sweeps this vorticity around to the other side producing a thrust wake. We also find that the wake undergoes three-dimensional transition at low Reynolds numbers (Re ≈ 100) to an instability mode with a wavelength of about two cylinder diameters. The experimental results also indicate that the development of three-dimensionality in the wake leads to significant distortion of the previously two-dimensional wake.

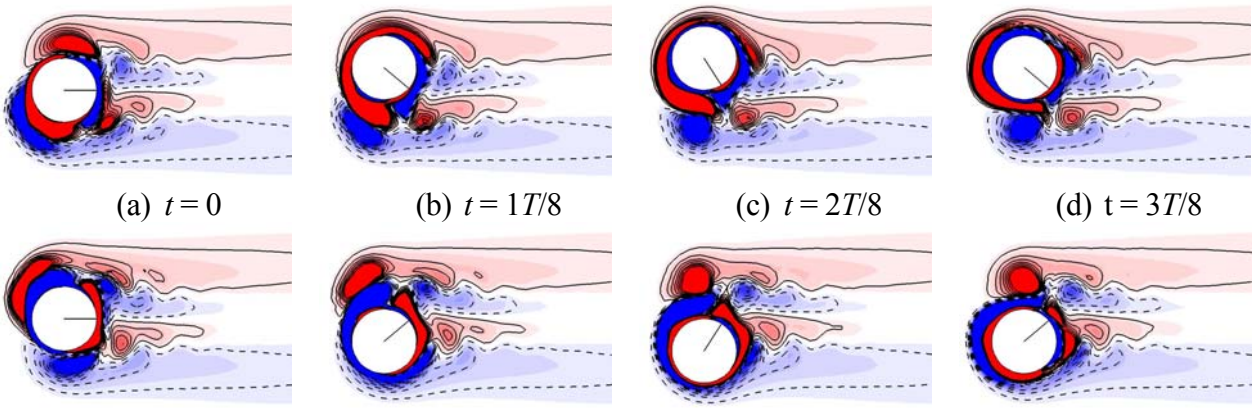

Figure 4. Flow produced by cylinder with combined oscillatory translation and rotation. This figure shows the sequence and development of the ω_z vorticity for one complete cycle, (a) $t = 0$ to (h) $t = 7T/8$ at $KC=\Phi=\pi$ and $\beta=90$ where T is the period of oscillation. The radial line shows the rotational displacement of the cylinder. The dashed lines (blue) are showing the clockwise direction of vorticities, negative, where the solid lines (red) are showing the counter clockwise direction, positive.

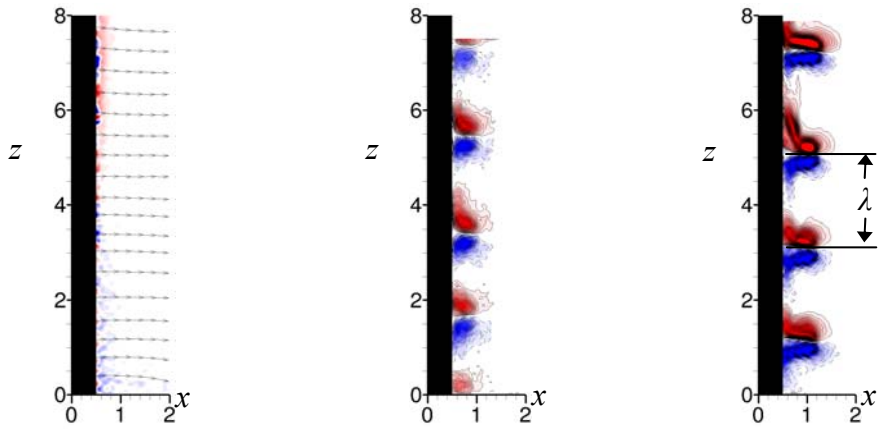

Figure 5. Spanwise distribution of flow for three values of β at $KC=\Phi=\pi$: (a) $\beta=20$: streamlines showing parallel and therefore two-dimensional vortex shedding; (b) and (c) β =45, 90, respectively: ω_x out-of-plane vorticity contours showing the mush-room structures along the span.

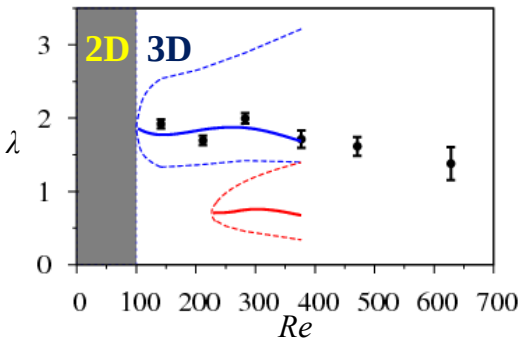

Figure 6. Comparison of the Floquet analysis predicted values for the wavelengths as a function of Reynolds number with experimental measurements for $KC=\Phi=\pi$.

FLOW PROFILES ON THE FIN SIDE OF A PLATE FIN-AND-TUBE HEAT EXCHANGER EXPERIENCING GROSS FLOW MALDISTRIBUTION

J. Hoffmann-Vocke*, J. Neale, M. Walmsley
Energy Research Group, The University of Waikato, Hamilton, New Zealand

ABSTRACT. Flow profile measurement using thermal anemometry has been carried out for various conditions in a plate fin-and-tube airside inlet header. Commonly applied inlet header geometries, with an area ratio of 9:1 are used with results from wide-angle square diffusers compared with a sudden expansion. All geometries provided poor flow distribution leading to gross flow maldistribution at the outlet of the header. Considerably higher magnitudes of flow maldistribution were measured in an open header than with the test plate fin-and tube heat exchanger in place. Gross flow maldistribution entering a plate fin-and- tube heat exchanger results in a complex inlet profile that can only be accurately determined by the measurement of all three velocity components. Significant differences exist between magnitude of flow maldistribution entering and leaving the test plate fin-and-tube heat exchanger. Flow profile changes are caused by the spreading of the flow as it passes through the heat exchanger. Internal flow spreading occurs only in the axis perpendicular to the orientation of the tubes. Therefore it is concluded that using the unmixed fin side assumption in plate fin-and-tube heat exchangers is not valid in cases of inlet flow maldistribution.

Keywords: *heat exchanger, gross flow maldistribution, plate fin-and-tube, unmixed flow*

INTRODUCTION

Compact heat exchangers such as plate fin-and-tube geometries are widely used in various chemical and process industries for applications such as; process gas heaters and coolers. In order to increase compactness and overcome the low density and thermal conductivity of gases, a secondary heat transfer area in the form of fins are commonly employed. The secondary heat transfer area to primary area ratio is commonly as large as 30 or 50. The hydraulic flow resistance on the fin side (gas side) can become a significant factor due to the large number of small passages created between the fins. The gas side pressure drop is approximately proportional to the velocity squared, and as a result in most cases velocities are kept low to minimize the required pumping power, since this can be a major operating expense [1]. The large air side surface area and desire for low pressure drop, results in a heat exchanger geometry consisting of a large frontal surface area and a short flow length.

Typically the gas side design is based on the assumption of a uniform mass flow distribution through the fin-and-tube bundles [2, 3]. In industrial applications such as in process gas heaters, this is typically not the case [4, 5]. Non uniform distribution (maldistribution) of gas flow on the fin side of fin-and-tube heat exchangers can be caused by a variety of factors. Common variables causing flow maldistribution are; entry conditions, bypass, fabrication tolerances, shallow bundle effects, and general equipment and exchanger system effects [6]. One of the most common causes

of flow maldistribution in large industrial gas heat exchangers is the design of entry conditions, such as headers and inlet ducts [7]. The gas side header transitions between the higher velocity transport ducting and the much larger heat exchanger inlet face. Typical industrial applications usually exhibit an area ratio of 8 to 10 between the ducting and heat exchanger inlet. This inlet header is typically some form of 3D compound angle diffuser, providing a sudden uncontrolled transition from the ducting to the heat exchanger inlet face. Expanding fluid flow under an adverse pressure gradient as experienced in any diffusing geometry, leads to significant boundary layer growth. In most industrial applications the rate of uncontrolled expansion is very high, leading to separation of the flow. As a result the uniformity of the mass flow leaving the header and entering the fin-and-tube heat exchanger in an industrial setting is typically quite low.

The effect of flow maldistribution on the gas side of a fin-and-tube heat exchanger can vary considerably depending on the specific case. Generally the effects can be classified into two groups; performance, such as duty and pressure drop, and mechanical; such as increased wear or reduced service life. There are a considerable number of variables involved in determining the effect of flow maldistribution on the performance and mechanical integrity. The complexity and multitude of variables associated with flow maldistribution in heat exchangers have contributed to the lack of systematic effort to predict the occurrence and effects of flow maldistribution. A contributing factor has been the difficulty in actually identifying flow maldistribution within a heat exchanger. Past research has shown that heat exchangers with high effectiveness, or low temperature differences such as fin-and-tube heat exchangers are especially prone to a reduction in thermal performance from flow maldistribution [6].

Various researchers [2, 3, 8-11], have investigated the effects of flow maldistribution on fin- and-tube heat exchangers using experimental and numerical methods. Investigations commonly involve the exposure of particular heat exchanger geometry to a specific magnitude of flow maldistribution. In the experimental investigations the specific heat exchanger geometry, pass arrangement, tube bundle depth, and fin and tube materials mean that each case is exclusively relevant to those conditions. The researchers do not have a sufficient variety of test results to allow trends and performance relations to be attained. Most of the past work has focused on fin-tube heat exchangers used in air conditioning and heat shedding applications. These types of applications utilise axial fans to force air through the heat exchanger. The diameter of the axial fan outlet is typically quite similar to that of the heat exchanger face, meaning that only small magnitudes of flow maldistribution are typically experienced. The effects of flow maldistribution of the magnitude possible in industrial process gas heaters utilising centrifugal fans and small diameter higher velocity ducting have had little investigation. Typically past numerical work on flow maldistribution is not limited to a specific case by case basis. However, the common shortfall is the simplifications made regarding the fin side flow profile. The most common and questionable assumption is the unmixed fin-side flow assumption [12, 13] that are used in fin-and-tube heat exchanger design and performance evaluation. Simplifications of this order are typically used to make the numerical simulation manageable, however this trivialises the complexity of the flow behaviour encountered in flow maldistribution within a heat exchanger. The past research provided results for specific cases; however this limited amount of work does not provide a relevant and comprehensive foundation for assessing the effects on fin-and-tube heat exchangers used as industrial process gas heaters and coolers.

Accurately assessing the performance changes associated with flow maldistribution in fin-and tube heat exchangers requires first; a detailed understanding of the gas flow profile, and how it evolves throughout the heat exchanger system. The current investigation aims at providing a valuable contribution to this point. Experimental measurements quantifying the magnitude and direction of flow maldistribution entering and leaving the heat exchanger are presented.

EXPERIMENTAL SETUP

Experimental investigations of air flow profiles and hydraulic performance of a plate fin-and tube heat exchanger have been carried out on a laboratory scale forced draught air heater model. The air heater model consists of modular sections that can easily be interchanged to allow the investigation of multiple configurations. Figure 1 below shows the inlet configuration starting with a 4.0 kW FlexLine D634DD centrifugal fan (A). This is followed by an outlet contraction (B) which adapts the rectangular fan exit to the square inlet ducting (D_h = 0.3 m). The initial 3.3 hydraulic diameters of inlet ducting (C) are then followed by a circular honeycomb matrix (D) consisting of plastic drinking straws. The matrix has an aspect ratio (x/D_h) of 12 and is used for flow conditioning and bulk flow measurement. The circular straw matrix is then followed by a further 5 hydraulic diameters of inlet ducting (E). Figure 1 shows the sudden 180° expansion (F) in place following the inlet ducting. Various square expansion sections all with an area ratio of 9:1 can be placed in location F, to provide different inlet conditions to the heat exchanger. The expansion section is then followed by various lengths of square straight ducting (G) comprising of a hydraulic diameter of 0.9 m.

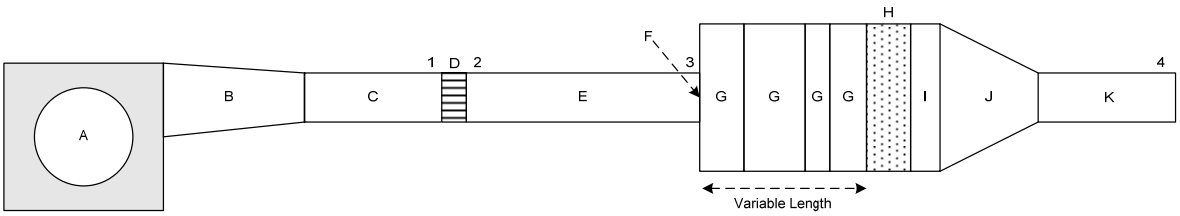

Figure 1. Schematic showing the main aspects of the experimental rig

Various lengths of large (D_h = 0.9 m) inlet ducting are available and allow the variation of the distance between the expansion and heat exchanger inlet face. A four row staggered plate-fin and tube heat exchanger (H) has been used as the test heat exchanger geometry. The 13.3 mm OD copper tubes are arranged with a 31.75 mm transalation and 28 mm longitudinal spacing. The aluminium continuous plate fins have a pitch of 310 fins per meter with an average thickness of 0.2 mm. The overall dimension of the heat exchanger is 0.9 m in height by 0.88 m in width and a 0.11 m in depth. The exit of the heat exchanger is followed by further straight ducting (I), giving a development length after the heat exchanger exit face. The development length is important in smoothing out some of the non-uniformities associated with the flow exiting the tube bundle. The straight exit ducts are followed by a 60° contraction diffuser (J) with an area ratio of 9:1. This is then followed by an outlet duct identical to inlet duct C. The numbers detailed on Figure 1 show the location of important pressure tap points for measuring system performance (3 & 4) and bulk flow rate (1& 2).

Point wise air velocity measurement is carried out using a calibrated TSI VelociCalc Plus thermal anemometer. This film thermal anemometer provides averaged readings over a time interval of 2 seconds or greater. Each 2 second average is compromised of 20 individual readings taken at a frequency of 10 Hz. Multiple time-averaged velocities where taken at each point in the line or plane of interest. In most locations, 25 individual two-second averaged measurements provided a stable average of the local velocity. The draw back of thermal anemometry using a single hot-film sensor is that only the velocity magnitude is attained. Flow direction cannot be determined with positive and negative velocities giving the same result. To overcome this problem, a tuft of fine

yarn made from bamboo fibres was located near the hotwire probe to allow the visual estimation of flow direction. This method is most accurate in steady flows, where the yarn tuft provides a stable direction indicator. In fluctuating flows the error of this method becomes higher; however, it still provides important additional information on the state of the local flow field. Through the use of the yarn tuft, the velocity readings can be more accurately interpreted.

Measurement of the bulk inlet velocity is carried out by determining the pressure drop across the circular straw honeycomb screen. The screen pressure drop has been calibrated to flow velocity using thermal anemometry measurements. Static pressure measurements were taken at wall mounted pressure taps.

Velocity measurements at the inlet and outlet of the test heat exchanger where measured 0.03 m and 0.212 m from the inlet and outlet face respectively. Measurements in front and behind the heat exchanger were carried out along lines corresponding to the vertical and horizontal axis of symmetry. Where visual flow direction measurements are made using the yarn tuft, the x-axis corresponds to the main flow direction, normal to the heat exchanger. For vertical profiles, the y-axis runs from the bottom to the top of the heat exchanger. Correspondingly, the z-axis flow direction for horizontal profiles corresponds to running from right to left of the heat exchanger inlet face. Distance locations of the velocity measurements are taken from bottom to top and right to left of the heat exchanger inlet face.

RESULTS

Characterisation of potential flow maldistribution

Initial investigations involved the measurement of air flow profiles exiting 3D square diffusers similar to those used as transition headers in process gas heat exchangers. In industrial process gas heat exchangers such as the air heaters used in milk powder plants, the minimisation of space and capital cost is the main driving force for the gas side header and ducting design. The area ratio of 8-10:1 between the transport ducting and heat exchanger inlet face requires a significant angle of expansion to achieve the transition within limited space. The common range of total included expansion angles is typically between 25° and 90°. Uncontrolled expansion rates of this magnitude in a diffusing passage lead to excessive boundary layer growth and then flow separation. Figure 2 below displays the exit velocity profiles of two different square diffusers each with and area ratio (outlet to inlet) of 9:1. Each diffuser has an equal mass flux. Due to the unsteady nature of the fluctuating flow in the square diffusers the contours are a time averaged representation of the steady flow. As illustrated by the profiles, significant non-uniformity exists and the majority of the flow is confined to a separated jet. The magnitude of the flow maldistribution can be summarised numerically by the use of a mass weighted average velocity. For the ideal case of a uniform distribution of the same mass flux the mass weighted velocity would be 2.67 m/s. In comparison the exit mass weighted velocity for the 30° case is 11.37 m/s, while for the 90° case a further increase to 16.60 m/s is achieved. It is thus apparent that under flow conditions common in industrial process gas heat exchanger headers there is potential for significant flow maldistribution to occur. While the potential for flow maldistribution is clear, the effect of the downstream heat exchanger on the upstream flow profile needs to be characterised.

Wide angle diffuser simulation by sudden expansion

The flow profiles shown in Figure 2 illustrate the flow maldistribution possible in a wide angle square diffuser. As mentioned previously the nature of the flow in these diffusers is quite unstable and in the case of the 30° diffuser highly non-symmetrical.

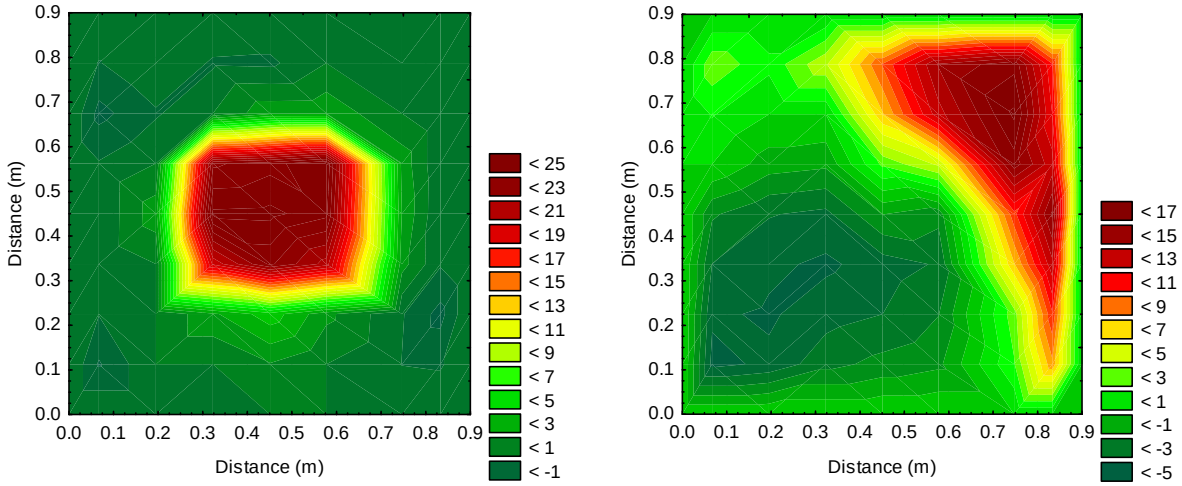

Figure 2. Square diffuser exit velocity (m/s) profiles for (left) 90° diffuser and (right) 30° diffuser

In order to simplify the maldistribution profile and reduce the fluctuations a sudden expansion with an identical area ratio (9:1) has been used to generate the flow maldistribution for the subsequent heat exchanger investigation. The sudden expansion provides a comparatively stable maldistribution with reliable lines of symmetry. This allows a reduction in measurements from a full plain traverse to just two line traverses along the vertical and horizontal lines of symmetry. Figure 3(A) shows the velocity profile comparison between the vertical and horizontal centre lines of the 90° diffuser and sudden expansion. These profiles show the velocity magnitudes of the different geometries at similar distances from the expansion entrance. As expected the sudden expansion provides a more symmetric and consistent profile. In order to further simplify the number of variables, the effect of Reynolds number on the jet profile has been investigated for the sudden expansion geometry. The jet profiles are in the so called development region ($0 \leq x/d \leq 25$) for common self-similar free shear flows such as the round jet. The self-similar behaviour (within a reasonable approximation) is commonly exhibited for a range, but not all x [14]. As confirmed by Figure 3(B) the mean jet profiles exhibit Reynolds number independence for the range tested. Due to the wall and downstream blockage effects, it is unlikely that the jets exhibit any of the self-similar behaviour as seen with the true free shear flows. As part of the experiments carried out with the sudden expansion geometry, the Reynolds number independence has been checked for each configuration.

Plate-fin and tube inlet velocity profiles following sudden expansion

Velocity measurements before and after the test heat exchanger have been carried out for two different inlet velocity profiles. Both profiles were formed by the sudden expansion inlet condition but, differed in the number of duct diameters from the expansion to the heat exchanger inlet face. Configuration A1 placed the heat exchanger inlet face 0.35 hydraulic diameters (D_h = 0.9m) after the sudden expansion. Configuration B1 provided a longer inlet length giving 2.13 hydraulic diameters for the jet profile to develop prior to entering the heat exchanger. Figure 4 shows the velocity magnitude of the vertical and horizontal centre lines for flow entering and exiting the heat exchanger. Figure 4A illustrates the smoothing effect the extra development length provides to configuration B1. Comparison between plots A and B shows the evidence for some form of flow spreading occurring as there is a significant reduction in velocity magnitude

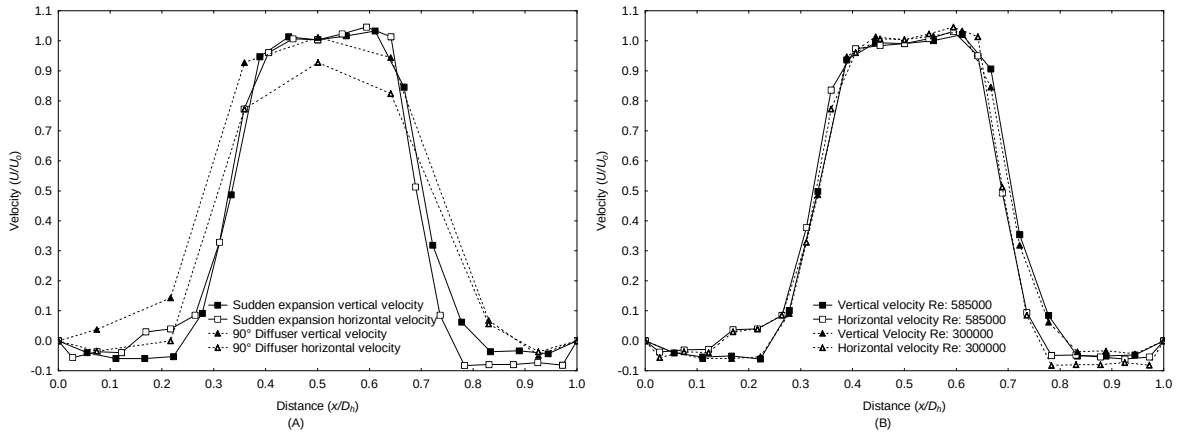

Figure 3. (A) Comparison between 90° diffuser and sudden expansion exit velocity magnitude, (B) Reynolds number independence of jet profile for sudden expansion geometry

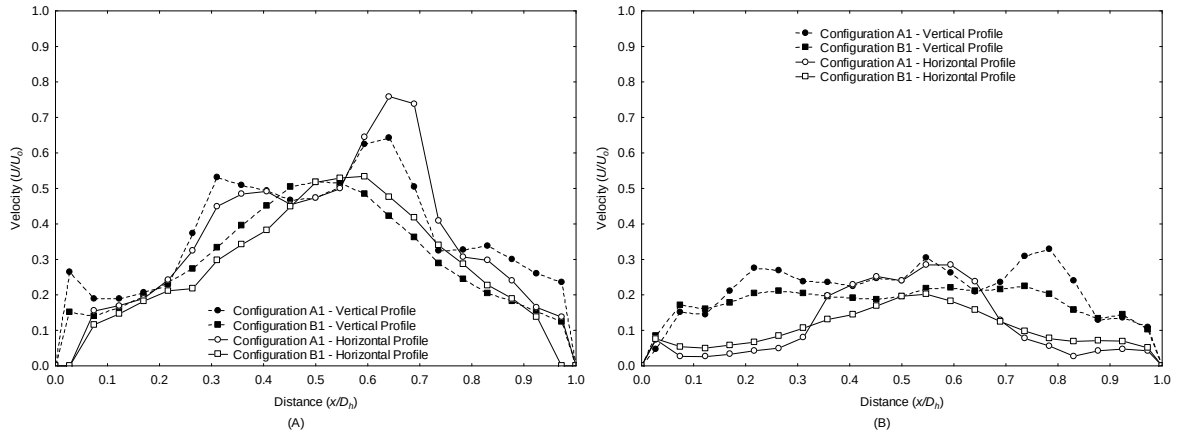

Figure 4 (A) Inlet velocity magnitude, (B) outlet velocity magnitude

While Figure 4 clearly shows that some form of flow spreading is occurring as the flow travels through the heat exchanger, it is difficult to determine any further detail in relation to the direction of the flow as it passes through the heat exchanger. By measuring the inlet flow direction and determining the individual velocity components, a more accurate representation of the flow field can be made. Figure 5 below splits the inlet velocity magnitude into individual components. It becomes clear from Figure 5 that the inlet velocity profile is a lot less uniform, and that only the central region contains significant amounts of flow perpendicular to the inlet face. Significant amounts of air flow are moving in the y and z axis parallel to the heat exchanger face. A proportion of the parallel flow then recirculates at the sides and vertical extremities of the heat exchanger as shown by the negative x-velocities and decay of the Y and Z velocity components. It is clear from the magnitude of the negative x-velocities found at the heat exchanger extremities that the majority of the flow does not recirculate. Instead, the slope of the y and z velocity profiles suggests that a portion of the flow is continuously bled off, passing through the heat exchanger. The resulting outlet profile becomes a combination of flow spreading before and through the heat exchanger. Flow spreading within the heat exchanger is predominantly associated with the dissipation of the x-velocity jet. Comparison of the vertical and horizontal outlet profile indicates that the flow spreading in each direction is not equal. The outer regions of the horizontal exit profile indicate a reduction of flow through these sections of the heat exchanger.

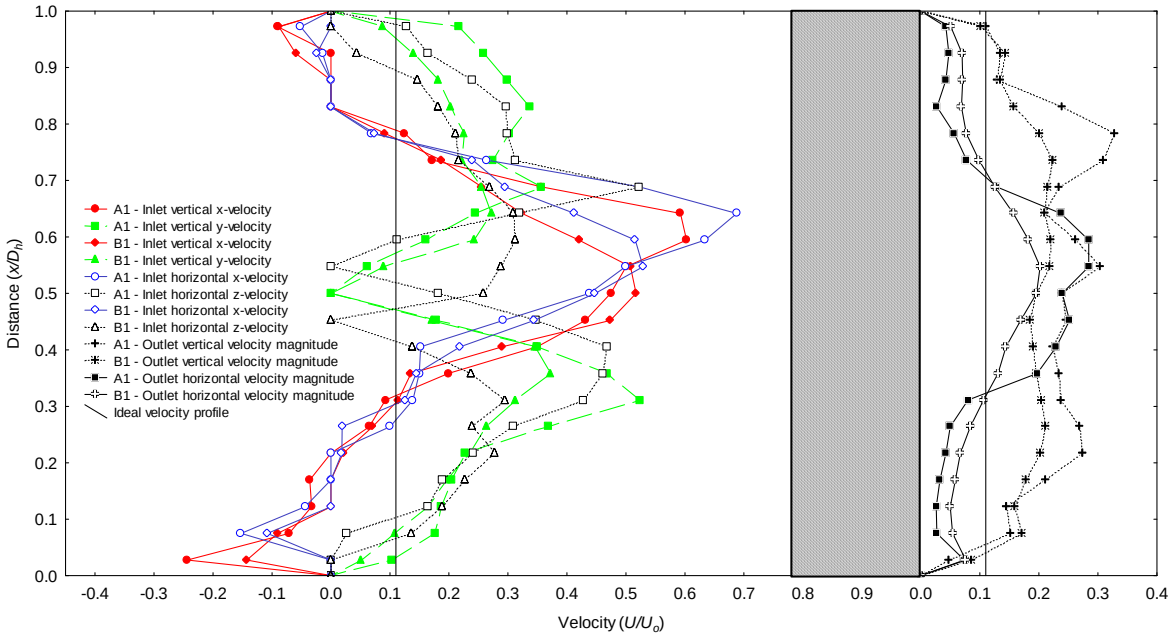

Figure 5. Inlet velocity component profiles and outlet velocity magnitude profiles

This can be explained by vertical orientation of the continuous plate fins. The reduction of flow spreading in the horizontal axis increases the magnitude of the vertical outlet velocity profile. The average vertical outlet velocity magnitude is over twice the ideal value (0.111); corresponding to a uniform flow distribution. Further insight into the extent of flow spreading can be attained by comparing the jet width on the inlet and outlet of the heat exchanger. The jet width is commonly determined by the spacing of the points corresponding to a velocity half the magnitude of the central velocity. Using this methodology, there is no significant horizontal spreading, while spreading in the vertical axis approximately doubles the width of the jet.

Dividing the heat exchanger entry and exit faces both into three by three square grid segments (300 mm square) the following flow conditions are experienced. On the inlet face, the central segment contains the majority of the high velocity jet at approximately five times the ideal flow velocity. The other eight remaining segments have a majority of the flow parallel to the heat exchanger, gradually reducing in velocity and resulting in a negative recirculation at the edges. On the outlet face the three segments corresponding to the vertical line of symmetry contain an average velocity two times the ideal. The remaining segments all contain velocities equal or below the ideal.

CONCLUSIONS

Experimental results using square wide angle diffusers confirm that exit flow conditions are highly non-uniform. As the expansion rate is increased, the non-uniformity of the exit flow condition increases, reaching a maximum corresponding to a sudden expansion. Significant differences exist between the sudden expansion jet profile in an empty duct and that entering the face of the test heat exchanger. Accurate measurement of the inlet flow profile requires the determination of flow direction, not only magnitude. Actual flow measurements 0.03 m before the heat exchanger inlet face reveal a complex flow profile containing flow normal and parallel to the heat exchanger. Only

the central jet region contains high velocities normal to the heat exchanger inlet face. The magnitude of the central jet entering the heat exchanger is approximately halved compared to that of a jet in an unobstructed duct. Flow measurement into, and out of the plate fin-and-tube heat exchanger illustrates changes in the flow profile, resulting in a more uniform exit flow distribution. The flow spreading is most significant in the vertical direction, normal to the orientation of the tubes. Due to the continuous vertical fins, flow spreading in the horizontal axis only occurs before the heat exchanger. Accurate calculation of heat exchanger performance variables such as pressure drop and heat transfer need to take into account inlet maldistribution and flow spreading through the heat exchanger. Performance calculations using the inlet profile throughout the whole depth of the heat exchanger, as commonly used in the unmixed fin-side flow assumption will result in significant error.

AEROSOL PARTICLE FOCUSING IN AN ACOUSTIC CHANNEL

P. Vainshtein* and M. Shapiro

Laboratory of Transport Processes in Porous Materials, Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa 32000, Israel

ABSTRACT. We investigate analytically and numerically focusing of aerosol micron-and-submicron size particles in the incompressible laminar flow in a three-dimensional quadrupole acoustic channel of hyperbolic cross-section. The fluid-particle interaction of micron-size non-diffusive particles is described by a linear drag force. Considering motion of diffusive submicron particles, we account for their random displacements. It is shown that acoustic oscillations with frequency of about 1 kHz focus micron size particles on axial distance comparable to channel cross-sectional size. Submicron diffusive particles cannot be focused exactly at the channel axis owing to the adverse effect of Brownian motion leading to the diffusion broadening. It is shown that the achievable focusing width decreases with increasing the strength of the acoustic field.

Keywords: *focusing, acoustics, channel, aerosol*

INTRODUCTION

Lens arrays used for aerodynamic particle focusing in aerosol instrumentation [1] have disadvantages related to early flow separation adversely affecting focusing efficiency. In work, [2] we proposed and investigated focusing scheme in a model planar channel with oscillating walls free from this shortcoming. However, in the planner channel the axial oscillatory pressure growth takes place. This precludes possibility of its practical implementation. Here we develop that study and consider aerosol particle focusing in a three-dimensional channel of hyperbolic cross-section (Figure 1). The channel walls undergo acoustic excitation resulting in quadrupole pressure disturbances.

Previously such a quadrupole channel with hyperbolic electrodes was employed for ions focusing by means of an ac electric field [3].

ANALYSIS OF FLUID MOTION

We consider wavelength, λ satisfying condition $\lambda >> r_0$. Here r_0 is the distance shown in Figure 1. Cross-sectional acoustic field is generated at the channel walls (1) and (2) by pressure disturbances described by Eqs. (1) and (2).

$$p' - p_0 = -p_s \cos \omega t' \quad \text{at} \quad z'^2 - y'^2 = r_0^2 \tag{1}$$

$$p' - p_0 = p_s \cos \omega t' \quad \text{at} \quad y'^2 - z'^2 = r_0^2 \tag{2}$$

here and below primed variables are dimensional, $\omega = 2\pi f$ is the angular frequency of pressure

E-mail address: merpeva@tx.technion.ac.il

oscillations, f is the corresponding frequency, p_s is the amplitude of the pressure oscillations. Under condition $\lambda >> r_0$ and assumption on small oscillations amplitude, $\varepsilon = p_s / p_0 << 1$ (here p_0 is the undisturbed gas pressure), the flow velocity field within the channel may be considered incompressible and creeping. It is described by Navier-Stokes and continuity equations (3).

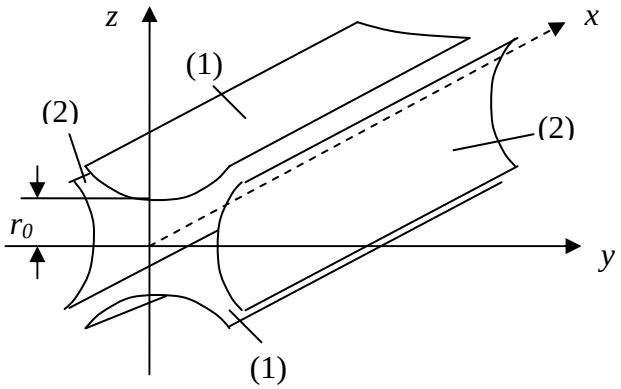

Figure 1. Quadrupole acoustic channel.

$$\frac{\partial \mathbf{u}'}{\partial t'} = -\frac{1}{\rho_f}\nabla p' + \nu\nabla^2\mathbf{u}', \ \nabla\mathbf{u}' = 0 \tag{3}$$

where $\mathbf{u}' = (u', \mathrm{v}', \mathrm{w}')$ is the velocity vector, ρ_f is the fluid density, ν is the fluid kinematic viscosity. According to (3), the pressure distributions satisfy the Laplace equation.

We assume flow velocities in a channel cross-section to be *x*-independent. Let the channel have a length *L*. The imposed pressure drop leads to the axial flow with maximal velocity *U*, say. The obtained solution for the pressure is

$$p' - p_0 = x'\frac{\partial p'}{\partial x'} + \frac{p_s \cos\omega t'}{r_0^2}\left(y'^2 - z'^2\right), \ \frac{\partial p'}{\partial x'} = \text{const} \tag{4}$$

In (4), the first hydraulic term is assumed much smaller than the second acoustic one. This restriction is fulfilled in a wide range of flow and acoustic parameters. Let us set for instance $r_0 = 0.5\,\text{cm}$, U=5 cm/sec, L=1 cm, SPL=140 dB. Then in air where $\rho_f = 1.29\,\text{kg/m}^3$, $\nu = 1.5\times10^{-5}\,\text{m}^2/\text{sec}$, one has $-L\partial p'/\partial x' = 10^{-3}\,\text{Pa}$ while $p_s = 300\,\text{Pa}$. Under this restriction pressure distribution (4) satisfies boundary conditions (1) and (2).

According to (4) the axial pressure does not contain oscillatory components. This situation is different from that occurring in the planner channel [2]. The axial velocity component is independent of time and axial coordinate. It may be approximated in the near-axis region by Poiseuille formula

$$u' = \frac{r_0^2\partial p'/\partial x'}{4\rho_f\nu}\left(1 - \frac{r'^2}{r_0^2}\right) = U\left(1 - \frac{r'^2}{r_0^2}\right) \tag{5}$$

here $r' = \left(y'^2 + z'^2\right)^{1/2}$ is a magnitude of the radius-vector.

The cross-sectional velocity components are

$$\mathrm{v}' = -\mathrm{v}_s\frac{y'}{r_0}\sin\omega t', \quad w' = \mathrm{v}_s\frac{z'}{r_0}\sin\omega t' \tag{6}$$

where

$$\mathrm{v}_s = 2\frac{p_s}{\rho_f \omega r_0} = 2\varepsilon \frac{p_0}{\rho_f \omega r_0} \tag{7}$$

is the characteristic amplitude of fluid velocity oscillations occurring in the channel. For a given channel half-size, r_0, this amplitude is determined by the frequency of acoustic field and sound pressure level (SPL).

According to (6) the channel walls perform oscillations perpendicular to the channel axis. Opposite walls of the channel contract and expand aerosol-filled channel interior in phase. On the contrary, adjacent walls act in counter-phase. By such a way quadrupole excitation of fluid oscillations inside the channel is accomplished.

The fluid velocity (6) is independent of viscosity; however it satisfies the equations of the viscous flow and no-slip boundary condition. This is because the cross-sectional velocity vector on the walls is normal to the walls (Figure 2). Moreover, this vector is normal to the surfaces equidistant to channel walls. Indeed, cross-sectional vectors tangent to the surfaces equidistant to (1) and (2) are $\mathbf{T} = (2z', 2y')$ and $\mathbf{T} = (-2z', -2y')$, respectively. The scalar product of these vectors and that given by (6) is equal to zero. Thus no velocity oscillations in directions parallel to the channel walls take place. Moreover the *z'-y'* shear stress components in any channel's cross-section are identically zero everywhere and hence no secondary streaming is present.

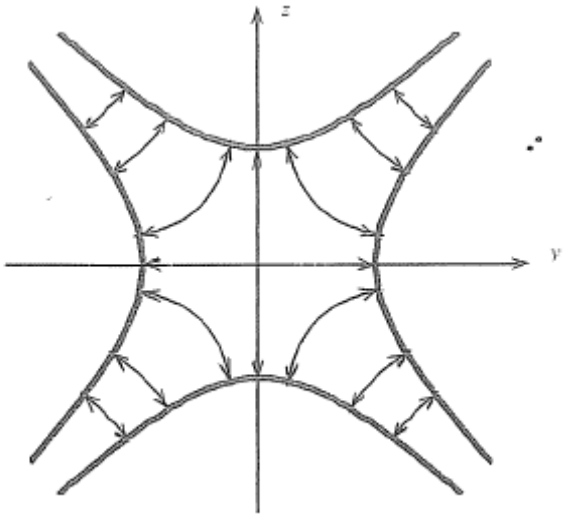

Figure 2. Sketch of cross-sectional fluid streamlines. Arrows show directions of fluid oscillations.

Then the fluid velocity oscillates along the streamlines (Figure 2). It is linearly distributed and vanishing at the channel axis. This leads to particles drifting motion towards the axis and their focusing there. We describe this effect below.

ANALYSIS OF PARTICLE MOTION

We assume a dilute aerosol of rigid particles so that particle-particle interactions are negligible and the presence of particles does not affect the fluid flow. Consider trajectories of a diffusive particle of radius *a* in flow field (5), (6). The fluid-particle interaction is described by the Langevin equation

$$\frac{\mathrm{d}\mathbf{v}_p'}{\mathrm{d}t'} = \frac{\mathbf{u}' - \mathbf{v}_p'}{\tau} + \Xi_{\mathbf{Br}}, \tag{8}$$

where $\mathbf{v}_p^{'}$ is the particle velocity vector, $\tau = 2a^2 C(Kn)/9\nu\Pi_\rho$ is the Stokes relaxation time, Π_ρ is the fluid-to particle-density ratio and $C(Kn)$ is the Cunningham correction factor expressed via the Knudsen number, $Kn = \ell / 2a$ where $C(Kn) = 1 + Kn\left[A + Q\exp(-B/Kn)\right]$ with A=2.51, Q=0.8, B=0.55. Here ℓ is the molecular free path which under normal atmospheric conditions is equal to 65 nm. This approximation is valid for aerosol applications when $\omega\tau\Pi_\rho << 1$. In Eq. (8) $\Xi_{\mathbf{Br}}$ is the Brownian acceleration which describes the effect of Brownian diffusion, important for submicron and nanometer particles [1].

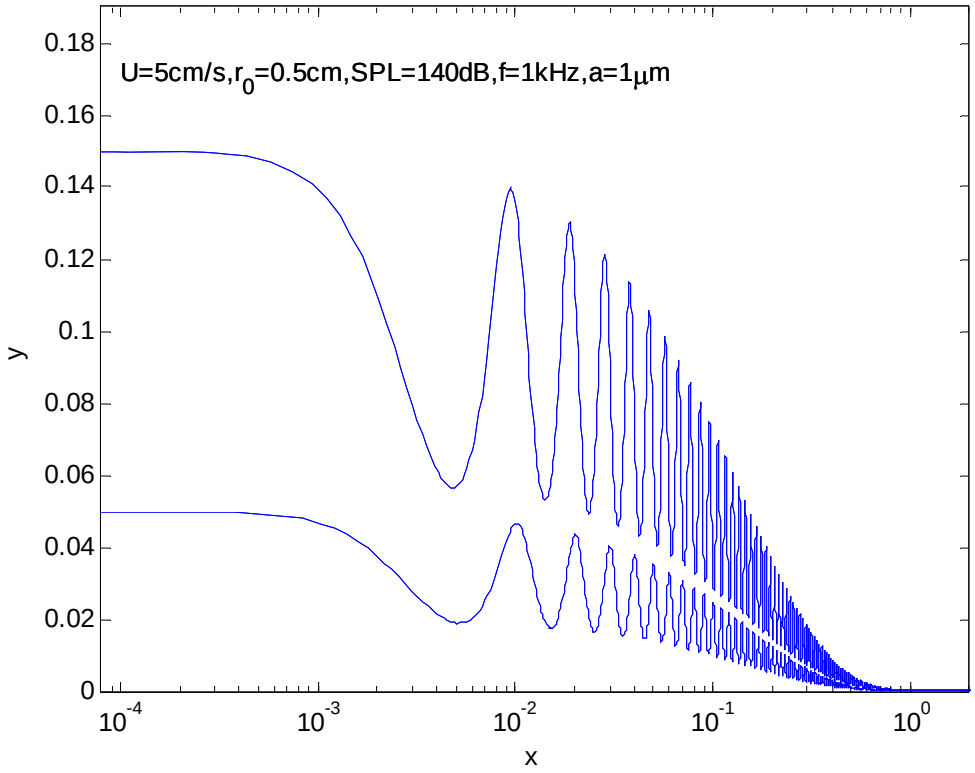

Figure 3. Particle trajectories in the quadrupole acoustic channel.

We define the following dimensionless variables

$$t = \omega t^{'},\ x = \frac{x^{'}}{r_0}, y = \frac{y^{'}}{r_0},\ \ z = \frac{z^{'}}{r_0},\ \ r = \frac{r^{'}}{r_0}, \mathbf{u}_p = \frac{\mathbf{u}_p^{'}}{\omega r_0},\ \mathbf{u} = \frac{\mathbf{u}^{'}}{\omega r_0} \tag{9}$$

Focusing efficiency is investigated for variety of flow and particle parameters expressed in terms of the dimensionless group, namely

$$\beta = \frac{\mathrm{v}_s}{\omega r_0} = 2\frac{p_s}{\rho_f (\omega r_0)^2},\ \ \Pi_U = \frac{U}{\omega r_0}, \Pi_D = \sqrt{\frac{D}{\omega r_0^2}},\ \ \omega\tau \tag{10}$$

Here $\omega\tau$ is the frequency parameter, representing the particle Stokes number of the problem, β is the acoustic strength parameter, Π_U is the axial flow velocity parameter, Π_D is the particle diffusion parameter, D is the particle diffusion coefficient.

Equations of particle motion represent a special case of the damped Mathieu equations. Their stability is governed by parameters $\omega\tau$ and β. The analysis shows that practically interesting cases of acoustic field intensities and frequencies and particle sizes lie well in the stability region.

To characterize the focusing efficiency we consider 10-fold focusing when particle ordinate

decays by a factor of 10 [2]. It is found that there exists a critical value of the Stokes number $\omega\tau$, namely $(\omega\tau)_1 = 1$ determining the maximal focusing efficiency.

In calculations we seed the particles at $x_0 = 0$, at various values of $y_0 = z_0$, and with initial velocities coinciding with those of fluid.

Figure 3 shows trajectories of 1μm non-diffusive particles in the acoustic channel. Particles are seeded at $x_0 = 0$ and $y_0 = z_0 = 0.15$ and $y_0 = z_0 = 0.05$. All particles approach steadily the channel axis in about one radius distance. This happens due to particle drifting motion towards the channel axis and downstream axial motion.

Considering small diffusive particles, we assume $\omega\tau << 1$. Such particles can be regarded inertialess. Computer simulations of Brownian walks can be made by adding at each time-step of $\Delta t^{'}$ a random displacement $\mathbf{A}^{'}G_n$ to the systematic displacement $\mathbf{u}^{'}_{ps}\Delta t^{'}$ [4]

$$\mathbf{R}^{'}_{n+1} = \mathbf{R}^{'}_{n} + \mathbf{u}^{'}_{ps}\Delta t^{'} + \mathbf{A}^{'}G_n \tag{11}$$

where $\mathbf{R}^{'}_{n}$ is the vector of particle displacement at previous time steps, G_n is the zero-mean, unite-variance, independent Gaussian random numbers and $\mathbf{A}^{'}$ is the vector of the random displacement amplitude, each component of which is given by

$$A^{'} = \sqrt{2D\Delta t^{'}} = \sqrt{\frac{2k_B T\tau}{m_p}\Delta t^{'}} \tag{12}$$

here k_B is the Boltzmann constant, T is the local absolute temperature, and m_p is the particle mass. For determination of the systematic particle velocity we consider separately axial and cross-sectional particle motion. Steady axial component of drag will produce a steady axial particle velocity coinciding with that of fluid (see (5)). To describe the cross-sectional systematic velocity we use the smallness of the frequency parameter, $\omega\tau << 1$. Under this condition, the cross-sectional particle velocity can be expressed as a power series of $\omega\tau$ [2]

$$\mathbf{u}_p(y,z) = \mathbf{u}(y,z) - \omega\tau\frac{\mathrm{d}\mathbf{u}(y,z)}{\mathrm{d}t} + O((\omega\tau)^2) \tag{13}$$

Substituting Eq. (6) into Eqs. (13), one obtains for cross-sectional particle velocity the expression which contains periodic and also non-periodic terms. The latter give rise to the steady part of the velocity about which the oscillations proceed. This steady part is said to be a systematic cross-sectional particle velocity. Then, one can rewrite (11) in the following dimensionless form

$$x_{n+1} = x_n + \Pi_U(1 - r_n^2)\Delta t + \Pi_B G_n \tag{14}$$

$$y_{n+1} = y_n - \frac{1}{2}\omega\tau\beta^2 y_n\Delta t + \Pi_B G_n \tag{15}$$

$$z_{n+1} = z_n - \frac{1}{2}\omega\tau\beta^2 z_n\Delta t + \Pi_B G_n \tag{16}$$

here

$$\Pi_B = \sqrt{\frac{2k_B T\tau}{m_p r_0^2\omega}\Delta t} \tag{17}$$

is the dimensionless amplitude of the random displacement. In (14)-(16), the second terms on the r.h.s stands for the systematic velocity.

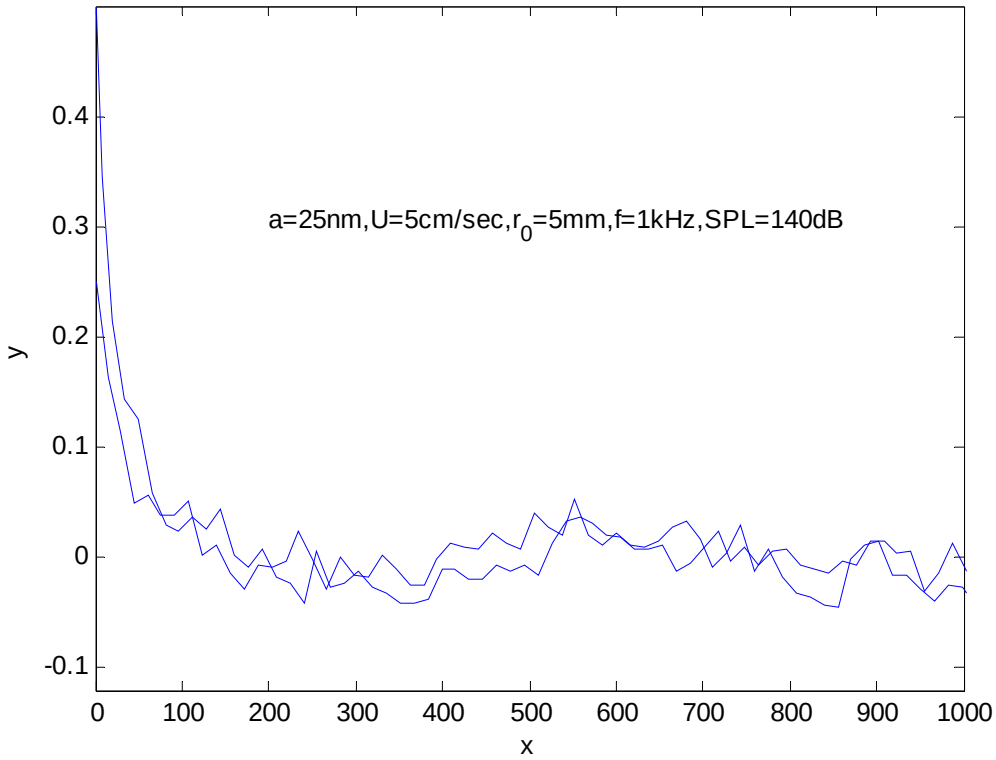

Figure 4. Simulated diffusion particle trajectories $y(x)$ starting from x=0, $y_0 = z_0 = 0.5$ and $y_0 = z_0 = 0.25$.

Figure 4 shows such simulated particle trajectories $y(x)$ starting from x=0, $y_0 = z_0 = 0.5$ and $y_0 = z_0 = 0.25$ for a=25 nm. It is seen that particles move towards the axis and reach it, i.e. they focus. This occurs in about one hundred radius distance.

The acoustic force does not affect the particles arrived at the axis. In the absence of Brownian motion particles moving along the axis will stay on it. However, Brownian motion causes the particles to walk randomly about the channel axis. These random walks lead to diffusion broadening of the stream of the moving along the axis particles. Thus, the diffusion broadening prevents forming narrower particles stream. We note that intensity of the diffusion broadening increases with decreasing particle size.

Besides, it is seen from Figure 4 that the width of particle stream does not grow with increasing x but is on average unchangeable. This is explained by the balance between velocities related to the random and systematic particle displacements occurring while particles continue to walk randomly about the axis. The achievable focusing half-width, $y_B^{'}$, can be estimated proceeding from this velocity balance. Differentiating the expression for the average free random particle displacement $(2Dt)^{1/2}$, one obtains for the corresponding velocity the following equation

$$v_{pB}^{'} = \sqrt{D/2t^{'}} = D/y^{'} \tag{18}$$

For the systematic velocity one has, from Eqs. (15), (16)

$$v_{ps}^{'} = -\frac{1}{2}\beta^2\omega^2\tau y^{'} \tag{19}$$

Equating magnitudes of the velocities given by (18) and (19), one obtains

$$y_B^{'} = \frac{1}{\beta}\sqrt{\frac{2D}{\omega^2 \tau}} \tag{20}$$

Figure 5 shows the dependence of $y_B^{'}$ on particle size in the acoustic channel at SPL=140 dB and *f*=1 kHz. Calculated values of $y_B^{'}$ are in agreement with diffusion broadening seen in Figure 4.

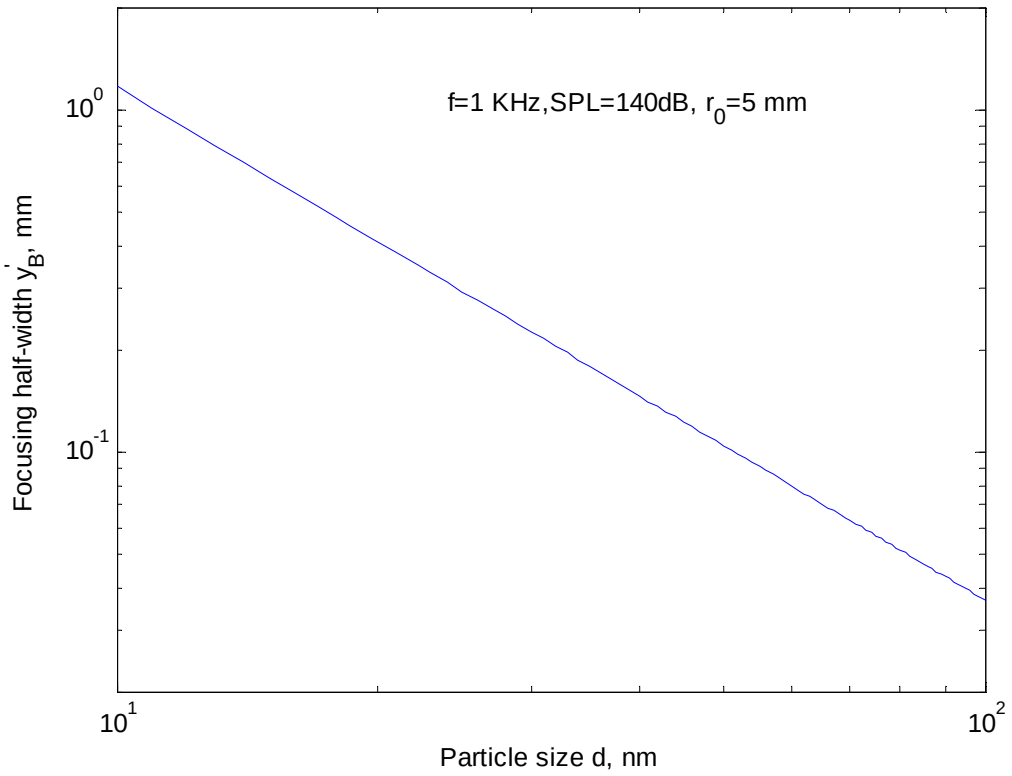

Figure 5. Dependence of focusing half-width on particle size in the acoustic channels

It is seen in Figure 5, for instance, that for a particle of $d = 50$ nm and $d = 30$ nm one has $y_B^{'} = 0.1\text{mm}$ and $y_B^{'} = 0.2\,\text{mm}$, respectively (see also Figure 4).

It is also seen in Figure 5 that a particle of $d = 10$ nm cannot in fact be concentrated in the considered channel of $r_0 = 5\text{mm}$, because focusing half-width for such particles (~1 mm) is comparable with the channel half-size.

At the same time, nanometer particles can in principle be concentrated in narrower channels.

Recall that acoustic strength parameter grows with decreasing channel size as $\beta \sim r_0^{-2}$ (see Eq. (10)). Thus the diminution of the channel size is equivalent to the increase the acoustic field intensity. Such a diminution would result in the increase of the focusing rate: the particles would reach the channel axis by a shorter time. Besides, $y_B^{'}$ diminishes with decreasing channel size as $y_B^{'} \sim r_0^2$ (see (20) and (10)).

CONCLUSIONS

An exploration of acoustic focusing of micron-and-submicron size aerosol particles in a three-dimensional quadrupole acoustic channel of hyperbolic cross-section has been carried out. Acoustic wavelength is considered much larger than the channel cross-sectional size, $\lambda >> 2r_0$.

The channel walls undergo acoustic excitation resulting in pressure disturbances leading to a linearly distributed oscillating cross-sectional fluid velocity vanishing at the axis. This results in particles drifting motion towards the axis. At the same time, the imposed axial flow drives particles downstream. As a result the particles focus along the channel axis.

The drifting particle motion is described by the damped Mathieu equation, solutions of which can, generally, be stable or unstable. The stability is governed by the frequency parameter $\omega\tau$ (the Stokes number of the problem) and acoustic strength parameter β. It is shown that the practically interesting values of these parameters lie well the stability region.

It is found that there exists a critical value of $\omega\tau$, namely $(\omega\tau)_1 = 1$ determining the maximal focusing efficiency of non-diffusive particles.

The motion of diffusive particles is studied under condition $\omega\tau << 1$. It is shown that acoustic focusing of submicron diffusive particles is possible: they reach the channel axis. The focusing rate increases with increasing acoustic strength parameter β. However, the focusing is degraded by the adverse influence of Brownian motion. This motion leads to diffusion broadening of stream of particles while they move along the channel axis. The broadening increases with decreasing particle size. The achievable focusing width is determined by the balance of random and systematic particle velocities. Its estimate shows that this width diminishes with increasing acoustic strength parameter β. Hence acoustic field controls the diffusive particle broadening.

Thus a quadrupole acoustic channel has attractive characteristics and can be applied in the development of new systems of aerosol particles focusing. The ideas developed in this paper were used in the rational design of the acoustic channel capable of generating a focused beam of micron-and-submicron size aerosol particles [5].

COMBINED PIV AND SCHLIEREN INVESTIGATION OF SEPARATED BUOYANT JET MIXING: INFLUENCE OF AXIAL SEPARATION

Ankur Deep Bordoloi[1], P. K. Panigrahi[2, *]
[1]Masters student, of Mechanical Engineering, IIT Kanpur, U.P., India

ABSTRACT

The flow field and the mixing of two inclined separated jets inside a tubular reactor have been experimentally investigated using stereo Particle Image Velocimetry and schlieren deflectometry technique. Effect of axial separation distance between the two jet exit planes is examined by keeping the O_2 nozzle exit plane at two different downstream locations (L/d_1 = 4.8 and 6.7, d_1 is the diameter of the O_2 nozzle). The velocity field, stream traces, turbulent kinetic energy, vorticity and coherent structure identifier results are used to explain the flow field responsible for jet mixing. Due to the opposition between the buoyancy force and the inertia force, flow reversal takes place in He-jet and recirculation structures appear in the neighbourhood of the jet exit. Depending on the relative buoyancy strength (Richardson number, Ri_2), the flow reversal takes place at different axial locations of the He-jet. At high Richardson number (Ri_2 = 1.8), the recirculation zone is almost symmetric about the He-jet axis and there is no interaction between the two jets. On the other hand, when the Richardson number is low (Ri_2 = 1.0), the He-jet penetration depth increases. Schlieren deflectometry has been used to obtain qualitative visualization of the mixing at different flow conditions. At the low Richardson number and low jet axial separation distance, the He-jet and O_2-jet mixing is highest due to the direct interaction between the two jets due to turbulence. The extent of mixing between the two jets depends on the axial separation and jet mixing is higher for smaller axial separation between the two separated jets.

Keywords: *jet mixing, buoyant jet, stereo PIV, Schlieren, recirculation*

INTRODUCTION

The proper mixing of jets has critical influence on the performance of many industrial applications i.e. burners, chemical reactors, combustion chambers etc. Separated jet is an important jet-mixing configuration where two jets are vertically inclined to each other at particular angle. If there is a significant difference of density between the jet and the ambient air, the buoyancy effects play a significant role in the mixing. A buoyant jet can either be positively or negatively buoyant depending on whether the buoyancy force is supported or opposed by the jet's inertia force. The relative magnitude of buoyancy and inertia force determine the evolution and growth of buoyancy dominated jets.

Literature on mixing of separated jets is surprisingly less. Bordoloi and Panigrahi [1] have recently studied the importance of buoyancy in mixing of He-jet with non-buoyant O_2 jet. They reported that the Richardson number of the buoyant jet plays a crucial role to control mixing in the near exit region of the O_2 jet. Turner [2] and Mizushina et al. [3] investigated negatively buoyant jets and reported some important fundamental observations. In a negatively buoyant upward jet, the

E-mail address: panig@iitk.ac.in

buoyancy force always acts downwards and there should be sufficient momentum for the jet in order to reach a steady height. The jet spreads axially with a constant slope. They observed that the penetration height of a negatively buoyant jet depends only on the discharge Froude number of the jet. Subbarao and Cantwell [4] observed that buoyant jets undergo transition to turbulence at Richardson number above unity exhibiting highly structured and repeatable breakdown while intermixing with the co-flowing stream. He et al. [5] observed in case of negatively buoyant wall jets, the influence of buoyancy to have stabilizing effect on the jet with increase in Richardson number, which restricted the jet's penetration depth and its lateral spread. This gives rise to a strong shear layer in the interface between the jet and the ambient fluid with large amount of turbulence in the flow. Kikkert et al. [6] presented the analytical solution for negatively buoyant jets and compared it with results from experiments. Pantzlaff and Lueptow [7] studied positively and negatively buoyant jets separately in order to understand the transient behaviour of buoyancy driven jets using PIV technique. They suggested that a negatively upward buoyant jet is an optimal mixing strategy in designing systems for jet mixing of different densities. Pham et al. [8] have investigated three dimensional behaviour of thermal plume and mass entrainment rate of the ambient fluid into the plume using 3D PIV technique.

The present study is an extension of the work done by Bordoloi and Panigrahi [1]. The potential benefit of using separated nozzle geometry is the controllability of mixing zones by adjusting the separation distance between the exit planes of the two nozzles. This paper experimentally examines the influence of axial separation distance between the exit planes of two jets on mixing of two variable density separated jets inclined at ±3º to the vertical axis. The laser schlieren deflectometry technique has been used to investigate the mixing between two jets. The stereo-Particle Image Velocimetry technique has been used to obtain the velocity field for explanation of jet mixing.

EXPERIMENTAL SETUP

The experiments are conducted in a vertical tubular reactor of octagonal cross-section with 1 m length and having distance between two parallel faces as 21.67 cm. The geometrical details of the separated nozzle can be seen in Figure 1. The two nozzles are mounted on the top of a reactor. The Helium nozzle has a perforated circular plate with 21 randomly distributed perforations of uniform size (diameter = 1 mm) at the end of a circular pipe (outer diameter = 12.5 mm). The special Oxygen nozzle configuration is adopted for increasing the jet mixing. The exit plane of the He – nozzle is located at 100 mm below the top wall of the reactor.

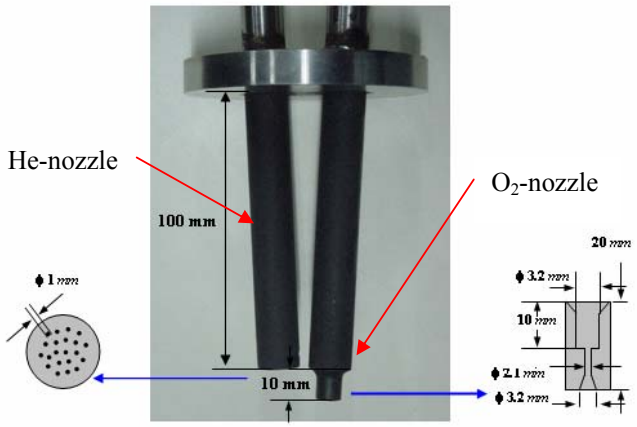

Figure 1. Schematic of the separated nozzle geometry

The axial separation distance between the two nozzles are varied between L/d_1 = 4.8 and 6.7 where d_1 is the diameter of the O_2 nozzle. Relevant notes on the detail of the experimental setup can be found in [1].

The PIV measurements are carried out in the central plane of the jets. The central region of interest is illuminated with a thin laser sheet. A double pulsed Nd: YAG laser (New Wave) of wavelength 532 nm and 15 mJ/pulse with maximum repetition rate 15 Hz has been used. The laser sheet has a maximum span area of 10 x 10 cm^2 and the sheet thickness is about 0.8 mm. Two Peltier-cooled 12 bit CCD cameras (PCO, Sensicam: 1280 x 1024 pixels) in stereo settings were used for acquisition of PIV images.

Both the cameras and the laser are synchronized with a synchronizer controlled by a dual processor PC. The cameras are oriented at a fixed angle with respect to the normal of the measurement plane. The PIV image calibration has been carried out using a fixed three dimensional grid with marker points located in alternate planes. The two planes are separated by a distance of 2 mm. The calibration target is placed at the image plane for calibration image and this image is used for mapping the camera plane to the object plane. The laser light sheet is carefully aligned with the calibration grid to ensure same measurement and calibration locations. The time of separation between two successive pulses is between 205 - 312 μs depending on the flow conditions. The time-averaged velocity field is obtained by averaging a sequence of 800 velocity vector images. The 2D to 3D conversion of velocity is done by using VidPIV 4.6XP software. The unwanted part of a PIV image is annotated before performing PIV cross-correlation calculations. For present analysis, multi-pass interrogation technique, with local median filtering followed by outlier interpolation, has been used. The percentages of valid vectors were about 97%.

Table 1: Experimental Details.

	Helium Jet	Oxygen Jet
Nozzle Index	1	2
Nozzle Pipe Diameter (mm)	9.5	9.5
Perforation Diameter (mm)	1.0	--
Throat diameter (mm)	--	2.1
Volume flow rates (lpm)	1.25, 2.25	0.25
Reynolds number (*R*e)	47, 63	170
Richardson number (*Ri*)	1.8, 1.0	8.65×10^{-05}
Axial separation distance (L/d_1)	4.8, 6.7	

The Richardson number (*Ri*) is calculated individually for two gas jets considering the ambient air to be at rest using the relation, $Ri = \dfrac{|\rho_g - \rho_a| gd}{\rho_g U_g^2}$ [Favre-Marinet *et al.* [9]]. Here subscript '*g*' indicates the dominant gas jet (i.e. Helium or Oxygen) and '*a*' indicates the ambient fluid. For the same O_2-jet velocity, the Richardson number of the He-jet is kept at Ri_2 = 1.8 and 1.0. These two experimental sets were repeated for two different axial separation distance between the exit planes of the Helium and the Oxygen jets. The details of experimental conditions, i.e. the volume flow rates, Reynolds number and Richardson number for both gases are summarized in Table 1.

RESULTS AND DISCUSSIONS

The controllability for jet-mixing, that separated jet configuration may offer in terms of relative buoyancy strength and axial separation distance, is examined in the present study. The effect of relative buoyancy strength has been studied for two different axial separation distances. The smoke visualization, mean velocity, turbulence kinetic energy, coherent structure identifier and Schlieren results are systematically discussed in the following sections.

Visualization

Figure 2 shows the instantaneous visualization images for two different Richardson numbers (Ri_2 = 1.8 and 1.0) of the Helium jet. Figure 2 also shows the effect of axial separation (L/d_1 = 4.8, 6.7) between the exit planes of the two jets. At high Richardson

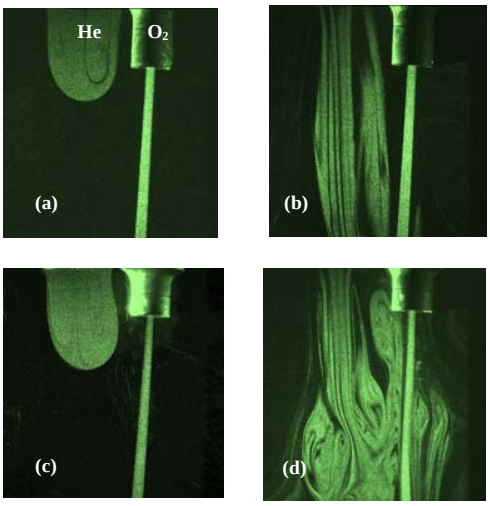

Figure 2. Instantaneous flow visualization images for (a) L /d_1 = 6.7, Ri_2 = 1.8, (b) L /d_1 = 6.7, Ri_2 = 1.0, (c) L /d_1 = 4.8, Ri_2 = 1.8 and (d) L /d_1 = 4.8, Ri_2 = 1.0

number (Ri_2 = 1.8) the flow reversal takes place in the neighbourhood of the He-nozzle exit without interacting with the O_2-jet due to the dominance of buoyancy (Figure 2(a), (c)). The presence of O_2-jet generates a low pressure zone in the inter-jet region. Depending on the axial separation distance, the intensity of the low pressure region varies. This leads to variation in the shape of the recirculation bubble near the jet exit region at high Richardson number. When the axial separation distance is high (L/d_1 = 6.7, Figure 2(a)) the recirculation bubble is almost symmetric about the nozzle axis. However, when the axial distance between the two jets is low (L/d_1 = 4.8), the low pressure region intensifies and distorts the recirculation bubble. Figure 2(c) shows that the recirculation bubble bulges asymmetrically from its jet axis towards the inter-jet region at L/d_1 = 4.8. At low Richardson number (Ri_2 = 1.0), the He-jet penetrates deeper into the ambient air due to higher strength of inertia and the two jets interact in the downstream of the flow. It can be seen that the extent of interaction is inversely dependent on the axial separation between the two nozzles. Figure 2 (b) and (d) show that when the axial separation is high (L/d_1 = 6.7), the interaction between the two jets is less as compared to when the axial separation between the two jet is low (L/d_1 = 4.8). Overall, qualitative information on the effect of Richardson number and axial separation distance between the two nozzles could be obtained from the visualization pictures of the flow field.

Mean velocity field

The time averaged normalized radial velocity (v/u_{max}) field super-imposed with time-averaged stream traces is shown in Figure 3 for two different Richardson numbers of the He-jet and for two different axial separation distances between the jets. Here u_{max} is the corresponding maximum local O_2 jet velocity. The radial velocity field is important for radial mixing problem of jets as it gives a clear picture on the radial entrainment of the jet into the ambient. The stream-traces provide an understanding of the recirculation patterns if flow-reversibility is prevalent in the flow field. At Ri_2 = 1.8 and L/d_1 = 6.7 (Figure 3(a)), there are two strong and opposite radial velocity regions in the neighbourhood of the two recirculation bubbles of the He-jet. Due to the low pressure region generated, the strength of radial velocity is more in the inter-jet region as compared to the opposite side. When the Richardson number is decreased to Ri_2 = 1.0 (Figure 3(b)), keeping all the other conditions the same, the inertia force dominates and the strong radial velocity region is extended

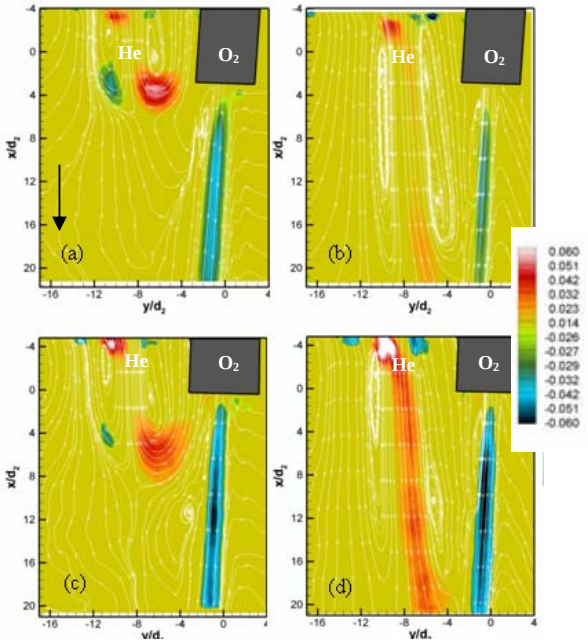

Figure 3. Time averaged radial velocity (v/u_{max}) contours superimposed with stream traces for (a) L/d_1 = 6.7, Ri_2 = 1.8, (b) L/d_1 = 6.7, Ri_2 = 1.0, (c) L/d_1 = 4.8, Ri_2 = 1.8 and (d) L/d_1 = 4.8, Ri_2 = 1.0

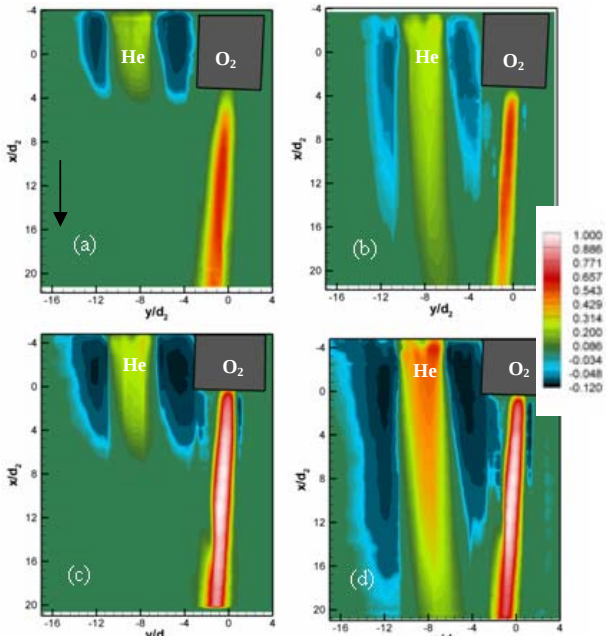

Figure 4. Time averaged axial velocity (u/u_{max}) contours for (a) L/d_1 = 6.7, Ri_2 = 1.8, (b) L/d_1 = 6.7, Ri_2 = 1.0, (c) L/d_1 = 4.8, Ri_2 = 1.8 and (d) L/d_1 = 4.8, Ri_2 = 1.0

downstream. This also gives rise to stretching of the two recirculation bubbles along the downstream direction as can be seen. The influence of axial separation on radial velocity distribution can easily be distinguished by comparing Figure 3(a) and 3 (c) for Ri_2 = 1.8 and 3(b) and 3(d) for Ri_2 = 1.0. When the axial separation distance is more (L/d_1 = 6.7), the effect of low pressure region in the inter-jet region is not as pronounced as when this distance is less (L/d_1 = 4.8). In Figure 3(c), the radial velocity in the inter-jet region becomes stronger and that in the opposite side almost insignificant. At lower Richardson number (Ri_2 = 1.0), the effect of axial separation can more prominently be seen. As a combined effect of low axial separation and buoyancy force, the He-jet strongly drifts towards the O_2-jet. Moreover, the recirculation bubbles become largely asymmetric about the jet axis. Figure 3(d) shows that the strong radial velocity in the inter-jet region extends further downstream when the axial separation distance is low (L/d_1 = 4.8). This is the case where the two jet interacts vigorously with each other (refer to Figure 2(d)).

Figure 4 shows the time averaged normalized axial velocity field (u/u_{max}) for the above four conditions. The individual Helium jet through the pores interacts with each other at downstream region and merges as a single jet flow. For all the four cases, the merged Helium jet is having a core positive axial velocity region. Due to the flow reversal taking place in the shear region of the jet, negative axial velocity regions also appear around the core, after a balance between the buoyancy and inertia takes place. The length of the positive axial velocity core gives an estimate of the extent of axial penetration of the jet into the ambient air and is dependent on the relative strength of buoyancy with respect to inertia force. At Ri_2 = 1.0 and L/d_1 = 6.7 (Figure 4(a)), the extent of axial velocity penetration is the lowest. Moreover, the negative velocity region is more or less symmetrically distributed around the core without influencing the O_2 jet. When the axial separation distance is decreased (L/d_1 = 4.8) at Ri_2 = 1.0, the penetration distance increases and the reversing flow with negative velocity intrudes the inter-jet region (Figure 4 (c)). When the axial separation distance is less, the presence of negatively buoyant He-jet also influences the growth of O_2 jet even at high Richardson number (Ri_2 = 1.8) of He-jet. The shear layer of O_2 jet, facing the He-jet, is distorted by the reverse flow of Helium and there is subsequent increase of velocity magnitude in the central core region of the O_2-jet. At low Richardson number (Ri_2 = 1.0) and high axial separation distance (L/d_1 = 6.7), the penetration distance increases but the negative velocity region is more or less symmetrically distributed around the positive velocity core (Figure 4(b)). On the other hand, at low axial separation (L/d_1 = 4.8) and low Richardson number (Ri_2 = 1.0), the reversing flow with negative velocity engulfs the interj-et region substantially influencing the growth of the O_2 jet (Figure 4(d)).

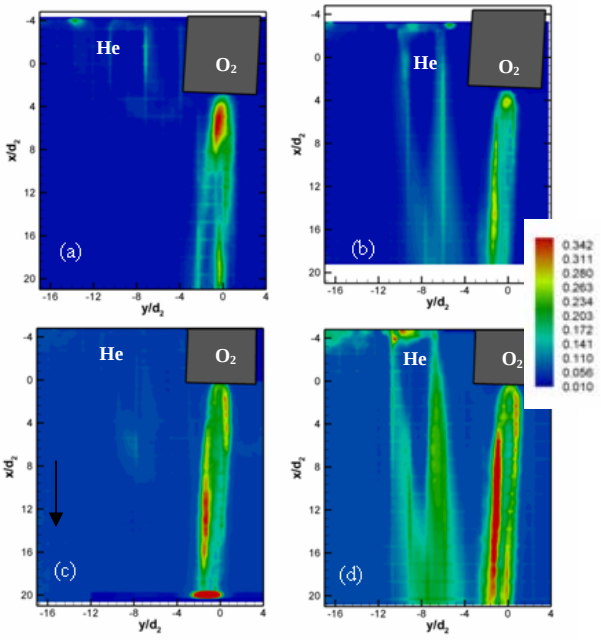

Figure 5. Turbulent kinetic energy (e_k) contours for (a) L /d_1 = 6.7, Ri_2 = 1.8, (b) L /d_1 = 6.7, Ri_2 = 1.0, (c) L /d_1 = 4.8, Ri_2 = 1.8 and (d) L /d_1 = 4.8, Ri_2 = 1.0

Turbulent kinetic energy

The overall fluctuating nature of a flow field can be understood by the total turbulent kinetic energy (e_k) of the flow. It is important for understanding the effective mixing and interaction between the two jets. The normalized total kinetic energy is calculated as

$$e_K = \frac{1}{2}\left(\frac{\langle u'u'\rangle + \langle v'v'\rangle + \langle w'w'\rangle}{U^2}\right) \quad (1)$$

Where, u', v' and w' are the fluctuating velocity in streamwise (x), radial (y) and transverse (z) directions respectively. The turbulent kinetic energy of the O_2 jet depends both on jet inertia and its interaction with the He-jet. At Ri_2 = 1.8 and L/d_1 = 6.7, a region of strong turbulent kinetic energy (e_k) appears in the near exit region of the O_2 jet. Further downstream, contours of e_k appear along the two shear layers of the O_2 jet with almost zero e_k in the central core of the O_2 jet (Figure 5 (a)). When the axial separation distance is low (L/d_1 = 4.8), the shear layer in the O_2 jet facing the He-jet encounters large fluctuations giving rise to strong turbulent kinetic energy. Figure 5 (c) shows that the distribution of e_k is uneven in the two shear layers of the O_2 jet. Due to entrainment of He-jet, the e_k concentration is much higher in the inter-jet region as compared to the opposite side. The influence of He-jet entrainment into the O_2 jet is stronger when the Richardson number is low. At Ri_2 = 1.0 the fluctuating field also becomes prominent in the He-jet (Figure 5 (b) and 5(d)) due to greater penetration depth of the jet. When both axial separation distance and Richardson number are low, there is the maximum turbulent kinetic energy appears in the mixing region of the O_2 jet. In Figure 5 (d), a very strong concentration of e_k appears in the O_2 jet along the side of the inter-jet region giving indication of maximum mixing taking place between the two jets.

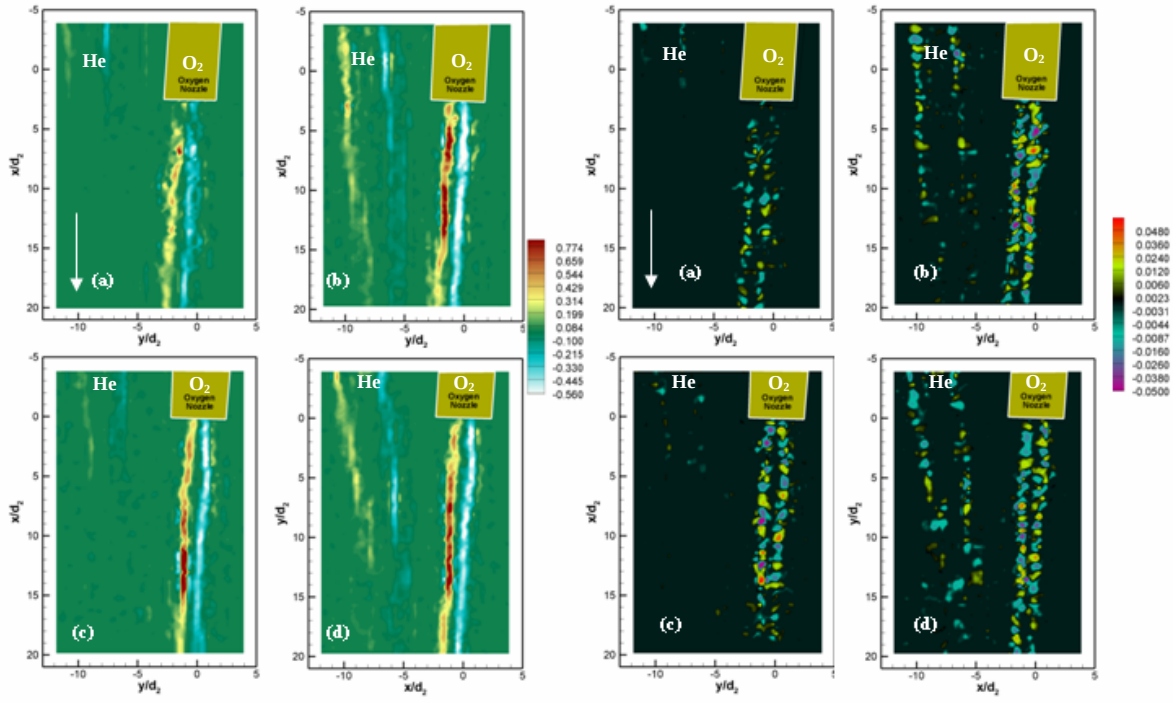

Figure 6. Instantaneous vorticity contours for (a) L /d_1 = 6.7, Ri_2 = 1.8, (b) L /d_1 = 6.7, Ri_2 = 1.0, (c) L /d_1 = 4.8, Ri_2 = 1.8 and (d) L /d_1 = 4.8, Ri_2 = 1.0

Figure 7. Instantaneous coherent structure identifiers (second invariant of velocity gradient tensor) contours for (a) L /d_1 = 6.7, Ri_2 = 1.8, (b) L /d_1 = 6.7, Ri_2 = 1.0, (c) L /d_1 = 4.8, Ri_2 = 1.8 and (d) L /d_1 = 4.8, Ri_2 = 1.0

Vortical structure identifiers

The instantaneous vorticity distribution can be used to get a picture of the behaviour of velocity shear and rotation of the fluid in motion. But vorticity distribution can not distinguish between

rotational motion associated with a vortex and shear due to velocity difference between a pair of fluid element. In jet mixing problems it is useful to find the second invariant of velocity gradient tensor ($Q = 0.5\left(tr\left(\Omega\Omega^t\right) - tr\left(SS^t\right)\right)$, where S and Ω are symmetric and anti-symmetric components of velocity gradient tensor) in order to identify the region of vortex and shear.

For the 2-dimensional flow in x–y plane, the z-component of vorticity (ω_z) is expressed as,

$$\omega_z = \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \qquad (2)$$

The 2-D simplification of quantity (Q_{2D-z}) has been calculated using:

$$Q_{2D-z} = -\left(\frac{\partial v}{\partial x}\right)\left(\frac{\partial u}{\partial y}\right) \qquad (3)$$

Implementing Richardson's finite difference method the velocity gradient field has been obtained from the PIV data. The proper implementation of vorticity (ω_z) and second invariant of velocity gradient tensor (Q_{2D-z}) calculation has been verified using a numerically generated velocity field consisting of two Oseen vortices superposed on shearing motion with tan h profile.

Figure 6 shows the instantaneous vorticity (ω_z) contours for (a) Ri_2 = 1.8, L/d_1 = 6.7, (b) Ri_2 = 1.0, L/d_1 = 4.8, (c) Ri_2 = 1.8, L/d_1 = 4.8 and (d) Ri_2 = 1.0, L/d_1 = 4.8. Figure 7 shows the second invariant of velocity gradient tensor (Q_{2D-z}) for the above four conditions. Large positive Q_{2D-z} indicates vortex core and negative values indicate straining regions. When the Richardson number is high and axial separation distance is low (Figure 6 (a)), the shear layer strength of the He-jet is not significant. As a result, the vorticity distribution in the He-jet is relatively weak. The O_2-jet shows strong shearing motions with only negative values of Q_{2D-z} without powerful vortex core zones (Figure 7(a)). At lower Richardson number and for the same axial separation between two jets, strong concentrated vorticity distribution is observed in the downstream region of the He- jet (Figure 6 (b)). The O_2-jet also shows intertwined positive and negative Q_{2D-z} regions indicating presence of both straining and rotation (Figure 7 (b)). The axial separation also has influence on the evolution and merging of vortical structures. At the same Richardson number (Ri_2 = 1.8) as that in case (a), the small scale vorticity distribution is extended further downstream for the lower axial separation distance (Figure 6 (c)). Moreover, the rotational contribution of the He-jet is prominent when the axial separation distance is less (Figure 7 (c)). At low Richardson number (Ri_2 = 1.0) and low axial separation distance (L/d_1 = 4.8), the small scale structures merge leading to extended vorticity distribution in the inter-jet region with orderly positive and negative flow structures in both the jet (Figure 6 (d) and 7(d)). This is responsible for increasing the mixing between the two jets.

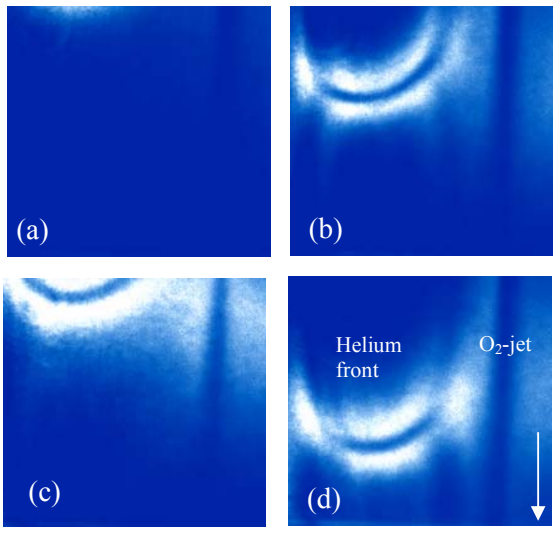

Figure 8. Instantaneous Schlieren visualization images for (a) L /d_1 = 14, Ri_2 = 0.2, (b) L /d_1 = 14, Ri_2 = 0.02, (c) L /d_1 = 10, Ri_2 = 0.2 and (d) L /d_1 = 10 Ri_2 = 0 02

Schlieren Deflectometry

Laser Schlieren deflectometry has been used to obtain the qualitative concentration distribution of mixing between He and O_2 jets in the inter-jet

region. Figure 8 shows the qualitative Schlieren visualization images in the inter-jet region for (a) Ri_2 = 1.8, L/d_1 = 6.7 (b) Ri_2 = 1.0, L/d_1 = 4.8 (c) Ri_2 = 1.8, L/d_1 = 4.8 and (d) Ri_2 = 1.0, L/d_1 = 4.8. The white region of Figure 8 is the interface between the He-jet and ambient air. The mixing between two streams leads to density gradient and hence a clear contrast in the schlieren images. When both axial separation and Richardson number are high (Figure 8 (a)), the He-jet front does not penetrate significantly into the inter-jet region. Therefore, the He-jet is visible only near the jet exit region. However, at low Richardson number and low axial separation distance (Figure 8 (d)) the front penetrates into the inter-jet region indicating higher possibility of interaction between the two jets. For all the other cases (Figure 8(b) and 8(c)), the jet front penetrates to an intermediate depth. The schlieren images in Figure 8 show similar evolution of jet boundary as that of the smoke visualization images in Figure 2. The large interaction between the two jets observed in Figure 2 (d) manifests as stronger mixing zone in the inter-jet region of Figure 8 (d).

CONCLUSION

The mixing of two separated inclined jets has been investigated using stereo PIV and laser schlieren technique. The combined effect of buoyancy and axial separation distance between the exit planes of two jets has been studied using time averaged velocity field, stream traces, total turbulent kinetic energy, instantaneous vorticity and coherent structure identifiers The Schlieren deflectometry technique has shown used for presenting both penetration depth and the mixing between two jets. It has been observed that both strength of buoyancy and axial separation distance between the exit planes of two jets are important control parameters for mixing enhancement between the two jets. Maximum mixing is observed at low Richardson number and low axial separation distance between the exit planes of two jets.

NON-STEADY FLOW IN PIPES

R. Tosato*
Department of Mechanical Engineering, University of Padua , Padova, Italy

ABSTRACT. Here the problem of a correct prediction of transient pressures and pulsations in pipes and in reciprocating compressors is considered, with a particular approach to connecting pipes and their specific boundary conditions (valves, closed and open ends, cylinder, etc.).
The possibility of employing the method of characteristics for gas flow is well known for ideal flows. We are using for real flows a numerical solution method which, in comparison with other mesh methods, decreases the mathematical errors of smearing because the influence of linearizations is much less than these mesh methods.
We suggest dividing pipes in three sections:
- the sections at the right and left ends have to be very short (only one cell) and mesh methods are used to apply the boundary conditions;
- the intermediate section is the longest part (more cells) and uses a modified inverse method which makes linear interpolations to determine $\Delta\lambda$, $\Delta\beta$ and ΔAA along characteristic lines. Linear interpolations are not used to determine λ, β and AA at initial points of characteristic lines.

Keywords: *Pipes, unsteady flow, numerical method*

INTRODUCTION

It is possible to get waves in liquids which are nominally incompressible, and these can have major effects on the behaviour of the plant in which they occur. Waterhammer, which occurs when a valve in a pipeline is closed rapidly, can generate pressures that are high enough to burst the pipe.
Unsteady gas flow occurs in many engineering fields and can have an important influence on the performances and on the design of devices if they are driven by unsteady gas dynamics. Pulsating combustion boilers are devices consistent of a constant volume combustion chamber fitted with automatic spring-loaded valves. The charge of air and gas is induced into the chamber at low pressure and then ignited by a spark. The pressure gas open the second valve and exhausted onto heat exchangers.
Pressure exchange engines is an alternative to the centrifugal compressor. The concept was to compress the air, by the direct action of another fluid, exhaust gas. The dynamic pressure exchanger has been applied as a `supercharger' for reciprocating engines.
A correct predicting of transient pressures inside the cylinder and inside the connection pipes in reciprocating compressors mainly depend from lengths of pipes and it is important because the vibrations and the life of valves are dependent from them.
The non-steady gas flow in pips is assumed to be one-dimensional with a good correspondance to the reality and two kinds of flows are usually considered:

a) the homentropic flow of a perfect gas;
b) the non-homentropic flow with area changes, friction, heat transfer and entropy gradients.

Many publications have fully described non-steady compressible flow basic equations and their solutions /1,2,3,4/.

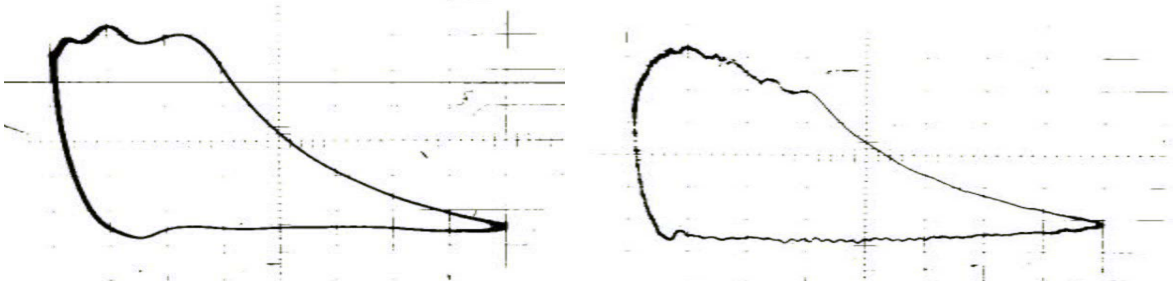

Figure 1. Experimental pressure pulsations of a compressor with long or short connecting pipes

By the method of characteristics continuity, momentum and energy conservation partial differential equations are transformed into three total differential equations (compatibility equations) along three characteristic directions:

- the path line characteristic U, - the λ characteristic U+A, - the β characteristic U-A.

The Riemann variables λ and β and the entropy level AA are used to define all physical parameters and the fluid velocity **u** in the pipe.

Non-homoentropic flow (area change, friction , heat transfer and entropy gradients):

I) <u>along a λ characteristic line</u>

a) direction condition dX/dZ = U+A = K1*λ - K2*β (1)

b) compatibility condition dA+(k-1)/2*dU = dλ = -(k-1)/2*A*U/F*dF/dX*dZ+A*dAA/AA-
-(k-1)/2*2*f*xref/D*U**3/|U|*(1-(k-1)*U/A)*dZ+(k-1)**2/2*q*xref/aref**3/A*dZ (2)

II) <u>along a β characteristic line</u>

a) direction condition dX/dZ = U-A = K2*λ - K1*β (3)

b) compatibility condition dA-(k-1)/2*dU= dβ = -(k-1)/2*A*U/F*dF/dX*dZ+A*dAA/AA+
+(k-1)/2*2*f*xref/D*U**3/|U|*(1+(k-1)*U/A)*dZ+(k-1)**2/2*q*xref/aref**3/A*dZ (4)

III) <u>along a path line U</u>

a) direction condition dX/dZ = U = (λ-β)/(k-1) (5)

b) compatibility condition dAA=(k-1)/2*AA/A**2*(q*xref/aref**3+2*f*xref/D*|U**3|)*dZ (6)

Pressure p and velocity **u** at every point are evaluated from the values of λ, β and AA at this point, by the relationships between pressures, velocity and speeds of sound:

(p/pref)**((k-1)/(2*k)) = a/aA = A/AA = (λ+β)/AA/2 (7)

u/aref=U= (λ-β)/(k-1) (8)

H**omentropic flow** (ideal gas)

Only two characteristic lines are used (λ and β) and equations (2) and (4) are simpler and reduced to dλ = dβ = 0 when the cross area F is constant.

I) <u>along a λ characteristic line</u>

a) direction condition dX/dZ = U+A = K1•λ - K2*β, (1')

b) compatibility condition dA + (k-1)/2*dU = dλ = 0 (2')

<u>II) along a β characteristic line</u>

a) direction condition dX/dZ = U-A = K2*λ - Kl*β (3')

b) compatibility condition dA-(k-1)/2*dU= dβ = 0 (4')

The graphical solution of the characteristic equations is precise, but it is only simple for homentropic flow and very complex for the non-homentropic one.

In the Example 1 in Benson's book /4/.a sudden opening of valve in pipe and discharge from a very large receiver is illustrated.

NUMERICAL SOLUTION OF EQUATIONS

Numerical solution is always preferred. It is based on the direct transformation of total differential equations (1) ... (6) into finite difference equations and on their integration advancing the solution for a series of time steps DZ and space steps DX, starting from initial conditions at time Z=0.
For non-homentropic flow, according to Zucrow and Hoffman /3/, three methods are usually employed to construct a finite difference grid and for marching through a flow field (X,Z) with a numerical algorithm:
a) the direct marching methods locate the solution point at the intersection of two characteristics (U+C, U-C or U) extending from two known initial data points; the values of flow properties at the third initial data point are evaluated by interpolation;
b) the inverse marching methods specify a priori the locations of the solution points (on lines of constant Z+ΔZ time and constant X coordinate for mesh method) and three characteristics are extended from the solution point to three initial points; three interpolations are used to determine flow properties at these initial data points;
c) the modified inverse marching methods only locate a priori the Z+ΔZ coordinate of the solution point and determine its X coordinate along a characteristic passing through one known initial point (non mesh method); two interpolations need to calculate properties at a further two initial points.

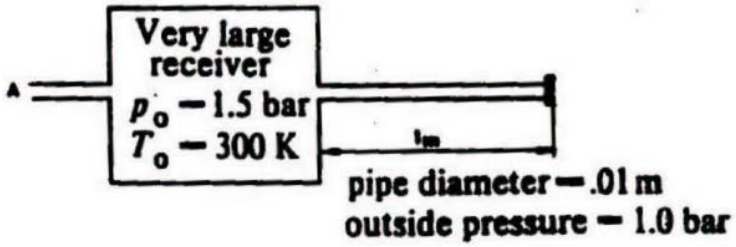

Figure 2. Example 1 (Benson's book /4/.)

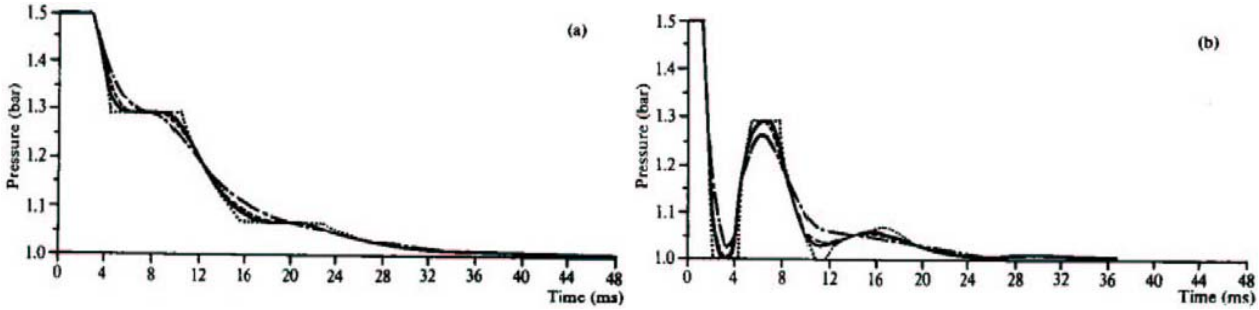

Figure 3. graphical and numerical results solving Example 1, at pipe entry a) and at mid-point b), as a function of the time T (Benson's book /4/.)

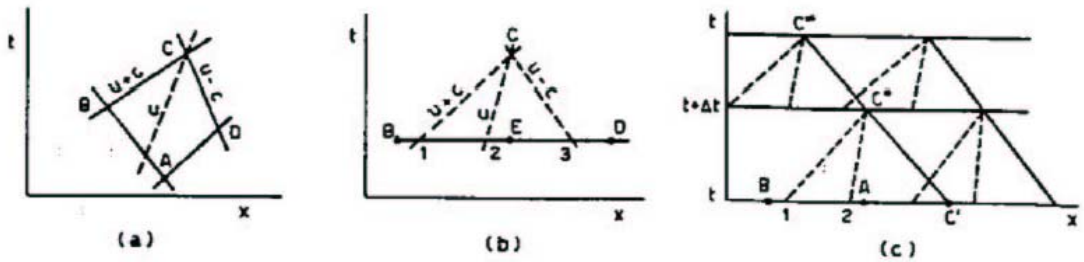

Figure 4. a) direct method, b) inverse method, .c) inverse modified method

Linear interpolations and other simplified assumptions, introduced to achieve an acceptable solution with a reasonable computing time, reduce the accuracy of the solution, in comparison with the graphical solution proposed by Jenny /5/ and experimental results. The solution is smeared and this mathematical damping prevents the model from predicting higher frequency pressure pulsations usually experimentally observed in reciprocating compressors. These pulsations have to be accounted for to simulate the dynamics of the valves.
The mesh method introduces the greatest smearing of the solution because of the amount of interpolations and because the interpolations are based on flow properties at points outside the domain of dependence.
Usual simplified assumptions are:
- the values of variables appearing in the equations are those existing at time Z;
- the characteristics connecting times Z and Z+ΔZ are straight and the slope is equal to the value at the beginning of the step;
- the pipe length is divided into a low number of elements.
- no iteration is carried out to account for the changes of variables during the step;
- a low number of characteristics is used and the total amount of old and new ones introduced at complex boundary conditions is controlled to avoid it becoming too large.
For non-homentropic flow, Pajri, Corberan and Boada /6/, discovered that the linear interpolations of λ and β along the grid interval may introduce errors and sharp pressure gradients. To improve the accuracy of numerical results, they used a modified non-mesh method along pathlines and a mesh method for λ and β calculations with linearizations made on the pressure values.
Also, the numerical solution mesh method for homentropic flow uses linear interpolations in such a way that smearing errors are still present and Benson /3/ plotted the difference of results comparing them with graphical solution results

EXPERIMENTAL AND NUMERICA RESULTS FOR SIMPLE BOUNDARY

Sudden opening of valve to the atmosphere, at total open end, different pipes are considered.
Pressure of the air in the pipe, at the closed end is plotted as function of the time, for the following test conditions:

Pipe lengths	TM =	3.20	m		Pipe diameter	DH =	2,2 1,2 0.4	cm
Initial pressare	P	=	2 bar		External pressure		=	1 bar

In Fig.4 Experimental results are compared with numerical calculations. It is possible to reduce the errors only by a high number of X points in the pipe and DZ steps near to the compatibility limit.

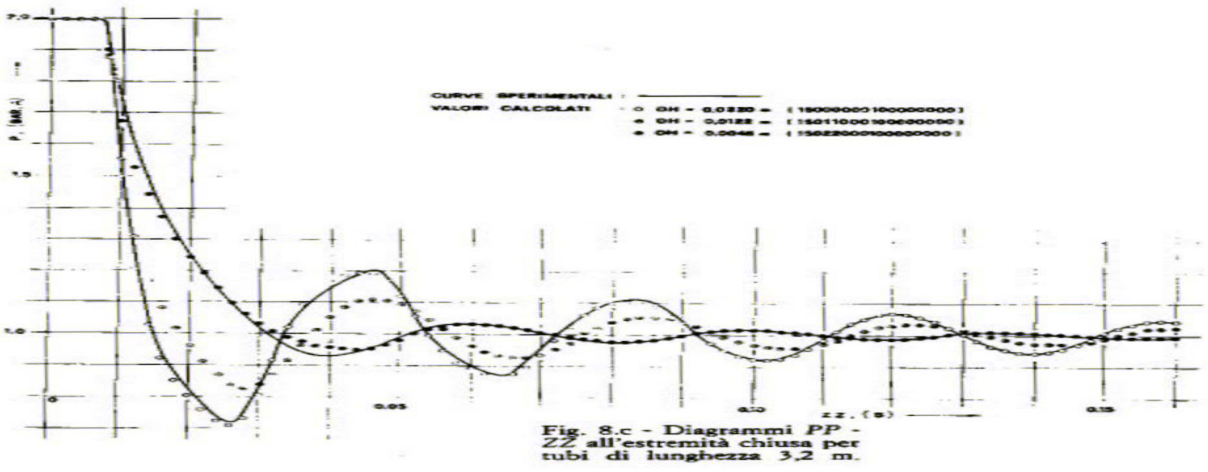

Figure 4. Experimental (------) and numerical results (…….)

CALCULATION METHOD

For pipes with the complex boundary conditions characteristic of compressors (the cylinder, valves, nozzles, junctions of pipes, sudden enlargements and contractions), the number of characteristics λ and β increases rapidly, those of the same family intersect. Algorithms become more complex and computing time longer, especially because of boundary conditions.

Internal of pipe

To reduce this problem we prefer to adopt:

- a non-mesh method, over the entire length of the pipe, to calculate AA along the U characteristics,
- a mesh method, in the cells near the boundaries, to calculate λ and β in the fixed nodes;
- a non-mesh modified method, in the interior part of the pipe, to calculate λ, and β along the corresponding characteristics;

By this method λ and β lines pass from the interior part of the pipe to the cells near the boundaries, and vice-versa, without any reflections and then without any number rise. All linearizations are avoided in the internal part of the pipe and only one characteristic, at the end of each time step, arrives at each boundary end of the pipe.

This method is also applicable in the homentropic case, without any integration of the equations along the pathlines U. Fig. 1 considers this kind of flow.

Therefore, referring to Fig. 5, we consider a pipe whose length L has been divided into a number N of equal elements. Initial conditions (λ, β and AA), at the time Z=0 and at the fixed points 1, 2, ... N+1, are known. The U characteristics start from these points, the λ characteristics from 1, 2, ... N points and the β ones from 2, 3, ... N+1 points. The same number marks a characteristic line and its intersection points with lines of Z and Z+ΔZ times.

We divided the pipe into:

I section between 1 and 2 mesh points,
II section between 2 and N mesh points,
III section between N and N+1 mesh points.

At the generic instant Z, the values of variables β, λ ed AA are known at corresponding moving points as results of previous steps. To determine flow conditions at Z+ΔZ time it is necessary to limit the value of ΔZ by the Courant-Friedrich-Lewy condition.

For all three sections we determine, at Z+ΔZ time, the positions of pathlines U (new points 1', 2', ... N+1') and the values of the variable AA (eq.6) by a non-mesh method, in these moving points, using values at old points.

Inside the I section, a mesh method is used to calculate λ at the fixed point 2, at time Z+ΔZ, using variables at points 1 and 2 at time Z.

Inside the section II we first locate the positions of new points 2", 3", ... N-1" and then, by linear interpolation, the values here of AA and of the variable ΔAA of eq. 2. The values of λ at these new moving points are calculated by eq. 2, using the variables of initial points 2", 3", ... N-1".

Inside the III section the values of λ at mesh points N and N+1 are evaluated by a mesh method using the variables at initial points N-1, N and N+1.

The calculation of β values at mesh points 1, 2 and N, inside I and III section, and at new points 3"', 4"', ... N"' inside the II section, is obviously made in the same manner and therefore we haven't described it.

The λ value in the left boundary (point 1) and β value at the right end (point N+1) are easily obtained by the well known boundary condition equations.

To increase the accuracy, an iterative procedure can be introduced using values still obtained at solution moving points at Z+ΔZ time.

Values of λ ,β and AA at mesh points, at time Z+ΔZ, are evaluated by linear interpolation.

The total number of U characteristics is maintained equal to N+1 introducing a new U line when a U line intersects the boundary ends and eliminating a U line when another U line enters from a pipe connected at the boundary end.
Also the number of λ e β lines is maintained equal to N-1 inside the II section of the pipe. When two lines of the same family intersect, they are substituted by only one or by two close and parallel characteristics.
For the first time step, the method is the same, the difference being that at the initial time all moving points are coincident with fixed mesh points.

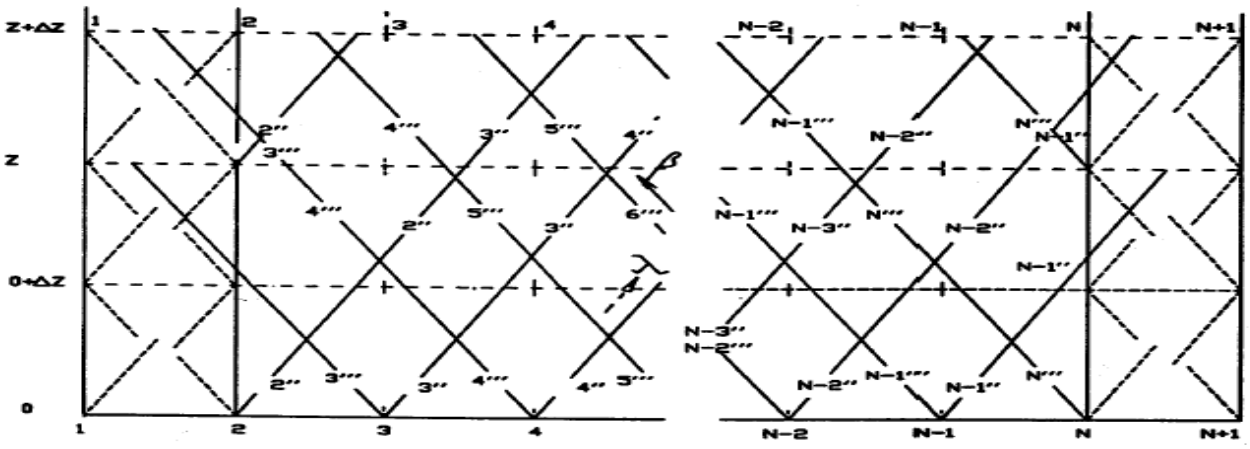

fig. 5. Characteristics λ and moving points 2", 3", N-1", characteristics β and moving points 3"', 4"', ..., N"', fixed points in the position diagram, for a homentropic flow, in a pipe with N intervals.

Boundary Conditions
Only one characteristic arrives at the pipe-end at the end of the time step and this is the simplest way to solve boundary condition calculations. The use of specific equations is done at the end of the time step.

TEST OF NUMERICAL METHOD FOR HOMENTROPIC FLOW
The proposed method can be adopted to simulate non-steady flow in reciprocating compressors and their piping systems. To show the accuracy of results Example 1 of homentropic flow is simulated and compared with graphical solution. illustrated in Benson's book /4/.
In order to test the numerical method, a Fortran program was written to simulate homentropic flow. Two subroutines allow to evaluate the positions of Riemann characteristics and the values of λ e β at moving and mesh points. Other subroutines simulate the normal boundary conditions of compressor pipes. The program considers the total number N of elements of three sections as a variable and it is possible to vary, from 2 to N, the number of cells of external sectors I and II in order to evaluate the influence of linearizations. No iteration procedure is used.
In this example a pipe connects an infinite reservoir, at the pressure of 1.5 bar and temperature of 300 K, to the atmosphere. The air (k=1.4) flows through the pipe, 1 m long, when the atmospheric end of the pipe is suddenly opened. Waves which start from the atmospheric end propagate as rarefaction to the reservoir side and reflect as compression waves which travel to the atmospheric end.
Pressures P1 at the open end, P3 at pipe entry and P2 at mid-point, when N=40, 30, 20 (continuous lines) and N=10 (dotted line) and only for one mesh in section I and III, are plotted against the time T, in fig. 6.

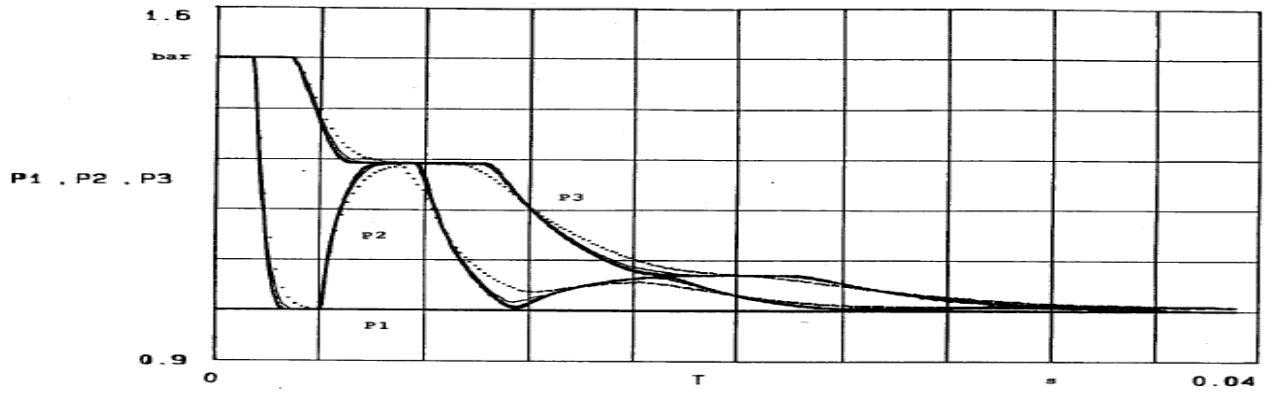

Figure. 6. Pressures at the open end P1, at pipe entry P3 and at mid-point P2, as a function of the time T. Effect of the number N of meshes on the accuracy.

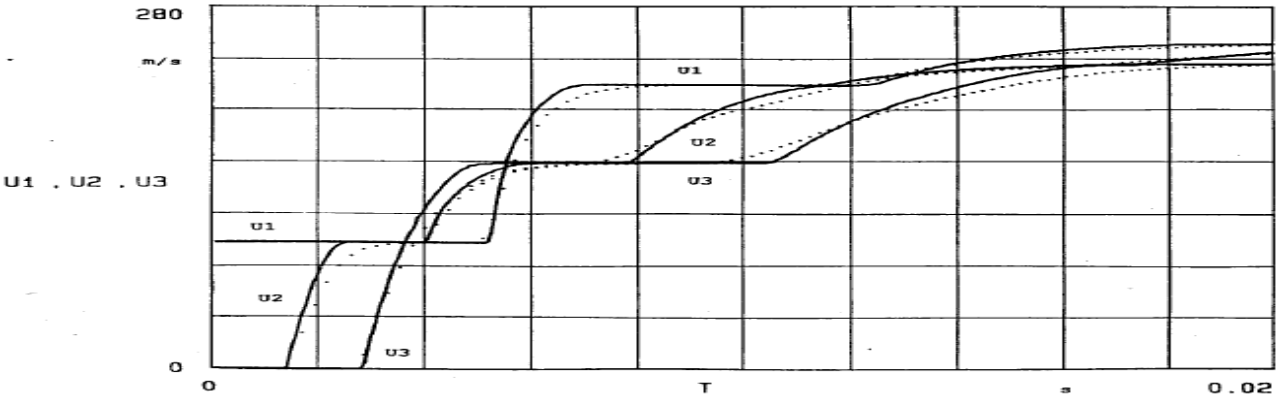

fig. 7. Velocity U1, U2 and U3 curves.

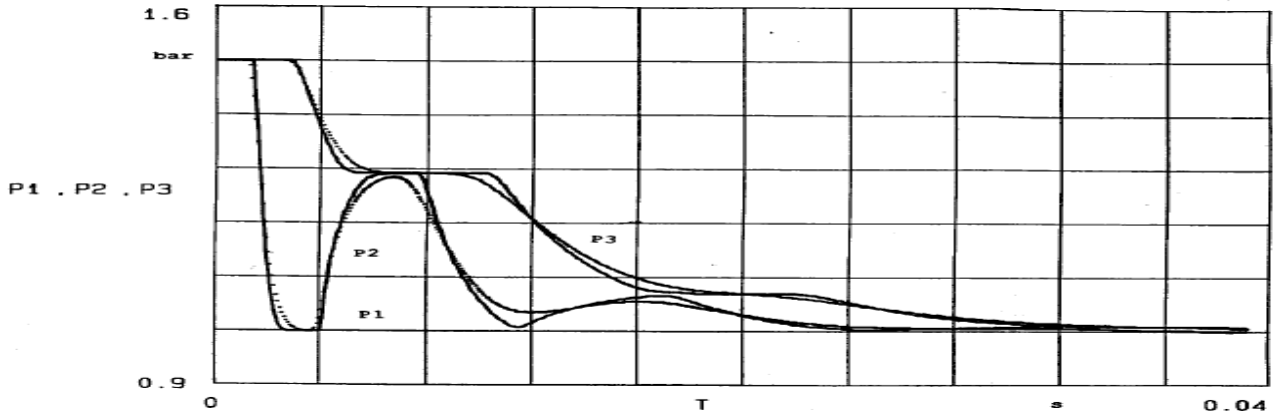

fig. 8. Comparison between mesh method (dotted lines) and the proposed method (continuous line) for N=30. Effect of linearizations.

Velocity diagrams of the same points are plotted in fig. 7.
For N=40, 30 and 20 these diagrams are very close to results obtained by graphical method. The shapes of the curves are not smoothed out and for this reason the method is able to simulate high frequency pressure pulsations.
Pressure diagrams calculated by the proposed method (continuous line) and by mesh-method (dotted line) are plotted in Fig. 8, with N=30.

CONCLUSIONS

Theoretical analysis has been carried on for homentropic flow in a pipe and compared with results obtained by graphical solution. Information on the possibility for the model to represent the flow with a high degree of accuracy is positive. The influence of residual linearizations still present in the proposed method is negligible, if the pipe is divided into a number of finite elements higher than 20. The method here described for homentropic and non-homentropic flow achieves, in this condition, the same accuracy as the graphical method of characteristics.

DEVELOPMENT OF CAPILLARY MOTION AT THE FREE SURFACE OF A FLUID

M.O. Denisova*, K.G. Kostarev
Institute of Continuous Media Mechanics UB RAS, 614013 Perm, Russia

ABSTRACT. The experiments on studying the solutal flows near the gas bubbles and liquid drops in narrow channels filled with inhomogeneous solutions of surfactants have shown that the development of capillary motion occurs with a considerable time delay with respect to the time of formation of the surfactant concentration gradient at the interface. To ascertain the reason of this phenomenon we investigated the development of the Marangoni convection in the vertical Hele-Shaw cells of varying thickness partially filled with water. The capillary motion was initiated by local injection of the droplet of surfactant solution of onto the free surface of water. The resulting distribution of the surfactant in the near-surface volume of water was visualized by the interference method.
The conducted experiment has provided supporting evidence for the view that the development of the capillary motion at the horizontal free surface is also of the threshold nature. It has been found that the value of the surfactant concentration threshold abruptly increases with the increase of the cuvette thickness and the initial concentration of the alcohol in water (in case when the alcohol solutions are used instead of water).

Keywords: surfactant, free surface, Marangoni convection

INTRODUCTION

It is well known that the Marangoni convection is a fluid motion driven by the capillary forces at the interface. These forces carry the fluid toward the regions with higher surface tension. In general, these are the regions with lower temperature and/or the regions with lower concentration of a surface-active substance (surfactant).
Since Newtonian fluids have zero force of rest friction, it is generally assumed that their free surface begins to move even at an arbitrary small difference in surface tension. On the other hand, in some cases for example in the case of surfactant diffusion from a drop of binary mixture into the surrounding homogeneous fluid the development of the Marangoni effects begins only at a certain proportion of liquid components in a drop[1]. A delay in the development of capillary motion is also observed in experiments investigating inhomogeneous surfactant solutions with gas and liquid inclusions [2,3] and buoyancy of higher concentration jets from the submerged surfactant sources [4,5]. The use of interferometry in these experiments provides visual evidence that interface motion begins only after formation of a marked (up to several percents) difference in the surfactant concentration. Moreover, in the case of a drop, initiation of the capillary motion is observed just after penetration of a surfactant through the interface and formation of its initial distribution in the drop. The analysis of the obtained results shows that it would seem more reasonable to relate the appearance of the surfactant concentration threshold in the observed phenomena to the existence of the original adsorption layer at the surface of a Newtonian fluid, owing to which the fluid acquires

rheological properties. The source of the layer is a group of surfactants non-removable by standard purification methods

The objective of this study is to determine experimentally the conditions favorable for development of the solutal Marangoni convection. Consideration was given to the process of initiation of a capillary motion due to local injection of a droplet of a controllable surfactant with concentration C_d onto the free surface of distillate or a water solution of this surfactant with lower concentration C_s.

In the experiment, the role of the controllable surfactant was played by isopropyl alcohol diluted with water to weight concentration of 0.5 to 15%. To generate a droplet of such a solution with a volume of 5 μL we used a mechanical pipettor with accuracy of 0.1 μL. manufactured by BIOHIT company. Then the formed drop smoothly came into contact with a free surface of a basic fluid or was injected into the fluid near its free surface.

The cuvette filled with a basic fluid had the form of a vertical rectangular cavity with dimensions of 90×40 mm and thickness b ranging from 1.2 to 20 mm. The walls of the cuvette were formed by parallel glass plates covered with a semi-transparent mirror film which with appropriate adjustment allowed us to create a working cell of the Fiseau interferometer for making observation of the concentration fields on the side of a wide face.

In view of the supposition that a certain amount of uncontrollable surfactant always exists on the fluid surface one could infer that the amount of such surfactants is specified both by the degree of purification of the fluid and by quality of cuvette preparation. In our experiments, for the zero level of preparation we adopted the threshold for initiation of the solutal Marangoni convection in distillate or in a water solution of isopropyl alcohol in the cuvette, which was washed three times by isopropyl alcohol, then, during 15 minutes, by running water and finally by distillate. Such cleaning procedure was widely used in investigations described in works [2,3] because it allowed us to get clear of the “traces” of fluids used for creation of drops insoluble in water.

The improvements in preparation of the cuvette led to development of a new technique according to which a cuvette after each series of tests was filled with 10% solution of a detergent “7X Serva” for a long period of time (~12 hours) and then was washed several times with concentrated detergent “Fairy” accompanied with mechanical cleaning of the cuvette walls after which it was washed for an hour with running water and a liter of distillate.

The next step toward improvement of the process of water purification was the use of deionizer “Vodoley” manufactured by Khimelectronika company (Moscow, Russia). The distilled water was passed three times through the device until its electrical conductivity was reduced by an order of magnitude (from 2.4 to 0.15 μS/cm). Deionized water was used in the experiments as a basic fluid and for final washing of the cuvette (repeated several times).

The result of such careful preparation of the cuvette was high purity of the free surface of the fluid filling the cuvette. A need for preliminary cleaning of the cuvette was supported by a number of tests with alcohol solutions, in which a noticeable evaporation of the alcohol and the resulting surface motion began already at $C_s = 4\%$ (in solutions prepared on the basis of a standard distillate the alcohol evaporation could be observed at $C_s > 10\%$ and only due to a sweat appeared on the glass walls) In view of these circumstances, an equilibrium distribution of the alcohol, at which the free surface of the working fluid remained stationary, could be obtained only by isolating the cuvette from the environment by means of a special cover with a hole for drop injections.

The interference patterns formed in the cuvette were recorded by a video camera. In thin cuvettes, such as the Hele-Shaw cells the majority of flows and concentration fields had a two-dimensional structure. Therefore, the optical path of the interferometer transmitted beam was dependent only on the cuvette thickness and the content of admixture in a fluid in the plane of wide cuvette faces. Thus, for cuvette of thickness $b = 3.8$ mm a transition from one interference band to another corresponded to a change in concentration of isopropyl alcohol in water by 0.085%.

During tests the ambient temperature and the fluid temperature was (24±1)°C.

RESULTS

At first, the development of convective motion was investigated in the situation, in which a drop of the surfactant solution was injected onto the free surface on the side of a gas phase. In this case, a drop hanging at the end of the needle was put slowly to the surface of the fluid. As soon as the drop touched the surface it was sucked into the bulk of water under the action of capillary forces minimizing the arising total surface (Figure 1*a*). As a result, the surfactant lying on the drop surface immediately landed up on the surface of the fluid.

When a drop of the surfactant solution was introduced on the side of the liquid phase it didn't deform the free surface of the fluid, although the time the drop took to reach the interface as a buoyant jet (Figure 1*e*) was rather long. Despite the fact that the whole bulk of the surfactant solution rose to the surface as a single portion it did not have its own surface. Therefore the processes of mixing and dissolution began well before the surfactant reached the fluid surface and caused a decrease in concentration of the solution coming into contact with the fluid surface.

The experiments showed that the initiation of a capillary motion on a horizontal free surface of the working fluid occurs in a threshold manner like in the case of curved interfaces [2.3]. An example is given in Figure 1, which shows a series of interferograms of the concentration field in the case when surfactant concentration in the drop is higher than the threshold value for a given thickness of the cuvette. Therefore, as soon as the drop reaches the fluid surface, there appears an intensive but rapidly damping capillary motion in the form of two cells (Figure 1b – 1c) or two convective cell trains (Figure 1f – 1g) [4].

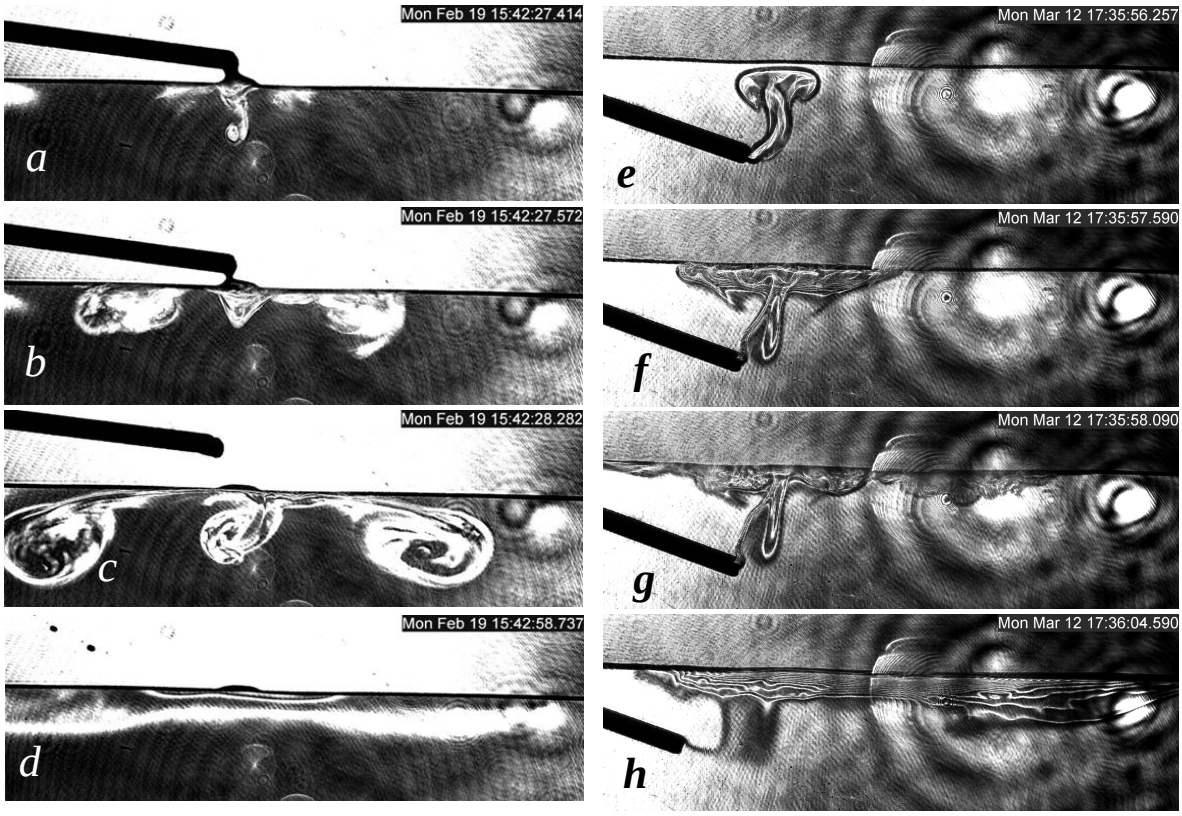

Figure 1. Injection of a drop of the surfactant solution onto the free surface of water in cuvette b = 1.2 mm on the side of gas phase(the elapsed time t, s: a – 0.2; b – 0.4; c– 0.9; d – 31.4), C_d = 6%; on the side of liquid phase (the elapsed time t, s: e – 0.8; f – 2.1, g – 2.6, h – 9.1) C_d = 12%

As it might be expected, the value of the surfactant concentration threshold decreases with increasing the degree of preliminary water purification and cleaning of the cuvette walls. Figure 2 shows the dependence of the threshold difference ΔC in the initial alcohol concentration between the droplet and the basic fluid on its content in the fluid and the degree of purification. It is seen that the use of a new procedure for preparation of the cuvette and deionization of water reduces the value of the threshold by 50%, yet a non-threshold development of solutal-capillary convection has not been achieved. Note that a similar behavior of the water surface is observed after injection of a microdrop of the surfactant on the side of the gas phase: a threshold value of the concentration difference is 7.0% for distillate, 5.0%- for distillate in the cuvette prepared in accordance with the new purification procedure and 3.0% - for deionized water and cleaned cuvette (cuvette thickness b = 3.8 mm).

As it is evident from Figure 2, the value of the threshold essentially depends on the content of an alcohol in water reaching a maximal value at minimal concentration of the surfactant in the solution. The obtained results confirm the supposition as to a complicated composition of the group of surfactants forming the initial adsorption layer at the free surface of the fluid. Most of the have the boiling point lower than 100°C and therefore survive during water distillation. Half of the surfactants (group *A*) can be removed by means of ion-exchange filter and cleaning of cuvette walls. The second half (group *B*) do not have electrical charges and therefore stay in the solution. Co-linearity of curves *1* and *2* in Figure 2 means that the surfactants of the group *A* are not sensitive to changes in the concentration of the alcohol in water and are held on the fluid surface as separate molecules. By contrast, the surfactants of the group *B* form the so-called hard film [6]. An increase of the alcohol concentration in a basic fluid gradually destroys the film but does not remove molecules of the surfactants from the surface which preserves conditions for delay of motion.

The assumption concerning the properties of the film formed by surfactants of the group *B* is supported by its poor deformability in thin cuvettes which is the reason for adding a greater amount of the alcohol for sustaining of capillary convection (Figure 3). Moreover, convergence of curves *1* and *2* in the region of small thickness of the cuvette cavity suggests that for thinner cuvettes the degree of purification is less important than for cuvettes with relatively large area of the free surface.

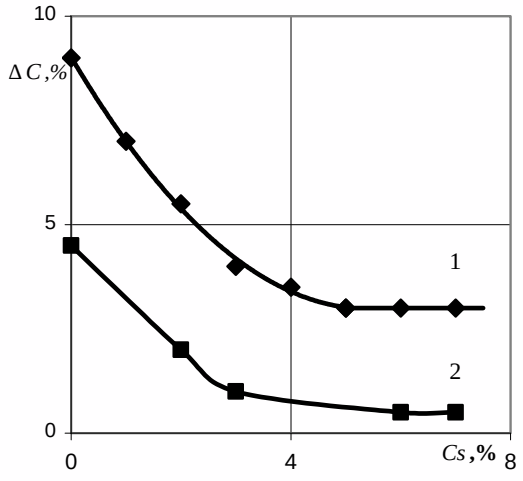

Figure 2. Threshold difference of alcohol concentration *versus* alcohol concentration in the basic fluid for different degrees of water purification: 1- distillate, 2 –deionized water Injection of the surfactant on the side of liquid phase (b =3.8 mm)

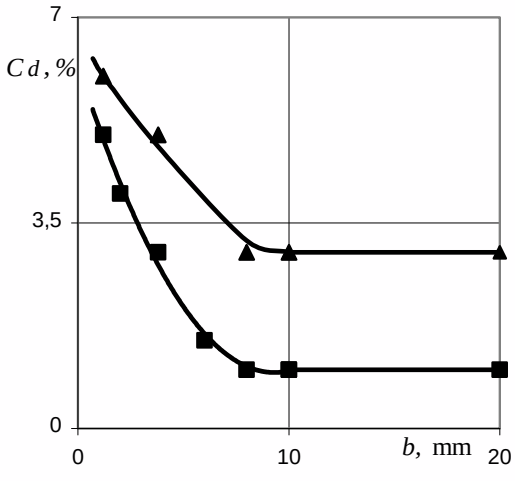

Figure 3. Threshold concentration of alcohol *versus* cuvette thickness for different degrees of water purification: 1- distillate, 2 –deionized water. Injection of the surfactant on the side of gas phase

Of no less importance for overcoming the threshold and development of the capillary motion is the direction in which the drop of the alcohol solution is injected onto the surface of the basic fluid. Figure 4 shows that for deionized water the value of the threshold decreases by 1.5 times in the case when the alcohol is introduced on the side of the gas phase (then, initial rupture of the film of non-controllable surfactants is realized mechanically). With the growth of alcohol concentration in the basic solution the threshold concentration difference rapidly decreases, and curves for different directions of surfactant injection converge until they coincide at C_s~ 4 – 6% and then tend to an asymptotic value, which in the examined interval C_s remains non-zero (ΔC ~0.5%). It should be noted that an increase in the surfactant concentration reduces the surface tension of the basic solution which provides explanation for the fact that the observed tendency to reducing the concentration threshold with increase of C_s agrees well with the results of investigations concerning development of capillary convection on the free surface of gas bubbles in vertically stratified solutions of some surfactants [2].

In cuvettes of different thickness and, accordingly, with different characteristic dimensions of the free surface, the direction of surfactant injection has a much greater effect on the development of capillary motion (Figure 5) Thus after injection of a droplet on the side of the gas phase the resulting local rupture of the adsorption layer accompanied by formation of longitudinal gradient of alcohol concentration at the surface of deionized water reduces the concentration threshold for initiation of the solutal Marangoni convection approximately by 3 times for all cuvettes used in the tests.

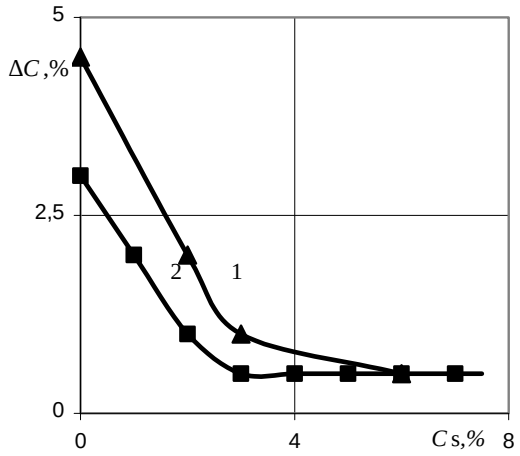

Figure 4.Threshold difference of alcohol concentration *versus* alcohol content in the basic fluid in the case of drop injection on the side of liquid*(1)* and gas *(2)* phase (b =3.8 mm)

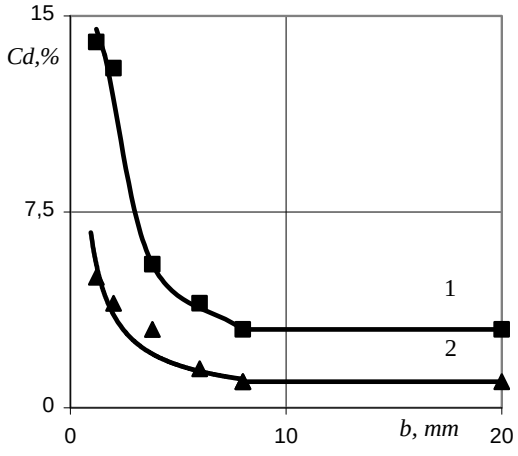

Figure 5. Threshold alcohol concentration *versus* cuvette thickness in the case of drop injection on the side of liquid *(1)* and gas *(2)* phase

An abrupt decrease of the concentration threshold in cuvettes of thickness more than 10mm accounts for the fact that retardation of the Marangoni motion is not discussed in most of the problems considering stability of shallow layers and films. It is also of interest to analyze the results of tests in which the boundary of the free surface of the basic fluid (water) coincides with the edge of the cuvette which allows us to change the curvature of the free surface and, respectively, the length of the arc connecting the walls of the cuvette, keeping the characteristic dimensions of the

cavity unchanged. The tests showed that in the absence of meniscus (the length of the arc is minimal) the concentration threshold increases markedly *(*ΔC =7%), whereas in the presence of the meniscus (no matter whether it is convex or concave) the concentration threshold decreases (ΔC = 5% at the meniscus deflection of 1.1-1.3 mm beneath or above the horizontal plane for cuvette with b =3.8 mm).

CONCLUSIONS

The performed experiments support the view that the reason for the observed delay in the development of the capillary motion at the surface of water and water solutions is the adsorption layer which is formed on the basis of surfactants showing different properties. Some of the surfactants can be removed by preliminary purification of water with the aid of ion –exchange filters. However even the remaining part of surfactants will suffice for generation of a rather high concentration threshold especially in the case of a free surface or interface with small characteristic dimensions. The observed effect may exert an essential influence on the mass transfer processes which occur in technological setups using drops and gas bubbles and are the object of investigations in chemistry, cellular biology and in microfluidics problems.

ABSTRACT. The present work deals with the common "twin jets in crossflow" configuration due to its wide presence in different applications and to its tight relationship with different domains. The jets handled in this experimental study are inclined, arranged inline with the oncoming crossflow and emitted according to different jet to mainstream velocity rates. Our main goal is to determine the influence of this parameter on the different characterizing features of the resulting flowfield and more particularly on the dynamic ones. The developed vortical structures as well as the velocity fields are some of these features and if they raise such an increasing interest; it is due to their close relation with various environmental problems and technical constraints. The examined data are experimentally depicted by means of the Particle Image Velocimetry (PIV) technique and the flow visualizations are realized by means of a CCD camera.

Keywords: *twin jets, crossflow, injection ratio, velocity field, vortical structures*

INTRODUCTION

Several industrial and/or academic applications make use of the common "Twin jets in crossflow" configuration. The most familiar industrial application making use of this configuration is without any doubt the chimney stacks exhaust. It is however found in further applications like the VSTOL aircrafts, the discharge of the liquid effluents through piping systems, the film cooling of turbine blades, the combustor wall cooling, the injection of gas in combustion or any other chemical chambers; etc...These various applications state of the wide applicability of the twin jets in crossflow configuration in several domains, of the different technical constraints to which it may be confronted, of the various environmental drawbacks it may engender, etc… These factors and others have largely enhanced the research on this particular theme.

Ziegler et al. [1] are pioneers in the domain since they considered the question since the early seventies by simulating the behavior of both side-by-side and tandem twin jets exhausting normally into a Crossflow. The elaborated physical model was based upon experimental data and allowed the description of the resulting flowfield mechanisms like the shielding effect provided by the upstream jet on the following one, the influence of the presence of the jets on each others, etc… It also justified the deflection of each of the jets in terms of the entrainment of the mainstream fluid and of the pressure forces acting on the jets' boundaries.

Schwendemann [2] considered the same arrangements but proceeded exclusively experimentally. The jets were also considered at different initial inclination angles in order to compare their trajectories. A further experimental consideration of both arrangements has been performed by

DiMicco et al. [3]. It was particularly dedicated to the different interactions taking place both between the emitted jets, and between the jets and the mainstream. The experiments captured by means of flow visualization; tested the impact of both the jet centerline-to-centerline spacing and the momentum flux ratio on the penetration of the jets. It was shown that the reduction of these parameters decreases the penetration of the jets among the main stream. In a second part, DiMicco et al. [4] demonstrated the insignificance of the effect of the momentum flux ratio on the depth penetration under different angular orientations and over a jet-spacing/diameter range contained between 2.7 and 12.1. This statement seems however no longer true under the largest spacing and at the lowest momentum ratio. Structurally speaking, constructive and destructive interferences take place as both the angular orientation and the jet spacing are changed. In a try to extend previous results, Kolar et al. [5] chose to consider experimentally the same arrangements (tandem and side by side) to explore a further feature: the distribution of the developed vortical structures and their overall circulation that was quite similar to the contrarotating vortex pair relatively to the single jet case.

Further authors restrained their attention to the twin inline jets in crossflow and confronted their behavior to that of the single jets in crossflow. This is the case of Disimile et al.[6] whose experimentations resulted in a relation between the jets development and some of their geometric parameters such as the jet-nozzle spacing and the jet to mainstream velocity ratio. The video digitization allowed also the determination of the average penetration of the jets within the crossflow and proved the similarity of the twin and single jets in crossflow characteristics.

The PIV experiments of Ibrahim and Gutmark [7] evaluated the impact of a further parameter; the injection ratio; on both single and double jets' evolutions. This impact was explored on different dynamic features such as the jets trajectories and penetration, the deflection of the jets trajectories, the mass entrainment approximation based on the jets trajectories, the windward and leeward jets spread, the size, location and magnitude of the reverse flow regions, etc…the turbulent kinetic energy proved that the behavior of a double jet in a tandem setup follows the same trend as that of a higher blowing ratio single jet in crossflow.

More recent works elaborated numerically by Radhouane et al. [8, 9] were exclusively devoted to the twin inline jets in Crossflow. The first one ([8]) examined rather the global behavior of the twin jets while progressing within the environing flow and gave even an overall idea about the influence of the injection ratio on the temperature distribution. The second ([9]) focused more deeply on the thermal distributions and cartographies and on their variation under a changing injection ratio.

In the present work, we propose to evaluate the influence of this same parameter (the injection ratio) but on the dynamic features of the resulting flowfield. The latter enclose the different velocity distributions as well as the established vortical structures whose understanding is as already said of a great relevance.

EXPERIMENTAL SET-UP

Consideration was given to two tandem inclined jets inline with the oncoming crossflow; both interacting flows are fed with air. In spite of its simplicity, the geometric configuration is however delicate to build due to the inclination of the jets and to the feeding of their corresponding nozzles by the same main air supply. For the matter, a 10 mm diameter cylindrical pipe is inclined and then connected to two further similar ones that are inclined according to the same angle. The nozzles are then razed at the level of the injection plate that is actually the ground of the experimental wind tunnel (figure 1). This operation generates two identical elliptic exit sections characterized by a small and a grand diameter respectively equivalent to d and $d/\sin\alpha$. The inclination angle of the jets is maintained constant in the present experimentations and equivalent to 60° with reference to the longitudinal leading direction (x coordinate). The centers of the jet nozzles are separated by a distance of D=3d and the emitted jets together with the oncoming crossflow are finally discharged to the atmosphere outside the laboratory through an exit cross section whose dimensions are 0.2m in width and 0.3 m in height.

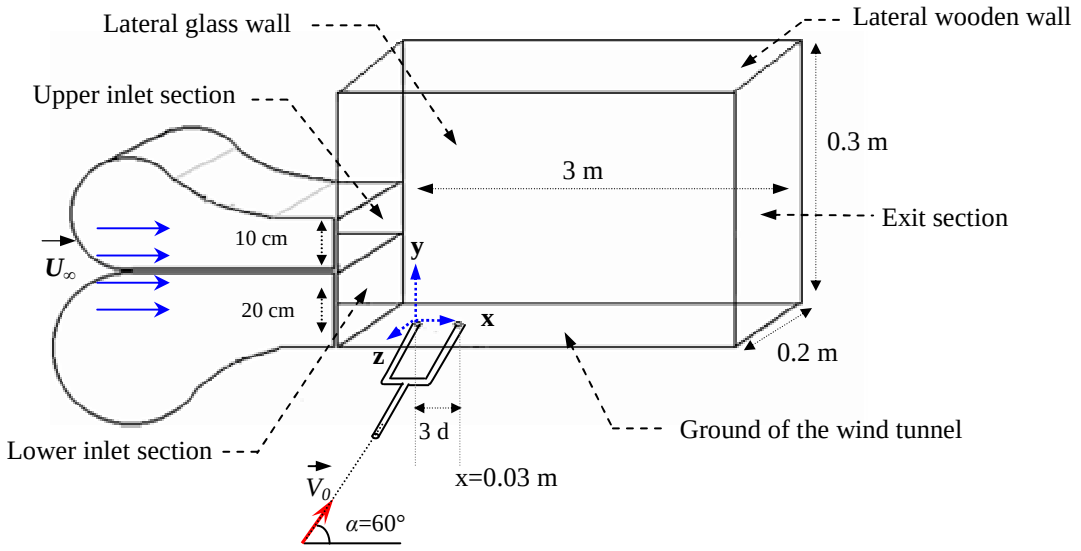

Figure 1. Description of the experimental set-up

The whole tunnel is characterized by an open top wall. The ground is made of wood and covered with plastic for the particle image velocimetry (PIV) technique and the visualizations requirements. One of the lateral sides is made of wood and painted black in order to reduce the possible light reflection. As to the second side, it is made of Pyrex to allow the optical access and then the observation of the interacting flows' progression.

A diffuser initially present at the entrance of the tunnel is removed during the experiments only for more commodities. The engendered sudden diameter change is likely to affect the flow dynamics, that's why we placed the jet nozzles approximately 2.5 m farther from the tunnel entrance. This disposition proved to be efficient. In fact, the mainstream velocities depicted by means of the hot wire anemometry technique showed a 10 mm width shear layer (figure 2) and a global turbulence intensity level that did not go beyond the percentage of 0.2%.

The velocity of the oncoming crossflow is actually generated by engines implanted at the entrance of the tunnel. The one relative to the lower inlet section generates velocities ranging between 0 and 16 m/s whereas the upper inlet section introduces velocities varying between 0 and 42 m/s. In our work, velocities will not go beyond 10 m/s that's why we will only use the lower inlet section.

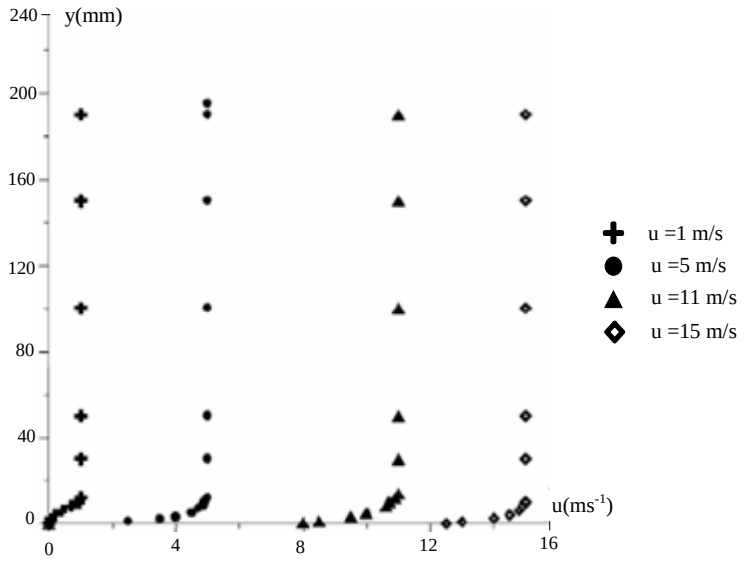

Figure 2. Velocity Profiles of the mainstream at the entrance of the test cross section (at x=0.2 m)

As already said, both jets are fed with the same main air supply. To detect the flows' progression, we added seeding particles. The jets are seeded with glycerin particles whose diameter is approximately equivalent to 1 µm (the seeding density is approximately 30 particles per ml of pure jet fluid). As to the main air flow, it is seeded with oil droplets of approximately 0.8 µm diameter, and is introduced into the tunnel at the ambient temperature (T_∞)

To be able to characterize well and locate the different flow features, we chose a Cartesian coordinate system whose origin is located at the upstream jet nozzle center. This choice is motivated by the possible asymmetry of the resulting flowfield in spite of the symmetry of the geometry as stated in the literature by several authors like Smith et al.[10], Muppidi et al.[11], Yuan et al. [12], etc…

Once the geometry built and the jets and the main air flow emitted; we proceed to the different two dimensional measurements by means of the particle image velocimetry (PIV) technique together with a CCD camera; the lateral behavior having been kept for a later exploration in future works.

The adopted technique (PIV) is essentially based upon a TSI PowerView system, including a 50 mJ dual YAG laser producing two flat pulses, the duration of one ranging from 5×10^{-9} to 10^{-8} seconds, a PowerView 4M high resolution cross-correlation camera (2 k × 2 k resolution, 12 bits), a synchronizer and "Insight" Windows-based software for acquisition, processing and post-processing. This software allows the synchronization of pulsations according to the observed phenomena, and the adjustment of the time step between two images. The final fields are averages performed on 100 successive acquisitions. For each point, experimental uncertainties were estimated as follows: $\frac{V_{\max} - V_{\min}}{V_{av}}$ where V_{max}, V_{min} and V_{av} are, respectively, the maximum velocity, the minimum velocity and the average velocity measured over the whole process. These uncertainties were about 5%.

Now that we defined the geometry and measurements technique, we propose to begin with the examination of the global structural evolution of the jets under a variable injection ratio. The images of the resulting flowfield are taken at the symmetry plane (z=0) and in the vicinity of the jet nozzles where the most significant interactions take place (figure 3). We even confronted them to the infinite injection ratio case (free jets in absence of crossflow) in order to find out the impact of its existence on the emitted jets. The variation of the ratio between the jets velocity and the one relative to the mainstream proved to highly affect the whole resulting flowfield structures. Figure 3 represents only the leading edge and the wake vortices as only theses can be observed on the symmetry plane (z=0). The first type vortices, also called jet shear layer vortices or ring vortices, develop on the upper periphery of the evolving jets and result from the direct interaction of the jets with the environing flow. They are quasi-steady and are a consequence of the Kelvin-Helmholtz instability established at the annular shear layer that separates from the edges of the injectors.

The second, the wake vortices, are also known as upright vortices, zipper vortices, tornado like vortices or Fric's vortices since they were first identified by Fric and Roshko [13]. They develop rather between the lower side of the jets and the injection plate. The upright vortices appellation comes from the fact that one side of the vortex string is connected to the jets and follows their trajectories whereas the other end stays close to the cross flow wall, positioning the vortex in an upright orientation.

The impact of the injection ratio on these two main features is summed up in the three following major points. The first one consists in the farther emission of the jets from the injection plate under an increasing velocity ratio thanks to the greater initial impulse brought to the jets. When on the contrary the injection ratio declines, the jets are rapidly confined against the injection plate. This shows the close relationship existing between the different flows interactions and progression and the imposed velocity ratio. It is like a duel between the emitted jets and the oncoming crossflow that is won by the flow characterized by the more significant velocity. The flow detaining the higher velocity is then more likely to impose itself: its trajectory, its magnitude, etc…

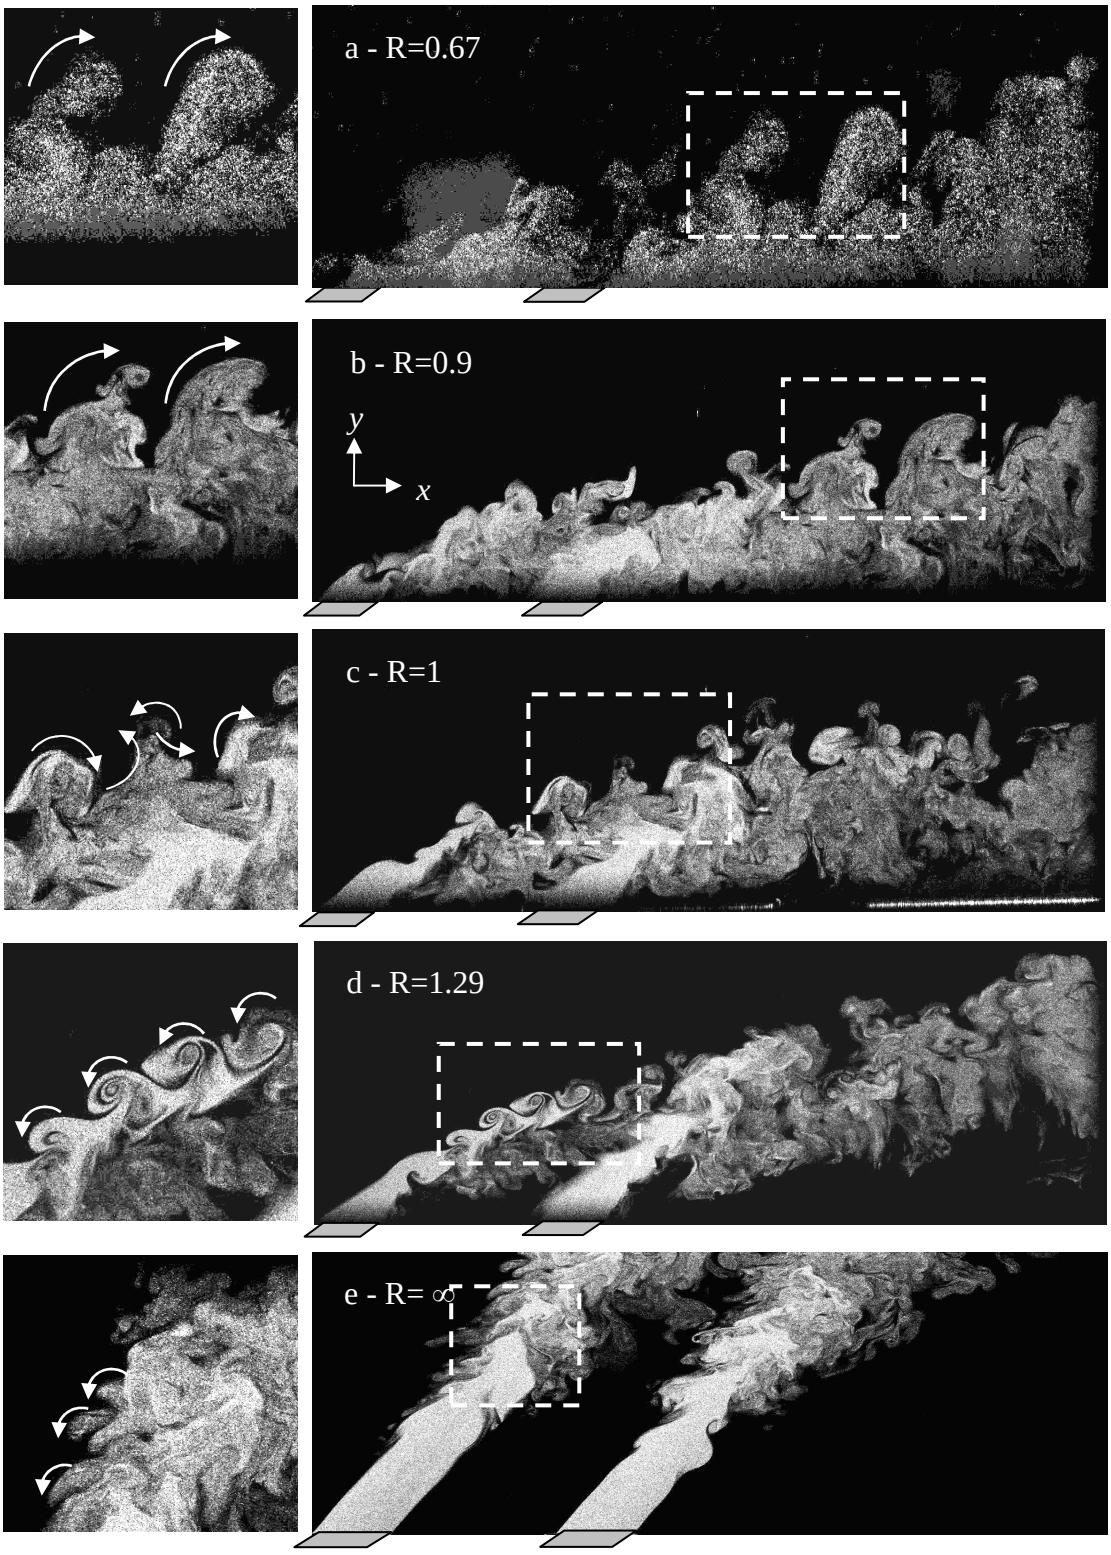

Figure 3. Impact of the injection ratio on the development and orientation of the resulting flow vortical structures on the symmetry plane (z=0)

So if the jets are confined against the injection plate under the weaker velocity ratios (fig. 3-a and b) it's due to the larger scale of the environing flow with reference to the emitted jets. The latter are consequently immediately deflected by the crossflow and flattened against the injection plate preventing them from fleeing it freely as it is the case in absence of crossflow when R=∞ (fig. 3-e). The flattening and deflecting processes are more manifest on the upstream jet due to its prior

confrontation with the oncoming mainstream. It is on the other hand sensibly reduced on the downstream jet thanks to the shielding effect brought to it by the rear jet.
When on the contrary the injection rate rises, the jets gain in strength with reference to the mainstream. They are consequently more likely to confront it and even to resist to its flattening effect. Of course this resistance is not total as soon as the crossflow exists, but it is proportional to the injection ratio. As already aid, it is total only in absence of mainstream (fig. 3- e) where the jets are not bent any more; but follow a straight trajectory imposed by the initial injection streamwise angle. The intermediate case relative to R=1 (fig. 3-c) contains both phenomena since the jets are bent in the direction of the environing flow initiating the confinement of the combined jets. The confinement is however neither immediate nor total. The jets are henceforth dynamically equivalent which justifies the confinement delay and its weaker impact. The latter is perceived through the detachment of the combined jets from the injection plate. This detachment is total is absence of crossflow.
We move now to the second feature affected by the variation of velocity ratio: the existence and the orientation of the developed vortical structures; we mean here rather the leading edge vortices whose sense of orientation may be clockwise, anticlockwise or both of them in particular cases. The vortices rotate clockwise under the weaker velocity ratios and this sense is imposed by the crossflow as shown in fig. 3-a and b. It is not clear on the figure but that must be the sense of rotation of the wake vortices too which may justify the attachment of the emitted jets to the injection wall. When the velocity ratio reaches the unity, we already said that both interacting flows are dynamically equivalent which is at the origin of the presence of double sensed vortices as shown in figure 3.c. Under R=1.29, we've just went beyond the critical ratio, that's why in addition to the anticlockwise vortices we note the existence of sparse clockwise ones (inside the dashed line in fig. 3-d). The latter are totally vanished in absence of the crossing flow (fig. 3-e) and even at the periphery of the downstream jet. In fact under this injection condition, the jets no longer interact together; maybe a closer distance between the jet nozzles would generate this interaction.
The third observation to make is precisely concerning what happens between the jet columns and its variation under a changing injection ratio. In fact, the jets are immediately flattened against the injection plate under the weakest values due to their quasi absent resistance towards the oncoming crossflow. This process generates pronounced interactions between the jets while evolving. These interactions are however less significant and take place progressively higher and then farther from the injection plate. This is actually due to the fact that the jets are progressively are strong (with reference to the crossflow) and then more likely to maintain their trajectories before expanding and generating mutual interactions; of course in addition to the interactions with the mainstream.

We propose now to check the above mentioned observations concerning the developed disturbances but in terms of mean velocity magnitudes and vectors. Both features are gathered on the mean velocity cartographies of the resulting flowfield; on which we also delimited the main characterizing zones of the domain; always in terms of the velocity feature (figure 4). Of course the cartographies were plotted under the different injection ratios apart from the R=0.9 case that is approximately identical to the R=0.67 one.
The first observation to make concerns the vertical domain extent of the plotted cartographies that translates well the impact of the injection ratio on the flow dynamics. In fact the major flow interactions are contained within a domain height of approximately 20 mm under the weakest ratio, to progressively become 25 mm, 45 mm and finally 60 mm respectively under R=1, R=1.29 and R=∞. This is the best way to comfort the jets' confinement reduction as their velocity is reinforced with reference to the oncoming crossflow. This confinement decrease is accompanied by a new dividing of the mean velocity field that is initially divided into three then four distinct zones to finally become a single zone. Under the weakest injection ratio; R=0.67; (fig. 4-a) three main zones develop. The first one contains the emitted jets that were immediately bent and entered in mutual interaction. The following zone contains the expanded jets that have combined. As to the upper layer, it contains the crossflow remained out of any interaction due to the limited extent of the

emitted jets. Scarce disturbances are present at the peripheral side of the jets which could be induced by too many light reflections in spite of all the adopted precautions.
When the injection rate attains the unity, the first zone contains always the emitted jets but this time they are still separate. They inter in interaction only in the following zone where they expand and generate a wake region close to the wall. The two following layers contain always the same phenomena: the combined jet streams and then the free crossflow. The extent of the different zones is however larger due to the further impulsion brought to the jets and then to their deeper crossing of the environing flow before bending and dispersing. The same partition of the domain is maintained for the next injection case relative to R=1.29. Only the height of these zones varies since the first zone extent changes from 4 to 10 mm, the second from 7 to 14 mm, the third from 10 to 17 mm (fig. 4-b and c). When the injection ratio becomes infinite, there is no longer a need nor a reason to divide the domain as there are no longer any interactions in absence of the crossflow.
It comes then from the abovementioned observations that the injection ratio is responsible for the organization of the established resulting flowfield.

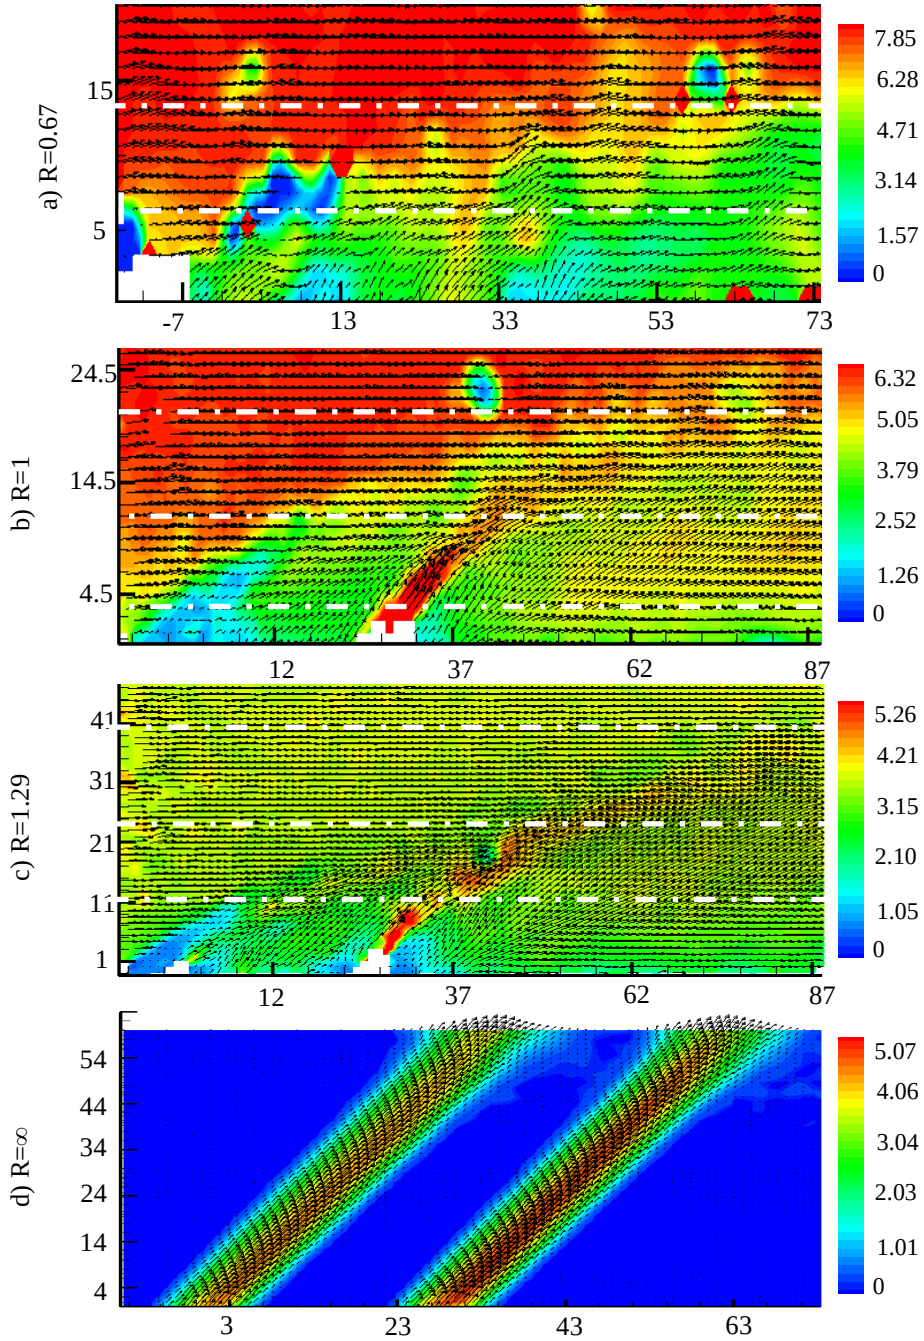

Figure 4. Mean velocity cartographies on the symmetry plane and under the different velocity ratios

When it is too low, the jets are unable to oppose any resistance to the oncoming crossflow which justifies their immediate flattening against the injection plate. At the vicinity of the critical R=1 case; the jets oppose a slight resistance to the mainstream which enables them to flee freely the injection plate before tilting. If the velocity ratio rises further, the jets are reinforced and cross more deeply the domain before sloping. The tilting process actually disappears when the ratio becomes infinite: when the crossflow no longer exists.

CONCLUSIONS

The present experimental consideration of twin inclined jets within a crossflow showed the complexity of the established resulting flowfield in spite of the simplicity of the configuration geometry. This complexity is expressed through the change in the sense of orientation of the developed vortical structures that change from clockwise to anticlockwise as the injection rate climbs… It is also manifest in the change of the whole flowfield organization in terms of the mean velocity cartographies; the borders were decided by the jets behavior that are initially emitted straight, then interact before combining and finally completely dispersing.

Heat and Mass Transfer

EXPERIMENTAL ANALYSIS OF VACUUM DRYING OF THE HIGH VOLTAGE BUSHING

ABSTRACT. This paper deals with the computational model and its experimental validation of the paper vacuum drying process. Proposed numerical approach is based on the commercial CFD software package, FLUENT. Complex vacuum drying multi-physics includes air flow, heat transfer, water evaporation, moisture diffusion, etc. For validation purpose small scale vacuum chamber and paper bushing were built. During vacuum experiment inside the paper bushing temperatures were measured, obtained experimental results demonstrated fairly good agreement computation results.

Keywords: *validation experiment, paper vacuum drying, bushing, computer simulations*.

INTRODUCTION

A crepe paper is one of the best insulation material which is commonly used in the electro-technology for instance, in the high voltage bushings (schematically shown in Figure 1). Bushings are parts of any high voltage electrical transformer they allow to carry current at high potential (by means of capacity-controlled electric field) through a grounded barrier [1] e.g. metal transformer casing. Working principle of the bushing made of conductor and insulator is schematically shown in Figure 1. Conducting core is carefully wrapped with the crepe paper (Figure 2), which is then impregnated with the epoxy resin and eventually cured. Such technology is widely known as the resin-impregnated paper (RIP) technology [1].

a) Dielectric breakdown strength b) Dissipation factor

Figure 3. Dependence of the paper insulation properties on moisture content

Unfortunately insulating properties of the crepe depend strongly on the moisture content. When the moisture content within the paper exceeds the value of 3% the paper dielectric breakdown strength weakens drastically. On the other hand the dissipation factor increases rapidly when the moisture content within the paper exceeds the value of 0.5%. Both these behaviours [2] are documented in Figure 3.

Considering above discussed paper properties it is strongly recommended to decrease the water content in the insulation material below 1% or even lower if possible. That is why a special attention should be paid to the proper planning and carrying out the drying stage of the production process. Production of the bushing begins in specialized computer-controlled winding machine where crepe paper together with conduction inserts is wrapped onto a solid mandrel rod or a central tube. Once the paper coil is precisely formed on the conductor the series of heating and vacuum cycles are applied. During each heating cycle buoyancy flow of hot air increases temperature of the paper. After that stage vacuum is applied to speed up of water evaporation and its evacuation. This process is often characterized by the significant temperature drop within the paper (up to 30^{o}C -50^{o}C) caused by very intense evaporation process and high value of the water latent heat of evaporation being equal to 2270 kJ/kg at room temperature.

The vacuum drying is generally time-consuming and consequently energy-consuming technology. One can even say that the drying stage is often the most significant part of the bushing manufacturing process. Although it is certain that the drying time is dependent on the product geometry, initial water content within the paper and process parameters, it is still not obvious how this relationships look like. Therefore it would be very desirable to possess precise mathematical model of the process, capable of improving it or even optimise it. Preliminary version of such a model was presented in [3, 4]. Model is built up utilising a commercial Computational Fluid Dynamic (CFD) software *Fluent* [4]. Some important effective quantities occurring in the model are measured experimentally. Unknown and/or uncertain fields required for the model are determined through inverse analysis described in details in other papers. Finally, the whole model is validated by comparison of computational results with measurements obtained in the specially designed experiment.

GOVERNING EQUATIONS OF THE MATHEMATICAL MODEL

Formulated mathematical model of the vacuum paper drying process utilises the concept of porous medium, which is in thermodynamic equilibrium with a humid air. As a consequence only one energy equation, common for both phases, is solved. Water is treated as a one phase regardless it state, i.e. no matter it is free or bounded water. Its distribution within the paper is resolved by considering so-called lumped diffusion equation containing the effective diffusion coefficient of water D within porous material (crepe paper). This coefficient, dependent on the water content and temperature, is calculated based on the sorption/desorption curves. Such curves have been determined experimentally within the course of the project as will be discussed further. The governing equations of the model consist:
Continuity equation

$$\frac{\partial \rho_a}{\partial t} + \nabla \cdot \left(\rho_a \mathbf{w}\right) = \dot{m}_{H_2O} \tag{1}$$

Diffusion equations of humid air constituents

$$\begin{aligned} &\left(\rho_a Y^a_{H_2O} \mathbf{w}\right) = -\nabla \cdot \left(\mathbf{J}^a_{H_2O}\right) + \dot{m}_{H_2O} \\ &\frac{\partial\left(\rho_a Y^a_{O_2}\right)}{\partial t} + \nabla \cdot \left(\rho_a Y^a_{O_2} \mathbf{w}\right) = -\nabla \cdot \left(\mathbf{J}^a_{O_2}\right) \\ &\sum_{i=H_2O,O_2,N_2} Y^a_i = 1, \qquad \mathbf{J}^a_i = \rho_a D_{i,a} \nabla Y^a_i \end{aligned} \tag{2}$$

Momentum equation

$$\frac{\partial(\rho_a \boldsymbol{w})}{\partial t} + \nabla \cdot (\rho_a \boldsymbol{w}\boldsymbol{w}) = -\nabla p + \nabla \tau_i + \rho_a \boldsymbol{g} + \mathbf{S}_i \tag{3}$$

Energy equation

$$\begin{aligned} &\frac{\partial\left[\gamma \rho_a h_a + (1-\gamma)\rho_s h_s\right]}{\partial t} + \nabla \cdot \left[\boldsymbol{w}_a \left(\rho_a h_a + p\right)\right] = \\ &= \nabla \cdot \left(\tau \cdot \boldsymbol{w}_a + k_{eff} \nabla T\right) + \dot{m}_{H_2O} \Delta h \\ &k_{eff} = \gamma k_a + (1-\gamma) k_s \end{aligned} \tag{4}$$

Porous media model

$$\mathbf{S} = -\left(\mu \, \boldsymbol{D} \cdot \boldsymbol{w} + \frac{\rho_i |\boldsymbol{w}|}{2} \mathbf{C} \cdot \boldsymbol{w}_i \right) \tag{5}$$

Lumped diffusion model of moisture transport through porous material

$$\frac{\partial X}{\partial t} = \nabla \cdot \left(D_{eff} \nabla X\right) + \frac{\dot{m}_{H_2O}}{(1-\gamma)\rho_s} \tag{6}$$

Turbulence model – standard κ–ε

$$\frac{\mathrm{D}(\rho_a \kappa)}{\mathrm{D}t} = \nabla \cdot \left[\left(\mu_a + \frac{\mu_t}{\sigma_t} \right) \nabla \kappa \right] + G_\kappa - \rho \varepsilon$$
$$\frac{\mathrm{D}(\rho \varepsilon)}{\mathrm{D}t} = \nabla \cdot \left[\left(\mu_a + \frac{\mu_t}{\sigma_t} \right) \nabla \varepsilon \right] + C_{\varepsilon 1} \frac{\varepsilon}{\kappa} G_\kappa - \rho C_{\varepsilon 2} \frac{\varepsilon^2}{\kappa} \tag{7}$$

Model of mass transfer between porous medium and air – Herz-Knudsen equation together with Henderson sorption isotherm formulation

$$\dot{m}_{H_2O} = -\frac{2 C_{mt} (1-\gamma)}{r_f} \sqrt{\frac{M_{H_2O}}{2\pi R}} \frac{p_{eq} - p_v}{\sqrt{T}}$$
$$p_{eq} = p_{sat}\, \varphi(X,T) \tag{8}$$
$$\varphi(X,T) = 1 - \exp\left[-(AT + B) X^n \right]$$

In the above equations ρ represents density, T is the temperature, $\boldsymbol{w}$ stands for the velocity vector and h is the enthalpy. Chemical composition of the humid air is defined using mole fractions Y_i while water content in the paper is described by symbol X. Equilibrium relationship between these two quantities should be found experimentally determining so called sorption isotherm. Practically they define equilibrium between wet paper and humid air at a given temperature and pressure. Index a in the governing equations identifies humid air while index s refers to solid part of the porous material (paper). Symbol τ represents stress tensor, $\boldsymbol{S}$ is the source term in momentum equation and k stands for the thermal conductivity.

It should also be stressed that in the proposed model both the mass flux of the water steam in the gaseous phase and the moisture transport within the wet paper are proportional to the water diffusion coefficients D. Although relevant value in the gaseous phase can be get from the subject literature, e.g. [1], its effective value in the porous material, specific heat of the paper as well as constants A and B describing sorption isotherms (equation (8)) should rather be found experimentally.

SELECTED MEASUREMENTS

As already mentioned the numerous of measurements have been carried out within the course of the project. The first experiment referred to determining sorption isotherms. It consisted of drying of the paper sample within the particular environment (temperature and relative humidity of the air) managed inside a desiccator. Investigated sample was hung using tiny thread on the balance pan and placed inside above mentioned desiccator filled with saturated salt solution. Temperature sensor PT100 was also placed inside the desiccator and connected to the regulator which controlled operation of the heating lamps. When temperature inside the desiccator decreased below the preset temperature minus threshold, regulator turned on heating lamps and causing increase of the temperature. When it rose above the preset value plus threshold, regulator turned off lamps. Threshold was equal to 0.2 K, what gave regulation tolerance equal to 0.4 K. The desiccator and heating lamps were placed inside glass tank which walls were covered with an aluminium foil to minimize ambient influence. Balance was connected to the computer for online reading acquisition. Balance reading was printed to the text file for further utilization. General view of the experimental stand together with the character of the obtained sorption isotherm are shown in Figure 4 and 5.

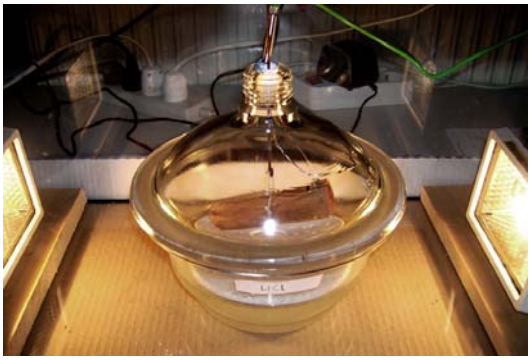

Figure 4. Experimental stand for determining of sorption isotherms

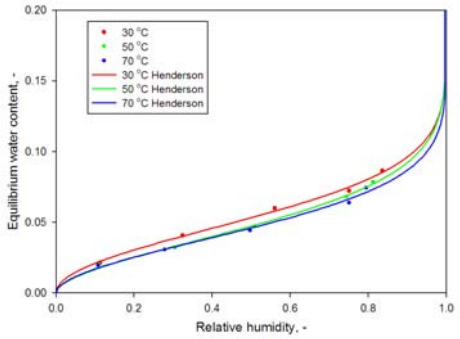

Figure 5. Exemplary sorption isotherms

Paper samples were prepared as rolls with mass equal to around 20 grams. At the beginning of the experimental procedure the sample was being dried for about 24 hours in temperature 110°C inside an electrical dryer. Then the dried sample was placed on the balance pan inside the desiccator and acquisition software was started. Measurements were carried out until equilibrium state between surrounding air and the moisture entrapped in the paper sample was established. Usually each measurement lasted between 12 and 30 hours. Humidity of the air inside the desiccator was not measured during experiment, since it was assumed that salt solution was saturated and therefore it was determined by the actual air temperature.

Measurements of the specific heat of the paper was carried out with Simultaneous Thermal Analysis instrument STA 409 PG Luxx produced by Netzsch. This instrument offers TG measurements resolution of 2µg and DSC resolution below 1µV. All specific heat measurements were carried out in the range from 30 to 170°C in dry air atmosphere with protective gas flow rate 20 ml/min. After calibration was preformed each sample underwent four-stage measurement procedure: moist sample run, vacuum, drying, dried sample run. Exemplary DSC and TG results for moist sample are shown in Figure 6 and 7.

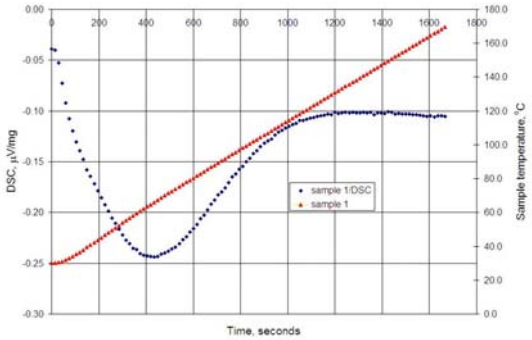

Figure 6. Exemplary DSC results

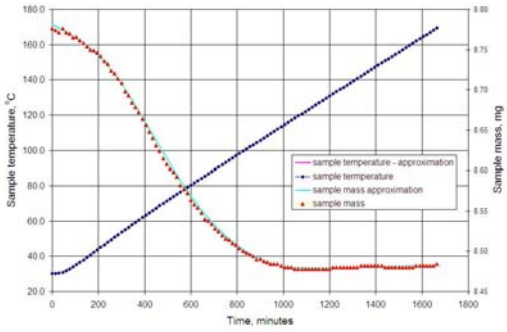

Figure 7. Exemplary TG results

The mean value of diffusion coefficient D_{eff} was in this work calculated with half equilibrium time method and its dependence on the water content was determined with the slope method. Exemplary results obtained for temperature 50°C is shown in Figure 8. It should be stressed that although curves show the diffusion coefficient dependent on the water content these values are actually averaged over the sample thickness for a given time instance. It explains to some extent dramatic increase and fall down of the diffusion coefficient values at the beginning and the end of a curve.

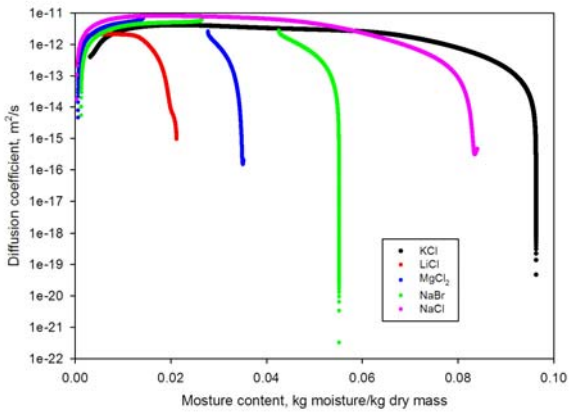

Figure 8. Water content dependent effective diffusion coefficient at temperature 50°C.

VALIDATION EXPERIMENT

To validate experimentally the developed mathematical model a special experimental rig has been prepared. It consisted of the vacuum chamber inside which paper coil on an aluminium rod (playing a role of the high voltage bushing) was placed. The paper coil has dimensions: height 200mm, external diameter 110mm, diameter of internal aluminium conductor 30mm. Chamber interior was connected through rubber hose with the vacuum pump. Part of the hose was coiled up and dipped in the vessel filed with a cold brine forming something like condenser of the vapour removed from the bushing. The vacuum chamber and the whole experimental rig are shown in Figure 9 and 10.

Figure 9. The vacuum chamber

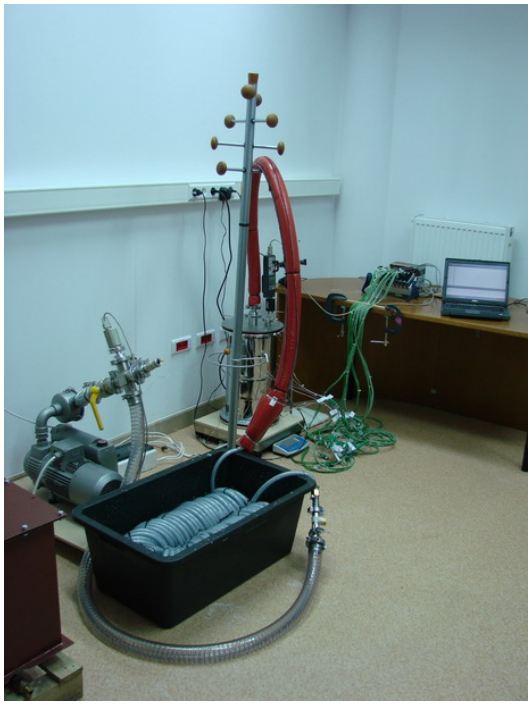

Figure 10. The whole experimental rig

Figure 11. The paper coil equipped with thermocouples

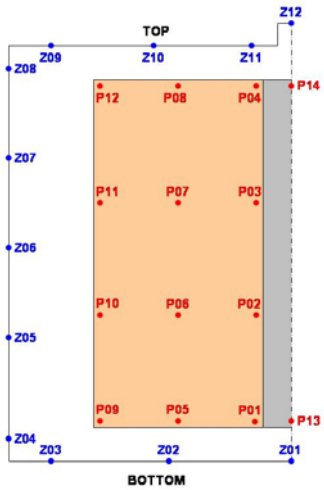

Figure 12. Location of the thermocouples

The paper coil has been equipped with 12 thermocouples as it is shown in Figure 11. These twelve thermocouples, marked in Figure 12 as (P1 - P12), were used for validation purposes. Because of axial symmetry of the object, Figure 12 contains only half of the coil cross-section. Additional twelve thermocouples marked (Z1 - Z12), were positioned on the inside walls, and were all used to establish boundary conditions. The last two thermocouples (Z13 and Z14) have been located inside the aluminium rod to measure its temperature.

At the chamber inlet/outlet static pressure was measured. These measurements were prescribed as a pressure type boundary condition. Temperature recordings are plotted in Figure 13.

To determine the changes of the water content within the experimental bushing it was weighted before and after experiment and after long drying in an oven in temperature over 100^{o}C. Recorded masses showed that approximate mass of water removed from the bushing in experiment was equal to 40 grams.

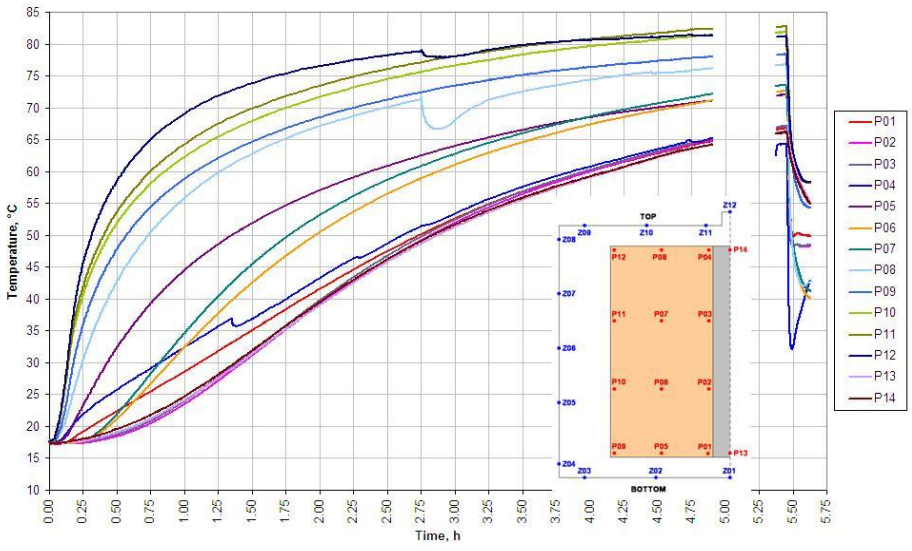

Figure 13. Temperature recordings within the paper coil.

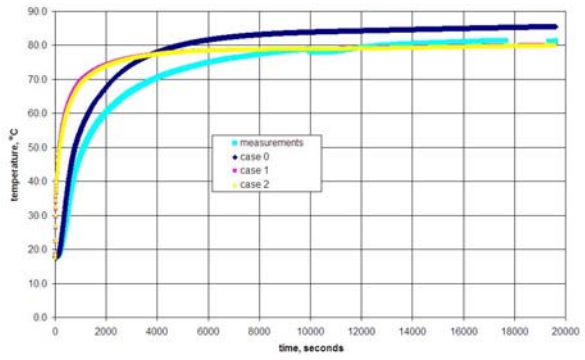

Figure 14. Temperature at point P12 with respect to heating time – comparison of calculated cases with measurement data.

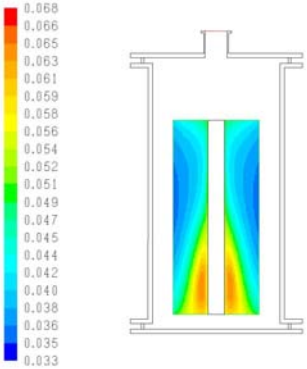

Figure 15. Water distribution inside the paper coil after heating period for one of the computational cases.

Heating period lasted about 6 hours and than vacuum was applied for about half an hour. Comparison between calculated temperatures at location of the thermocouple P12 and measurements at the same point for heating cycle are shown in Figure 14. Water distribution inside the paper coil after heating period for one of the computational cases is demonstrated in Figure 15. Many more results will be demonstrated during the conference.

CONCLUSIONS

Analysing carefully results of the carried out analysis the following general conclusions can be drawn:

- Developed model can successfully describe vacuum drying process,
- Presented model appears to be appropriate for engineering applications,
- Temperature and water content fields within computational domain are mainly influenced by the evaporation constant in Eq. (8),
- Cellulose thermal conductivity coefficient moderately influence temperature and water content fields,
- Lumped water diffusivity reveals almost no influence on temperature and water content. Its value has been measured experimentally,
- Preliminary research show the influence of anisotropy of porous material and shows its meaning influence on both temperature and water content fields.

EXPERIMENTAL INVESTIGATION OF HEAT AND MASS TRANSFER FROM A FALLING FILM

Džana Kadrić[1], Šefko Šikalo[1] and Ejup N. Ganić [2,*]
[1]Faculty of Mechanical Engineering, University of Sarajevo, www.unsa.ba
[2]Sarajevo School of Science and Technology, Sarajevo, Bosnia and Herzegovina, www.ssst.edu.ba

ABSTRACT. Results of an experimental investigation of heat and mass transfer from the falling wall film to humid air are presented in this paper. Falling film is formed on the top of vertical flat plates. Air of known humidity was blown along the plates in the counter-flow mode. Heat and mass transfer occurred between unsaturated air in direct contact with the falling film.
The influence of inlet film temperature and mass flow rates of film and air on the heat and mass transfer are investigated.
Results of three sets of measurements are presented: case A – film flow rate 0.019 kgs^{-1}, t_{in}=45°C; case B – film flow rate 0.029 kgs^{-1}, t_{in}=45°C and case C – film flow rate 0.019 kgs^{-1}, t_{in}=30°C. The air flow rate was varied in the range from 0.055 to 0.093 kgs^{-1}.
Experimental results of heat and mass transfer are analysed. Some of them are given as a function of dimensionless groups.

Keywords: *Falling film, heat transfer, evaporation*

INTRODUCTION

During the direct contact of the wall falling film and humid air the simultaneous heat and mass transfer occurs. This process is often found in industrial applications such as cooling towers, film cooling, drying, desalination etc. Therefore it has been a subject of investigations in many theoretical, experimental and numerical studies. There are a number of phenomena which could be investigated. Among them, we would like to emphasise the following:
Heat and mass transfer between the film and humid air and influence of different parameters on the film cooling. Some of the parameters which are studied are film flow rate, inlet film temperature, inlet air humidity, inlet air temperature, etc. [1, 2, 3, as well as references therein].
Values of latent and sensitive heat transferred and their ratio in a total heat exchanged. According to our experimental results the latent component of heat transfer has a dominant role in a total heat transferred. Some investigators have reported that the latent component could reach up to 95 % of the total heat transfer. As a result, the amount of evaporated water vapour is an important parameter. The water temperature decrease is mostly influenced by rate of water film evaporation [3, 4, 5, 6].
We experimentally studied the influence of inlet water film temperature, film flow rate and air flow rate on heat and mass transfer coefficient. Some results of the study are shown as a ratio of latent heat to total heat transfer rate.

APPARATUS AND EXPERIMENTAL TECHNIQUES

An experimental setup consists of water and air supply lines, and a test section. Simultaneous heat and mass transfer occur in direct contact between water and air, in a counter flow mode, as Figure 1 shows. Air is supplied from compressor and flows through a dust and moisture separator and a pressure regulator. To control and measure air flow easily, the air supply line separates in two branches. Compressed air flows through flow control valves, flowmeters and enters the test section. Two air flow meters provide more flexible and precise measurements. The flowmeters with measuring range from 0.85 to 4.25 m^3/min are used. A hygrometer and thermometer are built in the air line.
Distilled water is pumped from a storage vessel by a variable speed pump though a flowmeter to a large volume heater. A small volume heater with fine temperature regulation provided to control temperature of water at the inlet of test section. A water flowmeter with measuring range from 28 to 171 l/h is used. Temperature of water is measured at the inlet of test section and in a water drainage pipe.

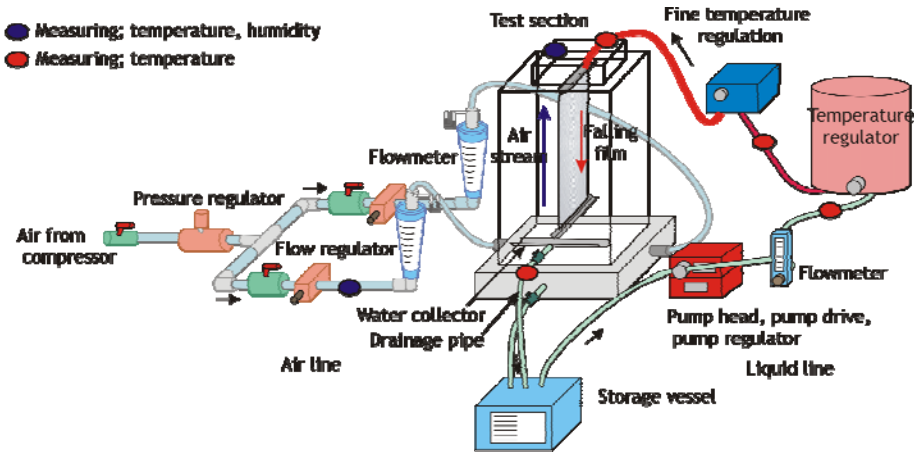

Figure 1. Schematic of the experimental setup

Test section consists of transparent Plexiglas wall. It is 0.61 m high, and has a square cross section area of 0.3 x 0.3 m^2. A set of five vertical flat plates are used as a packing to spread and cool falling water film. Salonite (concrete asbestos) plates, dimensions of L=250 mm width, H=500 mm height, t=6 mm thickness are used, where plates spacing were 40 mm. Salonite is a highly wettable material and allows highly equal distribution of liquid across the plates. A water distribution system equally spreads water flow rate from the top of the plates. A thin wall liquid film is formed on both sides of the plates. Water collects on the bottom of the plates and then drains out of the test section. A stainless steal segment supports the section, and distributes air flow cross over to the test section.

Experimental procedure

Heated distilled water spreads over the plates forming laminar falling film. Turbulent air flow cools the liquid film. Experimental setup and position of measuring points are shown in Figure 2.
Humidity and temperature of air is measured in five points at the section outlet.

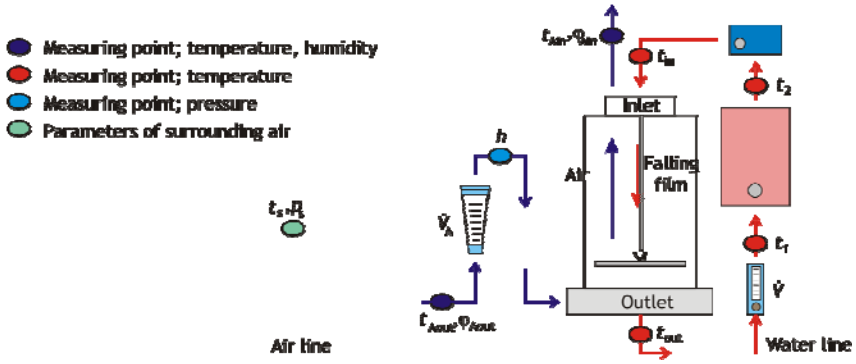

Figure 2. Measuring points

A number of measurements are performed and they are as follows: case A – film flow rate 0.019 kgs^{-1}, t_{in}=45°C; case B – film flow rate 0.029 kgs^{-1}, t_{in}=45°C and case C – film flow rate 0.019 kgs^{-1}, t_{in}=30°C. The air flow rate was varied in the range from 0.055 to 0.093 kgs^{-1}. One of the parameters is varied; others were constant to determine its influence on the transfer coefficients.

ENERGY BALANCES

In direct contact of laminar falling film and turbulent air stream, process of simultaneous heat and mass exchange occurs. Water temperature decreases, air temperature and humidity increases. Energy balance of falling film and air flow are analyzed.

Energy balance for the air flow

Total amount of heat transferred to the air flow consists of sensible heat, which is defined by change of temperature of dry thermometer, and latent heat, which is defined by change of absolute humidity of air. Energy balance for the air flow gives:

$$Q_{air}=Q_{sen}+Q_{lat}=\dot{m}_{air}c_p(t_{air,in}-t_{air,out})+\dot{m}_{air}(x_{air,in}-x_{air,out})h_{fg} \quad (1)$$

where: $\dot{m}_{air}$ is mass flow rate of air, kg/s, h_{fg} is latent heat of phase change at the average water temperature, J/kg.

Energy balance for the falling film

From the energy balance of the falling film, one could calculate the total heat exchanged in the process as:

$$Q=\dot{m}_{in}c_{p,in}t_{in}-c_{p,out}(\dot{m}_{in}-E)t_{out} \quad (2)$$

The water evaporation rate E, kg/s, could be calculated from the total change of the absolute air humidity:

$$E=\dot{m}_{air}(x_{air,in}-x_{air,out}) \quad (3)$$

Heat and mass transfer coefficients

Heat and mass transfer coefficients for air are calculated under the assumption that heat and mass exchange take place between the two layers of air. The first one is thin, saturated air layer in

proximity of falling film and the second one is a bulk air flow. The first layer has the temperature of the falling film.
Heat and mass coefficients are:

$$\alpha_{\text{air}} = \frac{Q_{\text{sen}}}{A\Delta t_{\text{air,lm}}}, \text{ W/m}^2\text{K and} \quad \beta_{\text{air}} = \frac{Q_{\text{lat}}}{A\Delta x_{\text{air,lm}} h_{fg}}, \text{ kg/m}^2\text{s} \tag{4}$$

where $\Delta t_{\text{air,lm}}$ is a logarithmic mean temperature difference, °C, and $\Delta x_{\text{air,lm}}$ is a logarithmic mean absolute humidity difference, kg/kg$_{\text{dry_air}}$.
Heat transfer coefficient for falling film is calculated as:

$$\alpha = \frac{Q}{A\Delta t_{\text{lm}}}, \text{ W/m}^2\text{K} \tag{5}$$

Dimensionless numbers

Dimensionless numbers for the air flow and for the falling film are calculated as follows.

Air flow
The Reynolds number, defined as for forced-convection heat transfer, for air is calculated as:

$$\text{Re}_{\text{air}} = \frac{(\dot{m}_{\text{air}}/\text{A}_{\text{c,air}})D_{\text{h,air}}}{\mu_{\text{air}}} \tag{6}$$

where: $\dot{m}_{\text{air}}$ is mass flow rate of air, kg/s, $A_{\text{c,air}}$ cross section of a flow, m^2, and $D_{\text{h,air}}$ is characteristic hydrodynamic length, m, given in Table 1.
The Nusselt number is defined as a dimensionless heat transfer coefficient, based on sensible heat of air flow,

$$\text{Nu}_{\text{air}} = \frac{\alpha_{\text{air}} D_{\text{t,air}}}{\lambda_{\text{air}}} \tag{7}$$

where λ_{air} is air conductivity, W/mK, and $D_{\text{t,air}}$ is characteristic thermal length, m.
The Sherwood number is defined as a dimensionless mass transfer coefficient, based on latent heat of air flow,

$$\text{Sh} = \frac{\beta_M D_{\text{t,air}}}{c\boldsymbol{D}} \tag{8}$$

where β_M mass transfer coefficient, mol/m^{2}s, c is molar concentration of water vapour, mol/m^3, and $\boldsymbol{D}$ is the mass diffusivity of water vapour into air.

Table 1
Characteristic lengths

Falling film	Air flow
Characteristic thermal length, $D_t = 4\,A_p/O_t$	
$A_p = 2{\cdot}5L\delta$; $O_t = 2{\cdot}5L$; $D_t = 4\delta$	$A_{p,air} = 0.3^2 - 5(t+2\delta)L$; $O_{t,air} = 2{\cdot}5L$; $D_{t,air} = 2{\cdot}0.3^2/(5L) - 2(t+2\delta)$
Characteristic hydrodynamic length, $D_t = 4\,A_p/O_h$	
$A_p = 2{\cdot}5L\delta$; $O_h = 2{\cdot}5L$; $D_h = 4\delta$	$A_{p,air} = 0.3^2 - 5(t+2\delta)L$; $O_{h,air} = 2{\cdot}5\,(L+t+2\delta)+4{\cdot}0.3$

Falling film

The Reynolds number of falling film is calculated as:

$$\mathrm{Re} = \frac{4\Gamma}{\mu} \tag{9}$$

where Γ is mass flow rate per unit perimeter L, kg/sm^2. The Nusselt number of falling film is calculated as:

$$\mathrm{Nu} = \frac{\alpha \mathrm{D_h}}{\lambda} = \frac{\alpha 4\delta}{\lambda} \tag{10}$$

RESULTS AND DISCUSSION

In this section, the results of direct measurements of an overall heat and mass transfer coefficients are presented and discussed.

The air flow results

The highest values of total heat transfer we had for case B (2.07 kW< Q_B < 2.52 kW). The lowest values of total heat transfer we had for the case C (0.97 kW< Q_C < 1.17 kW). For the case A (1.68 kW< Q_A < 2.07 kW) we had a total heat transfer between that for case B and C. Ratio of latent heat component to the total heat transfer is higher than 80 %, as Figure 3 shows. The highest ratio is obtained for case C.

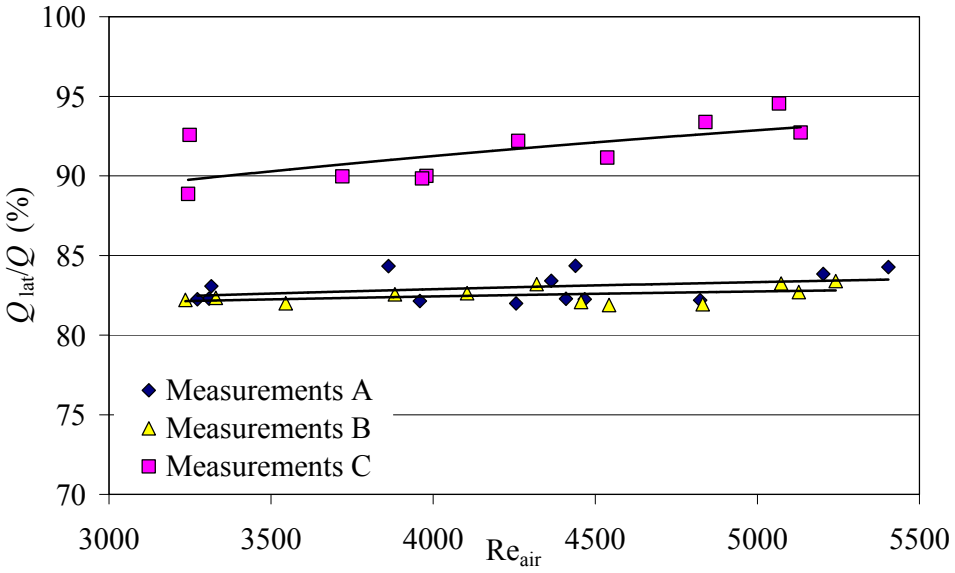

Figure 3. Ratio of latent and total heat transfer rates

Film temperature at the inlet of test section for the case C has the lowest value; as a result, the sensible heat transfer is the lowest, and the component of latent heat is the highest. Comparing the results for case A and case B shows that increase in the mass rate flow does not significantly affect this ratio. An increase of the air Reynolds number slightly increases the ratio of Q_{lat}/Q. These results are in agreement with other authors [1, 2, 4, 5, 6]. Thus, heat transfer between the falling film and air flow is controlled by mass transfer (vaporization of liquid film).

The Nusselt and Sherwood numbers for the air flow for case A and B are equal about one, as Figure 4 shows. For the case C (lower inlet film temperature) this ratio is about 0.6. For this case mass transfer is larger then in case A and B.

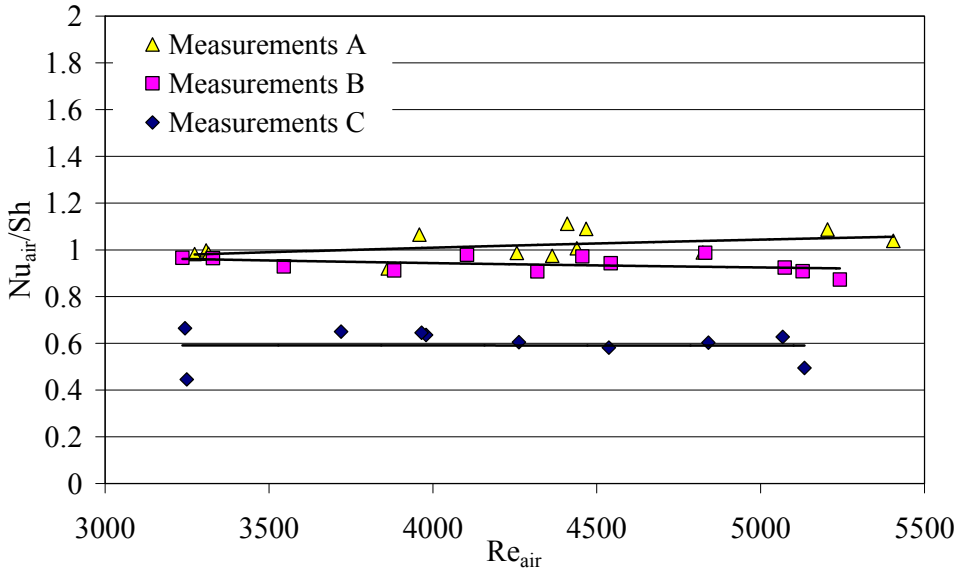

Figure 4. Ratio of Nusselt and Sherwood numbers for air

As a result of experimental investigation [7] of the simultaneous heat and mass transfer between the humid air and the moving water film, the following correlation is proposed for the Sherwood number:

$$\mathrm{Sh}=1.622\ \mathrm{Re}^{0.412}\mathrm{Sc}^{0.34}(1+\beta^{0.3}) \tag{11}$$

where Sc is Scmidt number and β is velocity ratio u_{air}/u.

Experimental results presented as Sherwood number in a function of Reynolds number is shown in Figure 5. Comparison of values calculated by equation (11) and obtained experimentally shows a good agreement. Some deviation in results is due to the experimental setup. Equation (11) is proposed for the heat and mass transfer between the horizontal moving water film and the flow of humid air while our experiment investigates the falling film formed on the vertical flat plates.

The percentage of liquid film evaporation is compared to the equation presented by Qureshi and Zubair [3]:

$$\frac{E}{\dot{m}} = -0.00849 + 0.1544(t_{\mathrm{in}} - t_{\mathrm{out}}) \tag{12}$$

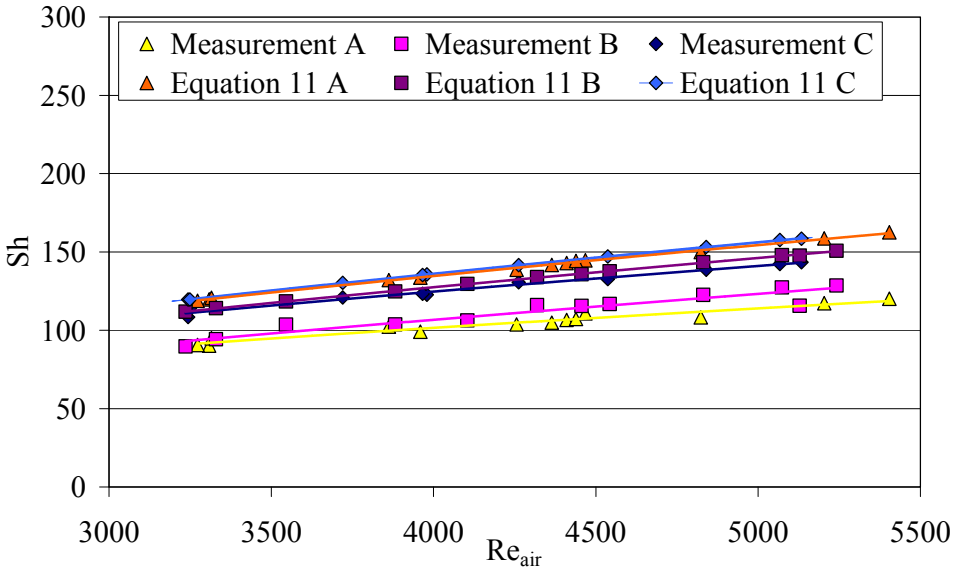

Figure 5. Sherwood number

For the case A good agreement is obtained, while for the cases B and C, the equation (12) slightly underpredicts the evaporation rate as it is shown in Figure 6.

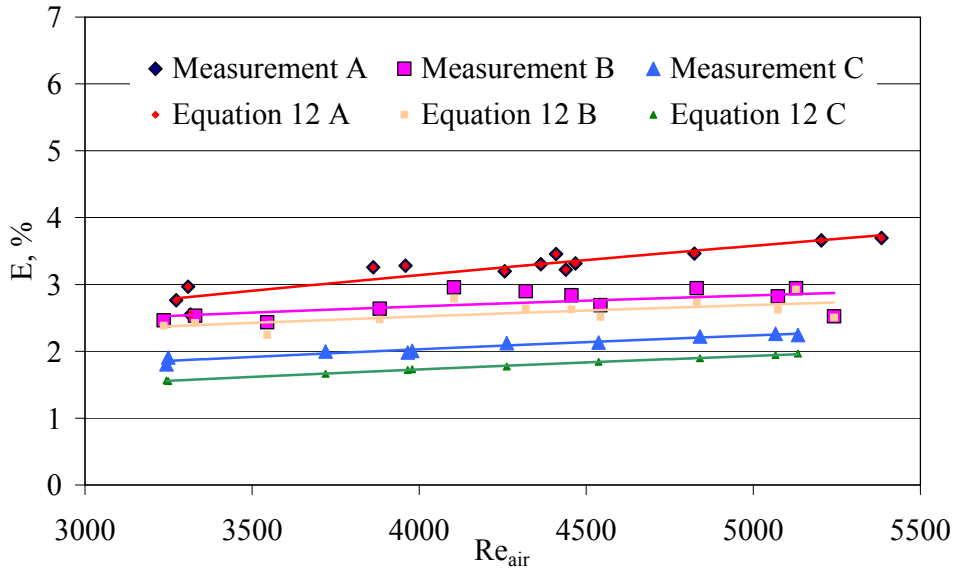

Figure 6. Comparison of measured and calculated vales of percentage evaporation loss

The falling film results

The overall film temperature drop is shown in Figure 7. Comparing the results of the cases A (0.019 kgs^{-1}, t_{in}=45°C) and B (0.029 kgs^{-1}, t_{in}=45°C), it is obvious that an increase of the film mass flow decreases the overall temperature drop. While comparison of the results for the cases A and C (0.019 kgs^{-1}, t_{in}=30°C) shows that increase of the inlet film temperature results in a larger temperature drop, these results completely coincide with the results [1, 2, 4, 5, 6]. The influence of

the air Reynolds number on the overall temperature drop is also obvious from Figure 7. The film temperature drop increases with increase of the air Reynolds number.

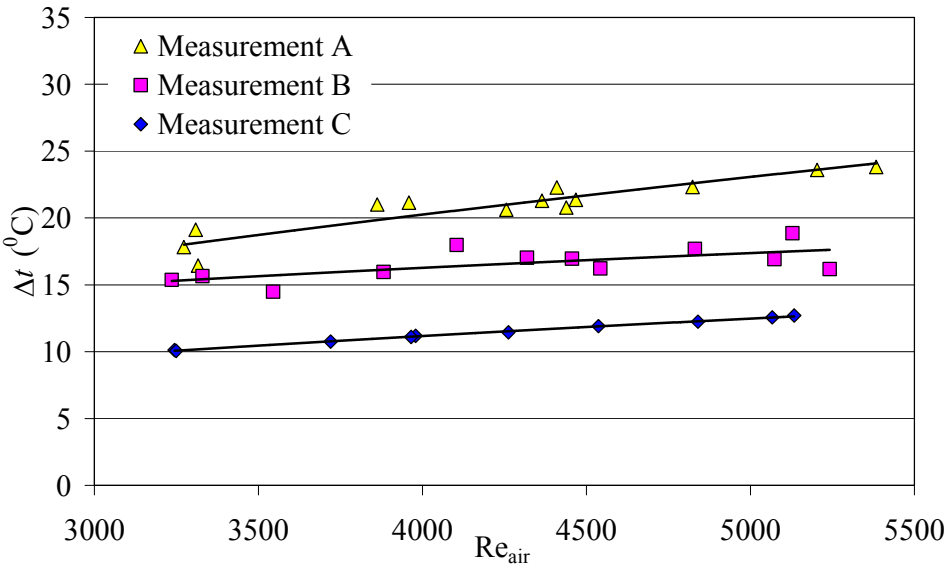

Figure 7. Overall film temperature drop ($\Delta t = t_{in} - t_{out}$)

FINAL REMARKS

Results of experimental investigation of simultaneous heat and mass transfer between wavy laminar wall falling film and a turbulent stream of humid air flow are presented in this paper. The effects of inlet water film temperature and its mass flow rates and cooling air flow on the heat and mass transfer are investigated. Latent heat component from the liquid film vaporization prevail in the total heat transferred. An increase of inlet film temperature and a decrease of film mass flow rates resulted in an increase of overall film temperature drop. An increase of the air mass flow rate results in an increase in more intensive water film cooling.

NUCLEATE BOILING OF NATURAL REFRIGERANTS IN A WIDE PRESSURE RANGE

Andrea Luke*, Björn Müller
Institute of Thermodynamics, Leibniz University Hannover, 30167, Hannover, Germany

ABSTRACT. Experiments with propane boiling on a horizontal mild steel tube (19 mm O.D.) with different surface structures have recently been started in a wide pressure range, in which the local heat transfer along the circumference of the tube, the roughness topography of the tube surface, and bubble formation and motion are measured in order to study the convective and evaporative contributions to heat transfer in nucleate boiling. First results show the variation of convective effects with heat flux, pressure and azimuthal position. The heat transfer measurements with propane are represented in a wide range of saturation pressure and heat flux and are compared with corresponding results of the literature. Large cavities within the drawn surface promote the activation of bubble nuclei for very small superheat and in consequence enhancement effects.

Keywords: *Pool boiling, surface roughness, natural refrigerants, heat transfer*

INTRODUCTION

Heat exchangers become more and more miniaturized to save energy and to take care of the natural ressources. High heat flux densities can be transfered by small temperature gradients in evaporators. This high transfer capability is now used even on fields, where two phase systems were avoided by reason of their complexity. New prediction methods for the heat and mass transfer in boiling will be therefore required in future to succeed the empirical correlations used until now. The calculation methods for the design of evaporators are based on more or less acurate heat transfer measurements. They are often not attended by equally accurate studies of the roughness of the heated surface and of the bubble formation, especially data for a large pressure range are rare in literature.
In order to provide experimental material that meets the above mentioned criteria, measurements with a horizontal plain mild steel tube (19 mm O.D.) have recently been started, because data for mild steel tubes are often not avaible in literature. In these experiments the local and the average heat transfer is measured by a great number of miniaturized thermocouples, the topography of the microstructure is analysed by means of a new stylus instrument and bubble formation and motion is investigated by a high speed video system. The microstructure of the originally drawn surface is prepared in a differently manner first a very smooth polished one and in future a uniformly fine sandblasted surface will be applied. In this paper heat transfer measurements with propane are represented in a wide range of saturation pressure and heat flux and are compared with corresponding results of the literature. Propane is a natural refrigerant and is discussed to replace refrigerants with high global warming potential.

DESIGN OF THE TEST TUBES AND EXPERIMENTAL PROCEDURE

The heat transfer measurements and the investigation of the bubble formation are carried out in a standard apparatus for pool boiling suggested by Gorenflo and Goetz [1]. The apparatus is modified by Kaupmann et al. [2] and recently by Kruck and Luke [3]. A new apparatus for pool boiling is now designed to investigate the heat transfer for boiling fluids like carbon dioxide with high pressures and for fluids in supercritical state. The main features of the apparatus are:

* Corresponding author: Prof. Dr.-Ing. habil. A. Luke

E-mail address: ift@ift.uni-hannover.de

- A natural circulation loop of the test fluid between evaporator and condenser both are situated in a PID temperature controlled chamber,
- the dc-heated horizontal test tube in the evaporator,
- the superheat of the tube wall is directly measured by miniature thermocouples (Ø 0,25mm) with one junction located in the boiling liquid below the test tube and the other junction in the test tube,
- Bubble formation on the different sections of the tube is observed through sight glasses in the evaporator, photographs and high speed video frames are taken.

Propane is used as boiling liquid on the outside of the test tubes. The saturation pressure is varied in a large range from p* = 0.03 to p* = 0.5 and the heat flux is varied from q = 50 W/m² up to 10^5 W / m^2, see Table 1. The electrically heated test tube is horizontally located inside the evaporator. The test tube consists of three coaxial tubes. The center tube is a round copper bar with one helix groove for the resistance heater element. This is inserted into an inner tube with 12 grooves on the outer surface to fix the thermocouples at their azimuthal and axial position. This tube is enclosed by the test tube itself and a cap at the end of the tube. In a special process all parts of the tube are soft soldered together under reduced conditions for an optimal heat conduction. The mild steel tubes and the copper tubes are designed similarly, for the details see [3].

SURFACE ANALYSIS

The material of the horizontal test tube is mild steel and copper. The outer surface with the diameter D = 19 mm is taken with the originally drawn surface provided by the manufacturing process. The outer diameter is varied slightly after the surface preparation, see Table 2. The drawn surface is the same basic surface for further procedure for enhancement (e.g. [4]). The surface is polished after the investigation of the heat transfer measurements. The polishing procedure results in a very smooth deterministic microstructure but the surface is more or less without real technical relevance. To provide a regularly structured more technical smooth surface in future, the surface will be fine sandblasted acc. to [5].
The heating surfaces are analyzed by a contactless stylus instrument [5]. A diamond tip swinging by ultrasound is driven slowly over the surface by special forward feeds. The movements of the tip correspond to the surface roughness and they are digitalized and amplified. One scan represents a conventional roughness profile (see Figure 2), where the standard parameters acc. to DIN EN ISO 4287 (10.98) can be applied. Measurements of more than 1000 scans in an axial direction with of the tube Δy = 0.5 µm represents a topography of the area 0.5 x 0.5 mm. The 2-dimensional standardized roughness parameters have equivalent counterparts in 3-dimensional characterization S_i [8] added to Table 2. The area and the profiles investigated are shorter than standardized due to the long measuring time [5]. Several scans are provided near each thermocouple and topographies at selected positions.

1) The three-dimensional parameters S_a, S_q, S_p, S_t, S_z correspond to the two-dimensional // gauge length = 0.5mm, without cut-off ($\lambda_c = \infty$)

The results of the roughness measurements in form of the standardized parameters acc. to DIN EN ISO 4287 (10.98) are listed in Table 2 for the polished and the drawn surfaces. Characteristic profiles with the typical enlargement z/x are shown in Figure 2, bottom, for the drawn (left) and the polished mild steel tube (right). Each profile represents a profile with the average mean roughness P_a of Table 2 of the surface investigated. The photorealistic and isometric representations of the topography are shown in Figure 2 (top) to demonstrate the 3-dimensional impression of the surface and the size and the local distribution of real cavities on the heated surface. The topography of the very irregularly drawn surface shows a typical structure due to the manufacturing process. Very large cavities – including several re-entrant ones – vary with small cavities, see the profiles in Figure 2. The result is a large scatter in the average values as the mean roughness P_a. The mean roughness – taken normal to the main roughness structure e.g. the grooves in the polished surface - represents the reference value in the empirical correlations for the heat transfer acc. to [6]. P_a scatters from values near the reference value of $P_a = 0.66$µm up to values three times larger $P_{a,max} = 1.95$ µm or to values four times smaller $P_{a,min} = 0.17$µm, see Table 2. This variation is reflected by high values of standard deviation and the wide distribution of the mean roughness value, s. Figure 3. The differences of the P_a-values within one topography is also visualized by Figure 3 considering the scattering in a very small distances ($\Delta y = 0.5$µm). The scattering of the mean roughness would result in a local variation of the heat transfer coefficient of ca. ± 16 % acc. to Stephan [7] or to the VDI-heat atlas [6]. The few large very deep cavities will be the favoured sites for beginning nucleation for small superheats and low pressures and the small cavities between the large ones will be only activated for high pressures and very high superheats.
The polished surface is prepared by the same devices as the emery ground surfaces investigated before [5], but with another emery paper (2000#). The result should be a mean roughness of $P_a = 0.02$ µm – 0.04 µm with a regular surface structure. The 3-dimensional mean roughness is always higher than the 2-dimensional value because a superimposed waviness for the topography has to be considered,

this is especially the case for the polished surfaces. The polished steel surface is in average somewhat rougher than the carefully polished copper tube because of the very rough original drawn surface, while the copper surface has some rougher grooves, see Figure 6 and Table 2. The first polishing procedure of the steel tube was not as successful as assumed, some of the deep cavities were not removed, s. Figure 5. The mean roughness is increasing ten times in the area of the cavity, see Figure, the heat transfer augments locally by more than 50% acc. to [6].

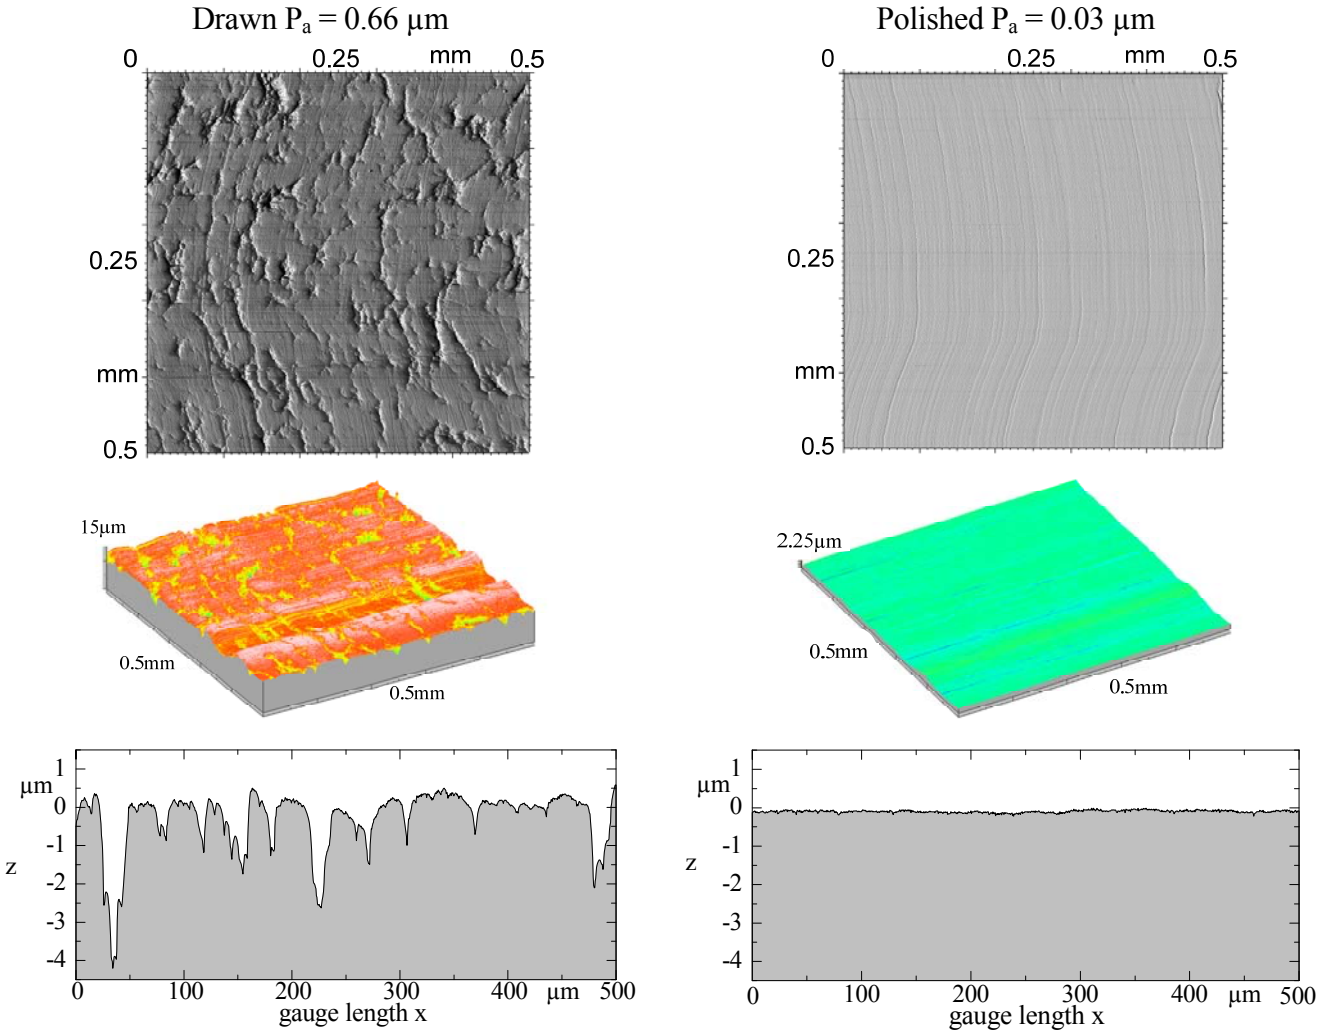

Figure 1. Top Photorealistic representations of the drawn (left) and polished (right) Profiles in azimuthal (x-) direction (bottom) with the common enlargement (z/x = 36) and isometric topography with the common enlargement (z/x = 5) of the drawn (left) and the polished (right) mild steel tube

AVERAGE HEAT TRANSFER PERFORMANCE

The heat transfer coefficient α is defined by the ratio of the heat flux q and the superheat ΔT

$$\alpha = \frac{q}{\Delta T} = \frac{q}{T_W - T_S} \qquad (1)$$

T_s is the saturation temperature of the boiling liquid in the pool and T_w is the wall temperature of the tube surface taking into account the heat conduction from the thermocouples to the surface. The

experimental error limits of α depend on the measured superheat from 2.5 % for low pressures and low heat fluxes up to nearly 7 % of high pressures and low heat fluxes.
The results of the average heat transfer performance of the mild steel tube for the three different surface structures are represented in form of the double logarithmic plot of α as function of q in Figure 4 for the drawn and the polished surface of Figure 2. Natural convective heat transfer without bubble formation on the heated surface and with smaller relative increase of the heat transfer coefficient occurs for low heat fluxes and pressures. The experimental results are in the transition area of $10^7 \leq \mathrm{GrPr} \leq 10^8$. The correlation for the laminar flow [6]

$$Nu \approx (Gr \cdot \mathrm{Pr})^{1/4} \tag{2}$$

describes quite well the data for lower pressures of the drawn surface and the polished one and the correlation for turbulent flow [6]

$$Nu \approx (Gr \cdot \mathrm{Pr})^{0.33} \tag{3}$$

the values for the higher pressure on the drawn surface. The well known strong increase of the heat transfer coefficient α with the heat flux and pressure in the range of fully developed nucleate boiling is demonstrated for all surfaces. The experimental values are interpolated by straight lines of the α-values acc. to

$$\alpha \propto q^n \tag{4}$$

for constant pressures. α increases with very uniform slope and reduced saturation pressure p* within the range of nucleate boiling for the polished surface, see Figure 5 right. The lines of the different pressures are quite separated for high pressures, while there is nearly no differences between the experimental results for the two lowest pressures investigated p* = 0.05 and 0.03, see Figure 4. The slope for the drawn surface is no longer constant for the whole pressure range. For low to intermediate heat fluxes the α-q relationship is similar to those of the polished surface, only the slope is smaller. For high heat fluxes the increase of α with q and p_s vanishes for pressures between p* = 0.5 and p* = 0.2. The α-values for the highest pressure are nearly parallel to those of p* = 0.2.

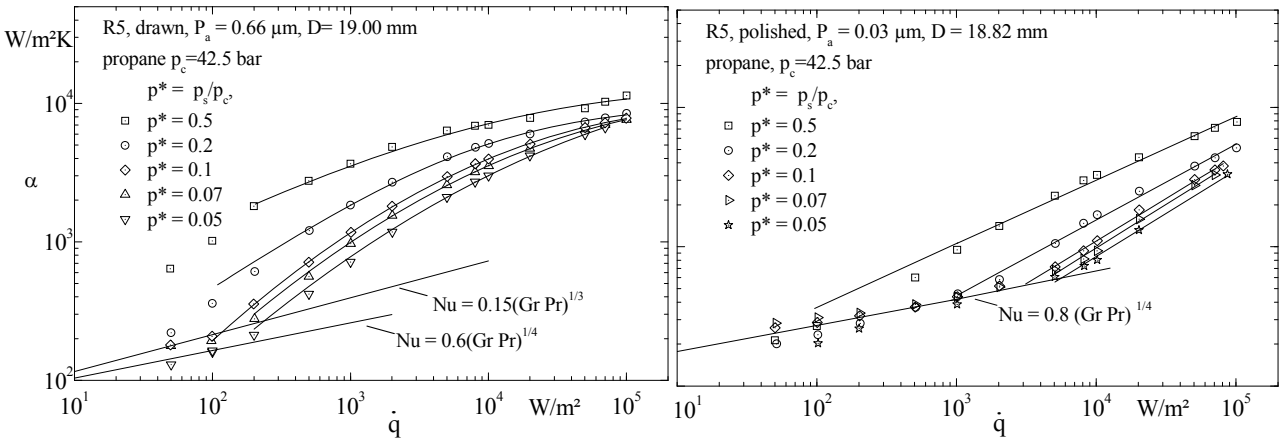

Figure 5. Average heat transfer performance of the mild steel tubes, propane boiling at different heat fluxes and pressures, left: drawn surface, right: polished surface (without cavities)

This behaviour may be explained by the bubble formation on the irregularly structured heated surface. Almost all large cavities within the topographies of Figure 2 are activated and the surface is covered with bubbles. The augmentation of the heat flux effects no more in higher heat transfer rates. For very high pressure as p* = 0.5, more and very small bubbles are activated, see Figure5. The main effect of the surface roughness is within the range of beginning nucleation, see Figure 5. The superheat for a stable bubble nuclei on the drawn surface is with ΔT = 0.85K ten times lower than on the polished surface with ΔT = 9 K for p* = 0.05 see Figure 6, left. For high to intermediate

pressures, the differences in the superheat for beginning nucleation are reduced to $\Delta T = 1.8$ K and $\Delta T = 0.2$ K for $p^* = 0.2$, see Figure 6.

The comparison with the measurements of propane boiling on a horizontal mild steel tube with different surface finishes demonstrates the well known effect, that the heat transfer coefficient augments with increasing mean surface roughness $P_{a,}$, figure 7.

The differences between the two polished surfaces is due to various deep re-entrant like cavities distributed equally over the surface, see the topography of figure 1 and 3. These cavities are the remains of the previous original drawn surface, not removed by the polishing procedure. They evoke very active stable nucleation sites especially for low heat fluxes or low superheats, respectively. This is also observed by the comparison of the bubble formation on emery ground and sandblasted surfaces, see [9]. For high heat fluxes the α-values of the two smooth surfaces are equal at $p^* = 0.1$. The comparison of the new data of Mertz et al. [11] for the same original surface and for the same diameter shows that the heat transfer coefficient is slightly higher and the slope is nearly the same. The decrease for high heat fluxes and the stronger increase of α for small heat fluxes is not observed by Mertz [11]. On the other hand, the values of Mertz correspond well with the recalculated data of the polished surface, see figure 7. The data of the drawn surface are similar to the rough sandblasted surface of [10], see figure 7. The data of the emery ground surface have the same superheat for beginning nucleation, while the slope of the α - q relationship is quite different. The increase of the α-values for Propane at constant intermediate heat flux q = 20 kW/m² with the reduced saturation pressure $p^* = p_s/p_c$ is shown in the lower diagram of Figure. The values of former investigations with a mild steel tube of smaller O.D. (D = 7.6 mm) and three different surface finishes [10] are added. The relative pressure dependence of α according to the correlation for organic fluids in the VDI Heat Atlas [6] predicts the experimental pressure dependence quite well at low to intermediate pressures after fitting to the pertaining experimental α-values at $p^* = 0.1$, cf. also figure 8. At high reduced pressures, the increase of the new experimental heat transfer coefficient for propane with p* is less pronounced acc. to eq. (5), cf. the curve and the symbols in the lower diagram.

$$F(p^*) = 1.2p^{*0.27} + \left(2.5 + \frac{1}{1-p^*}\right)p^* \qquad (5)$$

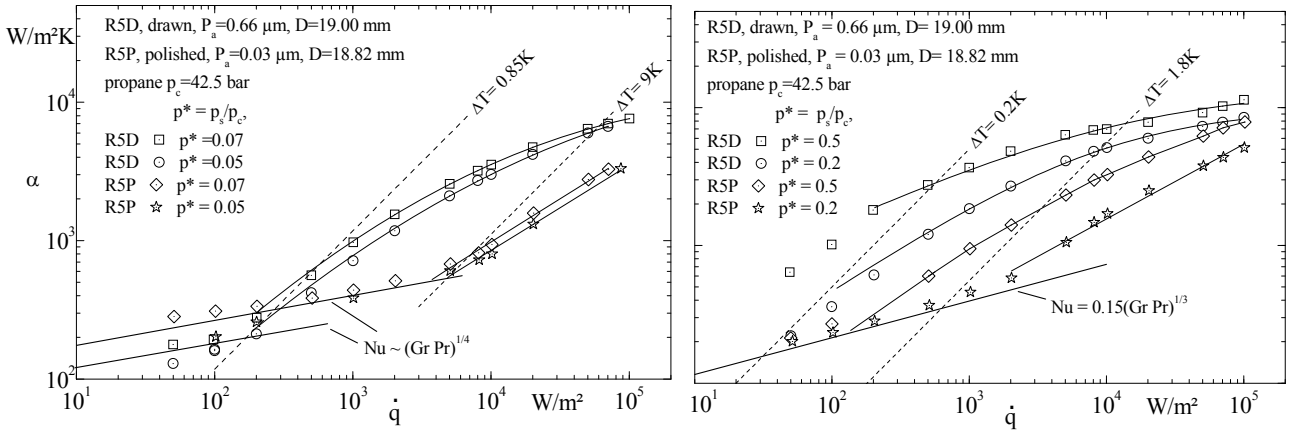

Figure 6. Comparison of the heat transfer coefficient α as function of the heat flux q for the drawn and polished mild tube for high pressures (right) and low pressures (left).

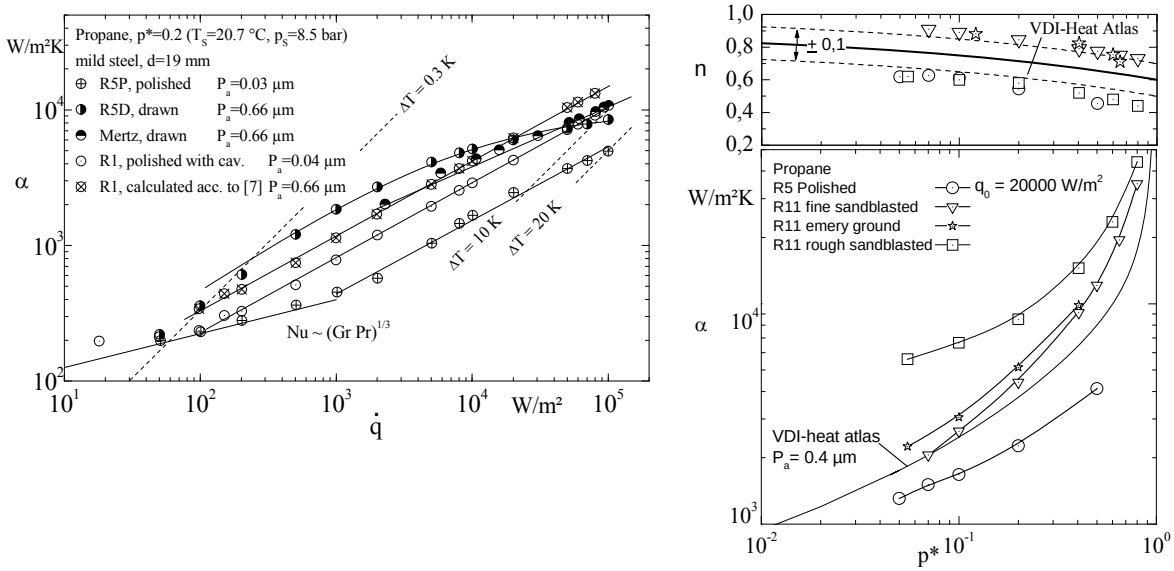

Figure 7. left: Comparison of the heat transfer coefficient α as function of the heat flux q for polished with and without cavities and drawn mild tube for p* = 0.1 and data of literature. right: pressure dependence of α interpolated for q = 20000 W/m^2 (bottom) and of the slope of the interpolation lines (top) for propane on the polished tube and three surfaces of literature.

$$n = 0.9 - 0.3p^{*0.3} \tag{6}$$

The same holds the increase of α with q over the entire pressure range, as can be conclude from the comparison between the experimental data for the exponent n with the correlation of [6] given as solid line in the upper diagram of figure 8. Similar deviations of the calculation method of the VDI Heat Atlas[6] also from new experimental results have been found in recent investigations [4].

ANALYSIS OF THE EFFECT OF OPERATING PARAMETERS ON THE EFFECTIVENESS OF INTERMITTENT SPRAY COOLING

S. Fest*, J. Schmidt
Otto-von-Guericke University Magdeburg, Magdeburg, Germany

ABSTRACT. An experimental study is reported on intermittent spray cooling in the film boiling regime. The presented measurements are obtained using the infrared measuring techniques and are conducted to quantify the effects of injection frequency and pulse duration on mean surface temperature, whereby, the coolant quantity is kept constant. Calculating the mean surface temperature, an area of 30 x 30 mm² is analysed, which conforms to the main impact area of the spray. It is observed that the lowest tested pulse duration of 5 ms yield intensified cooling in terms of maximum heat removal at predetermined cooling quantity. The effect of pulse duration on heat transfer is reduced with increasing injection frequency. All studied pulse duration features a maximum of heat removal at injection frequency of less than10 Hz.

Keywords: *spray cooling, intermittent spray, film boiling*

INTRODUCTION

Spray cooling heat transfer in the film boiling regime is of great importance to attain stable and uniform cooling. At this, spray cooling using intermittent sprays has been suggested as a technological concept in terms of effectiveness and controlling of the cooling potential [1]. A suitable combination of pulse duration and injection frequency promises a reduction of thermal stresses and distortion in components as well as a reduction of coolant.

The spray cooling process possesses a complex nature and depends on spray parameters, such as droplet size, velocity and mass flux, but also on liquid and surface properties. Previous works [1][2] have shown that neither the injection frequency nor pulse duration changes significantly the droplet diameter and axial velocity distribution in wide range of operating parameters. Thereby, changing in heat transfer can not be ascribed to changing of spray characteristics. A research program is being conducted aimed at characterising the effect of injection frequency and pulse duration on the mean surface temperature, whereby, the cooling quantity is kept constant. The effectiveness of the operating parameters is evaluated based on the approach of maximal heat removal at predetermined cooling quantity.

METHODS AND MATERIALS

The experimental configuration consists of a BOSCH multiple-orifice injector directed perpendicular to a sheet made of Inconel 600 (100 x 60 x 0.3 mm), which is directly electrical heated. A schematic of the experimental setup is shown in Figure 1. Using a self-build triggering system, the injection frequency f_{inj}, the pulse duration Δt_{inj} and the number of injections N are

controlled. The pulse duration is varied from 5 ms to 15 ms and the injection frequency is adapted to realise duty cycles, defined as $DC = (\Delta t_{inj} \cdot f_{inj}) \times 100\,\%$ [3], from 2.5 % to 40 %. All studied cases and their conditions are summarised in Table 1. During these experiments, the impinging distance is kept constant and equal to 150 mm and the injection pressure is set to 7 bar. The produced water spray features under these working condition a mean diameter of about 50µm as well as a mean velocity of about 5 m/s and the total spray angle is about 25 deg.

An infrared camera (Flir ThermaCam Sc 3000) records the surface temperature with a sampling rate up to 750 Hz. Hereby, one camera image corresponds to a certain time, and surface temperatures are obtained for the whole impact area of the spray. The temperature information of each camera image is converted to a 2-dimensional Matlab matrix, whereby, the matrix size amounts to the number pixel for the length and the width of the Inconel 600 sheet. The data are further processed in Matlab to a 3-dimensional matrix, whereas the third component is the time. As infrared measurements depend strongly on the emissivity of the surface, the camera facing sheet side is coated with a black painting called Senotherm UHT 600 with a thickness of about 20 µm. Since the emissivity is temperature-dependent, all temperature data of the 3-dimensional matrix needs to be subsequently corrected (see [4] for further details).

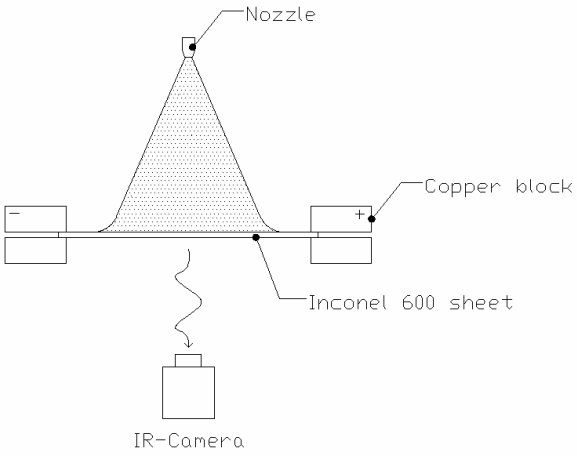

Figure 1: Schematic of the experimental apparatus

RESULTS AND DISCUSSION

Intermittent sprays are characterised by injection frequency and pulse duration. Both parameters are related with the variable duty cycle which is often used as influence parameter on heat transfer. Figure 2 illustrates the mass flux distribution and the corresponding decrease in surface temperature

after 40 consecutive injection cycles for pulse duration of 5 ms and duty cycles of 5 % and 15 %, respectively. The spray characteristic of the multiple-orifice injector is developed with local intensified mass fluxes in the centre of each single jet. A duty cycle of 5 % leads to relatively uniform cooling. In contrast, a duty cycle of 15 % yield strong surface temperature distribution and the local cooling depends on the local mass flux. Thereby, the mean surface temperature is used to evaluate cooling processes for various combination of pulse duration and injection frequency. Calculating the mean surface temperature along a serious of injection cycles, an area of 30 x 30 mm² is analysed, which conforms to the main impact area of the spray.
Studying the effect of pulse duration on mean surface temperature is based on a constant cooling quantity. Doubling the pulse duration, approximately, the double amount of liquid is atomised. Hence, changing of pulse duration requires an altering of injection numbers according Table 1.

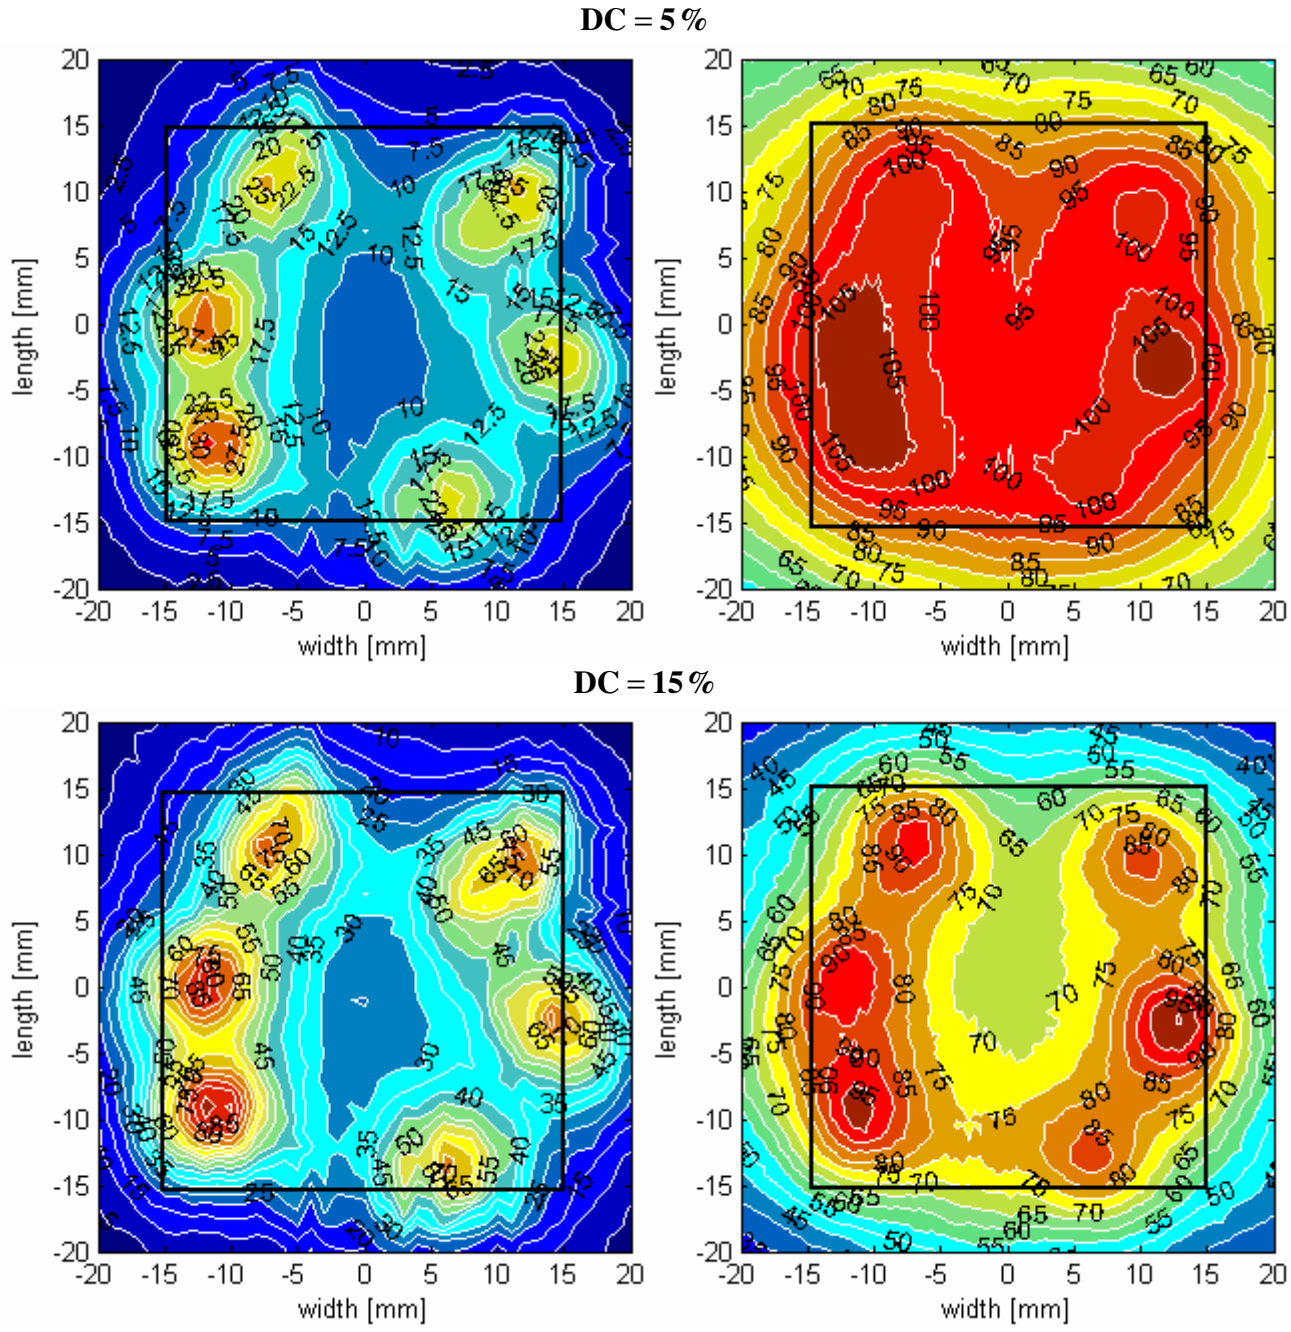

Figure 2. Mass flux [mg/(cm² s)] (left) and decrease in surface temperature [K] (right)

Figure 3 shows the initial mean surface temperature decays along a serious of consecutive injection cycles at a duty cycles of 5 %and illustrates the effect of pulse duration. The results indicate that the lowest tested pulse duration of 5 ms yields intensified cooling. In general, the cooling potential decreases with increasing pulse duration. The difference in mean surface temperature between the lowest and highest tested pulse duration amounts to 30 K. Obtaining a mean surface temperature of about 340°C, 13 injection cycles are approximately necessitated for pulse duration of 15 ms, and 26 injection cycles are only required for a pulse duration of 5 ms. This corresponds to a reduction of coolant of about 30 %.

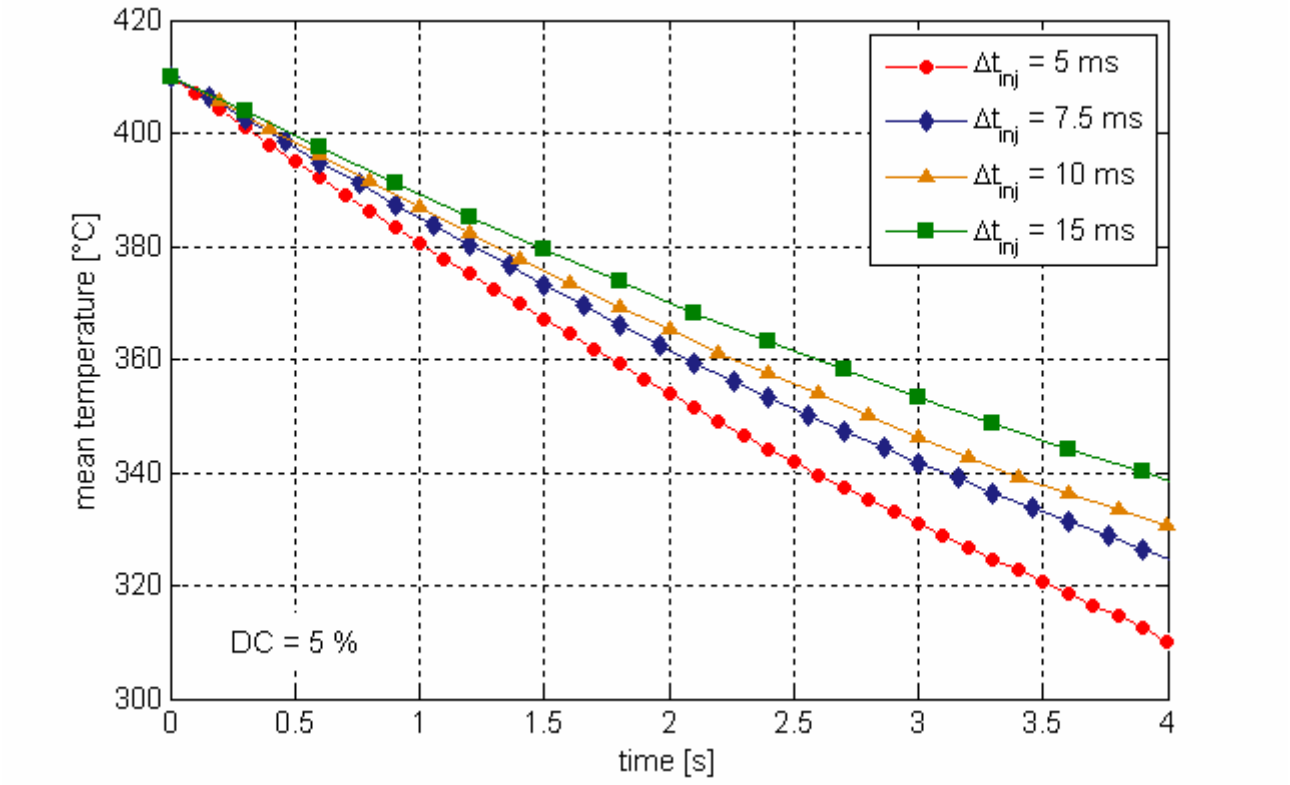

Figure 3. Mean surface temperature decays along a serious of consecutive injection cycles for duty cycle of 5 %

Figure 4 shows the transient surface temperature for pulse duration of 15 ms and a duty cycle of 5 %. Each injection features two periods: a period of direct liquid-solid contact during the initial phase of spray impact and a period, where a vapour layer is formed. The heat transferred from the wall in this first phase is in order of magnitude higher than the amount of heat through the subsequent formed vapour layer [5]. The length of the second period depends on the injections frequency, and the surface temperature drop depends on the initial surface temperature and on the corresponding boiling regime as well as the amount of injected cooling liquid. In the film boiling regime, the surface temperature drop decreases with decreasing surface temperature. At an initial surface temperature of about 400°C, the surface temperature drop is about 5 K for pulse duration of 15 ms. Decreases the surface temperature to about 300°C, the temperature drop amounts about 3 K. Hence, the development of the mean surface temperature, as shown in Figure 3, features a non-linearity, which is specially pronounced for pulse duration of 5 ms due to the intensified cooling.

Figure 4 illustrates that the surface temperature can also reheat during the period with formation of vapour layer. The experimental results are obtained by a non-stationary measurement method with

continuous electrical heating source. At this, the Inconel 600 sheet is directly electrical heated up to the steady state temperature, and heat is removed by natural convection and radiation. The heat flux by convection as well as radiation is a function of surface temperature and reduces with decreasing surface temperature (see [4] for further details). Hence, during the cooling process the ratio of heat flux by radiation and convection decreases and the surface temperature reheats during one injection cycles for low injection frequencies when the coolant is completely vaporised. However, the cooling efficiency can be improved by adapting the injection frequency.

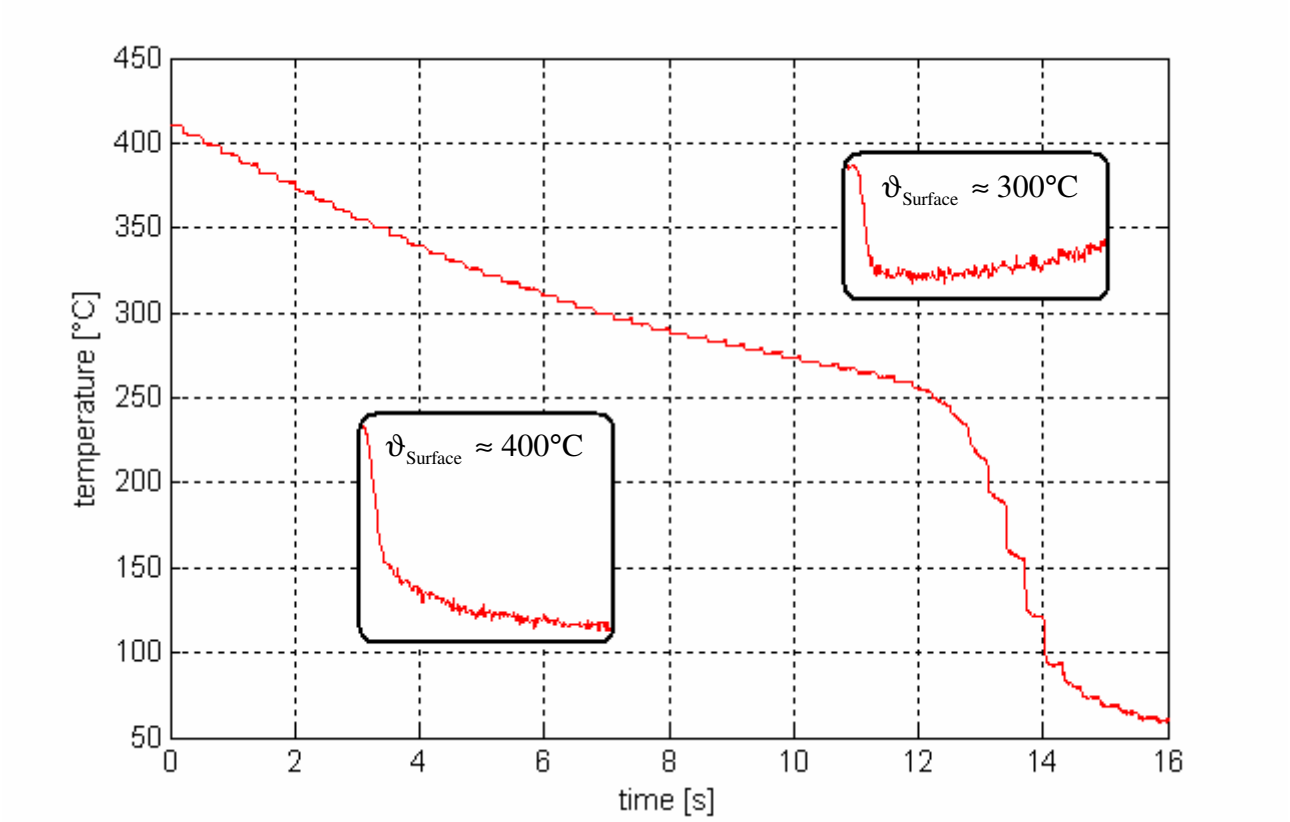

Figure 4. Temperature development for pulse duration of 15 ms and duty cycle of 5 %

The influence of the injection frequency on the cooling process is shown in Figure 5, where the mean surface temperature drop after N injection cycles is plotted versus the variable duty cycle. If the pulse duration is fixed and the injection frequency increases, the variable duty cycle increases, and the cooling process becomes faster. The lower mean surface temperature drop with increasing duty cycle points that the coolant does not completely vaporise during two subsequent pulses, and a liquid film is formed above the characteristic vapour layer of the film boiling regime. Local limited chilling effects (compare Figure 2) could result in thermal stresses and distortion in components at higher injection frequencies. However, the lowest tested pulse duration yields intensified cooling for all studied duty cycles. But, the effect of pulse duration on the cooling process is reduced with increasing duty cycles, and the surface temperature drop features an asymptotic behaviour. All studied pulse durations offer an optimum duty cycle, which is lower than 15 %, which correspond to an injection frequency of less than 10 Hz.

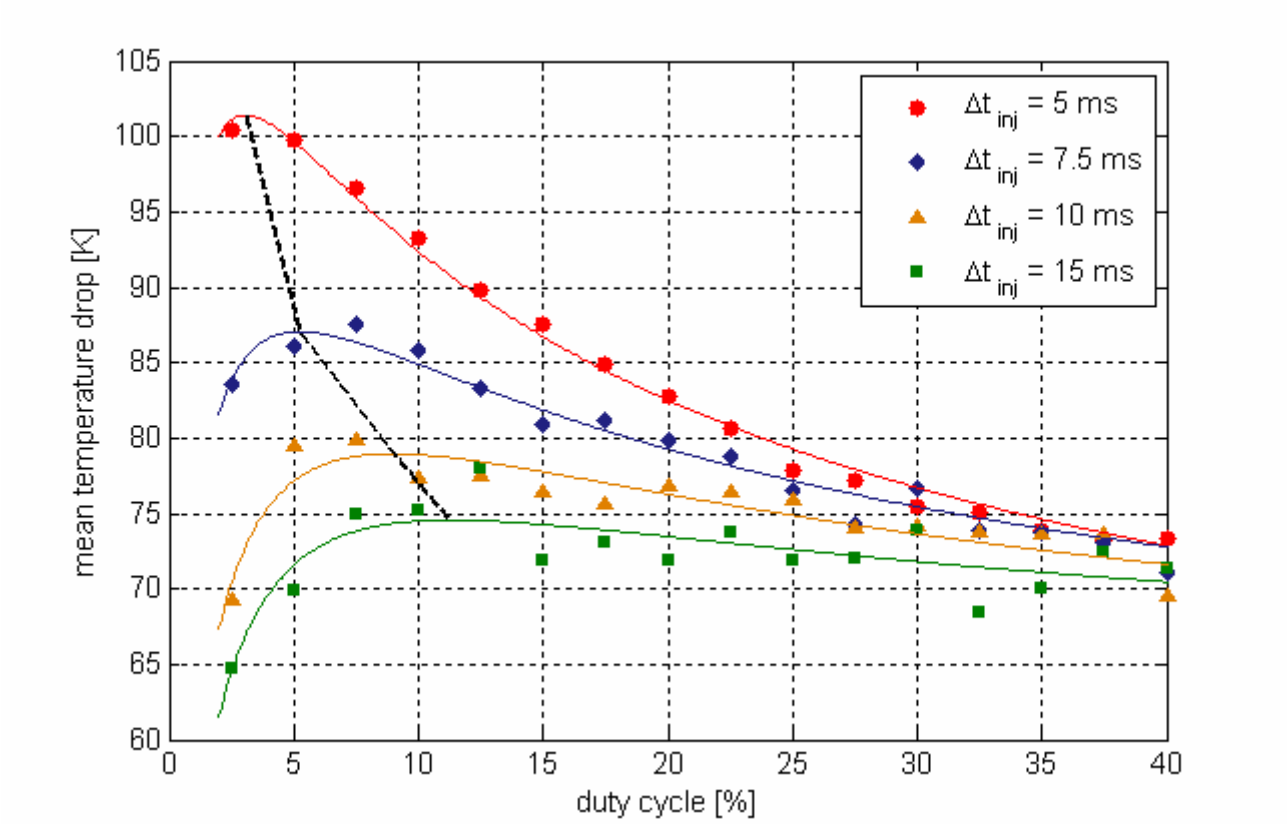

Figure 5. Mean surface temperature drop after a serious of consecutive injection cycles

CONCLUSIONS

An experimental study is carried out in the range of film boiling aimed characterising the effect of pulse duration and injection frequency on heat flow during intermittent spray cooling processes. The injection frequency has not only an impact on the cooling rate but also on the uniformity of the cooling process. In general, low injection frequencies lead to a relatively uniform cooling. High injection frequencies yield strong surface temperature distribution and the local cooling depends on the local mass flux. Thereby, the mean surface temperature is chosen as evaluating parameter on heat flow, whereby; the main impact area of the spray is used calculating the mean surface temperature.

The lowest tested pulse duration of 5 ms features the best heat flow behaviour at a predetermined coolant quantity for all studied injection frequencies. But, the influence of pulse duration on the cooling process is reduced with increasing duty cycles. All studied pulse durations offer a maximum of heat flow, which corresponds to a maximum of the mean surface temperature drop, for injection frequencies less than 10 Hz. At higher injection frequency and consequently higher duty cycles, the heat flow is limited, which points that the coolant does not completely vaporise during two subsequent pulses, and a liquid film is formed above the characteristic vapour layer of the film boiling regime.

HEAT LOSS AND EVAPORATION RATE FROM AN AGITATED WATER TANK

H. Alonso Martín, A. Revel, B. P. Huynh*
University of Technology, Sydney, NSW, Australia

ABSTRACT. Experiments have been performed to investigate the heat loss and evaporation rate from an open-top tank of heated water that is also agitated vigorously by air bubbling through it. High consumption of electrical energy in heating the solutions for an electroplating process prompted this study; and the experimental set-up thus serves as a model for an electroplating tank in this process. Air is injected from the tank's floor, and an electrical heater is used to maintain water at a constant, elevated temperature, compensating the heat being lost to the surroundings. A heat transfer model is developed for the process and is seen to agree well with measurements. Water's evaporation rate is found to be proportional to the injected air flow rate, and that most of the supplied energy goes into evaporating the water.

Keywords: *heat loss, evaporation rate, agitation, air injection*

INTRODUCTION

In some industrial processes like electroplating, air is bubbled through the liquid solutions to make them highly agitated, well-mixed and uniform to enhance the process. Often, the solutions are maintained at an elevated temperature, and the bubbling air increases significantly evaporation from the solutions. As a result, energy is spent on evaporating the liquid, in addition to the need to replace the lost liquid, as key properties like correct chemical compositions have to be maintained in the solutions.

High consumption of electrical energy in heating the solutions in an electroplating process provided the initial impetus for this work. This paper thus reports on an experimental study of the heat loss and evaporation rate from an open-top tank of heated water that is also agitated vigorously by air bubbling through it. The experimental set-up serves as a model for an electroplating tank.

Evaporation from bodies of water has been considered by a number of authors, but with water in a calm state or only mildly agitated (similar to a used swimming pool) [1-9]. Bubbling a gas through liquid solutions is also used in direct-contact evaporation process, for example, for concentrating aqueous solutions. In a typical such process, the equipment is basically constituted of a liquid column through which a superheated gas is bubbled [10-12]. However, the conditions and energy-flow paths pertaining to such evaporation process are different to those of the present work. The emphasis is also different. Here, the main aim of air injection is to create a highly agitated, well-mixed, homogeneous solution that is beneficial to a process like electroplating, and evaporation and its concomitant consumption of energy are by-products that have to be dealt with. In an evaporation process, on the other hand, evaporation is the aim itself.

A heat transfer model is also developed in this work to help predict energy consumption. Calculations based on this model, which is rather straightforward and robust, will be seen to compare well with measurements. It will also be seen that evaporation increases linearly with the rate of injected air for agitation, and that most of the supplied energy goes into evaporating the water.

EXPERIMENTS

The initial impetus for this work was to mimic an industrial electroplating process, and investigate the effects of air injection on the energy consumption and evaporation water loss. Thus an experimental set-up was developed in the Heat Transfer laboratory of the University of Technology, Sydney, Australia, for the investigation, and experiments were performed during the second half of 2008, using heated water as the solution, in an open-top small tank which serves as model for an electroplating tank. The set-up is shown in Figure 1. The main components are

- Stainless steel tank of dimensions Length×Width×Height = 900×300×280 mm; wall thickness 1.6 mm; open at the top
- Tank's walls and underside are insulated with expanded poly-styrene (EPS) sheet, 20 mm thick
- 3-kW electrical immersion-element heater, 275 mm long, with built-in rod-thermostat of range 10 − 80 ºC
- Power clamp meter to 600 V, 200 A rms
- Two analogue-to-digital converters to log the temperature and power signals into a laptop
- Air receiver with regulator (0 − 690 kPa) and 0.75 kW air compressor delivery (ambient air supply to the compressor)
- Calibrated rotameter for air-flow measurement (0 to 2.50 g/s)
- 2-m-long perforated plastic tube laid on the floor of the tank in a figure-8 shape, which distributes the injected air uniformly from the compressor to the water surface via 10 equi-spaced 3-mm-diameter holes serving as air nozzles. The tube free end was blocked
- Six type-T thermocouples for measuring temperatures
- An assembly of siphon and measuring cylinder for recording water level in the tank
- A laptop computer for data logging and processing

A measuring cylinder connected by a siphon tube to the tank shows the drop in water surface level from which evaporative mass loss is deduced. Temperatures within the liquid, on tank's internal and external walls and inside one of the holes of the perforated plastic tube are recorded using six type-T thermocouples. Approximate locations of the thermocouples are shown in Figure 2. Air required for agitation is supplied from a compressor. Air's mass flow rate is measured with a previously calibrated rotameter.

Water temperature is controlled by a thermostat switching an electrical immersion-heater on and off. The thermostat's temperature control band is within ± 1 K, so an average bulk temperature is assumed. When steady state is reached, thermal loss is balanced by the electrical energy supplied to the heating element. This energy is measured with an electrical power meter coupled to a data acquisition device and logging to a computer. Thus the energy required to maintain the water's temperature is obtained by summing the power meter's recorded square-wave inputs over an extended period. Figure 3 shows an example of a series of 2.79 kW inputs with "element-on" periods recorded over a duration of 30000 seconds. By integrating the instantaneous power reading over time, the electrical energy supplied to the heater is obtained. This energy maintains a steady

water temperature as required, and the derived averaged power is thus equal to the heat loss from the tank's water to the surroundings.

Thanks to strong convection resulting from the heating element being located at the tank's bottom, water temperature is fairly uniform throughout the tank. This is similar to measurements presented in [13]. Figure 4 thus shows a representative set of temperature records from an experiment without air injection, conducted on 15-09-2008. When there is air injection, this well-mixed condition is further enhanced by the strong agitation resulting from air bubbling through the water. Note that since the injected air's temperature is measured with a thermocouple inserted inside the figure-8-shaped plastic tube, when there is no air-injection (like the case shown in Figure 4), this temperature is close to that of the heated water. With air injection, on the other hand, as there is a continuous supply of cooler air from the compressor, air temperature is substantially lower than the water temperature. Air temperature, however, is not among the test parameters considered in this work.

Temperatures were recorded with an accuracy of ± 0.5 K, whereas measurement of air mass flow rate per unit tank's surface area is estimated to be accurate to ± 0.17 g/s·m^2. Uncertainties associated with the measured electrical power provided by the heater is ± 0.4 %, while water evaporation rate was measured with an accuracy better than about ± 10 %. Repeatability of the measurements was also good. Thus, in one set of 5 experiments to measure a water evaporation rate under similar conditions, the mean value obtained was 2510 g/h.m^2, with a standard deviation of only 125 g/h.m^2.

In the rest of this work, however, only mean values are shown.

RESULTS AND DISCUSSION

Experiments were performed for different air-injection rates. First, however, evaporation rate without air agitation was measured and compared with the correlation developed by Boelter et al. [9] and also used by Paulken [6]. This correlation for evaporation into still air is

$$J = 74.0\ (P_w - P_a)^{1.22} \quad (1)$$

where J is evaporation rate per unit surface area in g/h.m^2, P_w vapour pressure at the water surface in kPa, and P_a partial pressure of water vapour in the ambient air in kPa. The comparison shows very good agreement. Thus, from the experiment conducted on 15-09-2008, the following values

were obtained: surface temperature 59.7 °C, ambient temperature 24.6 °C, relative humidity 55 %, measured evaporation rate 2520 g/h.m^2. On the other hand, using thermophysical data of saturated water corresponding to the above condition [14], Boelter et al.'s formula gives 2500 g/h.m^2, differing from measured value by less than 1%.

Figure 5 shows the increase of evaporation ΔJ above that corresponding to non-agitation (zero air-injection) in terms of air-injection rate per unit surface area m. ΔJ is seen to be proportional to m according to

$$\Delta J = 22.7\ m\ ;\quad m \text{ in } g/s.m^2,\ \Delta J \text{ in } \% \tag{2}$$

Results of Figure 5 have been obtained with water temperature and the ambience maintained at fairly constant conditions, pertaining to this work as described above. Note also that the measured evaporation rate corresponding to zero air-injection is J =2520 g/h.m^2, from above.

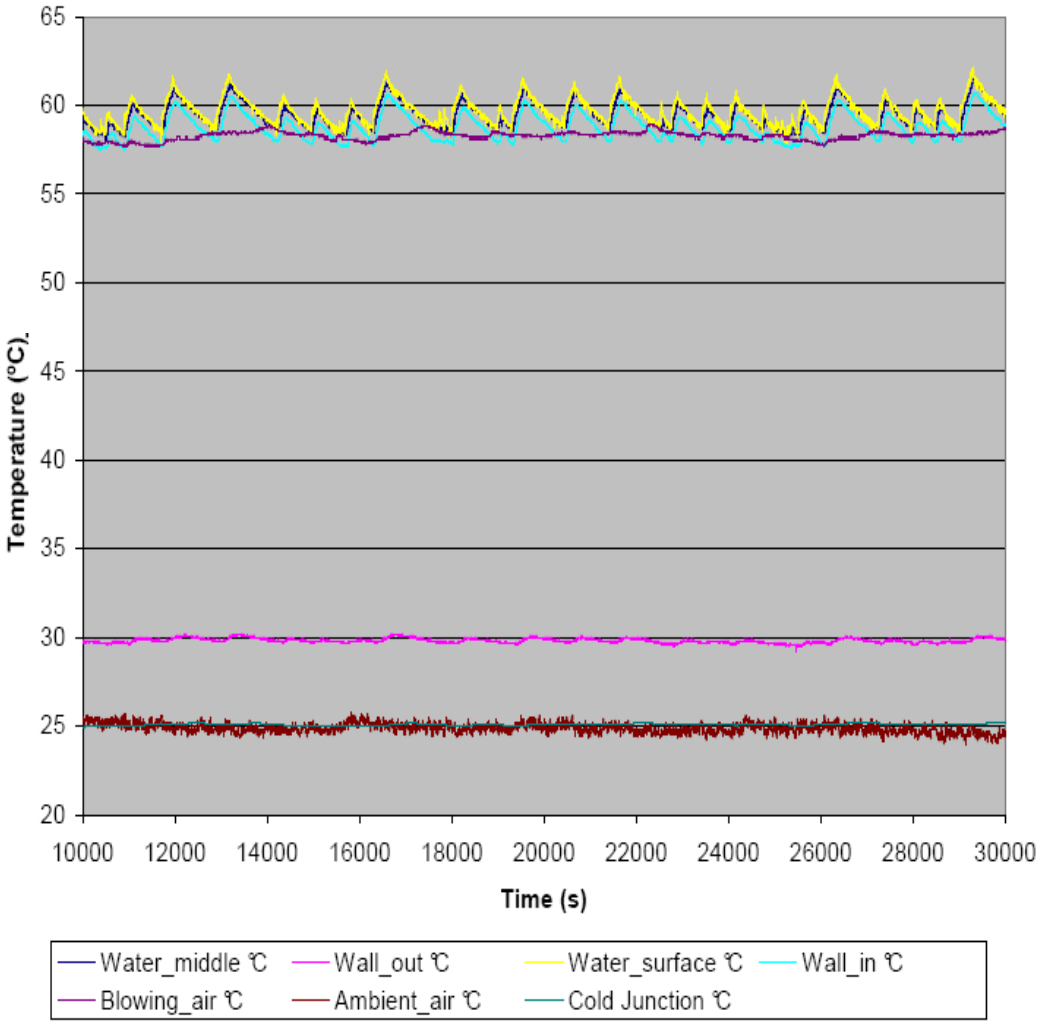

Figure 4. Temperature records from an experiment without air injection, conducted on 15-09-2008. The saw-tooth traces at the top are water temperatures at mid-tank and at surface, and internal wall temperature; they show that the tank is well mixed

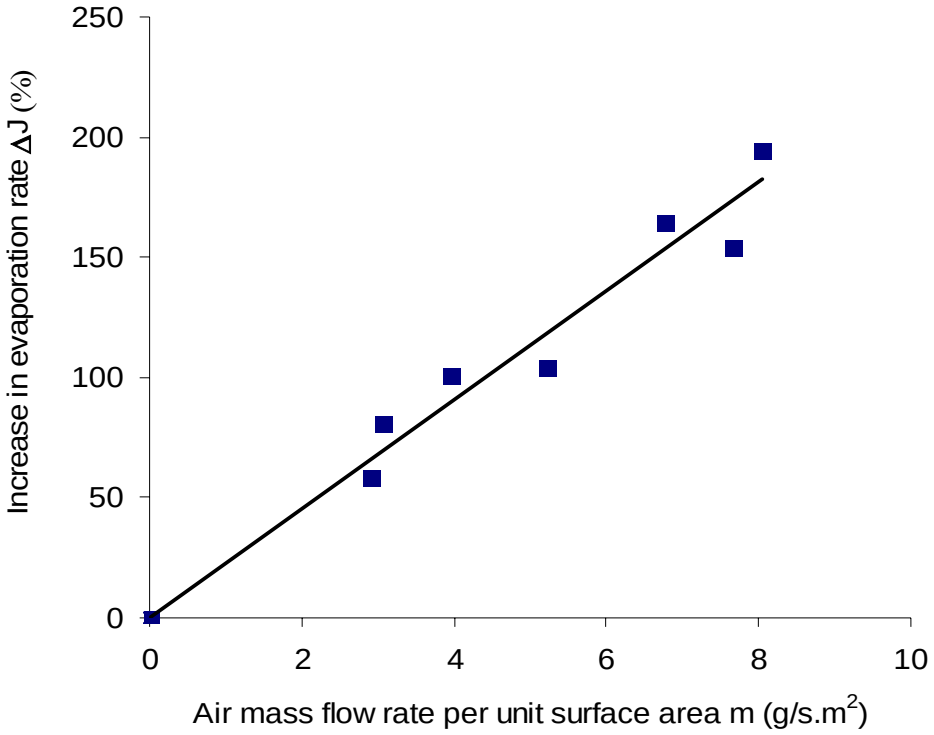

Figure 5. Increase in evaporation rate in terms of air-injection rate; correlation is $\Delta J = 22.7$ m.

The electrical power consumed by the heating element and measured with the power clamp meter (see Figure 3) is also seen to agree well with calculations based on a heat transfer model. In this model, total heat loss from the tank's water is due to (1) evaporation, (2) conduction through the tank's walls, (3) radiation from water surface, and (4) convective loss from the hot water surface to the air above. Taking 13.85 W/m.K for steel wall's thermal conductivity, 0.040 W/m.K for EPS wall cover's, 0.96 for water surface's emissivity [14], using the above measurements of 15-09-2008 which now also include internal wall temperature 58.9 °C, external wall (cover surface) temperature 29.7 °C, and using the convective heat transfer relation $Nu = 0.54Ra^{1/4}$ for water surface [14] where Nu is the Nusselt number and Ra Rayleigh number, both based on ambient air's properties, total heat loss from the tank's water has been calculated to be 616 W. On the other hand, consumed electrical power was measured to be 647 W, giving a difference of only 5 % between the two values.

The ratio of Heat-Loss-by-Evaporation over Total-Power-Consumed $Q_{evap}/Q_{total\text{-}elect}$ is of special interest. For the non-agitation case, using latent heat of evaporation 2.37×10^6 J/kg [14] heat loss due to evaporation has been calculated to be $Q_{evap} = 448$ W, thus representing 69 % (= 448/647) of the total power consumed.

When air is bubbled through the water, this ratio is higher. Thus, from another set of measurements (of experiment conducted on 17-09-2008) air-injection rate was 3.05 g/s.m^2 and evaporation rate 4560 g/h.m^2 (3.42×10^{-4} kg/s from a surface area of 0.27 m^2), therefore requiring an evaporation heat $Q_{evap} = 810$ W. The measured electrical power was 987 W. This gives a ratio of $Q_{evap}/Q_{total\text{-}elect}$ of 82 %. That $Q_{evap}/Q_{total\text{-}elect}$ increases with air-injection rate m agrees with expectation. For,

$$\text{Total heat loss (approximately equal to electrical power consumed } Q_{total\text{-}elect}) = \text{conduction loss } Q_{cond} + \text{radiation loss } Q_{rad} + \text{convection loss } Q_{conv} + \text{evaporation heat } Q_{evap} \quad (3)$$

As air-injection increases, Q_{evap} increases as a result of increasing ΔJ, while Q_{conv} and Q_{rad} stay unchanged, and Q_{conv} expected to increase only slightly (mainly due to water surface being more agitated). The ratio $Q_{total\text{-}elect}/Q_{evap}$ thus decreases, or $Q_{evap}/Q_{total\text{-}elect}$ increases.

In fact, this ratio can readily be calculated, as in the following example. Using above data from the experiment conducted on 17-09-2008, the following values have been obtained Q_{cond} = 55 W, Q_{rad} = 65 W, $Q_{conv} \approx$ 50 W, and Q_{evap} = 810 W. These then give a total heat loss of 980 W, in good agreement with the measured electrical power of 987 W above.

Using this procedure, at the highest evaporation rate measured in this work (ΔJ = 194.5 % or J = 7420 g/h.m^2) the ratio $Q_{evap}/Q_{total\text{-}elect}$ can be estimated to be 89 %. The concern of high energy consumption in industrial processes like electroplating where air bubbling is used is thus clear.

Figure 6 shows a comparison of the tank's surface region when there is no air injection versus when there is a significant injection. In the latter case, the much agitated water surface and high vapour concentration are evident. It should, however, be also pointed out that size and shape of the injected air that issues from the equi-spaced holes of about the same diameter on the plastic tube, causing strong mixing and stirring of the water, are not among the test parameters in this work.

Figure 6. Comparison of evaporation and agitation states on tank's surface when there is no air injection (left) versus when there is a significant injection (right)

CONCLUSIONS

Experiments have been performed using a heated water tank to investigate the effects of water agitation on evaporation rate and power consumption. Agitation was achieved by having air bubbling through the water. Evaporation rate has been found to increase linearly with higher rate of

injected air. A model developed for the heat loss from the tank's water agrees well with measured total energy consumed by the heating element. Most of the heat loss is due to evaporation. The ratio of evaporation heat over total energy consumed is seen to increase with air injection, starting from around 69 % at zero injection, for the conditions pertaining to this work. Calculation of this ratio agrees well with measurements; and this ratio has been shown to grow to 89 % at the highest air injection rate used in this work. Also, very good agreement has been obtained for evaporation rate between this work's measurements and the correlation developed by Boelter et al. when there is no air agitation.

ESTIMATION OF THERMAL CONDUCTIVITY AND EMISSIVITY USING CONJUGATE HEAT TRANSFER EXPERIMENTS

R. Krishna Sabareesh[1], S. Prasanna[1], S.P. Venkateshan[1,*]
[1]Heat Transfer and Thermal Power Laboratory, IIT Madras, Chennai, India

ABSTRACT. Steady state experiments on the basic aspects of conjugate heat transfer occurring from a vertical flat plate made of different materials (Aluminium, Titanium alloy and Bakelite), in quiescent air, with an embedded heater have been explored in the present work. Numerical studies are also conducted and the simulated temperature profiles are then compared with the experimentally obtained temperature distribution to obtain the residual, the minimization of which using, the Least Square Method, retrieves the parameters, surface emissivity and plate material thermal conductivity. The experiments have been carried out for various power inputs and the consistency of the proposed method is tested. The values of emissivity and thermal conductivity obtained by the present method are in good agreement with the previously reported values.

Keywords: *Conjugate heat transfer, thermal conductivity, emissivity, inverse problem, Interferometer*

INTRODUCTION

Conjugate heat transfer problems occur in many practical applications. Several studies have been made in the area of conduction-convection coupling. The heat transfer enhancement by extended surfaces such as fins, is an example that falls in this category. Vynnycky and Kimura [1] investigated analytically and numerically two dimensional conjugate free convection from a vertical plate adjacent to a semi-infinite fluid region. Córdova and Treviño [2] studied the effect of longitudinal heat conduction in the cooling of a vertical thin plate in natural convective flow, using both numerical and asymptotic techniques. Recently Nouanegue et al [3] investigated numerically the conjugate heat transfer by natural convection, conduction and radiation in open cavities. Despite a large number of publications available in the area of conjugate heat transfer, only very few experimental studies are found in literature. Miyamoto et al [4] performed both experimental and numerical studies on a vertical plate subjected to a uniform heat flux and identified the criteria for assuming, basically a constant heat flux situation as an isothermal one. Kimura et al [5] investigated experimentally and analytically conjugate heat transfer and proposed a simple expression for average heat transfer.

The determination of thermo-physical properties from the measured temperature profiles is essentially a parameter retrieval problem in heat conduction. Any parameter retrieval problem involves two stages, forward model and inverse problem. Forward model in the parlance of heat transfer refers to the determination of temperature profile in a material whose thermo-physical properties are known. The inverse problem refers to the determination of these properties by knowing the temperature distribution in the body. An accurate knowledge of the thermo-physical properties like emissivity and thermal conductivity is important in accurately modelling and simulating many engineering applications. Most

of the conventional methods used for the determination of emissivity require a vacuum environment to avoid other modes of heat transfer. Krishnan et al [6] proposed a novel method for the estimation of emissivity, by conducting transient cooling experiments on a vertical heated plate in quiescent air. Following that, Venugopal et al [7] proposed a new method for the simultaneous estimation of emissivity and specific heat by carrying out transient cooling experiments.

The main purpose of the present work is to estimate emissivity and thermal conductivity, by carrying out steady state conjugate heat transfer experiments.

EXPERIMENTAL SETUP AND PROCEDURE

Since the experimental setup has been described in detail in [7], only a brief review will be presented here. The setup consists of a vertical plate assembly suspended freely from two parallel stainless steel rods using two Teflon rods as depicted in figure 1. The test plate assembly consists of two plates of dimensions 150 × 250 × 3 mm with a flat heater sandwiched between them. The flat heater is formed by winding a Nichrome wire over a mica sheet and the same is electrically insulated from the unexposed side of the test plates by using mica sheets. The two halves of the test plate are fastened together using screws and nuts which are seated in countersunk holes to avoid disturbances to flow due to protrusion. The temperatures at different locations (as shown in figure 2) are recorded using calibrated K- type (36AWG) stainless steel sheathed thermocouples which are fixed to the plate by means of highly conducting copper cement. A separate K- type thermocouple is kept inside the test section to measure the ambient temperature. All thermocouples are connected to a personal computer based data acquisition system (Model No. 34970A, Agilent Technologies Ltd.) through compensating wires. The power input to the heater is supplied from a regulated dc power source (Aplab Systems Ltd., India, Model No. H0615).

Steady state experiments, simulating natural convection environment inside the test section, are carried out for various power inputs. Steady state is assumed to be reached when the variation in the temperature readings of all the thermocouples is within ±0.1 °C in 10 minutes. The experiments are carried out for three different materials of the test plate (aluminium, titanium alloy, and bakelite [supplied by M/S Bakelite Hylam, Hyderabad, India]) The experiments on aluminium and titanium test plate are conducted for three different surface conditions viz. ‘no coating’, aluminium paint and blackboard paint, while the experiments on bakelite are conducted only for the ‘no coating’ condition.

NUMERICAL SIMULATIONS

The experimental conditions have been simulated numerically using the commercially available CFD package FLUENT 6.3. Extensive grid independence study has been carried out and proper mesh has been selected. The result that is obtained from the numerical simulations is used as the forward model. The forward model involves obtaining the temperature distribution along the plate for different combinations of emissivity and thermal conductivity and for various heat inputs. The important observations from the numerical study are as follows.

Figure 3 represents the temperature profiles obtained for different values of thermal conductivity, for a fixed heat input and emissivity. It is seen that as the thermal conductivity of the material increases, the temperature gradient along the plate decreases. Therefore, the isothermal assumption is strictly valid for materials having high thermal conductivity, such as aluminium. Figure 4 shows the variation of local heat transfer coefficient along the plate for different values of thermal conductivity. It is seen that the heat transfer coefficient is *independent* of the thermal conductivity of the plate**.**

Table 1 shows the variation of the average temperature of the plate for a thermal conductivity of 200 W/m K, for different values of emissivity. It is seen that the average temperature of the plate decreases with increase in emissivity. It is also seen that the average heat transfer coefficient decreases with increase in emissivity which is in accordance with the observations made by Rammohan et al. [8]. Table 2 shows the dependence of the average temperature of the plate on the thermal conductivity for a given emissivity and power input. It is clear that for a given emissivity, the average plate temperature is *independent* of thermal conductivity.

(a) (b)

Figure 5. Interferogram for (a) aluminium and (b) titanium plates coated with aluminium paint

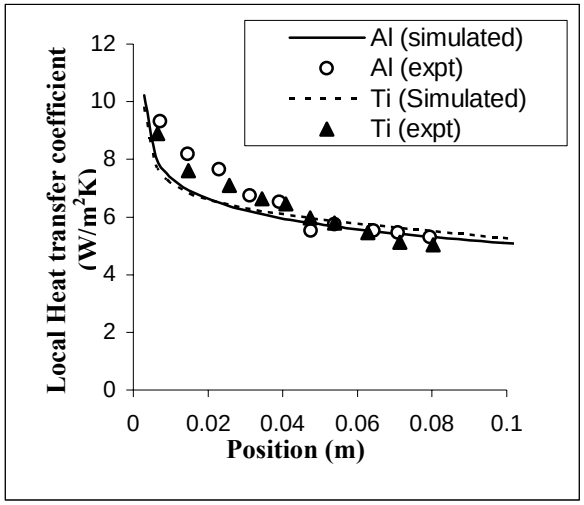

Figure 6. Local convective heat transfer coefficient for aluminium and titanium alloy coated with aluminium paint.

Local heat transfer measurements by a Differential interferometer (DI) have been further used to validate the numerical observation. The principle of operation of the DI has been explained in [9]. The optical setup used in the present study is same as that of [10]. The main advantage of the DI is that the convective heat transfer coefficient at the wall can be directly determined from the interferograms. Figure 5 shows the interferograms corresponding to aluminium and titanium plates coated with aluminium paint, for the same heat input. The field of view available for the interferometer used in the present study is only 9.5 cm and hence the studies have been restricted to that length of the plate starting from its leading edge. Figure 6 shows the comparison between the numerically simulated and experimentally obtained local convective heat transfer coefficient for both aluminium and titanium plates for the same experimental conditions. It is seen that the results from the interferograms corroborate very well with the numerical study far away from the leading edge. Close to the leading edge, the temperature gradients are very high and the fringes obtained are very steep. Hence the variation could be attributed to the errors in the calculation of fringe shift and other experimental uncertainties. Inspite of this, it is found that the local heat transfer coefficient obtained is more or less independent of the thermal conductivity of the material, justifying the use of the numerical scheme as the forward model for parameter retrieval.

INVERSE PROBLEM

From the experiments, the temperature distribution along the plate for a particular surface condition and thermal conductivity is obtained. The forward model gives the temperature distribution for known values of emissivity and thermal conductivity. So the inverse problem is to retrieve the unknown parameters, emissivity and thermal conductivity, by minimizing the sum of the squares of the differences between the numerically simulated and the experimentally obtained temperatures, which is called as the Least Square Residual (LSR), *R.* Mathematically, which can be represented as

$$R = \sum_{i=1}^{n} \left(T_i^{sim} - T_i^{\exp} \right)^2 \tag{1}$$

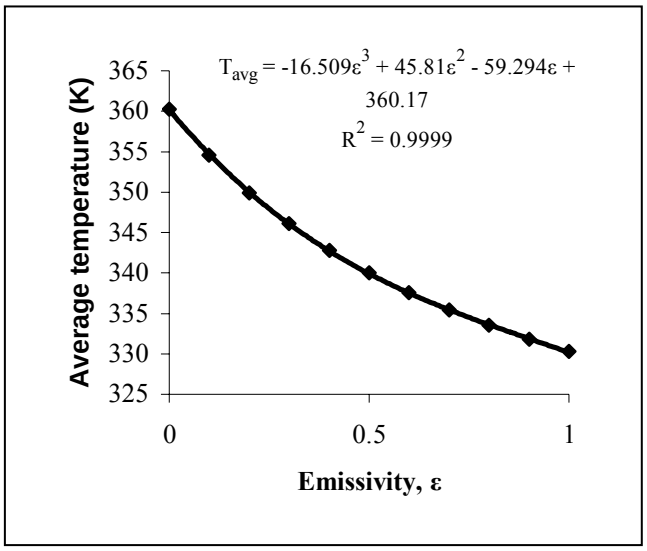

Figure 7. Cubic fit for the database

Retrieval of emissivity

From the numerical study, it is clear that for a given heat input, the average temperature of the plate as well as the average heat transfer coefficient are independent of the thermal conductivity, but depend only on the emissivity of the plate. A database of simulated average plate temperatures is created for different values of emissivity for a fixed value of heat input. The thermal conductivity independence ensures that even if a paint, whose emissivity is to be retrieved, is applied on a material of unknown thermal conductivity; the database can be generated using any value of thermal conductivity in the forward model. A cubic polynomial is then fit for that particular database. One typical example of such a database is shown table 3 and figure 7. The cubic equation is then solved by substituting the experimentally obtained average plate temperature in the equation. The root of the cubic equation gives the value of the emissivity which we are trying to retrieve. Thus this method of retrieving the emissivity of the coating is superior to other methods [6, 7] as it does not require the knowledge of any other thermo- physical property.

Retrieval of thermal conductivity

Once the emissivity and heat input are fixed, the temperature distribution along the plate depends only on the thermal conductivity. So the forward model is run with the retrieved value of the emissivity obtained by the previous method, for different values of thermal conductivity. The temperature distribution that is obtained for each value of thermal conductivity is given a cubic fit. Figure 8 represents one such fit for a certain thermal conductivity value. The temperatures at the positions where the thermocouples are located in the plate are then calculated using the fit polynomial. This is then compared with the experimentally obtained temperatures at the corresponding positions, to obtain the residual. The LSR for each value of thermal conductivity is calculated and then plotted against thermal conductivity. The minimum value of this curve corresponds to the value of the thermal conductivity which we are trying to retrieve.

Table 4 represents a typical database for a particular value of emissivity. The simulated temperatures for four different thermal conductivities are also shown. LSR, which is obtained by squaring the difference between the numerical and experimental temperatures at each point, is then plotted. Figure 9 represents one such typical graph where the LSR plots are shown for a power input of 60 W for the titanium plate and 15 W for the bakelite plate. The minimum corresponding to each curve represents the thermal conductivity for that power input.

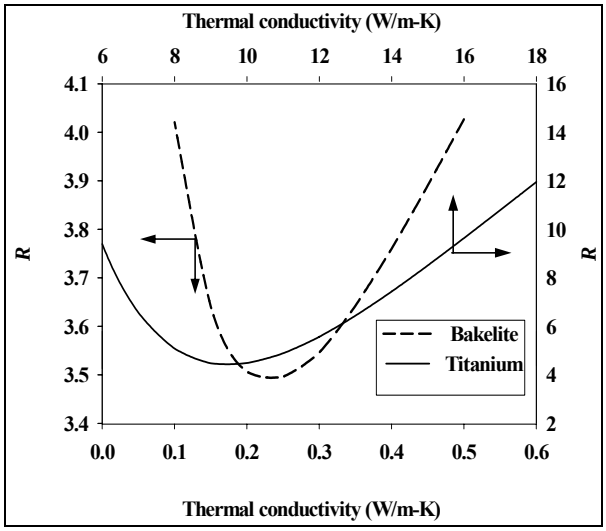

Figure 9. Least Square Residual plots for determining the thermal conductivity of titanium and bakelite

RESULTS AND DISCUSSIONS

The experiments are conducted for various power inputs ranging from 30W to 90W at an interval of 10 W for both aluminium and titanium plates. As bakelite is having very low thermal conductivity, the experiments are conducted for lower power inputs only (10W, 15W and 20W). This is to ensure that the independence of heat transfer coefficient on thermal conductivity is still valid and that the method proposed for determining both emissivity and thermal conductivity can be used without any modification. The mean value of the parameters, emissivity and thermal conductivity, along with the standard deviations, obtained from the present study are summarized in the tables presented below. The metallurgical compositions of the materials, Aluminium and Titanium, observed using scanning electron microscope (Make: FEI-Czech Republic, Model: QUANTA 200) are as follows. Aluminium: Al 92.48%, O 7.52%; Titanium: Ti 59.4%, O 15.31%, N 25.29 %(All in mole fraction).

Estimation of emissivity

Table 5 represents the results of the emissivity measurements done for three different materials of the test plate, with different surface conditions viz. with blackboard paint and aluminium paint (Manufacturer: Agsar Paints Private Ltd., Tutucorin, India) coating for Titanium and Aluminium test plates and with no coating for bakelite. From the present study it is found that the emissivity is a weak function of temperature in the range considered, which is in agreement with the observations made by Venugopal et al. [7]. The emissivity of blackboard paint coating was reported as 0.85 [9]

Table 5
Retrieved values of emissivity for different materials of the test plate with different surface conditions

Material	Paint Applied	Mean value	Standard Deviation *
Titanium alloy	Blackboard paint	0.859	0.010
	Aluminium paint	0.397	0.005
Aluminium	Blackboard paint	0.879	0.010
	Aluminium paint	0.411	0.018
Bakelite	No coating	0.725	0.002

Table 6
Retrieved values of thermal conductivity for titanium alloy and commercial bakelite

Material	Mean value (W/mK)	Standard Deviation * (W/mK)
Titanium alloy	9.95	0.840
Bakelite	0.22	0.011

* Standard deviation values quoted in Table 5 and 6 are based on repeated measurements.

and that of the aluminium paint was reported as 0.457 [11]. The very slight difference in the results obtained in the present study and that found in [9, 11] could be due to the difference in the surface condition of the plate, make of the paints and thickness of the coating applied. The emissivity of bakelite is obtained as 0.725 which is used as an *input* in the determination of thermal conductivity of bakelite. It is also observed that the emissivity of the plate is independent of the test plate material.

Estimation of thermal conductivity

Table 6 indicates the mean values of thermal conductivity obtained for titanium alloy and bakelite. The thermal conductivity of titanium alloy is reported as 9 W/m-K [12] while that of bakelite is reported as 0.233 W/m-K. [13]. As the proposed method requires a reasonable temperature gradient along the plate for determining the thermal conductivity, it cannot be used for materials with high thermal conductivity like aluminium, which will be having more or less uniform temperature profile throughout the plate.

CONCLUSIONS

A novel method which involves a judicious combination of both experiments and numerical simulations has been proposed to estimate the parameters, emissivity and thermal conductivity. The present experimental setup is simple to construct and does not demand vacuum for the estimation of emissivity. The thermal conductivity retrieval proposed here can be applied over a wide range starting from insulators to materials having moderate thermal conductivities, though it cannot be extended to materials having very high thermal conductivity due to the absence of appreciable temperature variation along the plate. Moreover the present inverse methodology for parameter retrieval does not require any sophisticated optimization technique. The consistency of the above method has been tested extensively for a wide range of operating conditions. The retrieval of the parameters depends only on the temperature measurements and is independent of any other thermo-physical property of the test material.

MATHEMATICAL MODELLING OF LOW TEMPERATURE CONDENSATION COUPLED WITH ADSORPTION

A. Rotkegel *
Institute of Chemical Engineering Polish Academy of Sciences, Gliwice, Poland

ABSTRACT. The mathematical model of Volatile Organic Compound (VOC) removal from air in the integrated system of low temperature condensation followed by adsorption is presented. Mathematical model of the integrated system consists of two different calculation steps: low temperature condensation of vapors in the presence of inert gas, and low temperature adsorption of vapors. Due to the character of two mentioned processes, each of them must be calculated otherwise. The removal of VOC from gases in the integrated process of low temperature condensation followed by adsorption enables to remove VOC from gases almost completely at relatively high condensation temperatures (240K). The sorption capacity increases with the lower of adsorption temperature, but gives smaller values of diffusional time constant. This fact leads to the increase of mass transfer zone in the adsorber, breakthrough curves become more flat, and in final result utilization of adsorber capacity is lower.

Keywords: *VOC removal, adsorption, condensation, low temperature*

INTRODUCTION

Volatile Organic Compounds (VOCs) are emitted into the atmosphere in the considerable amount by the chemical industry, as a result of the production, storing, transportation and the distribution of colors, varnishes, solvents and liquid fuels. The considerable growth of the consumption of volatile organic compounds in the industry will cause enlargement of the threat for natural environment and the health of the population, because about 80% of VOCs are emitted into the atmosphere [1-3]. To limit the harmful influence of emitted VOC on the natural environment it is necessary to reduce considerably the emission of these substances.

This requires lowering the concentration of VOCs in gases exhausted into the atmosphere to a very low concentrations, of a ppm range. The achievement of this aim needs further development and improvement of existing techniques of VOCs removal, such as: the catalytic or thermal oxidation [4], absorption, cryogenic condensation and adsorption [5, 6].

According to literature reports [5], the use of cryogenic condensation in the process of VOCs removal from gases is more frequently used in industrial installations.

The achievement of the high degree of the cleaning gas in the process of cryogenic condensation requires cooling down the gas mixture to the temperature of about 170 K, which can be realized practically by using the liquid nitrogen, as a cooling medium.

The alternative way to the cryogenic condensation, allowing to achieve the low concentrations of VOCs in gas mixtures emitted to the atmosphere, is the use of hybrid process of condensation followed by adsorption [7-8]. Applying such a hybrid arrangement is more effective than the application of each process separately [7-8]. The process of VOCs condensation can be realized in the considerably higher temperatures than in the process of the cryogenic condensation alone (240 to 250 K), using other cooling media such as: refrigerating brine, ammonia or glycols. The process of VOCs adsorption is done in the temperatures in which gas mixtures leave the condenser, and the

E-mail address: arot@iich.gliwice.pl

desorption process in the temperature insignificantly higher than 273 K. The gas mixture from the desorber is led to the condenser, which allows to recover the whole quantity of volatile organic compounds as condensates. This way of carrying of the process allows to avoid additional costs connected with the utilization of gases after desorption process.

EXPERIMENTAL SET-UP

The experimental studies of integrated process of low-temperature condensation coupled with adsorption, was described in detail in [9]. The experimental set-up was composed of: the condenser plus two working adsorbers running alternately in the cycles adsorption – desorption. Such settings of apparatuses allows continuous work of the installation of gas mixtures cleaning. As a cleaning gas the mixture of 2-propanol and nitrogen was used. The concentration of 2-propanol was changed in the range from 4 to 25 g/Nm^3. The active carbon AP3-60 made by Chemviron-Carbon was applied as the packing of adsorbers. The experimental set-up is presented in Fig. 1

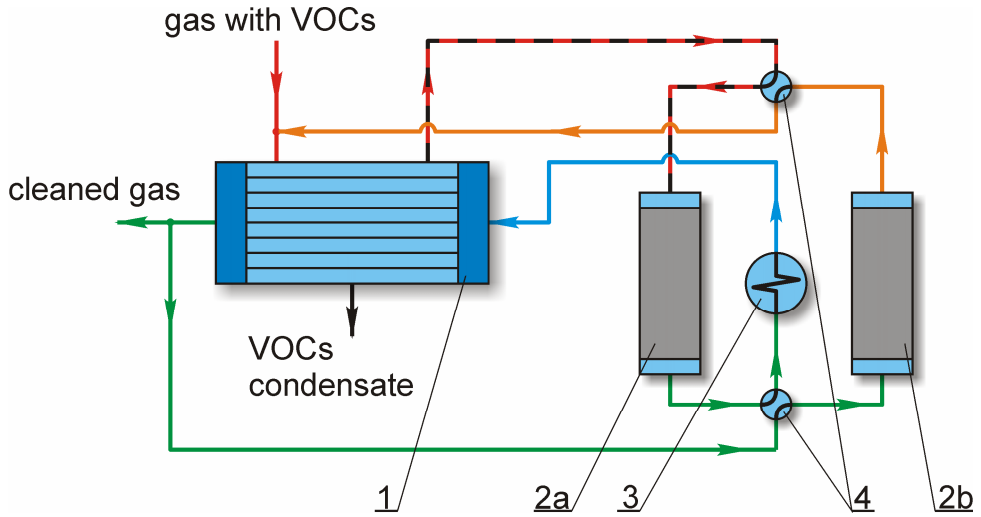

Figure 1. Experimental setup: 1 – condenser, 2a,2b – adsorbers, 3 – heat exchanger, 4 – 4-way valves

MATHEMATICAL MODEL

Mathematical model of the integrated system consists of two different calculation steps: low temperature condensation of vapors in the presence of inert gas, and low temperature adsorption of vapors. Due to the character of two mentioned processes, each of them must be calculated otherwise. The model of low temperature condensation was described using a system of ordinary differential equations with boundary conditions. The model of adsorption was described using the system of partial differential equations with initial and boundary conditions.

Mathematical model of low temperature condensation

The process of condensation is described using the set of four ordinary differential equations with the boundary conditions, together with the following assumptions:

- the process occurs under steady state, isothermal and adiabatic conditions,
- heat and mass transfer resistances in liquid film are neglected,
- on the interfacial surface of the condensate - vapor mixture a thermodynamic liquid-gas equilibrium exists,
- according to film theory, heat and mass transfer resistances occur only in the gas phase near the interface; these resistances can be determined by the respective heat and mass transfer coefficients.

To calculate the temperature and concentration profiles along the condenser it is necessary to set and solve the system of differential equations of mass and heat balances. Assuming that the mass flow of vapour to the liquid phase has a positive sign, the corresponding system of equations for one dimensional model can be presented as follow; mass balances in gas and liquid phase:

$$\frac{dG_k}{dl} = -nN_k \pi d \tag{1}$$

$$\frac{dG_c}{dl} = nN_k \pi d \tag{2}$$

heat balances in gas and liquid phase:

$$G\,\bar{c}_{pA}\frac{dT_A}{dl} = \pi\, nd\,(T_A - T_w)\,(N_k\,\bar{c}_{pA} - \alpha_A) \tag{3}$$

$$G\,\bar{c}_{pB}\frac{dT_B}{dl} = -\pi\, nd\,\alpha_B (T_w - T_B) \tag{4}$$

The wall temperature was calculated from the equation of continuity of heat flux, where the heat resistance in the liquid film was omitted :

$$N_k\,\Delta H_k + \alpha_A (T_A - T_w) = \alpha_B (T_w - T_B) \tag{5}$$

The heat and mass transfer coefficients were determined experimentally

Mathematical model of adsorption

The process of adsorption is described by the set of partial differential equations with the initial and boundary conditions and the following assumptions:

- the process is isothermal,
- thermal equilibrium occurs between gas and adsorbent grains,
- the gas flow rate by the adsorbent bed is fixed,
- in the adsorbent bed gas plug flow profile with axial dispersion exists,
- mass transport between gas phase and the liquid layer on adsorbent surface is described by a linear equation of mass transfer,
- the concentration profile in adsorbent pore is parabolic,
- the pressure drop through the adsorber bed is neglected,
- gas mixture flowing through the adsorber is treated as an ideal one,
- mass transport velocity given by linear driving force (LDF) equation.

With the above assumptions, the adsorption process of VOC on the adsorber bed can be described with the following equations [10][11]:

$$-D_L\frac{\partial^2 c}{\partial z^2} + w\frac{\partial c}{\partial z} + \frac{\partial c}{\partial \tau} + k_l\left(\frac{1-\varepsilon}{\varepsilon}\right)\left(q^* - \bar{q}\right) = 0 \tag{6}$$

At a parabolic concentration profile in the sorbent pore the value coefficient k_l can be calculated [12], [13] from:

$$k_l = 15\frac{D}{r_p^2} \tag{7}$$

Diffusion coefficient D_L for the axial dispersion can be calculated from relationship by Wakao and Funazkri [14]

$$\frac{\varepsilon D_L}{D_m} = 20 + 0.5 Re_L\, Sc_L \tag{8}$$

where binary diffusion coefficient was calculated from Schettler-Giddings [15] correlation:

$$D_m = 1.013\times10^{-2} T^{1.75} \frac{\sqrt{1/M_i + 1/M_I}}{P\left(\sqrt[3]{V_i} + \sqrt[3]{V_I}\right)^2} \tag{9}$$

To solve the partial differential equation (6) the following initial and boundary conditions were assumed:

$$\begin{aligned} c\big|_{\tau=0} &= 0 \\ q\big|_{\tau=0} &= q^*(t_{ads}, c) = 0 \end{aligned} \tag{10}$$

and

$$\begin{aligned} c\big|_{z=0} &= C_1 \\ \left.\frac{\partial c}{\partial z}\right|_{z=z} &= 0 \end{aligned} \tag{11}$$

NUMERICAL CALCULATIONS

Numerical calculations were carried out separately for the low-temperature condensation and adsorption process. For the low temperature condensation calculations the system of ordinary differential equations was integrated using the DE/STEP procedure of Shampine-Gordon [16]. Integration of the differential equations was carried out according with the direction of flow of gas-vapour mixture. In each integration step the physical and thermodynamical parameters of components were calculated.

For low temperature adsorption the system of partial differential equations (6) with initial (10) and boundary (11) conditions were solved using finite differences method with implicit scheme. In our calculations the QUICK method described by Leonard [17] was used. In this method the finite dfference $\Delta c_i/\Delta z$ in the i-node is described as:

$$\frac{\Delta c_i}{\Delta z} = \frac{1}{8\Delta z}\left(c_{i-2} - 7c_{i-1} + 3c_i + 3c_{i+1}\right) \tag{12}$$

With the above assumption the equation (6) can be presented in the form of finite differences in the i-node and the n-time step as:

$$\begin{aligned} \frac{c_i^{n+1} - c_i^n}{\Delta\tau} = \frac{D_L}{2\Delta z^2}\left(c_{i-1}^n - 2c_i^n + c_{i+1}^n + c_{i-1}^{n+1} - 2c_i^{n+1} + c_{i+1}^{n+1}\right) - \\ \frac{w}{16\Delta z}\left(c_{i-2}^n - 7c_{i-1}^n + 3c_i^n + 3c_{i+1}^n + c_{i-2}^{n+1} - 7c_{i-1}^{n+1} + 3c_i^{n+1} + 3c_{i+1}^{n+1}\right) - \left(\frac{1-\varepsilon}{\varepsilon}\right) k_l\left(q^*(c_i^n) - \overline{q_i^n}\right) \end{aligned} \tag{13}$$

and

$$\frac{\overline{q_i^{n+1}} - \overline{q_i^n}}{\Delta\tau} = k_l\left(q^*(c_i^n) - \overline{q_i^n}\right) \tag{14}$$

To solve such formulated problem the system of n equations should be solved in each time step (where n is equal to the amount of the calculation nodes in the adsorbent bed). Good calculation accuracy was achieved for n equal to 80 and time step equal to 10^{-2} sec.

COMPARISON OF CALCULATION RESULTS WITH EXPERIMENTAL DATA

To compare calculation results of low temperature condensation with experimental data the graph of calculated condensation efficiency vs. experimental one was done. The condensation efficiency was defined as:

$$\eta = \frac{C_0 - C_1}{C_0} \tag{15}$$

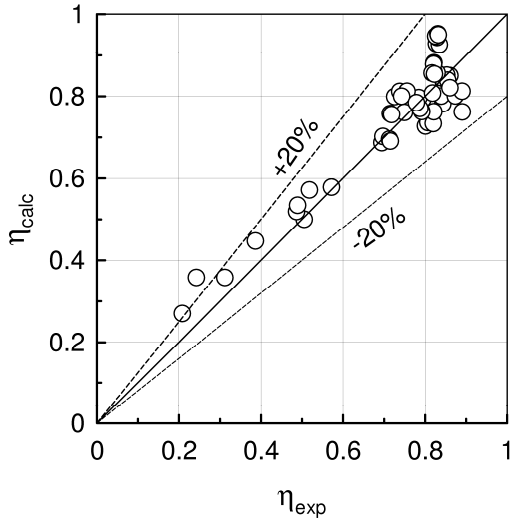

Figure 2. Calculated efficiency of condensation vs. experimental ones

Figure 2 shows that the calculated efficiency of the condensation process is consistent with experimental data within the range of about 20%. Average error of calculation of exhausted gas temperatures, concentration and condensation efficiency and their standard deviations, was given in the table 1.

Table 1. Standard deviation and average error of condensation process calculations

Parametr	Average error	Standard deviation
T_{A1} [K]	1.97	0.55
T_{B1} [K]	1.05	0.81
C_1 [g/Nm^3]	0.50	0.50
η	0.049	0.060

The comparison of calculated adsorption breakthrough time vs. experimental one was given in figure 3. Notation τ_{01}, τ_{05}, τ_{10} describes times at which the concentration of VOC in the outlet of the adsorber reached the value of 1%, 5% and 10% of inlet concentration respectively. Figure 3 shows that error of calculated breakthrough times was less than 25%. Absolute mean error of calculated breakthrough time was equal to 10.68 min, relative error was 8.77% and standard deviation was equal to 6.61 min.

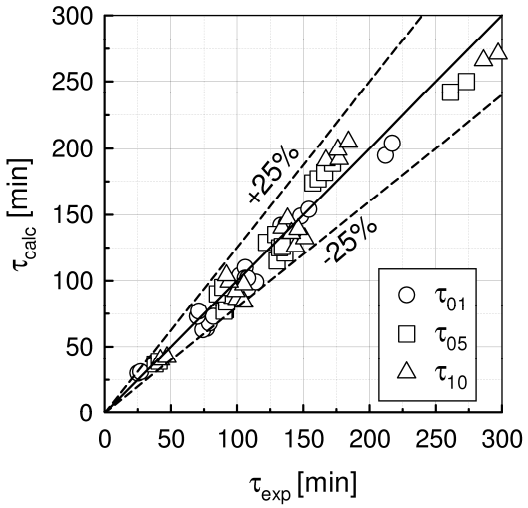

Figure 3. Calculated breakthrough times vs. experimental ones.

TEMPERATURE EFFECT ON THE ADSORPTION PROCESS

Adsorption isotherms of 2-propanol on activated carbon AP3-60 is presented in figure 4. As can be seen the maximum sorption capacity of adsorbent bed increases with the decrease of adsorption temperature, especially for small concentrations of propanol-2 in the inlet gas to the adsorber.

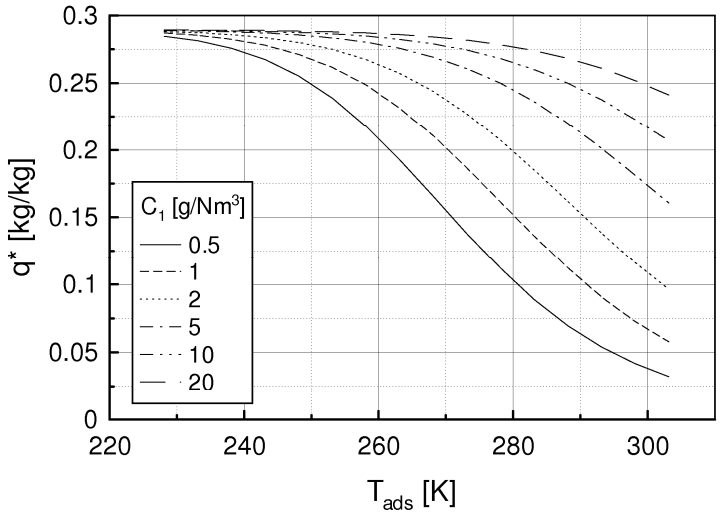

Figure 4. The dependence of the maximum sorption capacity of the adsorption temperature for different concentrations of 2-propanol at the inlet to the adsorber.

But with the reduction of the adsorption temperature the diffusional time constant decreases, which leads to a reduction of diffusion rate in the adsorbent pores and as a result the mass transfer zone in adsorber increases and breakthrough time decreases.

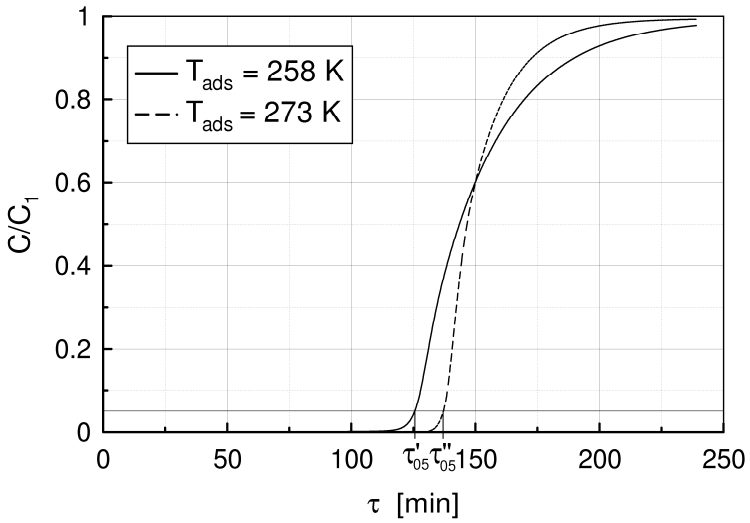

Figure 5. Calculated adsorber breakthrough curves for two different adsorption temperatures.

CONCLUSIONS

Based on the developed mathematical models of condensation and adsorption processes the numerical calculations were performed and compared with experimental data. Analysis of the numerical calculations all w to formulate the following conclusions:

- VOCs removal from gaseous mixtures in the integrated system of condensation and adsorption enables to remove almost completely VOCs from gaseous mixtures. High degree gas purification is possible in condensation temperatures higher than 235 K

- The purification of gaseous mixtures from VOCs in the integrated system of condensation and adsorption is especially useful when the concentration of VOCs in gases is relatively high. In this case the advantage of the two used processes increases:
  - condensation is a process of low sensitivities to the oscillation of inlet concentration of VOCs, in which the relatively low and stable concentration of VOCs in gases introduced to the adsorber can be achieved
  - adsorption of low concentration component from gases leads to the extension of adsorption cycle time and allows to limit the financial cost of apparatus.
- Numerical results, obtained by developed mathematical model, show good accuracy with experimental data
- Adsorber sorption capacity increase with decrease of adsorption temperature. On the other hand, lowering the adsorption temperature leads to decrease of the diffusional time constant, the mass transfer zone in adsorber increases and in final effect the utilization of adserber bed capacity decreases. For this reason, together with a decrease of adsorption temperature the "long" adsorber bed should be used, ie, those in which the ratio of the mass transfer zone length to the total length of the adsorber bed will be relatively small.

NOTATION

C – VOC concentration in the gas mixture , $g\ Nm^{-3}$
C_0 – VOC concentration on the inlet to the condenser, $g\ Nm^{-3}$
C_1 – VOC concentration on the outlet from the condenser, $g\ Nm^{-3}$
c – VOC concentration in the gas phase in the adsorber, $kg\ m^{-3}$
c_p – specific heat, $J\ kg^{-1}K^{-1}$

THERMAL CHARACTERISTICS IN A LAYER OF CORRODING IRON POWDER

K. Murata[1,*], H. Nakahata[1], K. Araga[1] and Y. Komatsu[2]
[1]Kinki University Technical College, Kumano, Japan
[2]FJ Tech Kumano Laboratory, Kumano, Japan

ABSTRACT. This paper presents an experimental investigation of the thermal characteristics in a layer of an exothermic powder mixture that is utilized in body warmers, hot compresses, etc. The research objective is to develop a manufacturing method that enables the exothermic temperature to be controlled in order to prevent cases of low-temperature burns. The exothermic powder mixture generally comprises metal powder, catalyst powder, and vermiculite particle absorbing some saline solution. The measurements of the oxygen volume consumed by corrosion of iron powder show that the reaction velocity depends on the reaction temperature, the volume of the saline solution, and the reaction rate of the iron, in addition to the ambient oxygen density; a correlation is suggested for the reaction velocity. The variation over time of the temperature distribution and the generated heat in a layer of the exothermic powder mixture is examined using a porous film to control the oxygen volume flowing into the layer.

Keywords: *corrosion, iron powder, chemical reaction, heat transfer, mass transfer, porous media*

INTRODUCTION

It is well known that reaction heat generated from the corrosion of metal is utilized in body warmers, hot compresses, etc. These products generally comprise an exothermic mixture of metal powder, a metal chloride, a water-absorbing agent, and a catalyst; the mixture is enclosed in a porous bag or spread on a sheet coated with a therapeutic agent. This exothermic powder mixture is in great demand worldwide, especially in the medical field; therefore, safety is an essential requirement for utilizing this mixture continuously while the patient is asleep. However, many cases of low-temperature burns have occurred recently because the temperature of the exothermic powder increased to a value greater than the estimated value. Research by the authors concluded that low-temperature burns are caused by variation in the maximum temperature of the exothermic powder; thus, it is necessary to comprehend the thermo chemical characteristics of the corrosive reaction of metal and to develop the manufacturing process in order to precisely control the temperature and its variation in the exothermic powder. This paper is an experimental investigation of the thermal characteristics in a layer of the exothermic powder mixture. The reaction velocity of corrosion and the time variation in temperature and heat generation in a layer of the exothermic powder mixture are reported.

OUTLINE OF IRON CORROSION

From the perspective of electrochemistry, corrosion occurs due to the presence of many local-action short-circuited cells with a small volume of water solution on the surface of the metal, as shown in

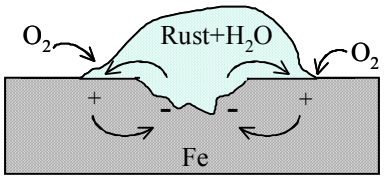

Figure 1. Oxygen concentration cells on an iron surface [1]

Figure 1. Metal ions are precipitated in the anode regions according to equation (1). This reaction is rapid in general environment.

$$Fe \rightarrow Fe^{2+} + 2e^{-} \tag{1}$$

In the general corrosion of iron, the reaction velocity in the cathode is much lower than that in the anode, so corrosion is controlled by the reaction in the cathode. The reaction in the cathode is promoted by equation (2) when oxygen is dissolved in the water solution.

$$2H^{+} + \frac{1}{2}O_2 \rightarrow H_2O - 2e^{-} \tag{2}$$

The dissolved oxygen reacts with the hydrogen atom adsorbed on the iron surface. This reaction velocity is rate-determined by the diffusion velocity of dissolved oxygen as it diffuses to the iron surface through the water solution. By adding equations (1) and (2) and using $H_2O \rightarrow H^{+}+OH^{-}$, equation (3) is obtained.

$$Fe + H_2O + \frac{1}{2}O_2 \rightarrow Fe(OH)_2 \tag{3}$$

A hydrate of ferrous oxide, FeO/nH_2O, or ferrous hydroxide, $Fe(OH)_2$, forms the barrier layer on the iron surface, through which the dissolved oxygen must diffuse to the iron surface. As it comes into contact with the dissolved oxygen on the outer surface of the barrier layer, the hydrate of ferrous oxide changes into a hydrate of ferric oxide, Fe_2O_3/nH_2O, or ferric hydroxide, $Fe(OH)_3$, as seen in equation (4). Iron rust generally comprises orange or reddish brown hydrates of ferric oxide, Fe_2O_3/nH_2O.

$$Fe(OH)_2 + \frac{1}{2}H_2O + \frac{1}{4}O_2 \rightarrow Fe(OH)_3 \tag{4}$$

By adding equations (3) and (4), equation (5) can be obtained. The reaction heat is 403kJ/mol-Fe.

$$Fe + \frac{3}{2}H_2O + \frac{3}{4}O_2 \rightarrow Fe(OH)_3 + 403kJ/mol \tag{5}$$

The reaction velocity depends on the solution film thickness, the pH and the concentration of dissolved oxygen and salt in the saline solution, in addition to the reaction temperature. However, it is known that the reaction velocity is independent of pH at pH 4-10, and reaches its maximum value at a salt concentration of 3 wt% [1].

MASS TRANSFER MODEL FOR OXYGEN IN IRON POWDER CORROSION

Figure 2 shows the distribution of the oxygen concentration in the region of the gas–liquid–solid phase reaction. In this model, it is assumed that the reaction velocity of equations (1) and (2) is significantly high, and equation (3) is rate-determined by the velocity at which the dissolved oxygen diffuses through the water solution and reaches the iron surface (in the cathode region).
The mole flux of oxygen that passes through the gas–liquid interface and reaches the iron surface, *N*, is represented by equations (6) and (7) in the gas and liquid phases, respectively.

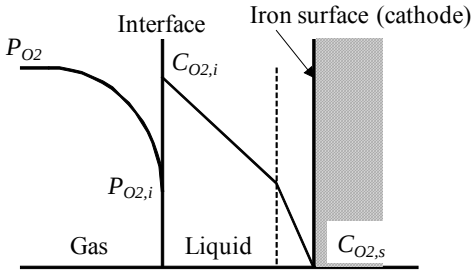

Figure 2. Concentration distribution in the reaction region

$$N = k_G\left(P_{O2} - P_{O2,i}\right) \tag{6}$$

$$N = k_L\left(C_{O2,i} - C_{O2,s}\right) \tag{7}$$

Here, k_G and k_L are the mass transfer coefficients in the gas and liquid phases, P_{O2} and $P_{O2,i}$ are the partial pressures of oxygen in the atmosphere and the gas–liquid interface, and $C_{O2,i}$ and $C_{O2,s}$ are the oxygen concentrations in the gas–liquid interface and the iron surface of the water solution, respectively. The reaction velocity of equation (2) is so high that the oxygen concentration in the iron surface, $C_{O2,s}$, is negligible (i.e., $C_{O2,s} = 0$). By equating (6) and (7), and eliminating $P_{O2,i}$ and $C_{O2,i}$ using Henry's equation for gas–liquid equilibrium, equation (8) is obtained.

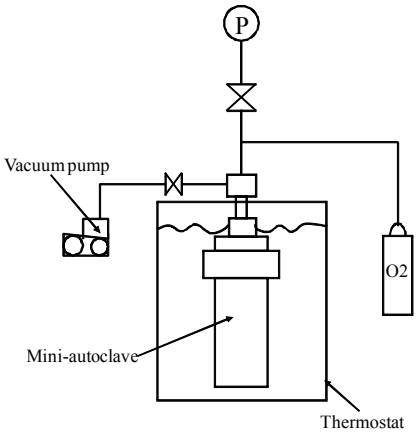
$$N = \frac{1}{1/k_G + H/k_L} P_{O2} \tag{8}$$

Here, H is Henry's constant, and $P_{O2,i} = HC_{O2,i}$. Accordingly, it is considered that the apparent reaction velocity in iron corrosion is proportional to the oxygen pressure; further, the apparent velocity is rate-determined by the mass transfer resistances in the gas and liquid phases.

MEASUREMENTS OF THE APPARENT REACTION VELOCITY

Experimental apparatus and method

Figure 3 shows the apparatus used for the reaction velocity measurements. A mixture containing specified weights of iron powder, activated carbon powder, and vermiculite particle absorbing saline solution is introduced into a mini-autoclave, and then placed in a constant temperature bath after the atmosphere inside the mini-autoclave has been replaced with pure oxygen. The apparent reaction



(a) Photograph (b) Schematic diagram

Figure 3. Apparatus for reaction velocity measurements

Table 1
Range of experimental parameters

Iron powder (mean powder size = 100μm)	2.0g
Activated carbon (powder size < 150μm)	0.4g
Saline solution (salinity = 3wt%)	0.5-1.1cc
Vermiculite (mean particle size = 1mm)	0.256g
Temperature	35-70degC
Initial oxygen pressure	about100kPa

velocity is obtained from the degradation of oxygen pressure in the mini-autoclave. Its volume is 47 cc. The weights of the iron powder, activated carbon powder, and vermiculite particle are 2.0, 0.4, and 0.256 g, respectively. However, the volume ratio is approximately 1:2.1:3.3 since their apparent densities are 3.08, 0.29 and 0.12 g/cm^3, respectively. The salinity in the saline solution is 3 wt%. Ranges of the experimental parameters are listed in Table 1.
The degradation rate of the oxygen pressure in the mini-autoclave is considered to be proportional to the oxygen pressure, so equation (9) is obtained.

$$\frac{dP_{O2}}{dt} = -aP_{O2} \tag{9}$$

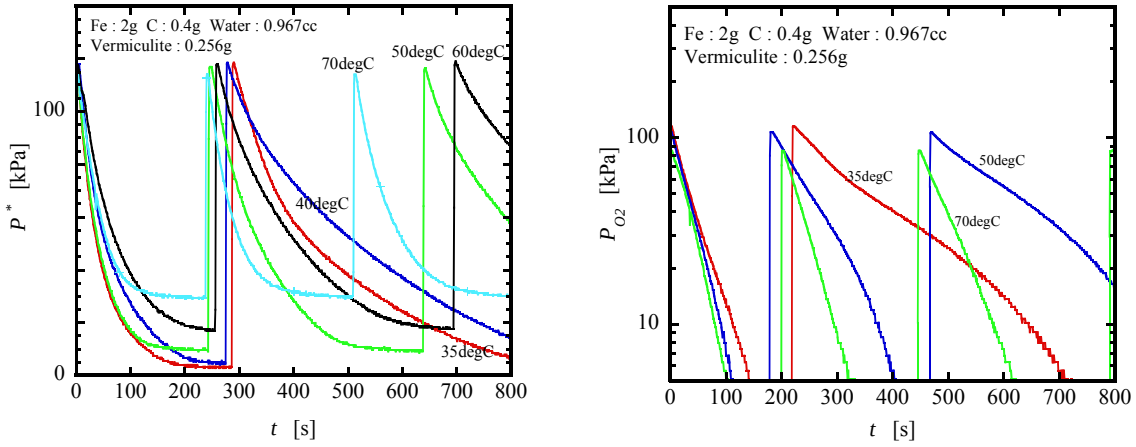
Here, t is the elapsed time, and a is the reaction velocity constant. Integrating equation (9) leads to

$$\ln\left(\frac{P_{O2}}{P_{O2,0}}\right) = -at \quad \text{or} \quad \frac{P_{O2}}{P_{O2,0}} = \exp(-at) \tag{10}$$

The mass transfer resistance in the gas phase is low compared with that in the liquid phase when the volume of the powder mixture is small and it is surrounded by pure oxygen, as in this experiment.

Experimental results and discussion

Figure 4(a) shows an example of the experimental results, where the vertical and horizontal axes correspond to the pressure in the mini-autoclave P^* and the elapsed time t, respectively. The amount of saline solution is constant at 0.967 cc, and this value is the stoichiometric volume of water needed for the complete reaction of all the iron powder. The amount of vermiculite is determined to be 0.256 g, so the saturation rate of water content in the vermiculite particle is 80%. In the preliminary experiments, it is found that the reaction rate increases gradually with the saturation rate of water content in the vermiculite particle when the amount of saline solution is constant, but the dependence is small. The reaction temperature is 35, 40, 50, 60, and 70°C. First, the inner pressure rises drastically due to the increased supply of oxygen after evacuation; then, the inner pressure falls gradually with elapsed time.



(a) The inner pressure P^* (b) The oxygen partial pressure P_{O2}

Figure 4. Variation in the inner pressure and the oxygen partial pressure with time

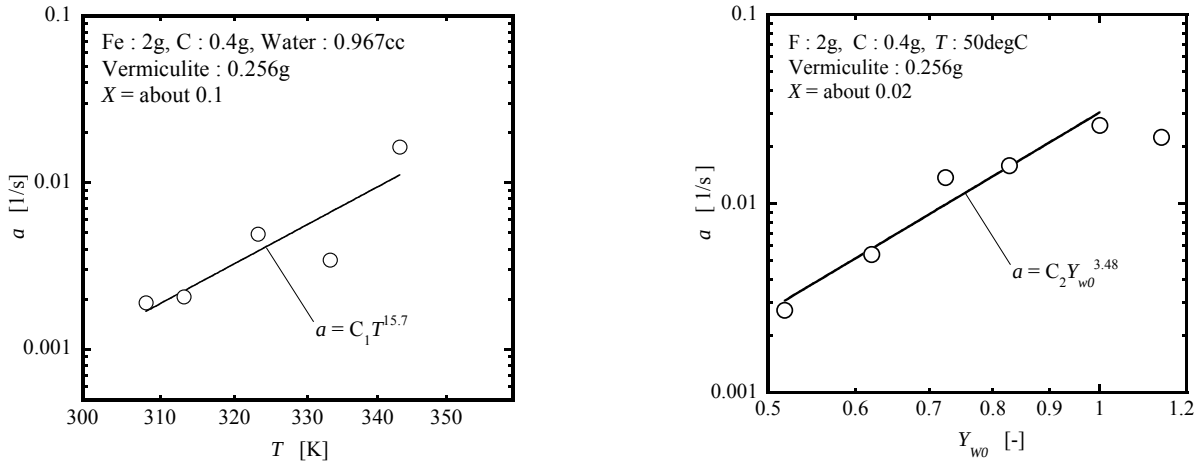
This degradation of the inner pressure indicates that oxygen is consumed due to iron corrosion. With time, the inner pressure approaches a constant non-zero value. This asymptotic value seems to correspond to the saturation vapor pressure of water since it increases with temperature. In order to examine the effect of the reaction rate of iron powder on the reaction velocity, oxygen is newly supplied several times after all the oxygen in the mini-autoclave has been consumed. Figure 4(b) shows the variation in the oxygen partial pressures at 35, 50, and 70°C; these partial pressures are obtained by subtracting the saturation steam pressure from the inner pressure in the mini-autoclave. The degradation rate of oxygen partial pressure corresponds to the reaction velocity constant, and the number of times oxygen is newly supplied corresponds to the reaction rate of the iron powder. Accordingly, it is found that the reaction velocity constant increases with temperature and decreases with the reaction rate of iron powder.

Figure 5 (a) and (b) indicate the variation in the reaction velocity constant with reaction temperature T and with the non-dimensional quantity of water absorbed in vermiculite particle Y_{W0}, respectively. Here, Y_{w0} is the initial volume of water absorbed in the vermiculite particle divided by the stoichiometric volume of water needed for the complete reaction of all iron powder. In addition, X is the reaction rate of the iron powder and represents the ratio of the reacted iron mass to the total iron mass. The reaction velocity constant a increases with the reaction temperature T, although the dependence is small. The reaction velocity constant a increases with Y_{w0}, i.e., water volume, but decreases when Y_{w0} is over 1.0. This can be explained as follows. The reaction velocity increases with the wet area of the iron surface, i.e., with water volume. However, the liquid film on the iron surface becomes thick and the mass transfer resistance also increases with water volume. Reaction velocity data are often plotted against $1/T$ to yield the well-known Arrhenius plot; however, it is not appropriate here because the rate-determining factor in the corrosion reaction, which is the mass transfer resistance through the liquid film on the iron surface, is different from that in general chemical reactions.

Figure 6 shows variations in the reaction velocity constant a with the rate of unreacted iron $1 - X$. The reaction velocity constant decreases rapidly as the reaction progresses. This is because the mass transfer coefficient in the liquid phase decreases due to the diffusion barrier layer of ferrous hydroxide, $Fe(OH)_2$, formed by the corrosion reaction. In addition, this layer is also considered to be one of the reasons why the mass transfer resistance in the gas phase increases, due to aggregation of the iron powder with the progress of the corrosion reaction. The reaction velocity constant data were correlated with equation (11) as a function of the volume of saline solution Y_{w0}, the reaction temperature T, and the reaction rate of iron powder X.

$$a = 9.7 \times 10^{-42} Y_{w0}^{3.48} T^{15.7} (1 - X)^{14.6} \tag{11}$$

The solid lines indicate equation (11) in Figure 6. If the reaction velocity r is defined as the reacted iron



(a) Variation with the reaction temperature T (b) Variation with the water volume Y_{w0}

Figure 5. Variation in the reaction velocity constant a

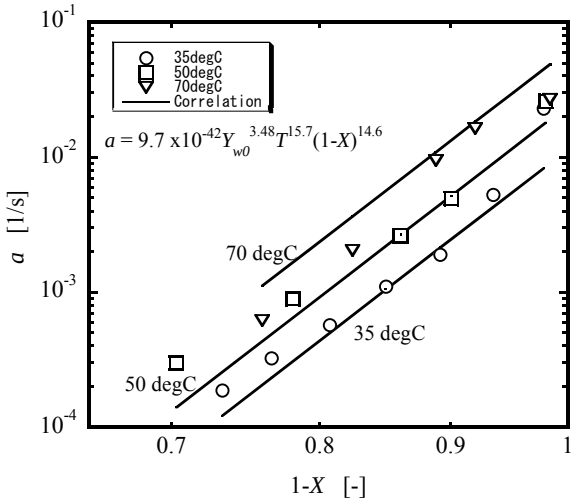


Figure 6. Variation in the reaction velocity constant a with the reaction rate of iron powder X

per unit volume of the powder mixture layer per second, it is represented by equation (12).

$$r = \frac{4}{3} a \frac{V_{aut}}{V_{lay}} C_{O2} = 9.6 \times 10^{-41} Y_{w0}{}^{3.48} T^{15.7} (1 - X)^{14.6} C_{O2} \qquad [\frac{kmol}{m^3 s}] \tag{12}$$

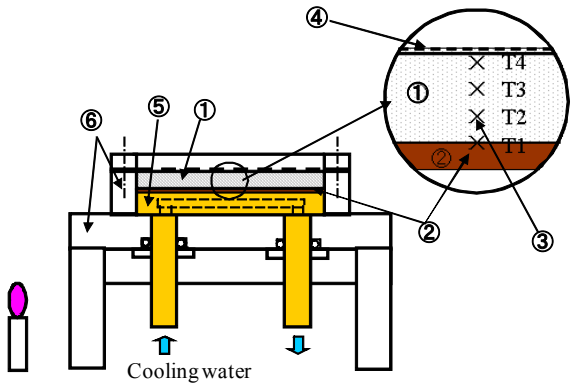
Here, V_{aut} is the volume of the mini-autoclave (=47cc), V_{lay} is the volume of the powder mixture used in this experiment (=6.3cc), and C_{O2} is the molar density of oxygen. This equation for reaction velocity will be used for thermal analysis in a layer of the exothermic powder mixture.

THERMAL CHARACTERISTICS IN A LAYER OF THE POWDER MIXTURE

Experimental apparatus and prodedure

Figure 7 (a) and (b) show a schematic diagram of the experimental apparatus and a photograph of the experimental chamber. The experimental apparatus comprises a 100 mm × 100 mm × 30 mm rectangular vessel made of polycarbonate resin. A copper plate, which is kept at a constant temperature (approximately 34°C) by cooling water, is installed at the bottom of the vessel. A heat flux sensor sheet (0.4 mm in thickness) is adhered to the cooling plate to measure the dissipated heat. A small amount of silicone compound is applied between the sensor sheet and the cooling plate so that the contact thermal resistance may be suppressed. The powder mixture is packed on the sensor sheet to a depth of 10 mm; this mixture is composed of 31.5 g of iron powder, 6.2 g of activated carbon powder, and 4.0 g of vermiculite particle absorbing 15.2 cc of saline solution (the salinity is 3 wt%). The volume of saline solution and vermiculite particle is determined so that Y_{w0} is equal to 1 and the saturation rate of water content in the vermiculite particle is 80%. The temperature distribution in a layer of the powder mixture is measured by C-A thermocouples (ϕ0.5 mm OD). The locations for temperature measurements are (measured in terms of the height from the surface of the sensor sheet) 0 mm (i.e., on the surface), 3 mm, 6 mm, 9 mm, and the inside of the sensor sheet, and the temperatures at these locations are denoted by T_1, T_2, T_3, T_4, and T_0, respectively. The experimental apparatus is installed in an acrylic chamber, which is indicated in Figure 7(b), and is operated from outside with vinyl gloves. The experimental procedure is as follows.

First, some activated carbon powder and vermiculite particle are dried at 100°C in an electric drier for 2 h and allowed to cool to the ambient temperature. This vermiculite particle absorbing a specified volume of saline solution is mixed sufficiently with the activated carbon powder. Second, the iron powder and the mixture of the activated carbon powder and the vermiculite particle are placed in the experimental chamber; then, the door is closed. Enough nitrogen gas is supplied into the chamber from the upper inlet so that the air inside the chamber is completely replaced with nitrogen. At the same time, cooling water is supplied to the cooling plate to keep it at a specified temperature (approximately



1. Exothermic powder mixture 2. Heat flux sensor
3. Thermocouples 4. Porous film 5. Cooling plate
6. Polycarbonate materials

(a) Schematic diagram of the experimental apparatus

(b) Photograph of the experimental chamber

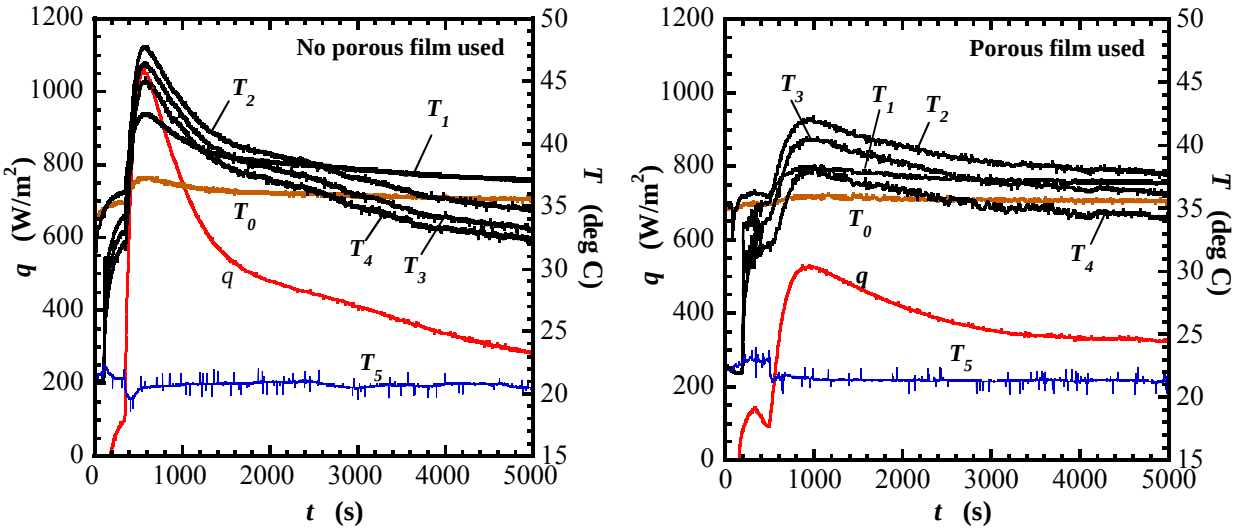
Figure 7. Experimental equipment

34°C). Next, the iron powder is sufficiently mixed with the mixture of vermiculite and activated carbon in the chamber to produce the powder mixture for the experiment. The powder mixture is packed on the heat flux sensor sheet to a depth of 10 mm, and the thermocouples T_2, T_3, and T_4 are placed in the specified positions inside the powder mixture layer. Finally, the door of the chamber is opened so that the chamber inside may be quickly replaced with air. The temperature distribution in the powder mixture layer and the heat flux dissipated to the cooling plate are measured over a time span of a few hours. Some experiments are conducted with a porous film fixed on the powder mixture layer to control the oxygen volume flowing into the layer. In the other experiments without a porous film, a piece of tissue paper is placed on the powder mixture layer to avoid the effect of air currents.

Experimental results and discussion

Figure 8 (a) and (b) are examples of the experimental result and show the variation over time of the temperatures T_0, T_1, T_2, T_3, and T_4 and the heat flux dissipated to the cooling plate q. Here, T_5 is the ambient temperature inside the experimental chamber, and T_0 is the inside temperature of the sensor sheet, which is nearly constant. First, the experimental result without a porous film (Figure 7(a)) is explained, where the volume of oxygen flowing into the exothermic powder mixture is not controlled. The abrupt increase in the temperatures T_2, T_3, and T_4 at the elapsed time t ~100 s indicates that these thermocouples are placed in the specified positions inside the powder mixture layer, so these temperature data make sense after this time. A small increase in the heat flux q is recognized at t ~180 s, although the door of the chamber is closed. This shows that the corrosion reaction begins gradually, with a small volume of oxygen remaining in the chamber, immediately after mixing the iron powder with the activated carbon and vermiculite particle. The temperatures T_2, T_3, T_4, and the heat flux q again increase drastically at t ~350 s when the door of the chamber is opened, but decrease rapidly after reaching the maximum at t ~550 s. The maximum T_2 is approximately 48°C. These variations show that the reaction occurs abruptly due to the large amount of oxygen present, but the reaction velocity decreases rapidly with the reaction rate of the iron powder. Thereafter, the temperatures T_2, T_3, and T_4 are lower than T_1. This occurs because the ambient temperature, T_5, is lower than the surface temperature of the cooling plate, so more heat is dissipated from the upper surface of the powder mixture layer. In addition, it is observed that some steam flows out to the tissue paper placed on the powder mixture layer.

Next, the experimental result with a porous film fixed on the powder mixture layer (Figure 7(b)) is explained, where the volume of oxygen flowing into the exothermic powder mixture is controlled. The abrupt increase in the temperatures T_2, T_3, and T_4 at the elapsed time t ~200 s indicates that the



(a) Without a porous film (b) With a porous film

Figure 8. Experimental results in a layer of exothermic powder mixture

thermocouples are placed in the specified positions inside the powder mixture layer, so these temperature data make sense after this time. The small increase and decrease in the heat flux q at t ~150 to 500 s shows that the corrosion reaction begins gradually with the oxygen remaining in the chamber, but the oxygen inside the layer of powder mixture is exhausted since the oxygen volume flowing into the powder layer is suppressed by the porous film. The temperatures T_2, T_3, and T_4 and the heat flux q again increase rapidly at t ~500 s when the door is opened, reach the maximum at t ~900 s, and decrease gradually thereafter. Although the variation in the temperature and heat flux observed in Figure 7(b) is similar to that observed in Figure 7(a), the variation in the latter case is more gradual. The maximum of the temperature and heat flux is also lower, which shows that the oxygen volume flowing into the powder layer is suppressed by the porous film. The steam and heat dissipated from the upper surface also decrease.

CONCLUDING REMARKS

1. Thermal characteristics in the exothermic powder mixture composed of iron, activated carbon, and vermiculite particle absorbing saline solution were examined experimentally.
2. The reaction velocity in the exothermic powder mixture is particularly dependent on the partial pressure of oxygen (or the molar density of oxygen) and the reaction rate of iron, in addition to the volume of saline solution and the reaction temperature. A correlation for the reaction velocity is proposed as a function of these parameters. In a future study, a numerical analysis using this correlation will be conducted on flow and heat transfer in a layer of the exothermic powder mixture.
3. It is important to adjust the volume of supplied oxygen for temperature control in a layer of the exothermic powder mixture.

EXPERIMENTAL STUDY OF DRYING FRESH PEPPER BERRIES IN A SOLAR DRYER

A. Vakhguelt*, C. J. Chong, T. B. Luk
Swinburne University of Technology, Sarawak Campus, Kuching, 93550 Sarawak, Malaysia

ABSTRACT. The Sarawak State of Malaysia is one of the main suppliers of white and black pepper to the world. Rural areas of the state do not always have a proper energy supply especially in the farming fields. The traditional method of drying pepper employed by farmers is outdoor drying, which is not effective especially in this area where the yearly rainfall level is about 4 m. The aim of this study was to develop a mobile drying device which can be easily relocated where the harvest is collected. The authors of this paper have proposed drying of the pepper using a natural-convection based solar dryer. At the initial stage a series of experiments was conducted to study the drying characteristics of fresh pepper berries with the aim of finding the optimal conditions for obtaining a high quality product as well as assessing productivity of the proposed solar dryer. The data obtained from experimental study has shown that the highest temperature of a drying process should not exceed 55° C for quality final product. At the same time it was found that the higher the temperature achieved in the dryer, the faster the drying happened. The drying characteristics obtained were used to design and study a solar drying device to achieve optimal conditions for the process of drying pepper berries. The experiments have shown the advantage of using the proposed solar dryer with natural convection driven process compared to traditional outdoor drying. This device reduces the time of drying and improves the quality of product as well as gives the opportunity for continuous process regardless of weather conditions. The limitation of the moisture content of the final product depends on external humidity of the surrounding air. The device does not use any external source of energy and can be used in any location.

Keywords: *pepper berries, drying, solar dryer, temperature, airflow*

INTRODUCTION

The drying of the agricultural products is a very important problem faced by many industries. It is an especially big problem for tropical countries with intensive rainfall level. During the rainy season with very high humidity levels, the drying of agricultural products becomes a major problem. Difficulty also comes when these agricultural products are located far away from the urban areas usually without electricity supply. This paper addresses these problems by investigating an alternative way to traditional drying of the white and black pepper, that is by introducing the solar dryer which uses the natural convection concept (see Figures 1 and 2). The main idea is to use a drying chamber with a transparent top surface for the penetration of the sun rays connected to a chimney of flexible height. The air flow through this chamber due to the pressure difference at the bottom and top end of the chimney is meant to remove the moisture from inside the pepper berries during the drying process. By varying the height of the chimney we may change the airflow rate which also helps to maintain the favourable temperature inside the solar drying chamber during high temperature time due to high solar radiation. Change of the height of chimney may also help to

E-mail address: avakhguelt@swinburne.edu.my

maintain a certain level of the moisture content in the chamber at different times of the drying process.

Figure 1. Drying of white pepper by spreading evenly on mats [1].

The study of the solar dryer operation was carried out initially by studying the drying characteristics of the fresh pepper berries in a lab scale dryer at the different temperatures. It was done to find the optimal regime of drying to address in the drying chamber of the proposed solar dryer. The next step of this study was to study airflow rate variations as a function of the height of the chimney and its diameter. Experimental investigations were carried out in the conditions when air was still. In this case the airflow rate is minimal in contrast to the case when we have windy conditions and the airflow rate will be increased through the chimney. Some of the experimental results are presented below.

EXPERIMENTAL STUDY OF THE FRESH PEPPER BERRIES DRYING

In order to study the drying characteristics of pepper berries, drying experiments partially based on investigation method adopted by A. Lopez et al. [2] were conducted to find out the effect of air temperature on the drying rate. To find out the drying characteristics of pepper berries, a number of the experiments were carried out at different temperatures using a lab scale dryer. During drying the weight of the berries portion was monitored by sensible scale to observe the change of weight of pepper berries with respect to time. The relationship between the moisture content of pepper berries with time was monitored at six different air temperature points which ranged from 30^{o}C to 55^{o}C at 5^{o}C intervals. Pepper berries were left in a gravity convection oven at constant temperatures. Weight loss was measured using load cell and was recorded at 30 minute interval. The study was carried out with pepper berries grown in Sarawak [1]. Samples of pepper brought in were divided into smaller samples for experiments and each sample was sealed in a plastic package and stored in the fridge at low temperature to prevent changing of initial moisture content. Before starting each package of pepper used was weighed prior to each drying experiment.

Each drying experiment was running until three constant readings of the weight of pepper berries were obtained consecutively. After each experiment, the moisture content of the dried pepper berries was determined using the AOAC Official Method 935.29 at temperature between 100-150^{o}C [11]. From literature [3-10], it was expected that the weight of pepper berries reduced exponentially with respect to time. As the air temperature increased, the moisture content lost faster during the

initial period of drying. Obtained results of the drying of the fresh pepper berries are presented in Figure 2. We can see that weight of the berries portion during real drying is reduced nearly exponentially with some variations which could be considered as error of the measurements. From these experiments the optimal regime of the pepper berries was found and used for design of the solar dryer. At initial stage of the solar dryer design, a number of experiments were carried out to find appropriate variation of the airflow rate as the function of height of a chimney.

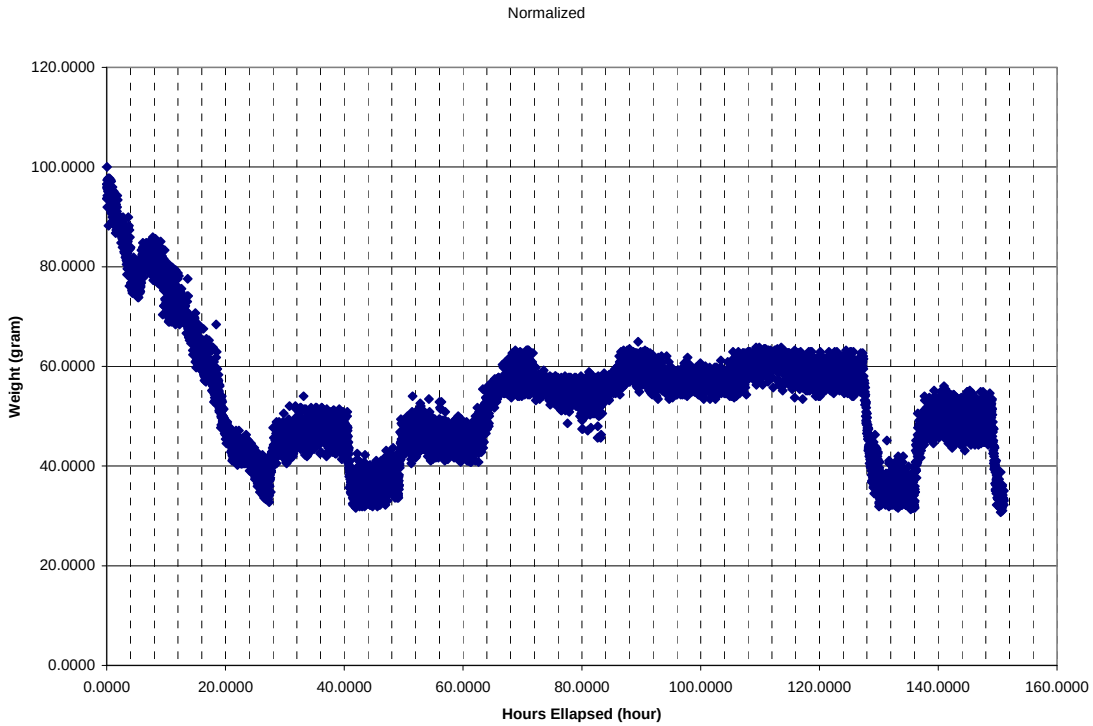

Figure 2. Drying of the pepper berries in the gravity convection oven at $50^{\circ}C$.

EXPERIMENTAL STUDY OF AIRFLOW CONTROL

It is known that in the solar dryer, the airflow is generated due to pressure difference at the lower and upper levels of the chimney. Airflow generated by this type of device is very important especially for the areas with the high relative humidity and heavy rainfall [12]. This airflow will be able to transport away excess moisture content which is delivered from the berries by diffusion during the drying process. Buoyancy also helps to increase airflow in addition to pressure difference during day time operation of the solar dryer in the transparent drying compartment. For the dryer equipped with a chimney, stack induced ventilation can be achieved. Our system utilizes the atmospheric pressure difference as well as the variation in air density across the height at different openings in vertical slope due to temperature difference. For a second part contribution we can consider that a vertical air velocity is approximately proportional to the air temperature rise in the heat collector and the stack height [13]. Using Boussinesq approximation we may expect that maximum free convection current could be:

$$V_{tower,\max} = \sqrt{2gH_{tower}\frac{\Delta T}{T_0}} \tag{1}$$

Here ΔT is temperature difference between ambient and the collector outlet and H_{tower} is the height of the chimney. Using this formula we are able to estimate airflow rate through the system which consists of the chimney and the drying compartment [14].

Conceptual Framework

The flow rate through the drying compartment can be changed by adjusting the pressure difference between two ends of the chimney or adjusting its height. If the pressure head loss along the chimney can be neglected, this is applied to the large diameters; infinite height may lead to infinite boost of airflow in the chimney and also the drying compartment. The variation of chimney height can be achieved by multiple-section telescopic constructions. Each section shall be air-tight sealed to prevent reduction of ultimate pressure difference due to leakage at any connecting joints; yet, at the same time, the chimney should maintain the flexibility of the telescoping action.

To check how temperature can affect the mass flow rate through drying compartment, we can monitor the temperatures at three points: at the inlet section of the chimney; at the outlet section of the chimney; and, at the surface of the mesh where the raw bits are to be dried. The temperature measurements at the top of the chimney will provide effective ambient operating temperature to the control system; and it is to be compared to the measurement obtainable at the bottom of the chimney. In this case, the driving force due to free convection in the chimney can be approximately measured, where from equation 1 the higher the differences, the higher the flow rates. When the drying compartment is properly sealed with only one inlet at the far end from the chimney, then mass flow rate can be predicted by relating the cross-sectional area of the drying compartment to the cross-sectional area of the chimney; provided it is longitudinal equal-width along the flow path.

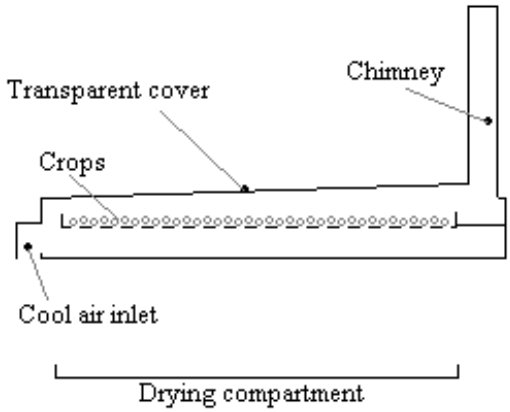

Figure 3. Proposed solar dryer mechanical outline.

Monitoring the temperatures at the different points gives the opportunity to control the height of the chimney which will be changed to create optimal airflow rate. This circumstance enables the controller to make decisions based on real-time difference in temperature captured, since drying force is the fraction of the temperature difference between both ends of the chimney. We know that the mass flow rate will have direct influence on the temperature profile inside the drying compartment. To achieve the shortest possible drying period while maintaining the quality of the final product, a stable supply of heat flux and controlling the efficiency of moisture transportation is extremely crucial. Fluctuation in heat flux would bring a negative effect to the transportation of the moisture content from inside to the surface of the crops. High flow rate may lead to case hardening especially for those crops which have high sugar content. The system to monitor the temperatures at three points is managed by a microcontroller based single board computer in which high resolution temperature sensors are utilized. The microcontroller compares the temperature values and makes the decision whether to lower down or pull up the chimney to obtain the most suitable temperature and flow rate.

Proposed outline of the solar dryer

The proposed solar dryer is based on direct heating mode where the raw bits of the agriculture product to be dried are placed inside the dryer facing upward directly to the sunlight (Figure 3). The upper part of the drying compartment is transparent, so it allows the sun radiation to access the internal area of the dryer and heat up both the air and the crop. The chimney is made of uPVC pipe

to make it light and strong with reasonably good thermal insulation properties. Each section of the pipe is sealed with PVC flexible pipe connecting two adjacent parts to prevent air leakage and heat losses. The "telescopic chimney" is supported by two supporting poles to provide a vertical arrangement as well as the mechanism for height adjustment (Figure 4a). The mechanism is connected to motor by tension-run driving system which converts rotational motion to linear motion. To protect the sensors and the drying compartment from direct contact with the water due to rain on the top of chimney, a cap is installed.

Free convection operation and control mechanism

As mentioned above the basic idea of the solar dryer operation is based on the necessity to move away the high moisture containing air from the drying compartment providing optimal conditions to deliver moist from inside of the pepper berries to their surface. The higher temperature in the drying compartment and the higher air velocity increases the diffusion and removal of moisture from the berries. To control the air velocity the mechanism of chimney height change is introduced. This also helps to control the air velocity during weather changes as well as to address it to the night conditions. In our case automation of the control is introduced.

The control system primarily depends on the readings from three temperature sensors (Figure 4b) and it is also assisted by two limit switches (Figure 4a) as well as preset flow rate and temperature setting to position the height of the chimney periodically. Temperature sensors placed at three different locations are used to observe the drying conditions inside the solar dryer. The control architecture is graphically illustrated in the block diagram shown in Figure 5.

Let the reading of temperature sensor 1 be represented by TS1, Limit switch 1 be LS1 and so on; and preset temperature and flow rate be PT and PF respectively. Note that PF means the maximum range of temperature difference between the projected TS2 and TS3. The control logic is illustrated with the following conditions:

- When TS2 <= TS3, Chimney rise to maximum height (until triggering the LS1)
- When (TS2 – TS3) > PF, Chimney retract and vice versa (until touching either LS1 or LS2)
- When TS1 > PT, Chimney rise to increase airflow

In normal conditions, TS2 should have higher value than the TS3; yet if it is reversed and the resistance of the chimney is low enough (at minimum height) reverse flow may lock up the proper transportation of moist air from the crops and thus slow down the drying process. On the other hand, when the value difference between the TS2 and TS3 is too far from PF, it would mean the airflow rate is far beyond the acceptable flow rate and could result in case hardening. In this case, lowering down the chimney would lead to a drop in the air flow and vice versa.

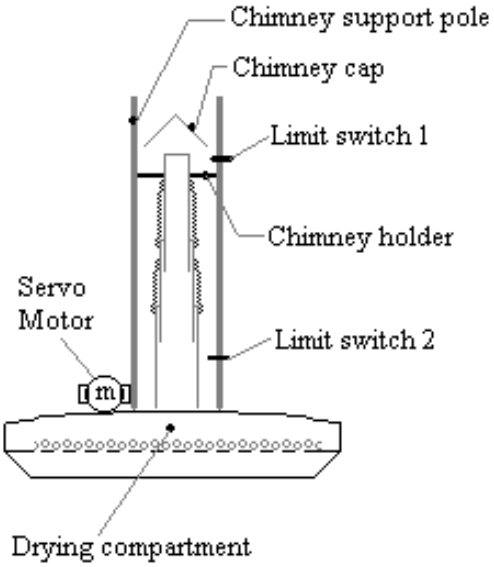

Figure 4a. Mechanical and electrical feedback system.

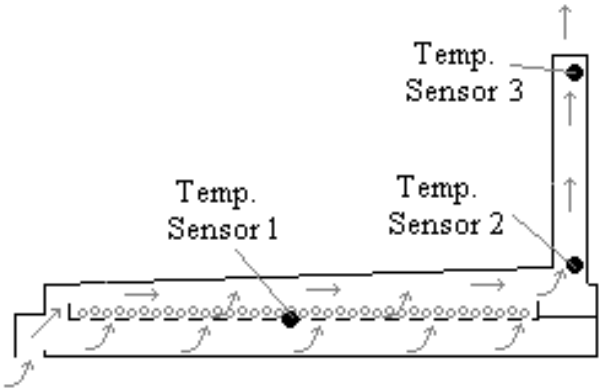

Figure 4b. Placement of the feedback sensors

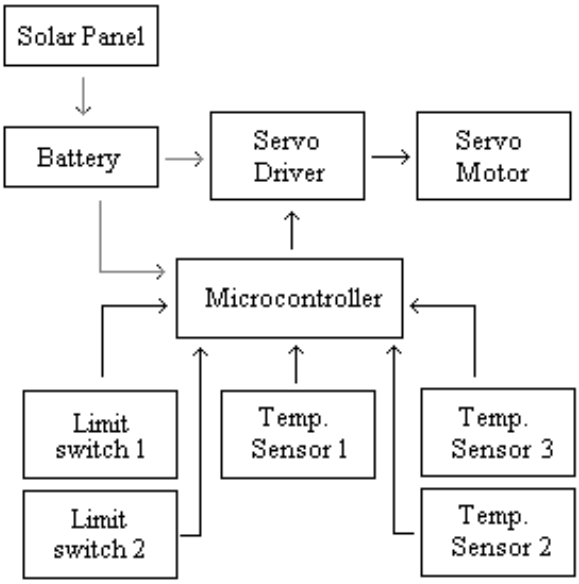

Figure 5. Mass flow control System Block Diagram

The last case explains that the surface temperature TS1 should be controlled by adjusting the flow rate as it indicates the drying temperature which will directly influence the
drying rate of the crops. The proposed outline will enable the alternative flow path above the tray. By boosting the horizontal flow, this will induce negative pressure to encourage bottom-up mass flow from the tray to decrease the heating temperature to desired level.
To cater for head loss due to changes in air properties and aging of pipe wall in dynamic environment over time, TS1 will be monitored against the time rather than solely comparing to PT. In conditions when the raising of chimney causes the TS1 to be elevated too fast, it is necessary to put an exception instruction to lower down the chimney until TS1 is stabilized. Although the surface temperature might still be higher than PT, yet optimum mass flow rate can be reached to achieve least possible overheat range and this will lead to warning being signalled to the operator.

CONCLUSION

The proposed solar dryer provides an efficient tool for drying any agricultural products in the fast changing environment of the tropical climate. This solar dryer could be used in any rural location as it does not need to have a power supply and can be operated as a mobile unit. Automation of this solar dryer helps to increase its efficiency for the crops drying in dynamic weather conditions as it can maintain the quality and boost the product throughput due to a consistent drying environment as

well as a shorter period of drying time. The system also utilizes active control over a passive system and thus makes room for utilization of green energy (solar panel) in an active control structure.

ABSTRACT. Measurements of boiling heat transfer coefficients in water, methanol and refrigerant R141b are reported for the bundles of smooth tubes that represent a portion of a flooded-type evaporator. Each bundle contained 19 instrumented, electrically heated tubes in a staggered triangular-pitch layout. The effect of heat flux density, tube pitch and operating pressure is studied in the paper. Bundle factor and bundle effect are discussed as well. A correlation for prediction a bundle average heat transfer coefficient is proposed.

NOMENCLATURE

D - diameter [m],
g - acceleration due to gravity [m/s^2],
I - current [A],
L – active tube length [m],
p - pressure [N/m^2],
q - heat flux density [W/m^2],
r - latent heat of vaporization [J/kg],
s - pitch [m],
t – temperature [°],
U – voltage drop [V]

Greek symbols
$\overline{\alpha}$ - average heat transfer coefficient [W/m^{2}K],
λ - thermal conductivity [W/mK],
ρ - density [kg/m^3],
μ - viscosity [Ns/m^2],
σ - surface tension [N/m].

Subscripts
cr - critical,
i – inner,
l – liquid,
o – outer,
v - vapour

INTRODUCTION

Flooded-type evaporators are widely applied in industrial heat exchange systems. Numerous studies were performed to understand bundle boiling heat transfer. In particular, the effect of tube position within a bundle, operating conditions, bundle layouts and tube spacing was examined [1-4]. Several correlations for the prediction of heat transfer coefficient of individual tube as well as tube bundle were proposed [5-8].

Marto and Anderson [2] made measurements of boiling heat transfer coefficients in R-113 for a bundle of 15 electrically heated, smooth copper tubes arranged in an equilateral triangular pitch with s/D=2. It has been reported that lower tubes within a bundle can significantly increase

nucleate boiling heat transfer from the upper tubes at low heat fluxes. This is referred to as *bundle effect*.

Qiu and Liu [4] investigated experimentally the effects of tube spacing, positions of tubes and test pressures on the boiling heat transfer of water in restricted spaces of the compact staggered bundles consisting of smooth horizontal tubes. A compact staggered bundle with a tube spacing of a 0.3 mm displayed a maximum heat transfer enhancement in the range of the low and moderate heat fluxes. For boiling in compact bundles, the position of the heated tubes within the bundle has some effect on the heat transfer for the tube spacings of 1.0 and 0.5 mm. However, the position of the heated tubes has hardly any effect on the heat transfer for a tube spacing of 0.3 mm. For the case where the tube spacing is equal to or larger than 1.0 mm, the effect of the pressure on the heat transfer enhancement was insignificant.

Gupta et al. [6] conducted experiments with water boiling at atmospheric pressure on a smooth stainless steel tube arrangements: two or three tubes placed one above the other at different pitch distances (s/d=1.5-6.0) of commercial finish having a 19.05 mm outside diameter heated directly by means of a high alternating current. Heat transfer characteristics of the lowermost tubes in a tube bundle have been found to be independent of the presence of the bundle. Besides, the maximum enhancement of the order of 100% was observed for the top tube of a 1x3 tube bundle under low heat flux conditions.

Kumar et al. [7] studied boiling of water at sub-atmospheric pressure on twin tube arrangement. Two copper, electrically heated, tubes having 32 mm outer diameter were placed one over another. Negligible influence of the tube materials on heat transfer coefficients was reported.

Leong and Cornwell [9] performed experimental study with large, 241-tube arrangement that simulated slice of the reboiler. Experiments have been conducted with refrigerant R113 at atmospheric pressure. The local heat transfer coefficients for bottom row tubes in the tube bundle were almost the same as for a single tube, whilst for the top row tubes were considerably higher.

Gupta [10] investigated nucleate boiling heat transfer in an electrically heated 5 x 3 in line horizontal tube bundle under pool and low cross-flow conditions of saturated water near atmospheric pressure. For configuration tested as well as for single column tube bundles heat transfer coefficients were nearly the same as that on a single tube. The maximum heat transfer coefficient on top tube of central column was about seven times higher than that on the bottom tube at the same heat flux of 23 kW/m^2 under pool boiling conditions.

Two-phase interactions that occur in tube bundles during boiling are very complex and can vary with heat flux density, operating pressure, fluid properties, tube surface, pool height and bundle layout. It is a known fact that heat transfer coefficients for a tube bundle are usually larger than those for nucleate pool boiling on a single tube under the same conditions. This is referred to as *bundle factor*.

In [11] it is pointed out that the boiling mechanism in a flooded refrigerant evaporator is different from that which occurs in a kettle reboiler used in the process industry. As a result it is difficult to use information from one type of bundle and fluid combination, and apply it to another situation.

The purpose of the present paper is to provide a comprehensive nucleate boiling database for water, methanol and refrigerant R141b from a small bundle of smooth tubes that represents a portion of a flooded-type evaporator. The effect of heat flux density, tube pitch and operating pressure is studied in the paper. Bundle factor and bundle effect are discussed as well. A correlation for prediction of a bundle average heat transfer coefficient is proposed.

EXPERIMENTAL APPARATUS AND PROCEDURE

Figure 1 shows a schematic diagram of the experimental apparatus. Essentially, it is consisted of a cylindrical test vessel made of stainless steel having a diameter and length of 0.3 m, a horizontal smooth tube bundle, a condenser, a measuring system, a visualization system and an electric power supply system. The vessel is equipped with three inspection windows for direct observation and visualization of the boiling process. Vapour from the test vessel flows through a stainless steel tube having an inside diameter 50 mm and gets to the condenser, installed above the vessel. The flowrate of cooling water through the condenser was regulated by manual valve and measured by a flowmeter. Test liquid entering the vessel is at the saturated state and its temperature is controlled by a heating element placed in the preheater.

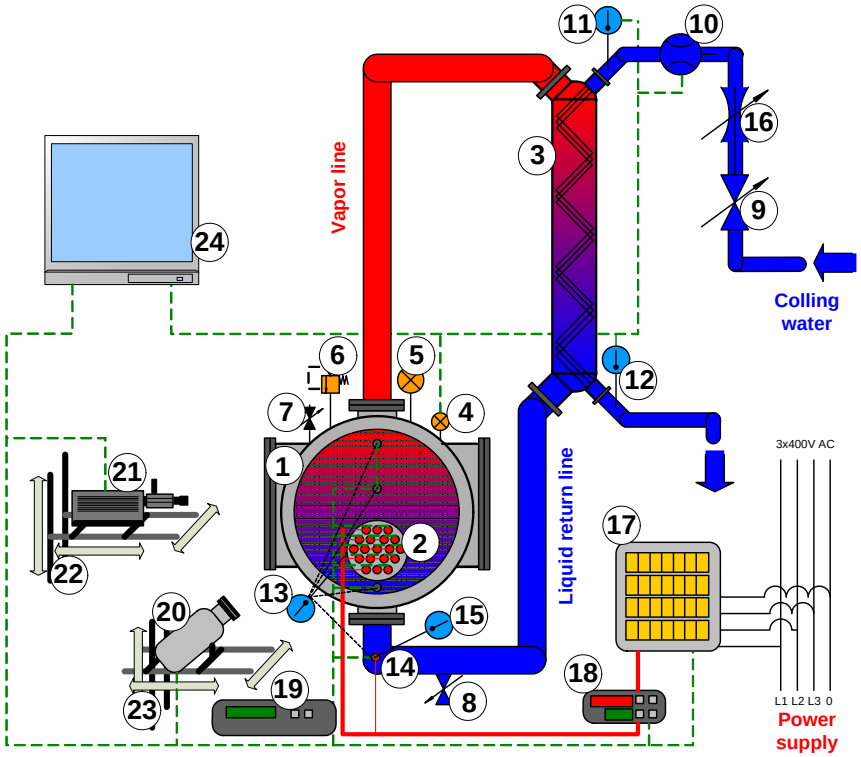

Figure 1. Schematic diagram of the experimental apparatus; 1 – test vessel, 2 – tube bundle, 3 – condenser, 4 – pressure transducer, 5 – pressure gauge, 6 – safety-valve, 7 – valve to setting of pressure in test vessel, 8 – drain valve of test liquid, 9 – drain valve of cooling water, 10 – flowmeter, 11, 12, 13, 15 – thermocouples, 14 – preheater, 16 – manual valve of flow control, 17 – wattmeter, 18 – regulators, 19 – multiplexer, 20 – high speed camera, 21 – CCD camera, 22 – mobile support (3d) of CCD camera, 23 – mobile support (3d) of high speed camera, 24 – computer aided data acquisition system

The evaporator was designed to simulate a slice of a flooded-type evaporator. The bundle consists of 19 electrically-heated smooth tubes which are arranged in a staggered triangular-pitch layout with a pitch-to-diameter ratio of 1.7 and 2.0. The bundles were cantilever-mounted from the back wall of the evaporator to permit in-bundle visualization. A stainless steel tube of R_a = 0.40 μm having 10 mm OD and 0.6 mm wall thickness formed single test heater. Electrical energy supplied to heating elements is controlled by electronic regulators. Each cartridge heater is equipped with a separate regulator.

Each tube was 180 mm long and effective length was 155 mm. The liquid level was maintained at ca. 15 mm above top row of tubes in the bundle.

As pointed out in [12,13] great care must be exercised with the cartridge heater and temperature measuring instrumentation to ensure good accuracy of the measurement of the inside temperature of the heating cylinder. In the open literature descriptions of very sophisticated temperature measuring instrumentation can be found [14].

Each tube was equipped with four thermocouples evenly spaced at 90° on the inner wall and midway between the heated length of a tube. The wall temperature t_w was calculated from the formula [15]

$$t_w = t_i - UI\frac{\ln(D_o / D_i)}{2\pi\lambda L}$$

where t_i was calculated as the arithmetic mean of four measured inside wall temperatures.

RESULTS AND DISCUSSION

Independently on pitch and operating pressure the highest bundle average heat transfer coefficients were obtained for boiling water. As an example Fig. 2 shows experimental results for three tested boiling liquids and bundle pitch-to-diameter ratio of 1.7 recorded at atmospheric pressure.

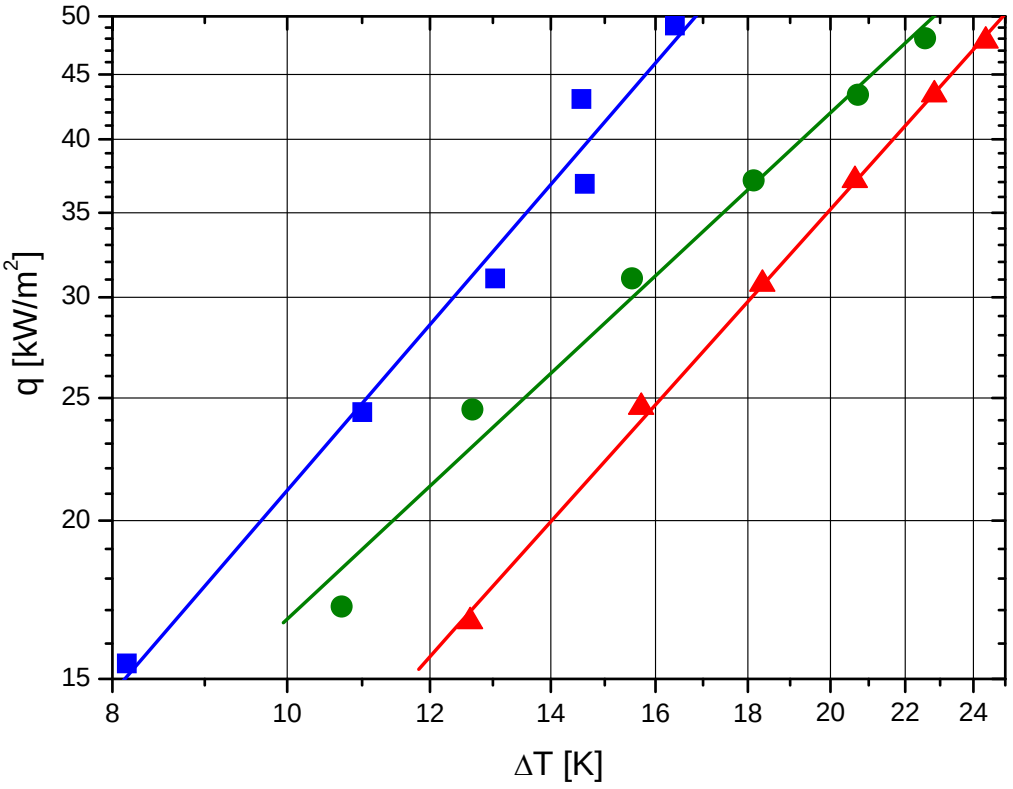

Figure 2. Boiling curves for three tested liquids at atmospheric pressure and bundle pitch-to-diameter ratio of 1.7; ■ - water, ● – methanol, ▲ - R141b

For all tested liquids, both atmospheric and sub-atmospheric pressure, higher heat transfer coefficients were obtained for greater pitch-to-diameter ratio examined, i.e. 2.0. Exemplarily, Fig. 3 illustrates influence of pitch-to-diameter ratio for refrigerant R141b boiling at atmospheric pressure.

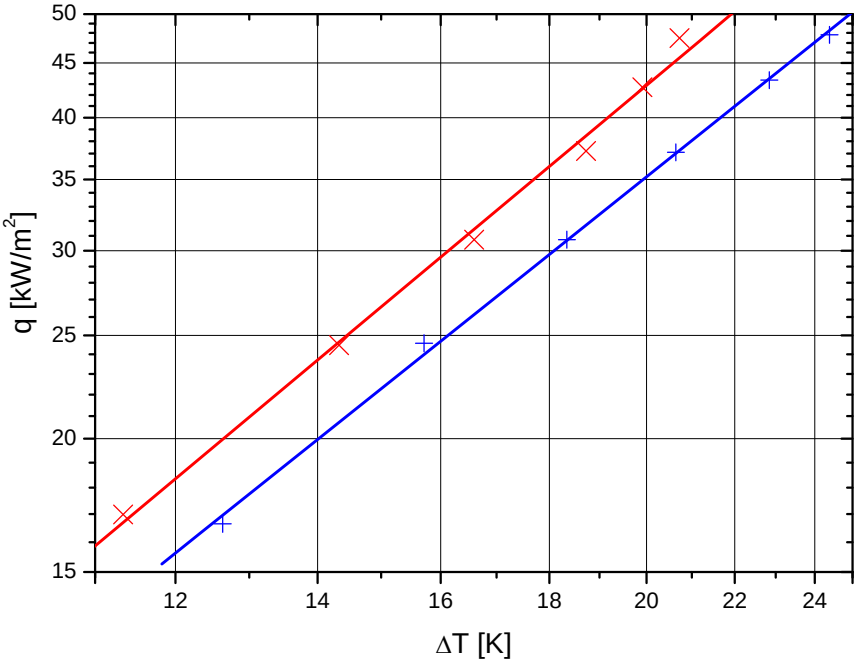

Figure 3. Influence of pitch-to-diameter ratio for R141b boiling at atmospheric pressure; pitch-to-diameter ratio: + 1.7, × - 2.0

Independently on pitch and kind of liquid tested higher heat transfer coefficients were obtained for atmospheric pressure. As an example Fig. 4 displays boiling curves for methanol boiling at atmospheric and sub-atmospheric pressure and bundle pitch-to-diameter ratio of 2.0.

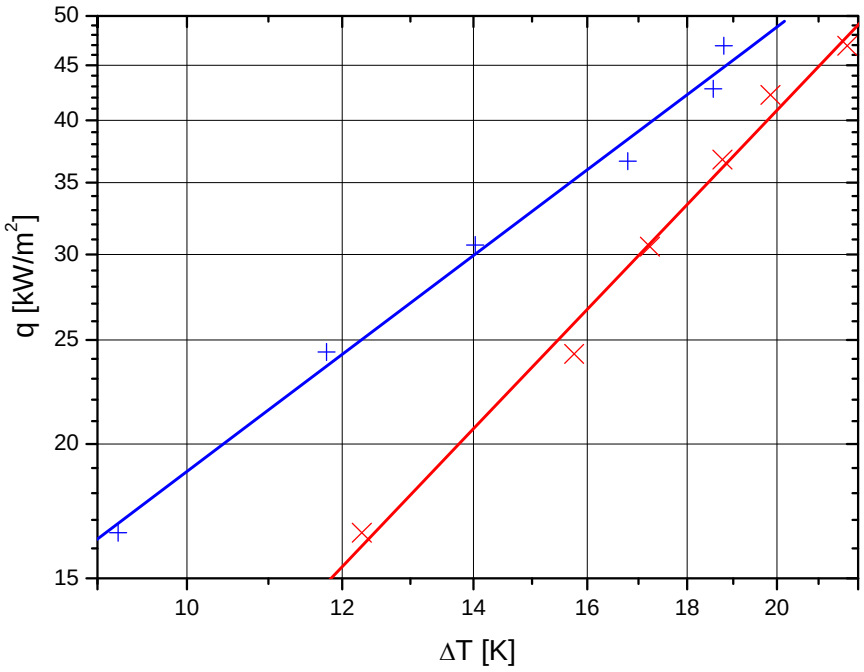

Figure 4. Influence of pressure for methanol boiling on smooth tube bundle with pitch-to-diameter ratio 2.0; × - sub-atmospheric pressure, + - atmospheric pressure

Figure 5 illustrates average heat transfer coefficients for row of tubes and selected heat flux densities in the case of water boiling at atmospheric pressure on tube bundle with pitch-to-diameter ratio 1.7. The higher was heat flux density the higher was heat transfer coefficient for all rows of tubes and simultaneously average heat transfer coefficient increases from bottom to the top row of tubes.

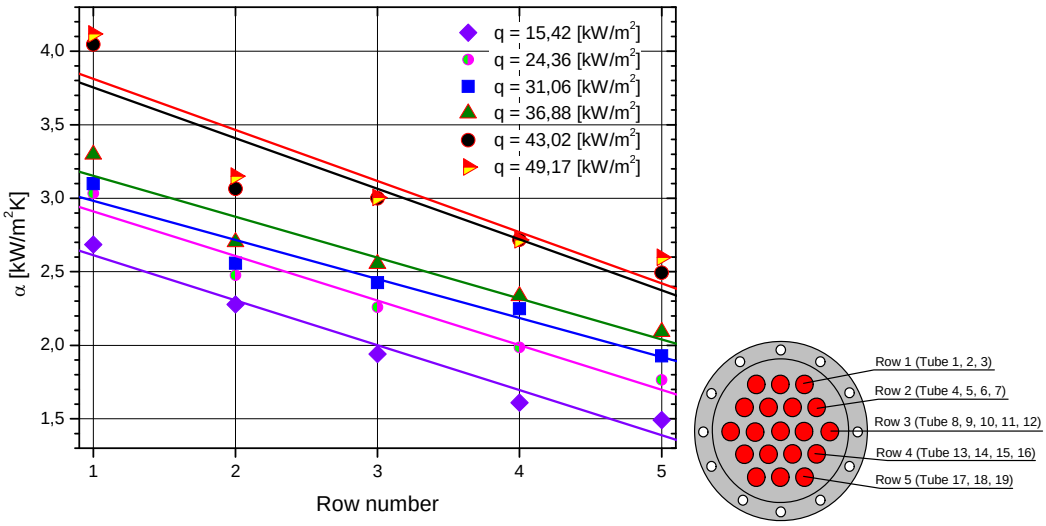

Figure 5. Row average heat transfer coefficient against row position in a tube bundle

Bundle factor and bundle effect (Fig. 6) decrease with heat flux density increase. Likewise literature data [16] bundle effect is slightly higher than bundle factor.

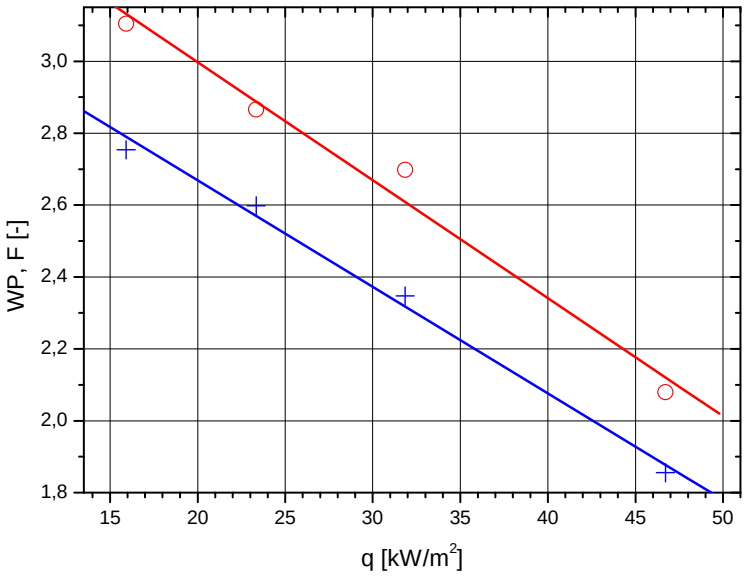

Figure 6. Bundle factor (F - +) and bundle effect (WP – ○) for methanol boiling at atmospheric pressure on smooth bundle with pitch-to-diameter ratio of 2.0

A multidimensional regression analysis using the least squares method was used to establish correlation equation for prediction of bundle average heat transfer coefficient

$$Nu = 61.392 Bo^{0.316} \left(\ln\left(\frac{p}{p_{cr}} \right)^2 \right)^{-1.55} \left(\frac{s}{D} \right)^{0.73} \tag{1}$$

where:

$Nu = \frac{\overline{\alpha} D_o}{\lambda_l}$ - Nusselt number,

$Bo = \frac{qLa\rho_l}{\rho_v r \mu_l}$ - boiling number,

$La = \sqrt{\frac{\sigma}{g(\rho_l - \rho_v)}}$ - characteristic length.

A comparison of predicted data against the experimentally obtained under the present investigation is displayed in Fig. 7. For about 96% of experimental points the discrepancy between experimental data and values calculated from proposed correlation is lower than ±40%.

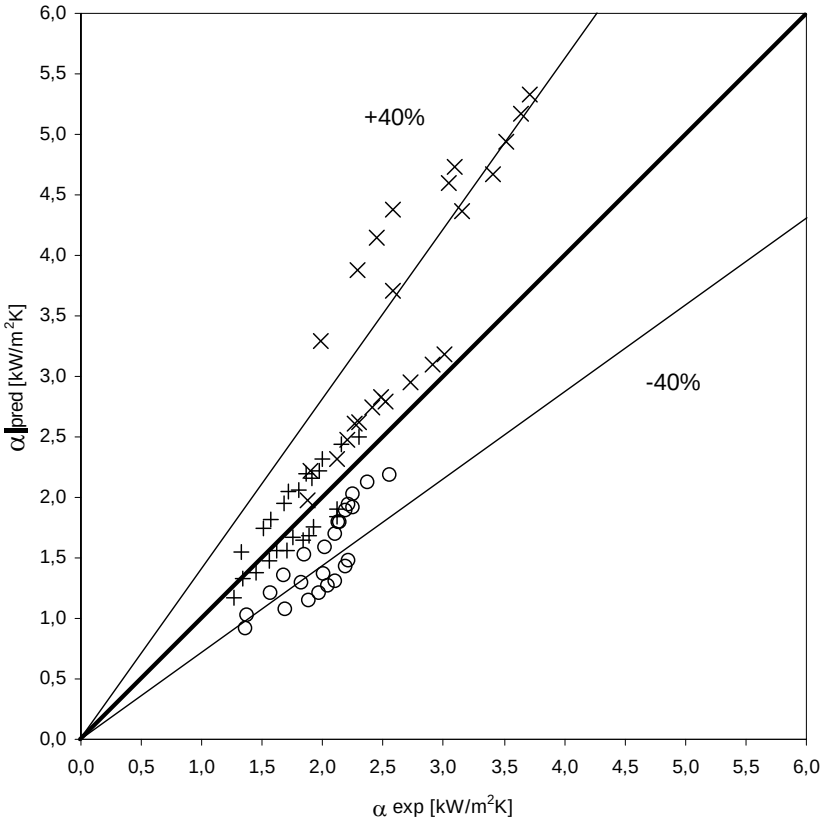

Figure 7. Predicted vs. experimental average heat transfer coefficients in smooth tube bundle; × - water, ○ – methanol, + - R141b

CONCLUSIONS

The following conclusions can be made from the present investigation on boiling heat transfer in smooth tube bundles under atmospheric and sub-atmospheric pressures:

1. Distilled water has an evident superiority over methanol and refrigerant R141b for each tested tube bundle.

2. For atmospheric pressure higher heat transfer coefficients were recorded than for sub-atmospheric pressure.
3. Increase in pitch-to-diameter ratio results in average heat transfer coefficient increase for all three liquid tested as well as atmospheric- and sub-atmospheric pressure.
4. Row average heat transfer coefficient increases from bottom to top row of tubes.
5. A Nusselt-type relation has been proposed to predict the heat transfer coefficient and the predicted values correlate satisfactory with the experimental data related to water, methanol and refrigerant R141b over some range of pressure.

Heat Transfer

FEATURES OF CONVECTION FLOWS AND HEAT TRANSFER IN MAGNETIC COLLOIDS

S.A. Suslov[1, *], A.A. Bozhko[2], G.F. Putin[2]

[1] Swinburne University of Technology, Hawthorn, Victoria, Australia
[2] Perm State University, Perm, Russia

ABSTRACT. Undertaken experimental observations and stability analysis have shown that a simple parallel buoyancy-induced flow in a differentially heated vertical layer of ferrofluid that is placed in an external uniform horizontal magnetic field is subject to a number of instabilities leading to the appearance of various convection patterns. Depending on the values of the governing parameters, the instability patterns are found to consist of vertical stationary magneto-convection rolls and/or vertically or obliquely counter-propagating thermo-gravitational or thermo-magnetic waves. Vertical rolls are the most prominent feature of the thermo-magnetic convection while inclined rolls and waves result from the interaction of the magnetic and gravitational mechanisms. Convective flow patterns are characterized by significantly increased heat transfer rates in comparison to pure conduction states. In particular, a significant intensification of an integral heat transfer was observed in convection regimes corresponding to vertical stationary rolls. It is found that these patterns are caused completely by a thermo-magnetic mechanism and are the consequence of an internal magnetic field gradient induced by the temperature dependence of fluid magnetization. These were not detected in earlier experiments and computations.

Keywords: *magneto-convection, thermo-magnetic waves, ferrocolloid, magnetic field*

INTRODUCTION

Common non-conducting artificial magnetic colloids (ferrofluids) consist of stable dispersions of single-domain ferromagnetic nano-particles in a liquid carrier. Such magnetic fluids respond to an external magnetic field similarly to natural paramagnetic and diamagnetic fluids (e.g. water, protein solutions, paramagnetic melts) and gases (e.g. oxygen). However the degree of magnetization in ferrofluids is many orders of magnitude higher than that in natural magnetic fluids. Therefore noticeable magnetic effects on fluid flows can be observed in magnetic fields created by ordinary permanent or electro-magnets which make these fluids suitable for a wide range of applications such as heat career in powerful loud speakers, controllable sealants in bearings, targeted drug delivery in cancer treatments etc.

Non-uniform heating results in non-uniform magnetization of ferrofluid that is placed in an external magnetic field. Subsequently, a ponderomotive force arises which drives stronger magnetized fluid particles to the regions with a stronger magnetic field. This phenomenon known as magneto-convection is different from convection caused by gravitational buoyancy forces. In fact, magneto-convection can be induced even if gravity is not present e.g. in outer space. Therefore it is potentially possible to use ferrofluids as a heat carrier in heat exchangers operating in reduced gravity conditions at orbital stations where adequate cooling by natural gravitational convection

cannot be achieved. The study of combined convection caused by the competing gravitational and magnetic mechanisms is undertaken in the current work with the emphasis on effects caused by fluid magnetization.

EXPERIMENTAL APPARATUS

A kerosene-based magnetic fluid used in experiments contained magnetite particles with the average size of 10 nm. The magnetic phase concentration was around 10%. Such a fluid is non-transparent for layers thicker than a few tenths of a millimeter. Therefore the only possible direct investigation of the arising convection patterns is via the measurements of thermal fields and heat fluxes. The focus of the undertaken study was on magneto-convection caused by ponderomotive forces arising in a fluid placed in an external uniform magnetic field. Thus the experimental conditions were chosen in such a way that magnetic effects were stronger or at least comparable with gravitational ones. Quantitatively, this meant that the ratio Gr_m/Gr exceeded the unity, where $Gr_m = \frac{\rho\mu_0 K^2\Theta^2 d^2}{\eta(1+\chi)}$ and $Gr = \frac{\rho^2\beta\,\Theta g\, d^3}{\eta^2}$ are the magnetic and gravitational Grashof numbers, respectively. Here $\rho = 1.25\cdot10^3$ kg/m^3 is the density of the fluid, $\mu_0 = 4\pi\times10^{-7}$ H/m is the magnetic constant, $\eta = 0.006$ kg/(m·s) is its dynamic viscosity, $\beta = 0.86\cdot10^{-3}$ is the coefficient of thermal expansion, $K\sim10^2$ A/(m K) is the pyromagnetic coefficient, $\chi = 5$ is the differential magnetic susceptibility, $2d$ is the thickness of a fluid layer and 2Θ is the temperature difference between the enclosure walls. Since $Gr_m / Gr \sim K^2\Theta / d$, in order to emphasize the magnetic convection mechanism thin layers of a strongly magnetizeable fluid subject to large temperature differences were used in experiments. Flows in three narrow cylindrical chambers with the diameter of 75mm and thicknesses of $2d$=2± 0.05, $2d$=3.5± 0.03 and $2d$=5± 0.05 mm were studied. A 3.5 mm vertical layer was used in order to investigate the evolution of convection patterns visualized by means of a liquid crystal thermo-indicator. The 2 mm and 5 mm layers were used to measure the integral heat flux across the chamber. The narrow cylindrical shape of the experimental cavities was chosen since it preserves the uniformity of the internal magnetic field when the apparatus is placed in an external uniform field generated by Helmholtz coils or an electromagnet [1]. Magnetic fields up to 200 kA/m were used in experiments.

Two experimental chamber designs are schematically shown in Figure 1. The 3.5 mm chamber intended for visual observations of convection patterns using a thermo-sensitive liquid crystal sheet is shown in the left diagram in Figure 1. One of the walls of this chamber was formed by a copper heater (2). Its temperature was determined by the water that was pumped through the channels drilled in the body of a heat exchanger. The opposite wall of this chamber was connected to a transparent heat exchanger (3) made of Plexiglas parallel plates separated by a gap filled with cool water. A circular Plexiglas frame (4) ensured the uniformity of the fluid layer thickness. The temperature variation of water pumped through both heat exchangers did not exceed 0.05 K. A 0.1 mm thick thermo-sensitive liquid crystal sheet (5) was glued to the outer side of a Plexiglas heat exchanger. In the absence of convection, a uniform temperature gradient establishes across the test fluid layer so that a liquid crystal sheet remains isothermal and thus is uniformly colored. When convection is present the heat flux across the fluid layer is non-uniform and the color of a liquid crystal changes from brown at approximately 24 °C to blue at approximately 27 °C. A 1 mm thick glass plate (6) protected the liquid crystal from direct exposure to the chemically aggressive ferrofluid. Even though the presence of such a “sandwich” structure reduced the thermal sensitivity and spatial resolution of the sensor it was still possible to reliably register surface temperature variations of several tenths of a degree. When the flow is relatively slow the relationship between the transverse velocity component and the convective distortion of the thermal field is approximately linear so that the color variations in the liquid-crystal thermo-indicator directly show

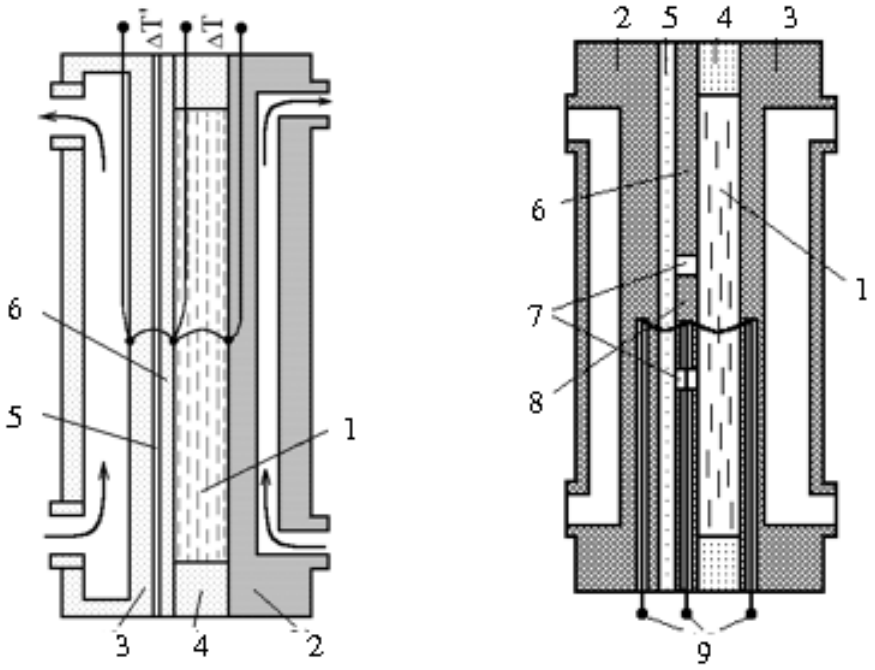

Figure 1. Cross-sectional view of test enclosures with thicknesses of (left) 3.50 mm: 1 – ferrofluid layer; 2 and 3 – copper or Plexiglas heat exchangers; 4 – circular Plexiglas frame; 5 – liquid crystal sheet; 6 – protective organic glass plate; (right) 2.00 and 5 mm: 1– ferrofluid layer; 2, 3 – copper heat exchangers; 4 – circular Plexiglass frame; 5 – fluoroplastic layer; 6 – copper plate; 7 – circular heat-insulating groove; 8 – copper bush; 9 – thermocouples.

the structure of the arising convective patterns. Their intensity is then estimated by comparing the local coloration with that observed in the non-convective state.

The schematic cross-sectional view of enclosures used to measure integral transverse heat flux is shown in the right diagram in Figure 1. A fluid layer (1) with the thickness of 2.00 (or 5.00) ± 0.05 mm was confined by two copper heat exchangers (2) and (3). The circular sidewall of the layer (4) was made of Plexiglas. In order to minimize the influence of the boundary effects on the heat flux measurements, the copper plate (6) was separated from the centrally located 17 mm circular integral sensor (8) by a groove (7) filled with a heat-insulating material. Thus the heat flux was measured only in the centre of the cavity. The use of such a design enabled us to significantly improve the accuracy of the convection threshold measurements in comparison with the other experimental designs in which a sensor occupies the entire sidewall.

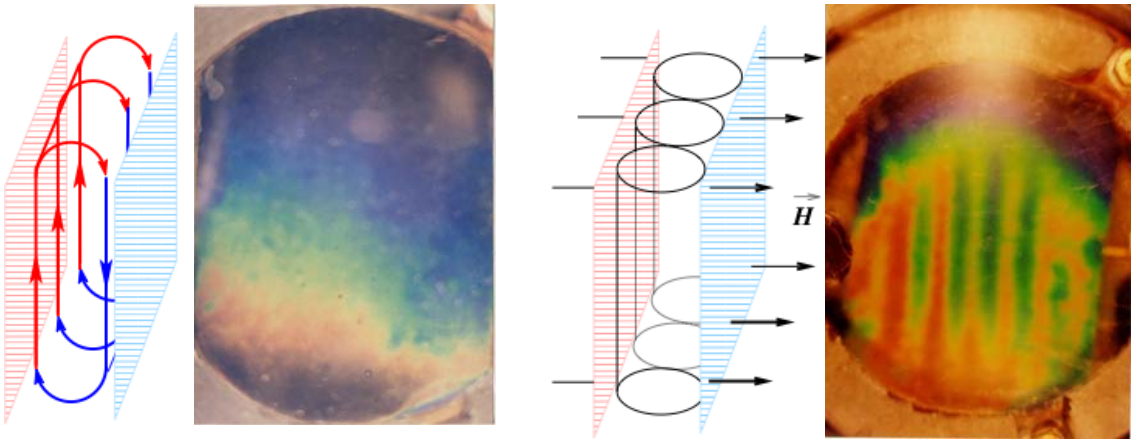
The intensities of the integral heat transfer across the ferrofluid layer (1) were determined using Schmidt-Milverton method [2] i.e. by comparing the temperature difference ΔT between the layer boundaries and the temperature difference $\Delta T'$ across the fluoroplastic layer (5). Temperature differences were measured using differential copper-constantan thermo-couples with a wire diameter of 0.1 mm. In steady and slowly varying states, when the temperature profile across the fluoroplastic layer is linear, Nusselt number Nu (the ratio of the total heat flux to purely conductive heat flux component) is determined from the expression: $Nu = k\Delta T'/\Delta T$. Here k is an empirical constant characterizing the ratio of the effective thermal diffusivities of fluid and fluoroplastic. In the absence of convection this constant is computed from the conductive heat flux balance condition $k = \Delta T / \Delta T'$.

When estimating the numerical values of the relevant nondimensional parameters such as gravitational and magnetic Grashof numbers it is important to keep in mind that the properties of ferrofluid, which in fact is a magnetic colloid, depend strongly on the way the fluid was prepared. In

particular, they are strongly influenced by the size distribution of solid phase particles, the interaction between these particles, the presence of a surfactant such as oleic acid, the composition of a base fluid (kerosene) and other factors [3]. In the context of the current investigation it is important that aggregates containing between a few tens up to a thousand magnetite particles are formed in an experimental fluid [4]. The number and sizes of such aggregates, and subsequently the rotational and magnetic viscosities of the ferrofluid, are determined by the history and type of experimental measurements [3, 5]. The value of a magnetic susceptibility χ, which is typically assumed constant, actually depends on the concentration of the formed aggregates [6]. In addition, the definition of the magnetic Grashof number Gr_{m} contains the pyromagnetic coefficient K, which is a function of the fluid's magnetization M. Even in an ideal situation the magnetization grows with the applied magnetic field H according to the linear law $M = \chi H$. Therefore strictly speaking the pyromagnetic coefficient K, which is a linear function of magnetization $K = \beta_M M$, where $\beta_M = 5 \cdot 10^{-3}$ 1/K is the relative pyromagnetic coefficient for the used ferrofluid, cannot be considered as constant in experimental conditions. These inevitable properties variations of magnetic colloids typically do not have a qualitative effect on the observed convection characteristics. However they may lead to noticeable quantitative deviations of the reported experimental values of parameters such as magnetic Grashof numbers from those assumed or found in the analysis and computations. To minimize possible confusion caused by this uncertainty in evaluating the experimental parameters the comparisons between experimental and analytical results given below use relative (to critical value) rather than absolute values of the governing flow parameters.

THERMO-MAGNETIC CONVECTION IN A VERTICAL LAYER

The liquid crystal temperature distribution on the lateral wide surface of the enclosure for the basic and secondary flows is shown in Figure 2. Figure 2(a) shows the schematic and the liquid crystal image corresponding to a shear flow arising in a pure conduction state when no magnetic field is applied. The blue upper and brown lower regions in the left photo show that the temperature stratification along the vertical layer exists so that the average temperature of the fluid increases upward. This is due to the finite vertical size of the enclosure. The thermal stratification effect is less pronounced in enclosures with larger aspect ratio (i.e. with a thinner gap width) and thus it is neglected in the analysis of infinitely tall layer presented below. Despite the presence of the thermal stratification, the resolution of a liquid crystal sensor was sufficiently high to detect the qualitative change in the flow behaviour after a magnetic field of sufficient strength was applied perpendicular to the fluid layer as shown in Figure 2(b). The applied external magnetic field causes magnetization of a ferrofluid. The degree of magnetization depends on the local fluid temperature: colder fluid magnetizes stronger. In turn, the fluid magnetization reduces the local magnetic field. In the considered geometry its magnitude decreases from hot to cold wall as discussed in [7]. As a result the arising ponderomotive force drives stronger magnetized colder fluid into the regions of stronger magnetic field near the hot wall. This is a physical reason for a change in the flow behaviour: once the ponderomotive force becomes sufficiently strong, the pure conduction state becomes unstable and magneto-convection begins. Experimentally this is detected by a characteristic change in the colour pattern of the liquid crystal sensor, see the photo in Figure 2(b). The observed patterns suggest that at the onset magnetic convection takes the form of stationary vertical rolls aligned with the direction of the base shear flow. This is in contrast to gravitational convection, which takes the form of horizontal rolls or thermo-gravitational waves propagating vertically in the considered configuration. Note that thermo-magnetic convection mechanism is completely independent of the direction of the gravity vector, but as discussed in [7] it is most pronounced in the absence of gravity. For this reason the analytical magneto-convection results, which are compared with experimental observations, below are obtained in the limit of $Gr \to 0$. The non-zero gravity, which is inevitably present in laboratory experiments, introduces a secondary effect leading to the inclination of convection rolls and their unsteadiness for larger values of the gravitational Grashof number. Such patterns have been observed experimentally and are illustrated in Figure 3.



(a) (b)

Figure 2. Qualitative diagrams and liquid crystal surface photographs of flows at Θ= 10 K: (a) H = 0; (b) H = 15 kA/m. The temperature variation from cool (brown) to warm (blue) liquid is approximately 3 K. The red/brown strips in photograph (b) correspond to a convective flow of a cool fluid away from the transparent enclosure wall while the blue/green strips show the location where warm fluid impinges the photographed surface. Magnetic field is perpendicular to the plane of photographs.

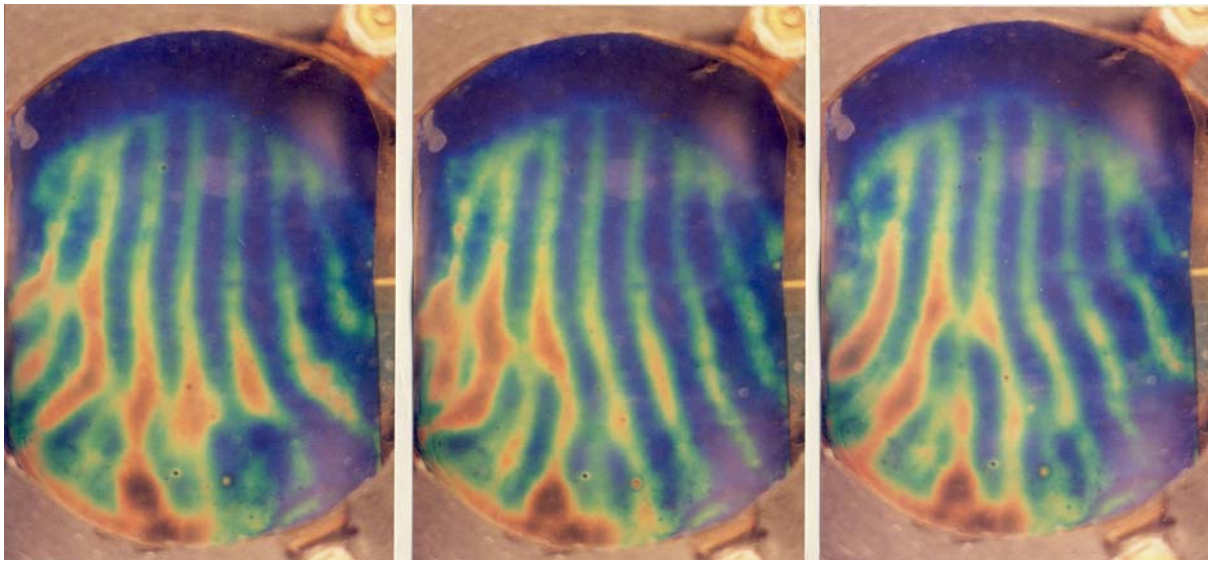


Figure 3. Inclined unsteady patterns in mixed thermo-magnetic and thermo-gravitational convection at $(Gr_m, Gr) \approx (15,8)$. The time interval between snapshots is 1 min.

The observed convection patterns are generally consistent with the pattern classification given in [7] for an infinitely wide and tall vertical layer of ferrofluid. It was shown there via comprehensive linear stability analysis of the basic shear flow that depending on the values of gravitational and magnetic Grashof numbers (with the other governing parameters being fixed, e.g. the fluids Prandtl number is taken to be 130 consistently with the current experiments) there are four major parametric regions summarized in Figure 4 (with up to 16 fine subregions which have been identified in [7]) distinguished by the dominant convection patterns and mechanisms. At low to

moderate values of the gravitational Grashof numbers (i.e. for thin fluid layers) vertical stationary thermo-magnetic rolls dominate the flow. The range of magnetic Grashof numbers for this regime is

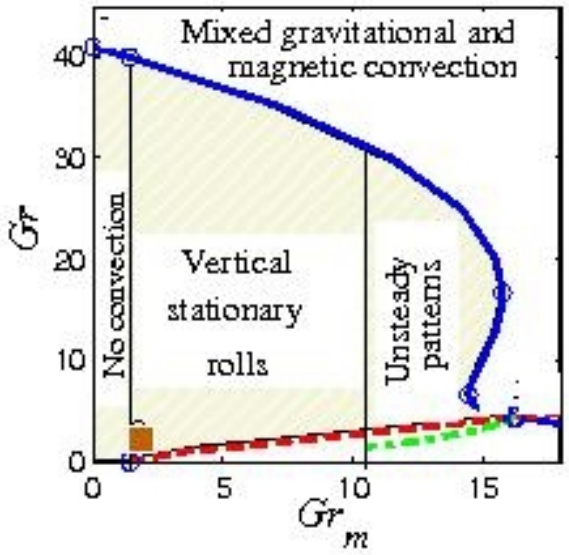

Figure 4. Convection pattern diagram for an infinite ferrofluid layer. See [7] for a detailed discussion.

the widest among all identified patterns, see the region between the two vertical lines in Figure 4. Since the gravitational buoyancy force is secondary in this regime, for the purpose of the initial weakly nonlinear analysis we disregard the buoyancy effects and only take into account magneto-convection. The mathematical details of this analysis are quite involved (see [8], for example) and will be reported elsewhere. Here we will only mention that the eigenfunctions of a linearised stability problem which are horizontally periodic with wavenumber β along the layer, and which represent vertical convection rolls, are taken as the basis of an asymptotic expansion carried out up to the third order in time-dependent roll amplitude $A(t)$. Consistently agreeing with experimental observations the analysis shows that the transition to a magneto-convection state occurs via a supercritical bifurcation. Therefore for the values of the magnetic Grashof number above critical (see the left vertical line in Figure 4) the roll amplitude grows until it reaches its saturation value A_s. Subsequently, the flow Nusselt number is computed at the enclosure wall as $Nu = 1 - A_s^2 \frac{d}{\Theta} \frac{d\Theta_{20}}{dx}$, where Θ_{20} is the average deviation of the temperature field from that corresponding to a pure conduction state, and x is the coordinate across the layer. The left plot in Figure 5 shows that the experimental and computed values of the Nusselt number are in reasonable agreement near the convection threshold. Yet the difference between the analytical and experimental values obtained for different enclosures is noticeable. While this discrepancy may be attributed to the difficulties with estimating the values of experimental parameters which were discussed above there appears to exist an experimentally observed trend: the Nusselt number values found for a thicker layer characterised by larger gravitational Grashof numbers are somewhat lower than those for a thin enclosure. This is consistent with the analytical conclusions of [7] where it was shown that the buoyancy effects characterised by the gravitational Grashof number tend to suppress magneto-convection. It was also found in experiments that the effective heat flux across the layer rapidly increases once convection sets, reaches its maximum and then starts decreasing for larger supercritical values of the magnetic Grashof number. Similar behaviour is predicted by our analysis, see the line in the left plot in Figure 5, even though strictly speaking the accuracy of weakly nonlinear approach is only guaranteed in the vicinity of a convection threshold. The right plot in

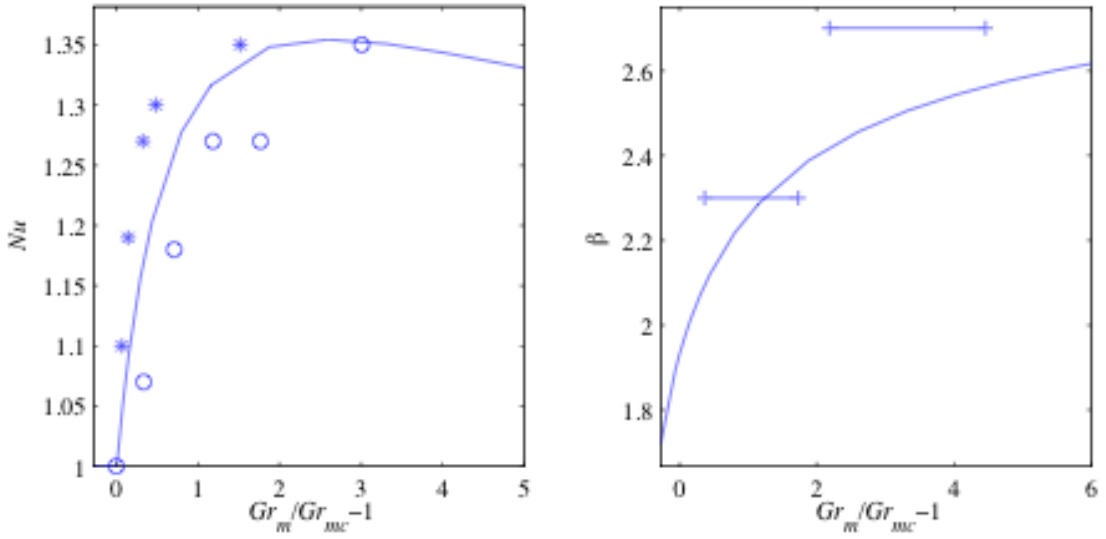

Figure 5. Experimental (symbols) and analytical (lines) results for Nusselt number and the dominant wavenumber for thermomagnetic convection taking the form of vertical stationary rolls. The star and circle symbols show experimental results for 2 mm and 5 mm thick enclosures, respectively. Convection roll wavenumbers experimentally observed in 3.5 mm enclosure over a range of magnetic Grashof numbers are shown by the connected plus symbols in the right plot.

Figure 5 presents the values of a dominant convection roll wavenumber as a function of the supercriticality parameter. According to the analysis it grows with magnetic Grashof number. The available experimentally measured wavenumbers are also shown in this plot. The agreement is very good near the criticality, but the analytical values are somewhat lower than experimental in far supercritical regimes. This is expected since in reality the unstable wavenumbers spectrum widens away from a bifurcation point so that a spatial modulation of periodic instability patterns brought about by the enclosure boundaries occurs. This may lead to the deviation of the dominant wavenumber predicted for an infinite layer from that observed in finite geometry.

Regimes qualitatively different from stationary vertical rolls are detected experimentally and predicted analytically for the larger values of magnetic Grashof number (to the right of the second vertical line in Figure 4). The analysis shows that waves counter-propagating along the hot and cold enclosure walls in the vertical or inclined direction appear in these regimes. Despite their relative weakness in comparison with stationary rolls they are nevertheless visible in experiments as they cause slow drift or blinking of the flow patterns. Disturbance energy analysis performed by the authors in [9] shows that such waves are caused by a magnetic mechanism which is different from that found in gravitational convection occurring in large Prandtl number fluids. In contrast to pure thermo-gravitational waves thermo-magnetic waves can propagate obliquely to the direction of gravity, which indeed was observed in experiments.

CONCLUSIONS

The performed linear and weakly nonlinear analyses of thermo-magneto convection flows in a vertical ferrofluid layer confirm and clarify the major features and characteristics of such flows observed experimentally. The qualitative agreement between analytical and experimental results is good. Both provide evidence of the dominant role of magneto-convection over gravitational convection in thin vertical layers of ferrofluid and demonstrate the existence of steady as well as unsteady convection patterns geometrically different from those observed in gravitational convection. However further analytical and experimental efforts are required before it can be concluded as to whether a consistent

quantitative agreement can be achieved. In particular, experiments in an enclosure of a larger aspect ratio are required to eliminate the enclosure boundary influence on magnetic field and flow patterns, and more accurate methods of estimating fluid properties and experimental flow parameters need to be developed. Further analytical development needs to incorporate the effects of gravitational convection competing with magneto-convection, the effects of spatial modulation and of three-dimensionality of the observed patterns. This work is currently underway.

PRESSURE DROP INSIDE A SMOOTH TUBE WITH DIFFERENT INLET GEOMETRIES IN THE TRANSITIONAL FLOW REGIME FOR WATER COOLED AT A CONSTANT WALL TEMPERATURE

J.P. Meyer*, L. Liebenberg and J.A. Olivier
Department of Mechanical and Aeronautical Engineering, University of Pretoria,
Pretoria, 0002, South Africa

ABSTRACT. Due to design constraints or changes in operating conditions, heat exchangers are often forced to operate in the transitional flow regime. However, there is not much design information available in this regime. It is also well known that the entrance has an influence on the transition position, exacerbating the absence of available design information in the transitional flow regime. The purpose of this study is thus to obtain pressure drop data for water inside smooth tubes, while the wall temperature is maintained constant. Adiabatic as well as diabatic experiments were conducted on water inside a smooth tube with an inner diameter of 15.88 mm. For diabatic experiments, water was cooled in the tube with chilled water in the annulus. Testing conditions were similar to those that can be expected in commercial chillers with Reynolds numbers in the transitional flow regime ranging between 1 000 and 20 000, Prandtl numbers between 4 and 6, and Grashof numbers in the order of 10^5. Four inlet profiles were investigated, namely hydrodynamically fully developed, square-edged, re-entrant and bellmouth. Adiabatic results confirmed that transition from laminar to turbulent flow was strongly dependent on the inlet profile, with transition being delayed to Reynolds numbers as high as 7 000. However, diabatic friction factor results confirmed that transition was independent of the inlet, with transition occurring at a Reynolds number of approximately 2 100. This was attributed to the buoyancy-induced secondary flows in the tube, interfering with the natural growth of the boundary layer.

Keywords: *smooth tubes, inlet, geometries, transitional, pressure drop*

INTRODUCTION

It is common practice to design heat exchangers of water chillers in such a way that they do not operate in the transition region. This is mainly due to the perceived chaotic behaviour as well as the paucity of information in this region. Due to design constraints or changes in operating conditions, heat exchangers are often forced to operate in this region. This is even worse for enhanced tubes as much less information in this region is available. It is also well known that the entrance has an influence on where transition occurs, adding to the scarcity of available information.

It is accepted in literature that transition from laminar to turbulent flow inside tubes occurs at a Reynolds number of approximately 2 300 [1]. Although this is an accepted value, transition in reality occurs in the range of Reynolds numbers between 2 300 and 10 000 [2]. It is normally advised when designing heat exchangers to remain outside these limits due to the uncertainty and flow instability of this region. For this reason, little design information is available with specific reference to heat transfer and pressure drop data in the transitional flow regime.

Furthermore, inlet profiles were found to have a profound influence on the transition Reynolds number. Ghajar and co-workers [2-10] performed extensive studies into the effect of three different types of inlets on the critical Reynolds number. However, Ghajar and co-workers used a constant heat flux boundary condition, which heats and does not cool fluids in a tube and does not ensure a constant wall temperature as would occur with water flowing in the inside of the tubes of a shell-and-tube heat exchanger (as is the case in the current work), where refrigerant boiling occurs on the outside.

Heat transfer also had an effect on the laminar friction factor, increasing with the amount of heat added [8]. This effect was also observed by Nunner [11], who performed similar heat transfer experiments. The increase (as much as 100%) was attributed to the buoyancy-induced secondary flow.

The main objective of this paper is to obtain pressure drop data in the transitional flow regime for water flowing through a horizontal smooth tube, while the temperature of the wall is kept constant. The constant wall temperature is the same condition experienced in water chillers where water is cooled in the inner tubes of a shell-and-tube heat exchanger with refrigerant boiling on the outside of the water tubes.

EXPERIMENTAL SET-UP

The experimental test section consisted of a tube-in-tube heat exchanger in a counterflow configuration. Water was used as the working fluid for both streams, with the inner fluid being hot and the annulus fluid being cold. The inlet tube temperature of the inner tube was 40-45ºC and the annulus inlet temperature was 20 ºC. Heating of the test fluid for the inner tube was done by means of a secondary flow loop containing water from a large reservoir. The temperature in this reservoir was maintained at approximately 60ºC by means of an electric heater, while the reservoir for the annulus water was cooled with a chiller.

The test fluid was pumped through the system with two electronically controlled positive displacement pumps. The two pumps were installed in parallel and were used in accordance with the flow rate requirements. The cold water loop was connected to a second large reservoir, which again was connected to a chiller. The water was circulated through the system via an electronically controlled positive displacement pump. Coriolis flow meters were used to measure the mass flow rates.

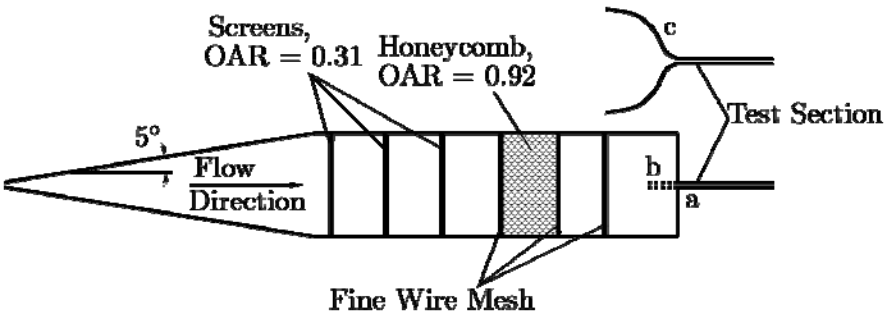

Figure 1. Calming section with the different types of inlet configurations: a) square-edged, b) re-entrant and c) bellmouth.

Prior to the flow entering the test section, for three of the four different types of test sections, the flow first went through a calming section as shown schematically in Figure 1. The purpose of the calming section was two-fold; first, to remove any unsteadiness in the flow and to ensure a uniform velocity distribution and, second, to house three of the four different types of inlets to be investigated. The calming section geometry was based on work conducted by Ghajar and Tam [10]

and consisted of a 5º diffuser, which increased from a diameter of 15 mm to 140 mm. This angle was chosen such to prevent flow separation from the diffuser wall. Three screens were placed after the diffuser with an *open-area ratio* (OAR) of 0.31. The OAR is the ratio of the area occupied by the holes to the total area occupied by the whole screen. A honeycomb section, which had an OAR of 0.92, followed the screens. Prior to and after the honeycomb, a wire mesh was placed with the wires having a diameter of 0.8 mm and the OAR being 0.54. Another fine wire mesh was inserted between the last honeycomb mesh and the test inlet. This mesh had a wire diameter of 0.3 mm and an OAR of 0.17.

Three different inlets could be housed on the calming section, namely a *square-edged*, *re-entrant* and a *bellmouth* inlet. These inlets are also shown in Figure 1 as items a, b and c, respectively. The calming section was designed such that the inlets could easily be interchanged. The square-edged inlet is characterised by a sudden contraction of the flow. This is a typical situation encountered in the header of a shell-and-tube exchanger.

The re-entrant inlet makes use of the square-edged inlet except that the tube slides into the inlet by one tube diameter. This would simulate a floating header in a shell-and-tube heat exchanger.

The third type of inlet is the bellmouth. The bellmouth is characterised by a smooth contraction, having a contraction ratio of 8.8. The shape of the bellmouth was calculated with the method suggested by Morel [12]. The use of a bellmouth is thought to help in the reduction of fouling, although practical application thereof is uncommon in heat exchangers.

The fourth type of inlet used was a fully developed inlet, which did not make use of the calming section. This inlet had an inner diameter being the same as that of the test section. The length of the fully developed inlet was determined in terms of the suggestion by Durst et al. [13], who required a minimum length of 120-tube diameters. To ensure this minimum was met, the length of the inlet was chosen as 160-tube diameters. Cooling started, in the case of adiabatic tests, after this inlet section, while for the other inlets, cooling started after the calming section.

All the insulated test sections were operated in a counterflow configuration and were manufactured from hard-drawn copper tubes. The total length of each test section was approximately 5 m. The tubes tested had a nominal outside diameter of 15.88 mm and inner diameter of 14.482 mm. A constant wall temperature boundary condition for the inner tube was enforced by having a high annulus flow rate. The annulus inner diameter of 20.7 mm was chosen such that the space between the annulus and the inner tube was small, ensuring high flow velocities and thus turbulent flow in the annulus, which further ensured that the annulus had a small thermal resistance compared with that of the inner tube. To prevent sagging and the outer tube touching the inner tube, a capillary tube was wound around the outer surface of the inner tube at a constant pitch of approximately 60º. This also further promoted a rotational flow velocity inside the annulus, producing a higher heat transfer coefficient and thus low thermal resistance.

Differential pressure measurements were made possible by means of two pressure taps inserted at the inlet and outlet of the inner tube. A full experimental uncertainty analysis was performed on the system using the method suggested by Kline and McClintock [14]. Uncertainties for the calculated heat transfer coefficient and friction factors were less than 5% and 18%, respectively.

DATA REDUCTION

The inner tube's average heat transfer coefficient was obtained by making use of the overall heat transfer coefficient and the sum of the thermal resistances, given by

$$\alpha_i = \frac{1}{A_i}\left[\frac{1}{UA} - R_w - \frac{1}{\alpha_o A_o}\right]^{-1} \tag{1}$$

where α is the heat transfer coefficient, A the heat transfer surface area, R the thermal resistance and the footnotes i and o denote inner and outer, respectively. UA is the overall heat transfer coefficient, which can be obtained by means of the overall heat transferred and the log-mean temperature difference T_{lmtd}, that is

$$UA = \frac{\dot{Q}_i}{T_{lmtd}} \tag{2}$$

$\dot{Q}_i$ is the heat transferred in the inner tube, calculated as

$$\dot{Q}_i = \dot{m}_i C_p \Delta T \tag{3}$$

where $\dot{m}$ is the inner-tube mass flow rate, C_p the average specific heat at constant pressure, and ΔT the temperature difference between the in- and outlet of the inner tube. The annulus heat transfer coefficient was calculated by means of the outer-annulus mean wall temperature T_a and inner-tube outer-wall temperature measurements T_{wo}:

$$\alpha_o = \frac{\dot{Q}_i}{A(T_{wo} - T_a)} \tag{4}$$

The inner-tube heat transfer rate was used for all the calculations since it had the lowest uncertainty. Throughout the tests the annulus flow rate was kept as high as possible as this reduced the thermal resistance of the annulus, reducing its influence in Equation (1) and hence decreasing the equation's overall uncertainty. Experimental data were only captured once an energy balance of less than 1% was achieved and steady-state conditions were reached. This entailed that the flow and temperatures did not vary over a period of 10 minutes. At low inner-tube Reynolds numbers (<6 000), this requirement was not met due to the high annulus flow rate and its uncertainty. Validation tests were, however, conducted by substantially lowering the annulus flow rate. These tests proved that the heat transfer error in the inner tube at low Reynolds numbers was indeed less than 1%.

The friction factor of the tube was determined by

$$f = \frac{2D\Delta p}{\rho u^2 L_{\Delta p}} \tag{5}$$

where f is the friction factor, D the tube diameter, Δp the pressure drop, ρ the density, u the average velocity, and $L_{\Delta p}$ the pressure drop length. Since it was not possible to measure inside the inner tube, as it would disturb the laminar velocity distribution and stability, the fluid properties were calculated at the average inner-tube fluid temperature, which, in turn, was determined by the resulting heat transfer coefficient, which was determined from Equation (1), as

$$T_i = \frac{\dot{Q}_i}{A\alpha_i} + T_{wi} \tag{6}$$

where T_{wi} is the inner tube inside wall temperature.

RESULTS

Adiabatic friction factors

Figure 2 shows the adiabatic friction factor results with various inlet profiles. This figure shows how the transition region is manipulated by the use of different types of inlets. The square-edged inlet delays transition to Reynolds numbers of around 2 600, while the bellmouth inlet delays it to about 7 000. Transition for the re-entrant inlet did not differ much from the fully developed inlet. Thus, the smoother the inlet, the more transition is delayed.

Laminar flow results for the various inlets, unlike the fully developed results, are slightly higher than the laminar friction factor obtained from the Poiseuille relation.

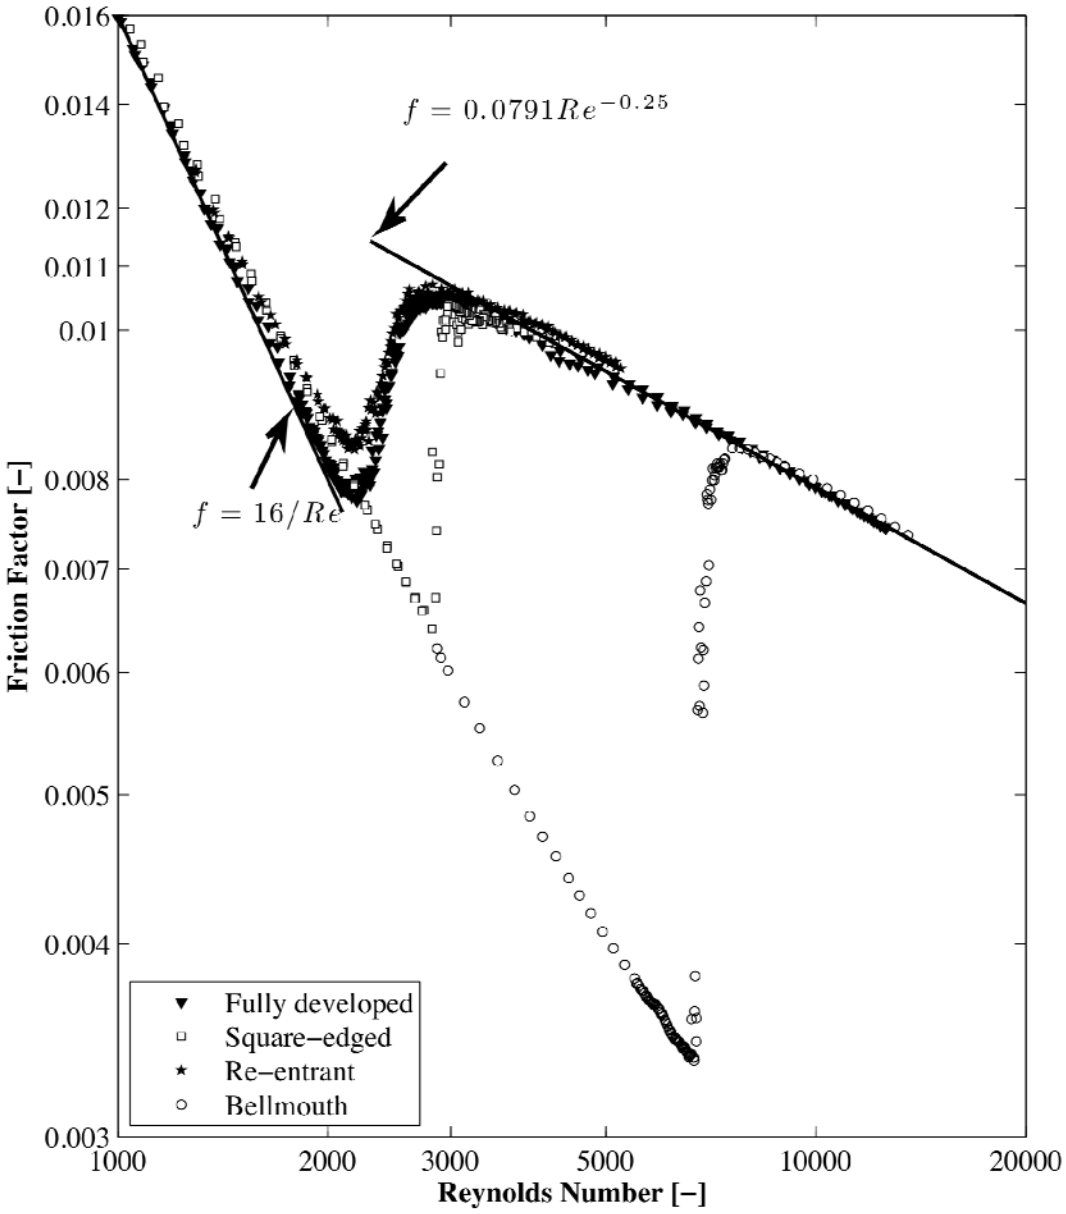

Figure 2. Adiabatic friction factors for the smooth tube with various inlets.

Diabatic friction factor

Since it has been shown that viscosity differences between the bulk of the fluid and the fluid at the wall have an effect on friction factors [15], it is of importance to report on the diabatic friction factors as well. This is further substantiated by the fact that there is a secondary flow component present [8]. The presence of this secondary flow is shown in Figure 3 with regard to the laminar and transition regions for all the different inlets of the two diameter tubes. Plotted on the graph are the experimental friction factors for the smooth tube during fully developed flow, the laminar Poiseuille relation, the turbulent Blasius equation and the Blasius equation with a viscosity ratio correction, $(\mu/\mu_w)^{-0.2}$, as suggested by Allen and Eckert [16].

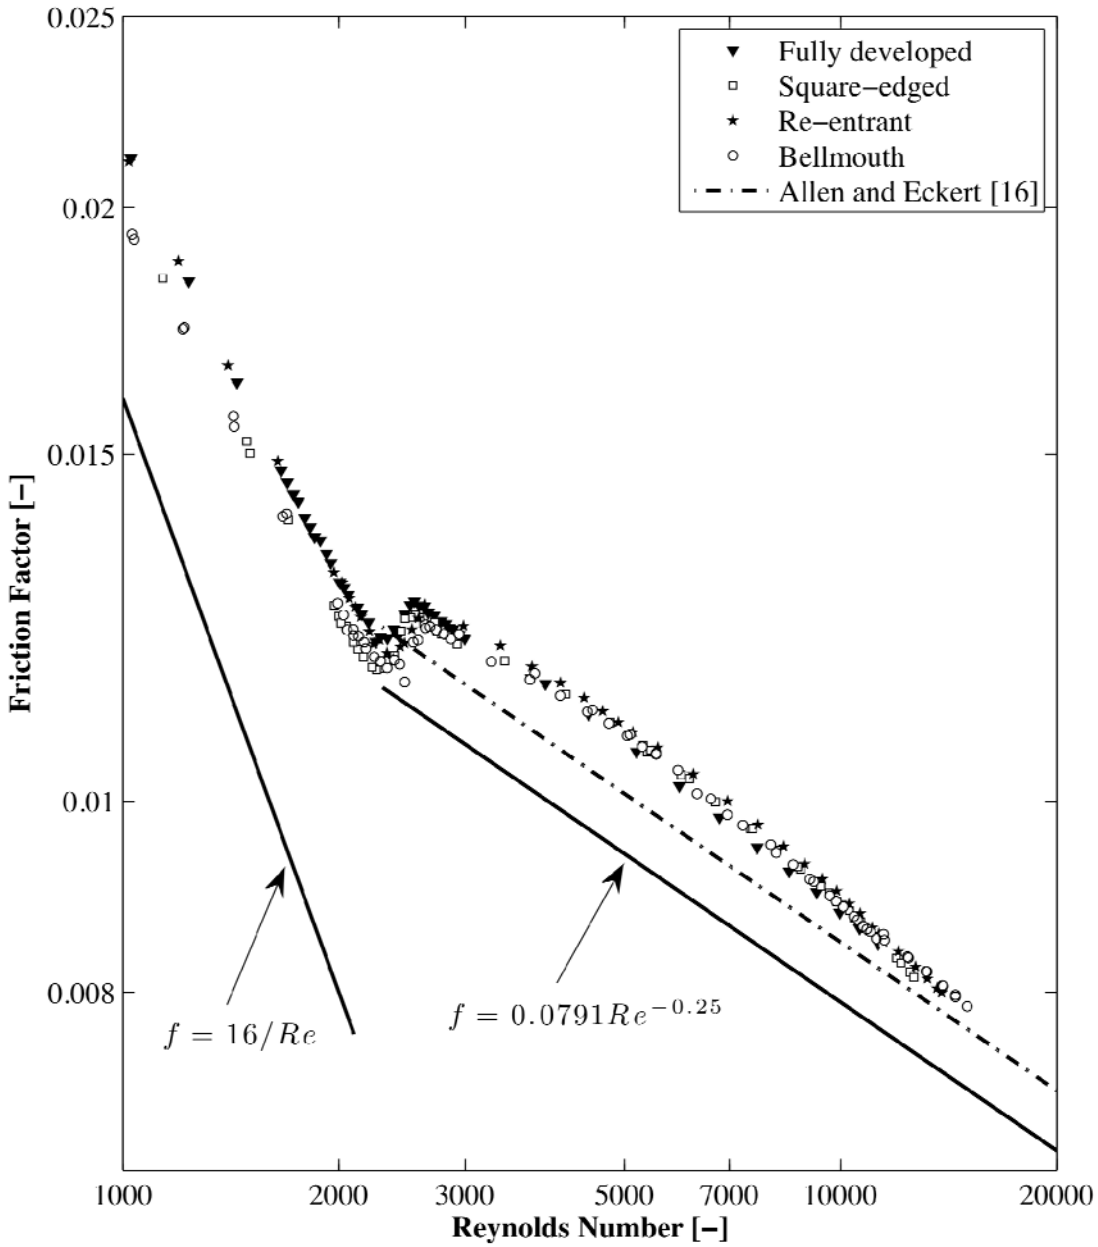

Figure 3. Diabatic friction factors for the smooth tubes with various inlets.

Turbulent flow results correlated fairly well with the viscosity ratio correction, although it would seem as if full turbulence is only reached at Reynolds numbers above 15 000. Unfortunately, the range of data was limited such that this could not be confirmed by taking measurements at Reynolds

numbers greater than 15 000. For the laminar flow region, friction factors were on average 35% higher than predicted by the Poiseuille relation. Even with a viscosity correction, the prediction only improved by 4%. This increase in friction factor can be attributed to the secondary flow effects, with data from Nunner [11] showing similar results. Tam and Ghajar [8] also noted this increase and found that it was dependent on the heating rate. This implies that since the friction factor is proportional to the wall shear stress, which in turn is proportional to the velocity gradient at the wall, secondary flows distort the velocity profile in such a way that the velocity gradient near the wall is much greater. This would then give rise to the higher friction factors. Many numerical and experimental studies have been performed showing this distortion [17-19].

CONCLUSIONS

Adiabatic friction factors showed that transition from laminar to turbulent flow was strongly dependent on the type of inlet used. The smoother the inlet, the more transition was delayed. Results for the bellmouth inlet showed the largest delay, with transition only occurring at a Reynolds number of approximately 7 000.

On the contrary, diabatic friction factor results also showed that transition was independent of the type of inlet. Laminar friction factors were, however, much higher than the values predicted by the Poiseuille relation. This was also attributed to the natural convection flows influencing the boundary layer to such a degree that the shear stress at the tube wall is higher than normal.

[2]Kanagawa University, Kanagawa, Japan

ABSTRACT. Spatio-temporal fluctuation of void fraction fluctuation is one of the typical and inherent characteristics of two-phase flow. So far conducted modellings are based on a time-averaging concept for making use of conventional hydrodynamic theory, which brings, on one hand, about the a substantial conflict in simulating such inherent thermal-flow fluctuations including flow pattern transition, void fraction, pressure drop and heat transfer. This paper describes alternative approach for two-phase flow dynamics in a horizontal flow. The developed model successfully simulated the void fraction fluctuation and thus the PDF, so that the flow pattern map was well reconstructed.

Keywords: *discrete bubble model, horizontal flow, flow pattern, void propagation*

INTRODUCTION

Two-phase flow is a very complex system due to an existence of interface between gas and liquid phases. In addition, the interface structures are spatio-temporally deformable, because break-up, coalescence and expansion of bubbles are always encountered while flowing downstream. In this field of study, this instantaneous geometrical configuration is referred to as a flow pattern. The thermal-flow characteristics of two-phase flow are greatly dependent on the combination of two phases, and thus the flow pattern is a very important planning and/or design factor of two-phase flow systems, such as boilers, boiling water reactors, steam generators of pressurized water reactors and other heat exchangers. At high heat flux condition in these boiling two-phase flow systems, a critical heat flux (CHF) may occur by the inherent fluctuations of two-phase flow. However, in the conventional two-phase flow modellings such as drift-flux model and two-fluid model, a spatio-temporally irregular two-phase flow, e.g. slug flow shows two peaks of probability density function (PDF) of void fraction fluctuation, is formulated as a continuous two-phase flow having a uniform distribution of void fraction. That is caused by a time-averaging process in the two-phase flow modelling, otherwise the conventional hydrodynamics theory is hardy applied. Thus, these conventional modellings fail to simulate the void fraction fluctuation, the flow pattern transition and the critical heat flux due to inherent fluctuation.

An alternative approach to solve the current problem, the discrete bubble model [1, 2] has been developed by the authors in the framework of a pattern dynamics approach. In the discrete bubble model, two-phase flow is simulated with the void propagation equation as a global rule applied over the whole flow filed and a few local rules corresponding to momentum effect, i.e. the wake effect of preceding bubbles, the compressibility of gas phase and the phase re-distribution causing by geometrical constraint. This discrete bubble model successfully realized void fraction fluctuation as well as the specific statistical nature of each flow pattern in vertical upward flow. In the present

investigation, the discrete bubble model is extended so as to be applicable to horizontal flow, which is a prime interest in this paper.

DISCRETE BUBBLE MODEL

The fundamental concept of the newly developed discrete bubble model for isothermal horizontal flow is the same as the previous one for vertical upward flow [1, 2]. The newly introduced and/or replaced relationships for local rules are the pressure jump condition and slip relationship suitable to horizontal flow, and the rest are unchanged.

Calculation model

Figure 1 shows the flow field considered. A one-dimensional horizontal flow is provided together with the isothermal assumption. A liquid phase is supplied at the left end and a gas phase is injected through a mixing chamber of length L_M. The two-phase mixture from the mixing chamber flows through the channel toward the right end, where the mixture flows out freely at the system pressure.

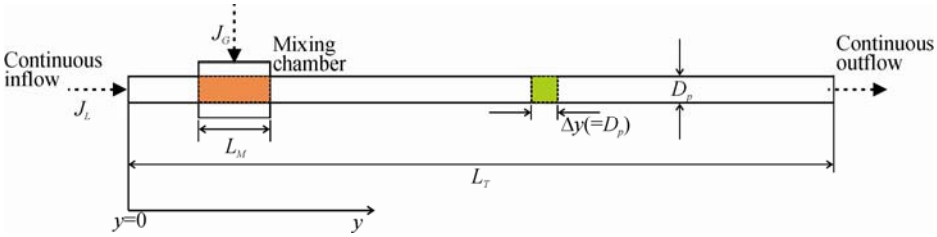

Figure 1. Flow model

The flow field is segmented into the cylindrical cells with the same length as the tube diameter D_p, and this cylindrical cell is used as the frame of reference. The representative bubble is defined as a single gas volume in the cell integrated over the frame of reference and having a geometrical similarity to the unit cell as shown in Figure 2.

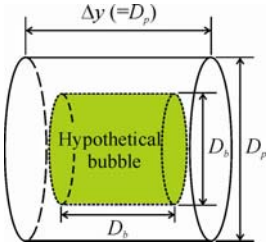

Figure 2. Single hypothetical bubble

Then the void fraction ε in the cell is simply given by

$$\varepsilon = \left(D_b / D_p\right)^3 \tag{1}$$

where D_b is the diameter and length of the single hypothetical bubble. The void propagation equation, as a global rule, is given by equation (2).

$$\frac{\partial \varepsilon}{\partial t} + \frac{\partial\left(\varepsilon U_G\right)}{\partial y} = q\left(= \frac{j_G}{L_M}\right) \tag{2}$$

where U_G is a velocity of gas phase, q is a source term of gas phase, j_G is a volumetric flux of gas phase. In the adiabatic section other than the mixing section, this source term is set at $q = 0$. The local rules which control the behaviour of each hypothetical bubble are needed to represent the two-phase flow dynamics, such as bubble coalescence, breakup, expansion and/or compression leading to the flow pattern transition. The following discussion covers newly introduced and/or replaced local rules together with the other rules applied consistently regardless of the flow direction.

Relative velocity between gas and liquid phases

The velocity of gas phase U_G is the sum of the total volumetric flux j_T (= a volumetric flux of gas phase j_G + a volumetric flux of liquid phase j_L) and the drift velocity of gas phase v_{Gj} which is a function of a void fraction and a slip velocity u_r (= U_G - the velocity of liquid phase U_L). In the vertical flow modelling, the slip velocity was estimated by the force balance acting on a single bubble, i.e. the buoyancy and the drag force. In this horizontal flow model, the following equation is used as the slip relationship.

$$Fr = 0.542 - 1.76Bd^{-0.56} \tag{3}$$

where Fr is the Froude number (= $u_r/(gD_p(\rho_L - \rho_G)/\rho_L)^{0.5}$), Bd is the Bond number (= $(\rho_L - \rho_G)gD_p^2/\sigma$), g is the gravitational acceleration, ρ_L and ρ_G are densities of liquid and gas phases, respectively. σ is the surface tension. This equation was derived from the analytical and experimental investigation on the gas cavity velocity in emptying process from a liquid-filled horizontal channel [3, 4].

Wake effect of the preceding bubble

The wake effect is one of very important factors of the flow pattern transition. When two bubbles moves successively, a succeeding bubble is affected by the wake due to a preceding bubble. The succeeding bubble is pulled by the preceding bubble, and these two bubbles coalesce into a single large bubble. The maximum wake velocity induced by the preceding bubble is given by equation (4), which is the same relationship as the previous vertical upward flow.

$$u_{w,\max,i} = c_1 u_{r,i+1}\left(C_D D_{b,i+1}^2 / \Delta y^2\right)^{1/3} \quad (\varepsilon_{i+1} \geq \varepsilon_i) \tag{4}$$

where $u_{w,max}$ is the maximum wake velocity, c_1 (= 0.715) is a constant, C_D (= 0.44) is a drag coefficient, Δy is a length of unit cell, i is a cell number from the inlet. In the case of $\varepsilon_{i+1} < \varepsilon_i$, $u_{w,max,i}$ is set 0. This wake effect is assumed to have an exponential decay and the local wake velocity u_w of the subjected bubble is given by the summation of the respective wake effects of the preceding bubbles.

$$u_{w,i} = u_{w,\max,i} + \sum_{j=1}^{c3} u_{w,\max,i+j} \exp\{-c_2(j+1)\} \tag{5}$$

where c_2 (= 0.14) and c_3 (= 20) are constant in this simulation. Finally, the substitution of this wake velocity into the following equation gives the ship velocity.

$$u_{r,i+1} = u_{w,i}\left\{\left(C_D D_{b,i+1}^2 / \Delta y^2\right)^{1/3}\right\}^{-1} \quad (u_{w,i} > 0) \tag{6}$$

Compressibility of gas phase

The flowing bubble is expanded or compressed due to the local pressure fluctuations. Isothermal state change of gas phase is assumed. In a horizontal flow, the gravity term plays only a minor role in the total pressure, while a dominant factor in a vertical flow. Then the pressure jump conditions across the cells are given by the regime-based modelling of slug flow [5].

$$p_i - p_{i+1} = \Delta p_f - \rho_L g\left(\varepsilon_{L,i} H_{eq,i} - \varepsilon_{L,i+1} H_{eq,i+1}\right)/2 + \varepsilon_{L,i+1}\rho_L U_{L,i+1}\left(U_{L,i+1} - U_{G,i+1}\right) - \varepsilon_{L,i}\rho_L U_{L,i}\left(U_{L,i} - U_{G,i}\right) \quad (6)$$

where p is a pressure, H_{eq} is the equivalent liquid height, ε_L is a liquid holdup. Each term of the R.H.S. in equation (6) represents the frictional pressure drop, the static pressure difference caused by liquid height difference, the scooped and shed momentum at the tail and the nose of the bubble. The frictional pressure drop is calculated as the sum of the part of liquid phase and the part of bubble. The wall friction factor of liquid phase is a function of Reynolds number similar to single phase flow based on hydrodynamics, while the wall friction factor around the bubble is 0.005 [6]. The equivalent liquid height in equation (7) is calculated by using the separated flow model as shown in Figure 3 [4, 5].

$$\varepsilon_L H_{eq}/2 = \frac{1}{A}\int_0^h y C_i dy \quad (7)$$

where A is the area of cross section, h is the height of gas-liquid interface, y is the distance from a gas-liquid interface and C_i is the chord length at y. The third and fourth terms in equation (6) are not limited in a horizontal flow, but are insignificant in a vertical flow relative to the gravity term.

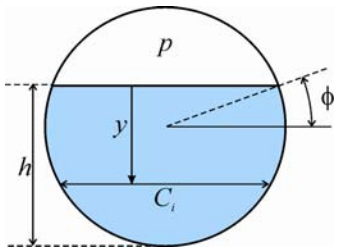

Figure 3. Equivalent liquid height based on separate flow model

Phase re-distribution due to geometrical construction

The large bubble is expanded due to the compressibility of gas phase in this model. In the course of simulation the diameter of hypothetical bubble becomes larger beyond the tube diameter. In order to avoid this inconsistency, the limiting void fraction ε_{cr} is set, and the excess amount ($\Delta\varepsilon_i = \varepsilon_i - \varepsilon_{cr}$) beyond the limiting void fraction is compensated through the re-distribution process to the downstream cell. On the other hand, a surplus liquid holdup pushed out of the downstream cell $\delta\varepsilon_L$ is uniformly re-distributed to upstream cells as shown in Figure 4.

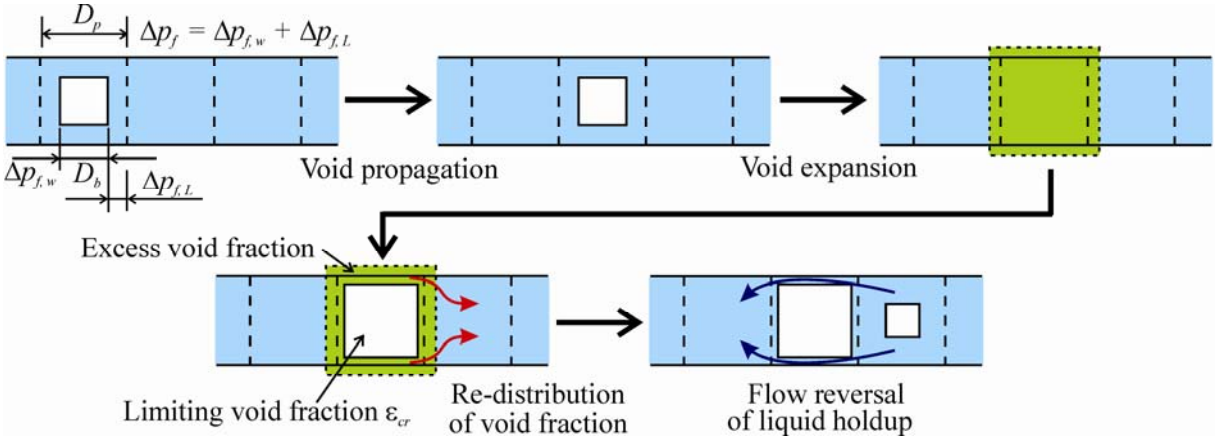

Figure 4. Sequence of simulation

The re-distributed liquid holdup is assumed to be a function of the limiting void fraction as follows:

$$\delta\varepsilon_{L,i} = \Delta\varepsilon_{L,i}/i = \left\{-\Delta\varepsilon_L \exp\left(-c_4\varepsilon_{cr}\right)\right\}/i \tag{8}$$

where c_4 (= 5) is a constant. The limiting void fraction is 0.95, by considering the thickness of liquid film in an annular flow.

NUMERICAL SIMULATION

The numerical simulation was conducted with a finite-difference method. The time derivative and the convective term were expressed by a forward difference and an upwind difference, respectively. To compare with simulation results, the experiment was conducted by using a one-through forced convective boiling system of CO_2 [7, 8]. The simulation conditions and the system configurations are set so as to meet the experimental condition list in Table 1.

Table 1
Simulation conditions and system configurations

Parameter	Set data
Working fluid	CO_2
System pressure	6.5 MPa
Mass flux G	50 to 800 kg/m^{2}s
Quality x	0.01 to 0.9
Length of the test section L_T	400 mm
Length of the mixing section L_M	20 mm
Pressure tap distance L_P	200 mm
Tube diameter D_p	2.0 mm
Number of mesh GN	200
Mesh length Δy	2.0 mm
Time step Δt	0.01 ms

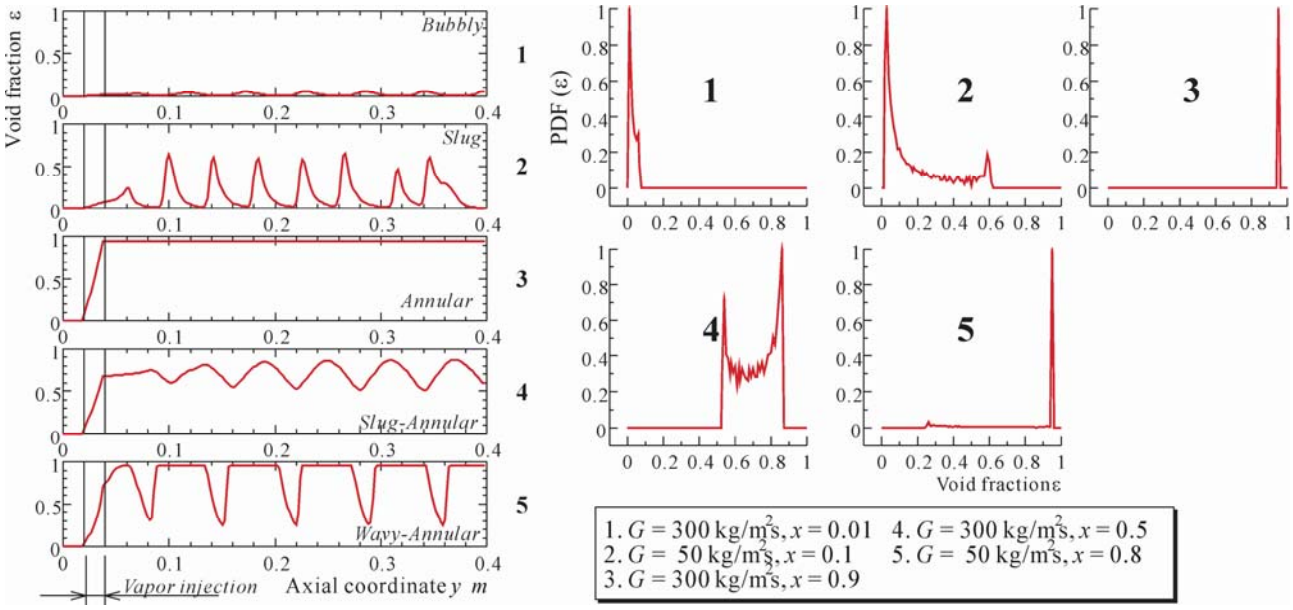
Void fraction fluctuation and flow pattern map

Typical snapshots of the void fraction distribution along the tube are shown in Figure 5 (1) together with the corresponding PDF in Figure 5 (2) detected at the middle position, y = 222 mm, along the tube. Two vertical lines in the snapshot represent the mixing section.

The first group of simulation results is similar to those in a vertical upward flow [1, 2, 9]. In Figure 5 (1)-1 (G = 300 kg/m^{2}s, x = 0.01), there are ripple-like void fraction fluctuation, i.e. void wave, travelling along the tube. The corresponding PDF has a single peak at low void fraction as shown in Figure 5 (2)-1. The flow pattern is considered as a bubbly flow. Increased vapour quality as shown in Figure 5 (1)-2 (G = 50 kg/m^{2}s, x = 0.1), relatively large void waves, corresponding to large bubbles, are intermittently formed along the tube. The PDF has two peaks at both low and high void fractions. The flow pattern is recognized as a slug flow. At the highest quality shown in Figure 5 (1)-3 (G = 300 kg/m^{2}s, x = 0.9), the void fraction becomes rather uniform, keeping almost constant value close to the pre-determinant limiting value. The PDF has a single peak at high void fraction as shown in Figure 5 (2)-3. This flow pattern corresponds to an annular flow.

The next two flow patterns are uniquely appeared in this horizontal flow simulation. In Figure 5 (1)-4 (G = 300 kg/m^{2}s, x = 0.5), there are the sinuous wave-like distribution of void fraction. This wave

fluctuates within a moderate range of void fraction. The corresponding PDF has still two peaks as in Figure 5 (2)-4, while the amplitude is relatively small compared with the slug flow. This type of flow seems a transitional flow pattern from the slug to the annular flow, and is quite similar to the slug-annular flow observed in the experiment. In the last case, Figure 5 (1)-5 (G = 50 kg/m^{2}s, x = 0.8), the void fraction is rather high at wave crest, however, with quite low void fraction at wave trough. Such flow behaviour is similar to the annular flow but with large amplitude waves on the liquid flow. Then the PDF shows two peaks, and this last flow pattern is quite similar to the wavy-annular flow observed in the experiment.



(1) Snapshot (2) PDF

Figure 5. Characteristics of void fraction

The flow pattern identification are conducted with the simulation data, when the identification is, at the first step, based on the above-mentioned typical feature together with the simulation results of discrete bubble model for vertical upward flow [1, 2, 9]. Threshold conditions are listed as a function of a maximum ε_{max} and a minimum ε_{min} void fraction:

Bubbly flow:	$\varepsilon_{min} < 0.1$, $\varepsilon_{max} < 0.6$
Slug flow:	$\varepsilon_{min} < 0.1$, $\varepsilon_{max} \geq 0.6$
Slug-Annular flow:	$0.1 < \varepsilon_{min} < 0.8$, $\varepsilon_{max} < 0.9$
Wavy-Annular flow:	$0.1 < \varepsilon_{min} < 0.6$, $\varepsilon_{max} \geq 0.9$
Annular flow:	$\varepsilon_{min} \geq 0.9$

The flow patterns are potted as a function of x - G in Figure 6 (1)-(a) together with Weisman's diagram [10] for conventional size channel, and the j_G - j_L system in Figure 6 (2)-(a) with Mandhane et al. [11]. The flow pattern map developed for CO_2 or micro-channel, e.g. Cheng et al. [12] and Revellin-Thome [13], does not agree with this experimental results. As a reference, the experimental flow pattern map and photographs of typical flow pattern are shown in Figure 6 (1)-(b), (2)-(b) and Figure 7, respectively.

The flow pattern map with numerical simulation approximately coincides with the experimental observation. The feature that the slug-annular flow penetrates into the annular flow regime predicted with the Weisman's threshold criteria is similar to the experiments. The slug flow has not been observed in the experiment owing to the limitation of pump system, while the comparison with experimental results [8] at 5.0 MPa verifies the relevance of the present model in predicting flow

pattern, including slug flow. Both the simulation and experimental results approximately agree, except the existence of the slug-annular flow, with the Weisman's flow pattern maps. On the other hand, Mandhane's flow pattern map does not agree with the experimental and simulation results, because the flow pattern map of Mandhane was developed based on the data of air-water system.

These results suggest the flow pattern in the mini-channel of CO_2 at high pressure to be similar in conventional channel. In the case of CO_2 at high pressure, a density ratio of liquid to vapour is small, but the effect of surface tension is much more weak. This leads to the applicability of the conventional these threshold criteria as well as the present discrete bubble model to rather small-bore channel, e.g. 2mm.

CONCLUSIONS

The discrete bubble model for a vertical flow was successfully modified so as to include horizontal flow mechanisms and the inherent void fraction and flow fluctuation in a horizontal flow of two-phase mixture. The numerical simulation with this model properly realized PDF of void fraction which was available for flow pattern identification. The flow patterns appeared in the simulation were bubbly, slug, slug-annular, wavy-annular and annular flows. The resulting flow pattern maps were in good agreement with the experimental results of CO_2 two-phase flow at high pressure.

ANALYSIS OF MELTING IN VERTICAL TUBES

H. Shmueli[1], L. Katsman[1], L. Fraiman[1], E. Benisti[1], G. Ziskind[1,*], R. Letan[1]

ABSTRACT. Melting of a phase change material (PCM) in vertical circular tubes is analyzed based on experimental results obtained in our previous studies. The total initial height of the PCM is divided into horizontal slices. As the melting process advances, the relative share of the solid phase inside each slice decreases. The images taken throughout the melting process are used to determine the volume of the solid phase in each slice at various instants. For each slice, the dependence of the volume on time is approximated by a polynomial function. Then, the melt fraction as a function of time is calculated for each slice separately. The time derivative of the polynomial function is calculated, yielding the heat transfer rate as a function of time for each slice. Based on the results, it is possible to observe the different heat transfer mechanisms that affect the melting process. In particular, at the initial stage of melting the heat transfer rate to the solid PCM is rather uniform along the whole height of the solid phase, corresponding to conduction from the wall to the solid through a gradually increasing liquid layer. As the process advances, heat to the upper part of the solid is brought by convection in the liquid phase. A sharp increase in the convective heat transfer to a certain slice is accompanied, however, by a reduction of the remaining solid volume in that slice. As a result, the heat transfer rate to a slice starts to decrease sharply at some instant, and reaches effectively zero when the melting process in the slice is complete.

Keywords: *melting, vertical tube, melt fraction, local heat transfer, convection*

INTRODUCTION

Phase-change materials (PCMs) are suggested for use in various thermal energy storage systems where their latent heat can be utilized. Vertical tubes are frequently cited as suitable PCM containers. A number of detailed experimental investigations of melting in vertical tubes are reported in the literature. Sparrow and Broadbent [1] studied melting of paraffin in a thin wall copper tube. Visualization was done by interrupting the melting process at various stages and observation of the solid taken outside the tube. Various temperature differences between the wall and the paraffin were explored. Sparrow and Broadbent [1] analyzed the role of convection and established the characteristic conical shape of the remaining solid, widely cited in the literature. Also, they established that the process of melting is governed by both conduction and convection. Menon et al. [2] studied melting of a commercial paraffin wax in vertical copper tubes. Various PCM heights were explored. Visual studies of melting were performed separately, in a glass tube. The observed patterns were similar to those reported by Sparrow and Broadbent [1]. More recently, Jones et al. [3] studied melting of in a vertical cylindrical enclosure heated from the side. The objective was to provide benchmark experimental measurements for validation of numerical codes, using rather sophisticated techniques for monitoring the melting front and image analysis. The melt volume fraction was determined experimentally from the reconstructed interface locations.

In our previous studies, Katsman et al. [4] explored experimentally the process of melting of a phase change material (PCM) in cylindrical geometry. The material used was a commercially available paraffin-type substance. The experiments were conducted using vertical tubes of four different nominal diameters, namely 1, 2, 3, and 4cm, filled with the PCM and immersed in a water bath. In each tube the experiments were performed at the water bath temperatures of 10, 20 and 30°C above the melting point of the paraffin. The experiments provided detailed phase fields inside the system which were compared with the experimental results from the literature. As the study was done for the same PCM height of 17cm inside the tubes, it was not possible to analyze the effects of the height on the process of melting. Using the same experimental set-up, Fraiman et al. [5] investigated melting at two additional initial PCM heights of 12cm and 6cm inside the tubes. Shmueli et al [6] compared experimental pictures, obtained in previous investigations, with simulation results, providing a detailed heat flux distribution on the inner wall of the tube.

The images of the melting solid, photographically recorded by Katsman [4] and Fraiman et al. [5], reflected transformation of shapes from a cylinder to a cone, which in the process changed in shape and size. Following these observations, the present study attempts to reach an insight into the physical phenomena, which govern this process, by focusing on the local heat transfer to the melting solid inside a vertical tube.

ANALYSIS

The objective of the present study is to obtain the melt fraction and heat transfer rate via determining the volume of the solid phase at various instants during the melting process, based on the experimentally recorded images. An example of image sequence is shown in Figure 1 for the entire melting process in tube with inner diameter of D=4cm, initial PCM height of H=12cm, and temperature difference of ΔT=10 degrees between the outside wall and the PCM melting temperature. The initial height of the solid PCM has been now divided into 12 horizontal "slices", each H_{sl} =1 cm high. The slices, as shown in Figure 1, were denoted from 00-01 at the bottom, to 11-12 at the top. A schematic description of slice definition and evolution is given in Figure 2.

One can see from Figs. 1 and 2 that as the process of melting advances, each of the slices shrinks in volume at rates that vary with time and slice location. Therefore, the image of each slice was measured at the recorded time, and the instantaneous volume was calculated, assuming axis-symmetry of the image. Figure 2 gives a detailed description of that procedure at two sequential instants, t and $t+\Delta t$: the given slice, k to k+1, where k runs from 0 to H/H_{sl}, is characterized by its maximum and minimum diameters, D_k and D_{k+1}. For instance, for the case shown in Figure 1, the maximum number of slices is 12. As can be seen from Figs. 1 and 2, the diameter of the same slice at different instants decreases, until the whole solid slice vanishes completely due to phase change. Thus, as the melting process advances, the number of remaining slices decreases due to the solid shrinkage. Once the maximum and minimum diameters of the slices are measured from the recorded images, the mean diameter is calculated for every slice as

$$D_m(t) = \frac{D_k(t) + D_{k+1}(t)}{2} \tag{1}$$

Then, the time-dependent diameter for each slice is plotted and approximated by a polynomial function using the MATLAB software.

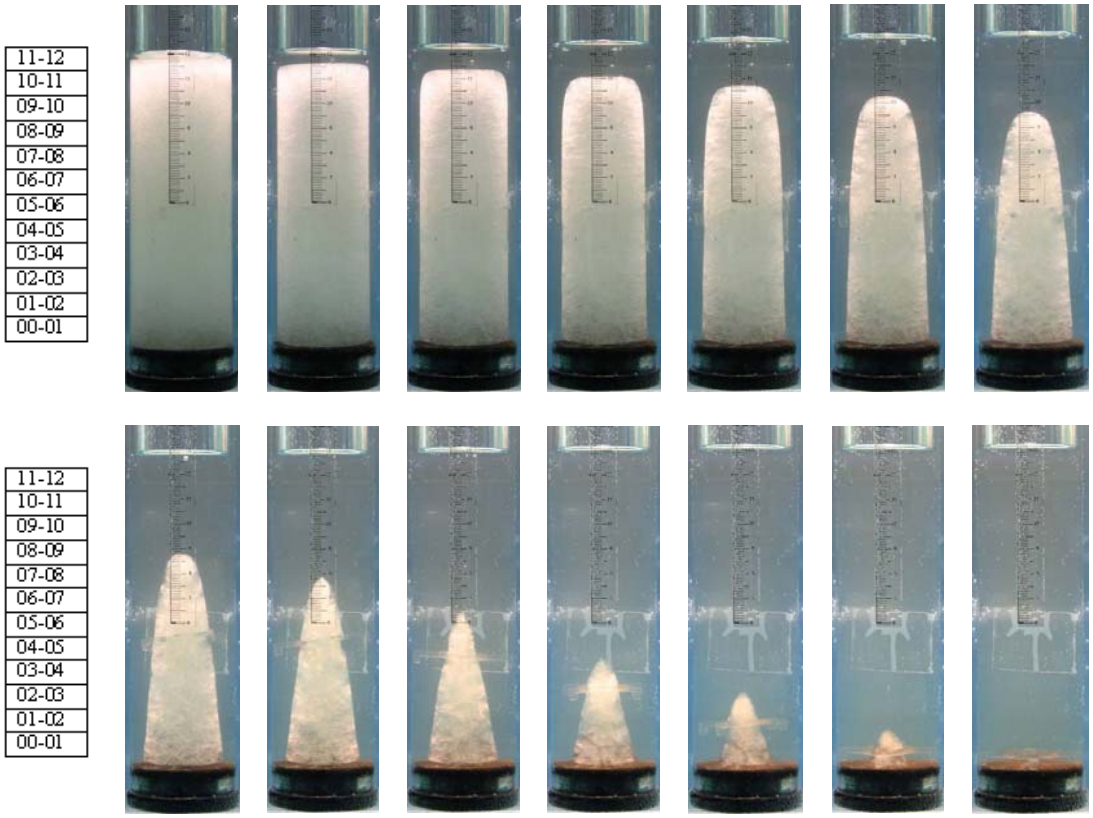

Figure 1. The entire melting process recorded D=4cm, H=12cm, and ΔT=10.

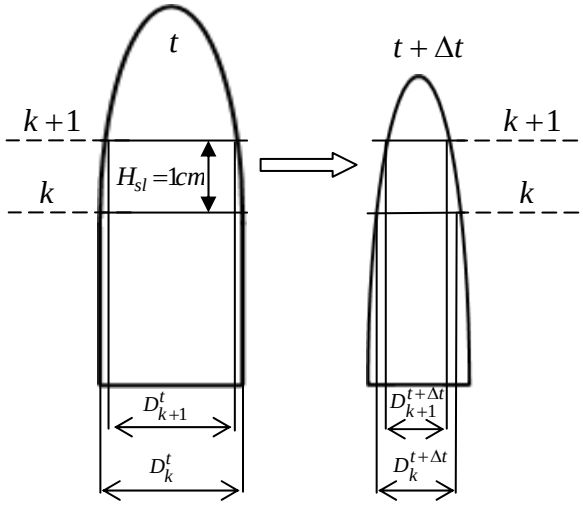

Figure 2. Schematics of slice definition and evolution.

Further, it is assumed that the volume of each slice can be calculated as that of a cylinder which diameter equals D_m, i.e.

$$V_{slice}(t) = \frac{\pi D_m^2(t)}{4} H_{sl} \tag{2}$$

Figure 3 shows the time-dependent volume for each slice of Figure 1 by a separate curve. One can see that at the initial stage of melting the volume of the solid PCM is rather uniform along the whole height of the solid phase, indicating that the dominant heat transfer mechanism during that time is conduction. At some point, the volume starts to deviate from the combined curve, reflecting the development of convective flow at various heights.

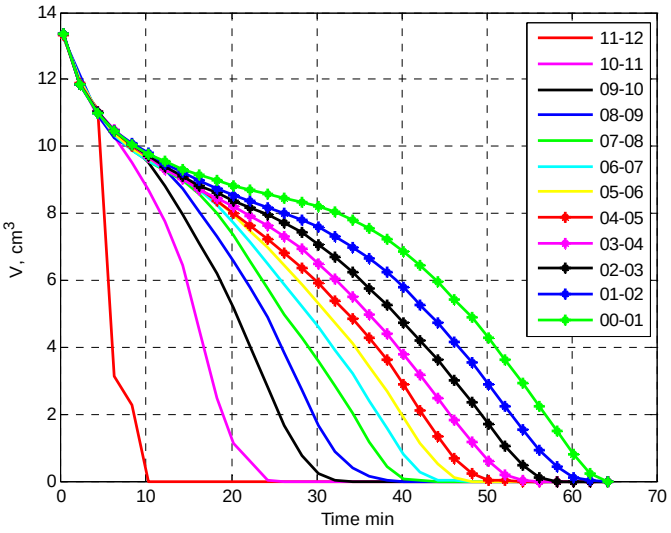

Figure 3. Volume of various solid slices as a function of time.

Having the solid volume, the melt fraction of each slice can be computed as follows:

$$mf_{slice}(t) = 1 - \frac{V_{slice}(t)}{V_{slice}(t=0)} \tag{3}$$

The melt fraction reflects the relative share of material mass which has already become liquid for the time t elapsed since the process has started. This share must be proportional to the heat stored in the PCM due to the phase change. Therefore, the heat stored in the PCM expresses itself in the change of the volume with time. Thus, the heat transfer rate is proportional to the time derivative of the volume:

$$q_{slice}(t) = -\rho L \cdot \frac{dV_{slice}}{dt} \tag{4}$$

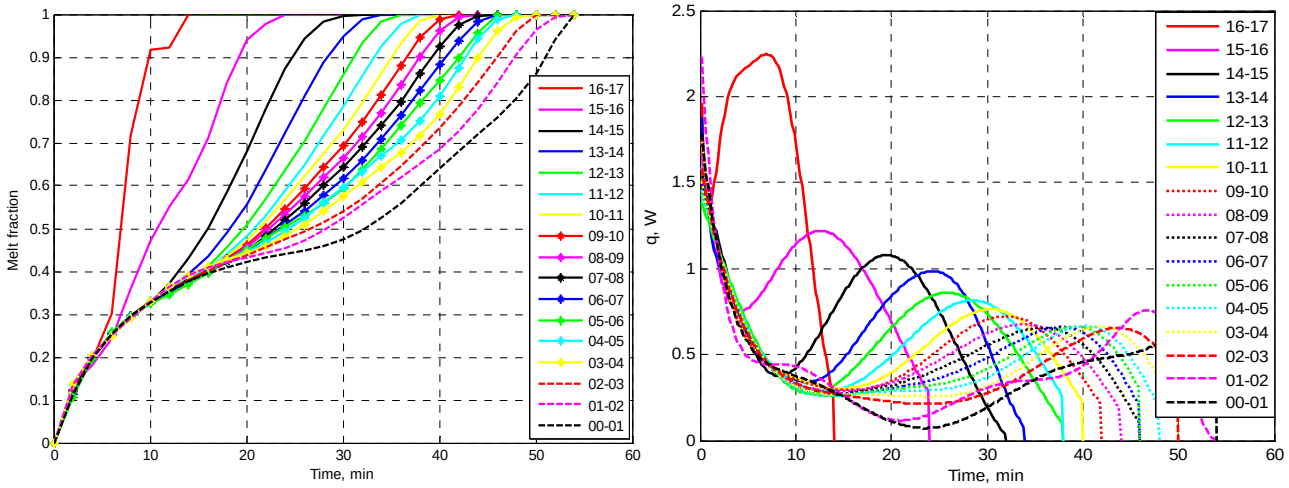
where L is the specific latent heat of the PCM. We note that integration of the above expression over a period of time gives the amount of heat stored in the PCM during that period.

RESULTS AND DISCUSSION

In the present paper, six different cases of melting in a cylindrical tube are examined. The cases vary with PCM height, namely 17, 12 and 6cm, in tube with inner diameter, 3 and 4cm and with the temperature differences of 10 and 30 degrees. Figure 4 shows the calculated melt fraction (a) and heat transfer rate (b) for melting with the inner tube diameter of D=3cm, initial PCM height of H=17cm and temperature differences of ΔT=10 degrees between the outside wall and the PCM melting temperature. For each slice, the melt fraction and heat transfer rate are shown by a separate

curve, as a function of time. One can see that at the initial stage of melting the heat transfer rate to the solid PCM is rather uniform along the whole height of the solid phase, causing the initial uniform melting, see Figure 1. Moreover, the lines reflecting the rates in different slices practically coincide during the initial stage. This combined curve shows a monotonic decrease in the heat transfer rate, which corresponds to conduction from the wall to the solid through a liquid layer. The layer width increases with time, thus leading to a gradual increase in the thermal resistance to conduction.

As the process advances, very high heat transfer rates are encountered in the upper slices. This result indicates that heat to the upper part of the solid is already brought by convection in the liquid phase, while conduction dominates the heat transfer to the solid outside the upper region. Gradually, the heat transfer rates for other slices, from the upper to the lower, starts to deviate from the combined curve, reflecting the development of convective flow at various heights. An increase in the convective heat transfer to a certain slice is accompanied, however, by a reduction of the remaining solid volume in that slice. As a result, the heat transfer rate to a slice starts to decrease sharply at some instant, and reaches effectively zero when the melting process in the slice is complete.



a. melt fraction b. local heat transfer rate

Figure 4. H=17 cm, D=3 cm, ΔT=10 ºC

Similar patterns are shown in Figure 5 for the same tube diameter and PCM height, but with the higher temperature difference of ΔT=30 degrees. Obviously, the complete melting time is now much shorter, namely 19 minutes instead of 54 minutes. Due to the higher temperature difference between the wall and the PCM, the local heat transfer rates reach higher values. However, their behaviour is similar for both cases.

Figure 6 shows the melt fractions and heat transfer rates for a case with a larger tube diameter, but smaller initial PCM height, namely H=12cm, D=4cm, for ΔT=10ºC. Again, the behaviour of the melt fraction and the local heat transfer rates follows the patterns described above. One can also see that while the temperature difference is identical to that of the case of Figure 4, the slice heat transfer rates here are higher. This result can be attributed to a stronger convective flow.

In Figure 7, the results are shown for the same tube diameter and initial PCM height, but with the higher temperature difference of ΔT=30 degrees. As expected, the melting time is much shorter than for the case of Figure 6. One can also note that, similarly to the difference between the results of

Figure 6 and 4, the local heat transfer rates here are typically higher than those in Figure 5 for the same temperature difference.

Figure 8 shows the melt fractions and heat transfer rates for a case with a larger tube diameter, but smaller initial PCM height, namely H=6cm, D=4cm, for ΔT=10ºC. In Figure 9, the results are shown for the same tube diameter and initial PCM height, but with the higher temperature difference of ΔT=30 degrees. The results here are generally similar to those discussed for other initial PCM heights. However, comparing Figures 4a-9a, one can see that the smaller the PCM height, the earlier the divergence of melt fraction curves for different slices appears. This result indicates on the increasing role of convection at the early stages of melting for smaller initial PCM heights.

Figure 10 shows the vector flow fields in the upper part of the tube for relatively early and advanced stages of melting, obtained numerically as discussed by Shmueli et al. [6]. One can see that at the initial stages, the solid shape is almost cylindrical, whereas later on the shape becomes more conical due to convection in the liquid phase. This result supports the analysis presented above.

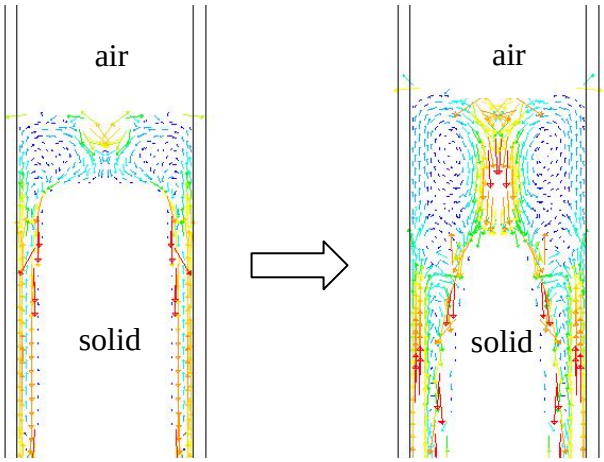

Figure 10. Examples of simulated flow fields.

CONCLUSIONS

Melting of a phase change material (PCM) in vertical circular tubes has been analyzed. The experimental images taken throughout the melting process have been used to determine the volume of the solid phase at various instants. The dependence of the local volume on time has been used to calculate the local melt fraction and heat transfer rate as a function of time. The results make it possible to observe the different heat transfer mechanisms that affect the melting process: at the initial stage of melting the heat transfer rate to the solid PCM is rather uniform, corresponding to conduction from the wall to the solid through a liquid layer. At the more advanced stages, heat to the upper part of the solid is brought by convection in the liquid phase, causing reduction and eventually disappearance of the remaining solid from the top to the bottom of the tube.

ABSTRACT. Phase change materials (PCM) have high latent heat of fusion with controllable temperature stability and have been used in thermal management for high power electronic device working in intermittent condition. Due to low thermal resistance of PCM, high porosity open-cell metal foams can be embedded in the PCM to improve the thermal conductivity to enhance solid-liquid phase change heat transfer. In this work, a hybrid heat sink whose substrate is hollow is proposed and cooper metal foams filled with paraffin wax are sintered inside the hollow space. The heat sink is heated by film heater attached to the heat sink to simulate the electric chip. The heater surface temperature variations are tested. The influence of metal foam porosity, pore diameter and PCM thermal property on total thermal resistance is studied. The finding is expected to provide guideline for thermal design of high power electronics working on transient condition.

Key words: *Phase change materials, metal foams, melting, solidification, thermal resistance*

INTRODUCTION

Thermal management of electronic device has encounter a great challenge due to the increasing power and decreasing size. Therefore, the traditional positive cooling systems sometimes can't accomplish the cooling task very well considering their economic cost, complex degree, operating conditions and so on [1]. Among the various methods of the thermal control technologies, the passive cooling method using phase change materials (PCM) is receiving considerable attention in recent years.

When PCM is used in the cooling system of electronic device, the latent heat of solid-liquid phase change absorbs heat released from the working electronic chip, keeping chip temperature at allowable range. When electronic device stops working, PCM just melt totally, then the molten PCM solidfies for reuse during the idle time. Therefore, passive thermal management using PCM is suitable for applications working on intermittent or transient conditions [2].

According to Shatikian et al. [3], PCM can be divided into three kinds：organic , inorganic like metals, alloys，and hydrated salts. Paraffin wax which belong to the organic group is the most promising PCM for electronic device cooling system due to its obvious advantages：high latent heat, easy availability, temperature and chemical stability, non-toxicity and so on. PCM cooling systems have proven to be effective in small volume applications with little paraffin wax [2,4]. However, the low conductivity (0.21-0.24W/mK) has become its fatal defect when it's used in larger volume. When the

PCM-based cooling system is used for high power applications, heat dissipated from heat source can not enter into the whole mass effectively, then the melting zone just appears near the heat source, whereas for higher conductivity, heat can be distributed throughout the whole block more effectively [5]. Therefore, heat transfer enhancement techniques is necessary in PCM-based cooling systems for high power electronic applications.

In order to overcome this problems, various methods to improve conductivity of paraffin have been proposed in decades, such as internal fins embedded in paraffin [3,6,7,8,9], inserting metal and graphite-compound matrices in paraffin [1], dispersing high-conductivity particles in the paraffin [10,11,5]. Akhilesh et al. [6] and Wang et al. [7] conducted numerical simulations about PCM-based heat sink with internal fins embedded in the paraffin for cooling portable electronic device, exploring the proper parameters such as sizes, PCM volume fraction, aspect ratio, PCM properties and so on to improve performance of the cooling system. Employing aluminium foams impregnated with PCM as heat sinks for cooling electronics applications, Lafdi et al. [12] implemented experiment to investigate how parameters such as foam properties, heat sink shape, heat sink orientation influencing cooling performance. The numerical simulation [1] they carried out later showed a good agreement of experimental results. Kim and Drzal [10] and Weinstein et al. [5] incorporated graphite nanofibers into paraffin and have a remarkable effects on enhancing paraffin conductivity in the heat storage and electronic device cooling systems.

It can be seen that there are few works exploring PCM melting in cooper porous foams. In the present work, a composite heat sink with paraffin embedded with cooper metal foams encapsulated in its substrate cavity is proposed for electronic device cooling system. The objective of the experiment is to investigate the effects of heat sink parameters such as paraffin property, cooper foam properties(porosity, pore size) on performance of the composite heat sink.

EXPERIMENTAL APPARATUS AND METHOD

Experimental apparatus

The schematic of the aluminium heat sink is shown in Figure 1 and its length is 110 mm, width is 110 mm and the height is 120 mm, and 12 fins is evenly distributed on the top part of heat sink whose height is 30 mm. The substrate of the heat sink is hollow in which the open cell copper metal foam (100×100×80 mm) is fixed compactly inside hollow cavity embedded with paraffin. and then contact thermal resistance between cooper foam and heat sink wall can be alleviated. Four heaters of dimensions 20×20mm are pasted tightly to the bottom of the heat sink to simulate electronic chips with highly conductive silicon paste (heat conductivity =2.5W/m^{2}K). A total of six T-type thermocouples are used, five of which are arranged between heater and bottom wall, the left one for measuring environment temperature and an OMEGA HFS-3 type thin film heat flux sensor is attached between heater and bottom wall of heat sink aiming to test the heat power accurately shown in Figure 2. Since the four heater is distributed symmetrically, so one film heat flux sensor can meet the test requirement. A 2700-multimeter/data acquisition system is used for temperature and heat flux tracking. The data is acquainted every five minutes. The melted liquid paraffin is injected into the open cell cooper metal foam and solidified in advanced before the experiment. With above methods, the heat conductivity of paraffin can be improved to great extend and the heat generated from chips passes through the wall into the cavity and then absorbed by the paraffin. The melting process for PCM will occur conjugated with metal foam matrix heat conduction and melted paraffin natural convection.

Data reduction

There are two kinds of paraffin used in this experiment and the thermal properties of the applied paraffin including latent heat of fusion and melting point are tested with DSC of TA-Q200 with liquid nitrogen cooling system. The DSC results are shown in Figure 3 and 4 for two kinds of paraffin respectively. It can be found that for two tested paraffin, the melting points are 52℃-54℃and 60℃-62℃; the latent heat are 129kJ/kg and 113kJ/kg respectively. The geometric structure parameters of cooper foams used in the experiment are shown in Table 1.

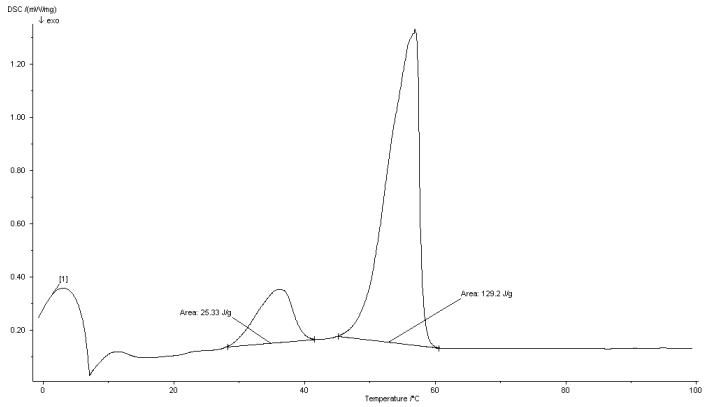

Figure3 DSC results of paraffin type 1

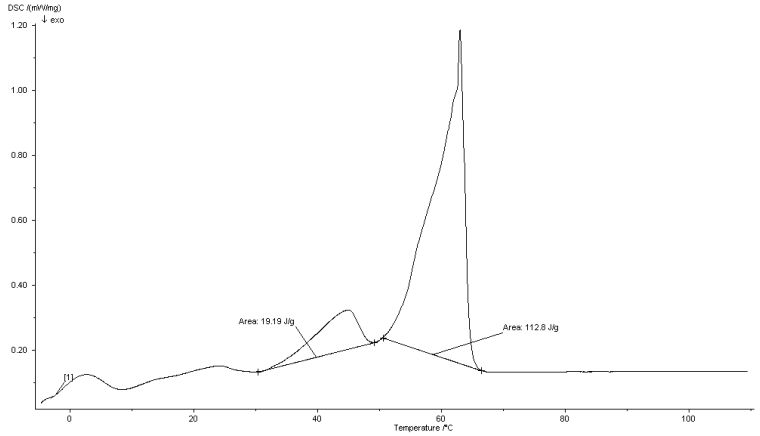

Figure4 DSC results of paraffin type 2

Table 1
Properties of Cooper Foams

Samples No.	Porosity ε	Pores per inch PPI	Size (length*width*height) (mm)
1	0.90	10	100*100*80
2	0.90	20	100*100*80
3	0.90	40	100*100*80
4	0.95	10	100*100*80
5	0.95	20	100*100*80
6	0.95	40	100*100*80

In order to remove the influence of variations of environment temperature and input power, junction temperature variation was tracked and transferred into thermal resistance which is defined as the temperature rise per unit input power. The relation of the two is as shown in equation (1).

$$R = \frac{T_j - T_a}{q * A} \quad (1)$$

Where R represents total thermal resistance of the heat sink (K/W); T_j represents junction temperature (℃); T_a represents the ambient temperature (℃); q represents heat flux of heater $\left(\mathrm{W/m^2}\right)$ which is $1.75\times10^4\mathrm{W/m^2}$; A represents area of heater (m^2). In order to compare the performance with metal foam embedded in PCM, the thermal resistance of heat sink with only metal foam is also studied as comparison reference.

RESULTS AND DISCUSSION

The experimental results are extracted in terms of above total thermal resistance-time. Here only the results of point 1 is only presented since the four heaters are completely identical and is located symetrically. The four key factors including paraffin kind, paraffin property, porosity and PPI on heat

sink thermal resistance are presented respectively. In the following presentation, when one factor is discussed, the other two are kept constant.

The effects of paraffin property

Fig.5 shows thermal resistance as a function of time for two kinds of paraffin wax saturated in the metal foam, with the same porosity of 0.9 and PPI (pore number per inch) of 40. The studied two kinds of paraffin with two different melting points, 52 to 54 and 60 to 62 are respectively and another pure metal foam are introduced to the experiment for comparison. It can be seen that thermal resistance for the pure metal is quite a little higher compared with those with filled with paraffin at the beginning and reaches to the steady state with least time. This phenomenon is mainly attributed to that the temperature has not exceed to the paraffin melting point, the heat condition mechanism dominates and the air heat conductivity is lower to one order than the PCM to create relative larger air thermal resistance in the foam pores which has a dramatically negative effect on heat transfer through the medium, in contrast, the other two porous media saturated with solid paraffin present a relatively less increasing trend in temperature before onset of melting since the equivalent heat conductivity of paraffin is enhanced to some extent by the metal solid matrix.

When the time continues, It is revealed that the paraffin begins to melt to absorb the heat to store as its latent heat in the melting process to lead that the thermal resistance is almost kept constanct and much lower than those with only metal foams. It is to noted that the average thermal resistance for the paraffin with fusion point between 52 and 54 is smaller than that between 60 and 62 due to lower melting temperature and the former medium starts melting earlier than the latter, However, the time duration of the melting process for the latter medium is longer than the former, 80min versus 70min respectively shown as melting zone 1 and melting zone 2 in Figure 5. The most significant discrepancy on thermal resistance (about 1℃/W) appears at the time of the 80thmin. After the melting process , the temperatures for both foams with wax go up sharply until the whole heat transfer process reaches to a steady state and the corresponding thermal resistance at phase change process is narrowed in a very small range.

From the above analysis, if the chip of electronic device works on transient condition, we can choose PCM with proper melting point, latent heat mass quantity based on the chip working interval to make the working time transient interval of chip is less than the melting duration time, the chip can be cooled effectively.

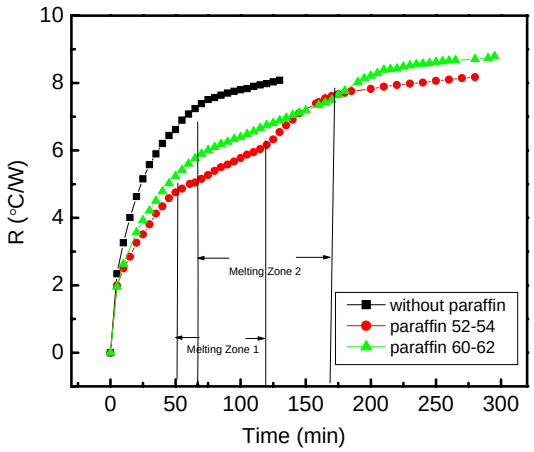

Figure 5 Thermal resistance variation with time for PCM with different melting point

The effects of pore density

The performance of heat sink under three PPI(10, 20 ,40) are studied and the comparison results are displayed in Figure 6. In the present part of study, the paraffin is employed as the type 1 with melting point between 52 to 54 degree and the foam porosity ε is fixed as 0.95. but different PPI(s) (PPI=10, 20, 40) have been chosen for the experiment. It is found that the thermal resistance has dramatically increased and the final steady-state temperature is reached quickly for foams without PCM.For the foams with PCM and the whole thermal resistance is much reduced during the melting process compared with the pure metal foam. It is also found that PPI has relatively mild impact on the performance in heat transfer during phase change process since the thermal resistance is mainly influenced by PCM mass quantity in the foam and in this case the porosity is fixed. It is noted that metal foam with higher PPI can provide more heat transfer surface areas when the porosity is fixed. Hence the thermal resistance of 40 PPI is the lowest while the value for 10 PPI is the highest in the melting duration. In the final steady state, although the foam of 40 PPI has the largest surface area, but it can create more flow resistance to make the heat conduction dominates the heat transfer process and the natural convection is very weak to lead that the thermal resistance is the highest. On the other hand, the foam with 20 PPI has relative larger heat transfer area than the foam with 10 PPI and has relative flow resistance to make natural convection is significant to lead to the smallest thermal resistance of the three PPI.

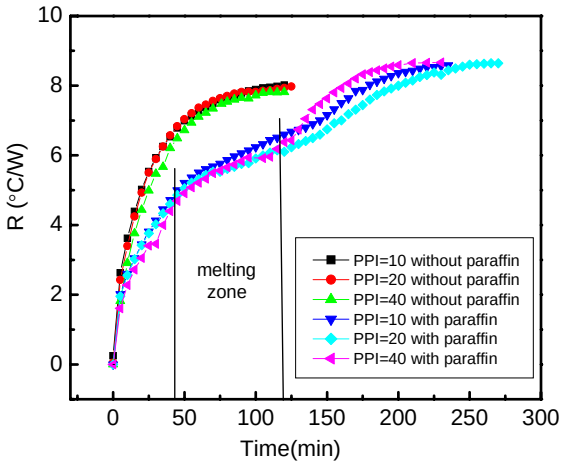

Figure 6 Thermal resistance variation with time for PCM with different PPI

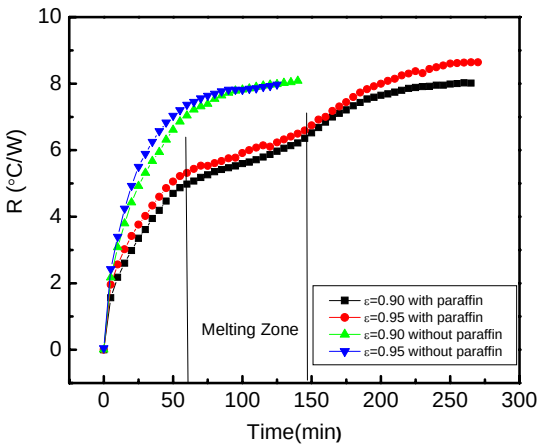

Figure 7 Thermal resistance varation with time for PCM with different porosity

The effects of porosity

The thermal resistance for two studied porosity ε=0.90 and ε=0.95 under the conduit on that the PPI equals 20 with melting point between 52 to 54 degree ia studied. The comparison results are shown in Figure 7. It is found that the thermal resistance is much lower than those with pure metal foam For the two metal foams with different porosity, the porosity plays important role to the thermal resistance and the higher the porosity is, the more thermal resistance it can be achieved in this experimental range. This is attributed that when the PPI is fixed, higher porosity means the metal matrix diameter is smaller that means the function of the metal matrix is more weak. However, the porosity can not be too small to achieve low thermal resistance, otherwise the PCM mass quantity will be reduced greatly and its function will be lost.

CONCLUSIONS

An experimental study on melting heat transfer of phase change materials in open cell cooper foams embedded in heat sink for electronic device has been carried out in this paper. Paraffin wax is introduced as PCM embedded in cooper foam in this experiment. The influencing parameters such as paraffin property, foam porosity and foam pore size are discussed. The major conclusions are as follows:

(1) The proposed campsite heat sink has much lower thermal resit ace for thermal management for higher power electronic devices working on transient condition. The chip surface temperature can be controlled by employing proper PCM thermal property and mass quantity.
(2) During the melting process, the effects of PPI has relative mild effect on thermal resistance and higher PPI can provide positive effect on thermal resistance due to the relative large heat transfer surface when the porosity is fixed.
(3) During the melting process, the effects of porosity has significant effect on thermal resistance and higher lower porosity can provide positive effect on thermal resistance when the porosity is greater than 0.9 due to the relative low heat conductivity resistance when the pore density is fixed. However , it can be predicted that the porosity can not be two small, otherwise, the mass quantity of PCM will reduced significantly.

WATER MIST HEAT TRANSFER FROM GLASS SURFACE

R. Karvinen*, O. Ovaskainen, A. Aronen
Tampere University of Technology, Tampere, Finland

ABSTRACT. The aim of the research is to study the possibility of increasing convection heat transfer from a glass surface using an air–water droplet mist instead of air jets when the glass surface temperature is over 500 ºC. This type of problem is met in tempering thin glasses where very high convection is needed in the cooling phase in order to create a compression stress in the surface and a tensile one in the centre. By using the mist cooling, energy consumption could be reduced and the optical quality of the glass improved.

The idea of using a mist is to utilize phase change when droplets hit the surface. However, it can happen that a vapour layer is formed between the surface and the droplet, and the convection heat transfer is very low. The surface temperature below which phase change occurs is determined by the Leidenfrost temperature, which must be obtained experimentally. The main parameters affecting the Leidenfrost temperature are the thermal properties of the liquid and the surface material to be cooled.

In experiments a hot glass plate with a known thickness was cooled from the upper surface by a mist jet and the lower surface temperature was measured. From the measured temperature the start of the phase change can be obtained, but determining the upper surface temperature requires the solution of an inverse heat conduction problem. In order to test the reliability of an experimental approach also the Leidenfrost temperatures of some metallic materials were measured and the results were compared with those in the literature. For glass the existing data is very sparse. In addition to water, also a mixture of water and ethanol was used. It was noted that the Leidenfrost temperature for glass is slightly more than 500 ºC.

Keywords: *water mist, Leidenfrost temperature, heat transfer, glass tempering*

INTRODUCTION

In glass tempering we want a compression stress in the surface of a glass plate and tension in the middle. This is achieved if cooling is efficient enough. The demand for thin low-cost tempered glass has raised the question of using a water mist in a glass tempering process. Traditionally, glass tempering is done by high- velocity impinging air jets, which can cause undesirable effects on glass flatness. Also air compressing requires lots of energy. By using a water mist, we could lower the energy consumption of the process and make it more cost-efficient. Water mist has been used extensively in the metallurgical industry for cooling and there is a great amount of knowledge concerning heat transfer between metal surfaces and a water mist [4-11]. Different kinds of heat transfer correlations exist, but they are insufficient to predict heat transfer from glass plates.

Water boiling on a hot surface can be divided into three regimes: film boiling, transition boiling and boiling regime. In our study, interest focuses on water mist changing from the film boiling regime to transition boiling, and what the critical heat flux (CHF) is, i.e. the highest value of the cooling

heat flux. For a film boiling region Sözbir et al. have suggested that the mist heat transfer and air convection can be treated separately and they presented a correlation for the mist heat transfer from a stainless steel plate [7]. Glass has not been studied properly yet. One correlation in a film boiling region has been presented for glass, but the authors presenting it suspect its reliability [5].

There are only a few articles dealing with glass tempering using a water mist [5, 6]. According to these articles, tempered glass has been made successfully in laboratory conditions with very short spraying times. In order to obtain the required stress field in glass, cooling should occur between 500–700 ºC. In our research, the main interest has been in determining the Leidenfrost (LF) temperature for a water mist with different mist properties and materials, especially glass. Above the LF temperature a thin vapour layer forms between water drops, i.e. we have a film boiling regime, which prevents efficient heat transfer. Below the LF temperature the vapour layer disappears and water is in contact with the surface and wets it. The transition boiling starts and the critical heat transfer occurs. If the glass temperature is low at this point, brittle glass usually breaks. For pyrex glass the LF temperature for saturated water drops has been about 500 ºC, and for drops at 26 ºC over 700 ºC [1,2]. Baumeister et al. and Bernardin et al. have investigated the LF phenomenon and reported factors affecting the LF temperature [1-3]. In the studies above, drops have been carefully located on the surface which is totally different as is the mist cooling. Different materials and liquids were used to determine the LF temperature.

In the case of metal plates the LF phenomenon and heat transfer depend on many characteristics of the mist and the drops in it. Maybe the most important property is the mist mass flux (kg/m^2s), which separates dilute and dense mists. According to Deb and Yao, the drops of a dilute mist do not interact with each other and can be viewed separately [10]. Thus, heat transfer can be modelled as one drop impinging on the surface. Drops of a dense mist start to influence each other by disturbing their hydrodynamic and thermal zones on a solid surface. For both cases Deb and Yao have developed correlations for heat transfer and they have found regimes of mass flux where a dilute mist changes to a dense one. Deb and Yao arrived at a value of about 2 kg/m^2s for the separation point for stainless steel plate. For glass the effect of mist properties has not been investigated.

Hoogendoorn and Den Hond suggested that the LF temperature for stainless steel increases with an increase in the water flux in a mist and in the drop velocity [4]. Also Sözbir and Yao confirmed the same phenomenon and reported that by increasing air velocity in a water mist also the LF point becomes higher [7]. In our study the aim was to investigate the same phenomenon for ROBAX® glass and aluminium plate. Also the effect of different fluid properties on the LF temperature was investigated.

EXPERIMENTAL SETUP

An experimental study was carried out with the setup shown in Figures 1 and 2, in which a full-cone atomizing nozzle was controlled by compressed air (AB Sibe). Also another atomizing nozzle (paint sprayer) with almost the same characteristics as AB Sibe was used for ethanol. Steel, copper, aluminium, brass and ROBAX® glass were used as materials in the experiments. The dimensions of plates were 50 x 50 mm. The thickness of ROBAX® glass plate was 4 mm and that of other materials equal to10 mm. Plates were located inside an insulation during heating. When the plate temperature was over the LF point, for metals 350–400 ºC and for glass 750–850 ºC, the plates were taken out of the oven and positioned under the mist. A shutter was displaced from the upper surface of the tested surface and quenching started. Cooling continued until strong evaporation had ceased. The metal plates were cleaned and polished after cooling. The liquids used in experiments were water, a mixture of ethanol and water and pure ethanol. Measurements were done mainly with plates in a horizontal positions, except in the case of ethanol, when plates were in a vertical position.

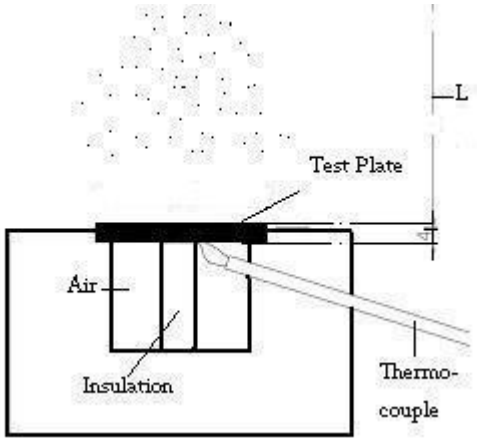

Figure 2. Schematic of experimental setup.

In the case of metal plates, temperature was measured in the middle and at the bottom. The temperature of ROBAX® glass was measured only from the bottom surface. K-type thermocouples were used and temperature was recorded at 0.1 s intervals. The distance between an impinging point and the nozzle could be adjusted and the water flux of the mist was adjusted with an air pressure valve. Distances used were from 150 mm to 300 mm and air pressure was 1.3- 6.0 • 10^5 Pa. Water temperature in the mist was 17 ºC.

Droplet sizes of water mists were measured with a laser Doppler anemometer. The results of different mists are shown in Table 1. Measurements of mist properties were done at the distances of 200 mm and 150 mm from the nozzle and atomizing air pressures were 1.3 - 2.2 • 10^5 Pa. 20000 drop samples were taken from the mist in every measurement.

Mostly aluminium and ROBAX® glass plates were tested. Aluminium was used because it is easy to handle and there are data from previous studies that can be compared with our results [3, 9]. The main interest was in glass. ROBAX® glass was chosen in experiments for its thermal endurance and its small thermal expansion (α (20–700 ºC) = 0.0±0.3•10^{-6} K^{-1}) which allow it to withstand severe stresses during quenching. Its properties are close to those of soda glass, which is usually the material in a tempering process. The properties of ROBAX® glass are: thermal conductivity k (90 ºC) = 1.6 W/mK, density ρ = 2.56 g/cm^3 and mean specific heat capacity c_p (20–100 °C) = 0.8 J/kgK.

EXPERIMENTAL UNCERTAINTY

Temperature measurements of metal plates are exact because the thermocouple was located in a hole inside the plate. In the case of a glass plate, the thermocouple head is in contact with the bottom of the plate and a piece of insulation presses the thermocouple against the plate. Because the thermal conductivity of glass was about 1.6 W/mK and that of insulation material 0.1 W/mK, heat transfer from insulation to the thermocouple can have an effect which cannot be taken into account in data treatment. High temperatures of glass can also contaminate the thermocouple and cause an

error. It is difficult to predict the error because there is no data on the temperature distribution in insulation. As to the properties of the mist the smallest drops could be ignored by the instrument.

MEASURED RESULTS

In Figure 3 a clear drop in the time-temperature curve for aluminium can be seen. Also the difference in the LF point with different mist properties is shown. In Figure 3, L is the distance between the nozzle and surface and p is the air pressure in the nozzle. However, the difference in the LF temperature is quite small for different mists. This is due to the fact that mass fluxes of mists were almost the same and they were probably in a dilute spray region for aluminium. The transition of the LF point is very clearly seen in Figure 4, when different fluids, i.e. water, ethanol and their mixture, are used. The effectiveness of cooling can be seen on the basis of the cooling curve and cooling time. The fluid properties change the LF point significantly. A change of almost 50 ºC is noted when use is made of a 50 % mixture compared with pure water. In reference [3] the LF temperature of the water drop for wiped aluminium is 171 ºC, which is lower than the mist results shown in Figures 3 and 4. The roughness of aluminium, which can have an effect, is unknown in our study. For ethanol the LF temperature in reference [3] is 157 ºC, which is very close to the result shown in Figure 4.

Time-temperature curves for glass are shown in Figures 5 and 6. In the figures for instance the parameter (250, 1.7) means that the distance from the nozzle to the surface is 250 mm and the air pressure in the nozzle is $1.7 \bullet 10^5$ Pa. The change in fluid and mist properties affects the LF point, but the change is not as great as with metals. The start in the boiling regime was difficult to see visually or hear in the case of glass. The greatest clear change can be seen at about 800 ºC in Figure 6 and the lowest is slightly over 500 ºC in Figure 5. Differences in LF temperatures for different mists are higher for glass than for aluminium. This can be seen by comparing the results for glass in Figures 5 and 6 with those for aluminium in Figures 3 and 4.

The measured LF point of 50 % ethanol mist is about 550 ºC. In our measurements with glass it was not possible to see any change in the cooling curve for 100 % ethanol. The amount of water in the mixture seems to control the LF temperature

The top surface temperature cannot be directly obtained from measured ones at the bottom surface.

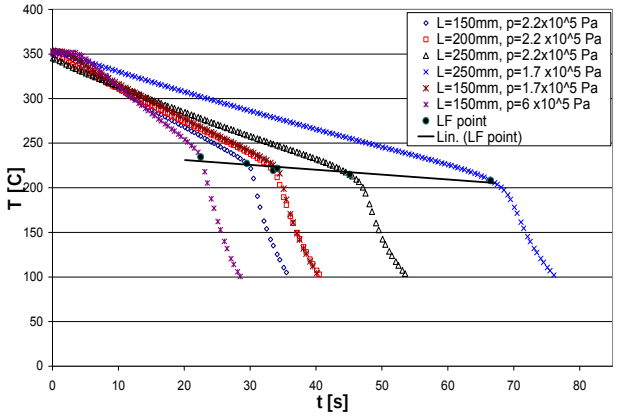

Figure 3. Effect of water mist on LF temperature for aluminium plate.

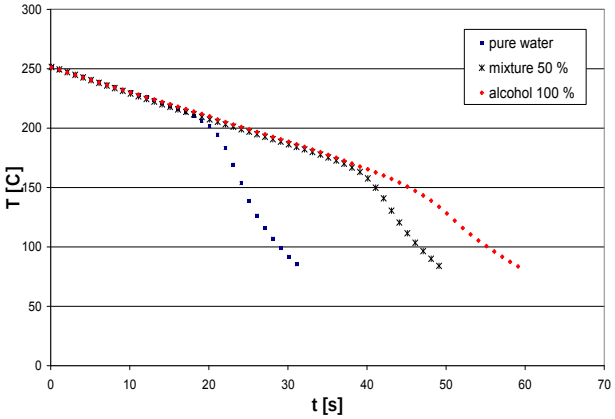

Figure 4. Effect of liquid mixture on LF temperature for aluminium. L = 200 mm, horizontal mist.

It is very difficult to get measurement data from the glass surface when it has been cooled by the mist. In that case it must be calculated from the measured temperature of the lower surface temperature

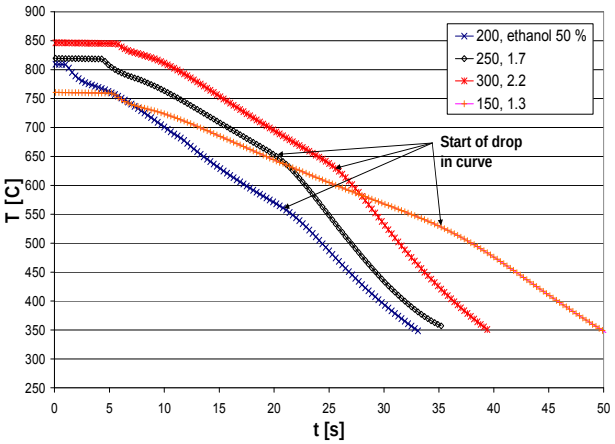

Figure 5. Time-temperature data for glass with 50 % ethanol mist and dilute water mists.

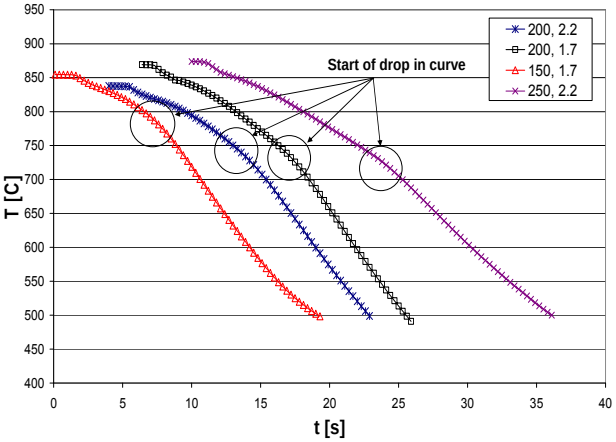

Figure 6. Time-temperature data for glass with dense mists.

SOLUTION OF INVERSE HEAT CONDUCTION PROBLEM

In order to obtain the surface temperature of the plate, an inverse heat conduction problem must be solved. The calculation is based on the basic equation of heat conduction. Mathematically, the inverse heat conduction problem belongs to so-called ill-posed problems, i.e. small changes in measured data can lead to large errors in calculated values. Soti et al. explain that the physical reason of ill-posed problem in heat transfer is that the variations of surface conditions are damped in moving towards the interior of a solid body [12]. Here, all material properties are assumed to be constant in the solution of the inverse problem, governed by the heat conduction equation(1) with the initial and boundary conditions (2) - (4):

$$\frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\alpha\frac{\partial T}{\partial x} \tag{1}$$

$$T(0,x) = T_o \tag{2}$$

$$-k\frac{\partial T(t,l)}{\partial x} = q_s \tag{3}$$

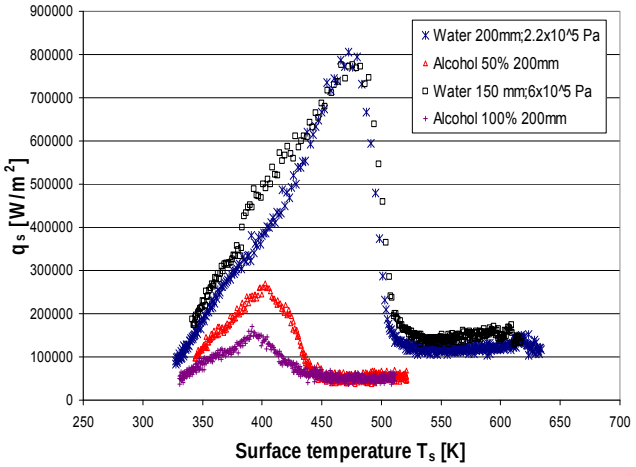

Figure 7. Calculated cooling heat flux at upper surface of aluminium.

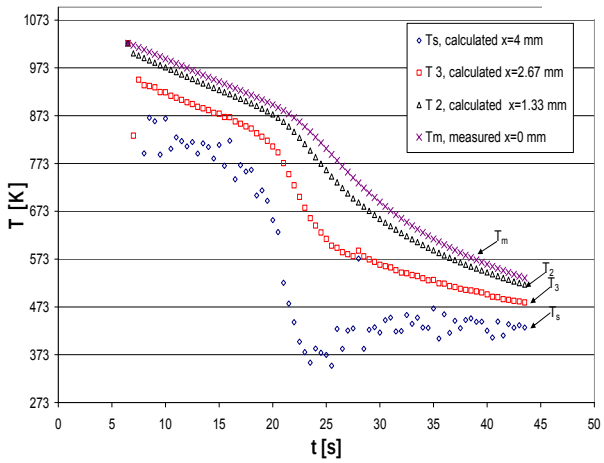

Figure 8. Calculated temperature field in 4 mm glass. Water mist #2 in Table 1.

$$T(t,0) = T_m\,,\quad k\frac{\partial T(t,0)}{\partial x} = 0 \tag{4}$$

Heat flux at the upper surface has to be solved when the temperature of the lower surface is known. In the equations above and below, α is the thermal diffusivity, τ is the conductive time constant of a solid, k is the heat conductivity, ρ is the density, l is the plate thickness and c_p the specific heat. T_0 is the initial plate temperature, T_m is the measured lower surface temperature, T_s is the surface temperature to be solved together with heat q_s flux from the upper surface.

A one- dimensional implicit difference method was used for equation (1). The method guesses the boundary values and starts to iterate until the result converges to the measured temperature. No optimization algorithm for solving temperatures and heat transfer was adopted.

Calculations for aluminium were reliable, because aluminium is almost isothermal and there is just a small difference between the measured temperature in the middle of the plate and the surface temperature. Results are shown in Figure 7. On the other hand, calculations for a glass plate, as can be seen in Figures 8 and 10, are not exact due to the low conductivity of glass, which causes oscillations in the surface temperature. To make calculations more reliable for glas, a more sophisticated solution method for an inverse problem is required [9,12].

An analytical method for solving the inverse problem is presented for the symmetrical configuration in [9] and is what we have used in our experiments. The solution of heat conduction equation (1) for the surface temperature and heat flux gives:

$$T_s = T_m(t) + \frac{1}{2}\tau\frac{dT_m}{dt} + \frac{1}{24}\tau^2\frac{d^2T_m}{dt^2} + \ldots \tag{5}$$

$$q_s = -\frac{k}{l}\left[\tau\frac{dT_m}{dt} + \frac{1}{6}\tau^2\frac{d^2T_m}{dt^2} + \ldots\right] \tag{6}$$

$$\tau = \frac{l^2}{\alpha},\quad \alpha = \frac{k}{\rho c_p}$$

The results of this method are shown in Figures 9 and 10. From Figure 10 it can be seen that the finite difference method gives almost the same result as equations (5) and(6). However, the result is oscillating due to uncertainties in measured data.

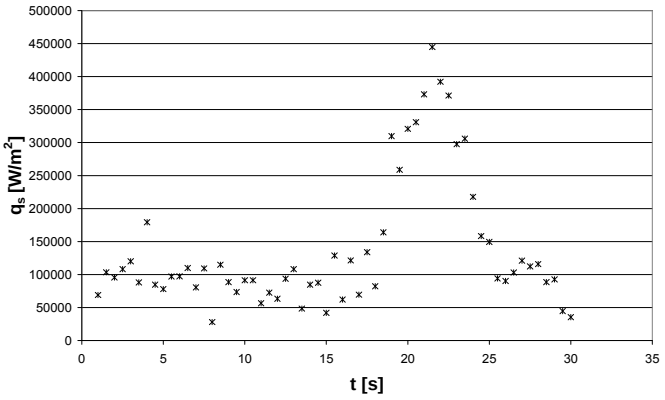

Figure 9. Calculated heat flux in surface using Eq. (6) for glass. L = 300 mm, p = 2.2 • 10^5 Pa.

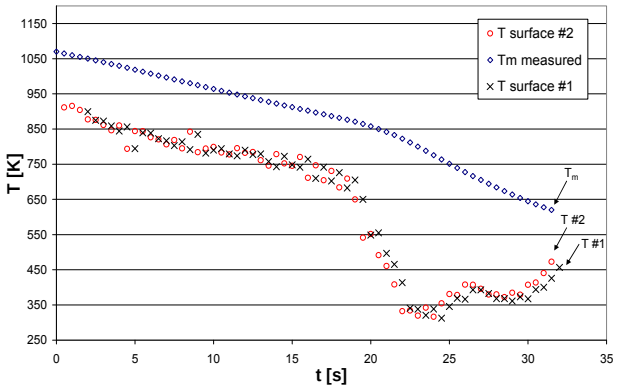

Figure 10. Measured data and calculated surface temperature in glass. #1 calculated with Eq. (5). #2 calculated with finite difference method. L =300 mm, p = 2.2 • 10^5 Pa.

CONCLUSIONS

The main aim of the study was to measure heat transfer of a water-air mist impinging on a hot surface of glass. The research was conducted by measuring the lower surface temperature of a plate when it was cooled by the mist from the upper surface. A practical application in which this type of heat transfer is of interest, is the tempering process for thin glasses. Metal surfaces and mixtures of water and ethanol as a fluid were also used in order to compare the reliability of our test facility, because results for these can be found in the literature.

The results for an aluminium plate showed that the difference between the Leidenfrost temperature (LF), i.e. the temperature below which heat transfer is essentially increased, for water mists with different properties is small, but a 50 % ethanol mixture decreases it by almost 90 ºC. The LF temperature was not measured directly, but was based on the solution of an inverse heat conduction problem. In the case of metal surfaces this type of approach is reliable, but for glass with a low heat conductivity it can give an erroneous result, because small changes in measured data can result in a difference of tens of degrees centigrade of calculated LF temperatures.

According to the measurements, when mist properties were changed, the denser ones gave a higher temperature where the increase in heat transfer occurs. This gives also a clear indication of the transition of the LF temperature. The change in a cooling curve for glass started at about 500 ºC and finished at almost 800 ºC with different mist properties. With the densest mists the change in the curve was not clearly observed. According to our measurements and calculations it seems that the LT temperature for glass, when water mist is used , is slightly higher than 500 ^{o} C.

HEAT TRANSFER CHARACTERISTICS OF A COUPLE OF ARGON JET IMPINGEMENT WITH SMALL JET TO TARGET SPACING

J. Aharon*[1,2], I. Hochbaum[1], M. Corengold[1], A. Marzuk[1], O. Ben Yehuda[1]
[1] N.R.C.N, P.O.Box 9001, Be'er Sheva, 84190, Israel
[2]Ben Gurion University of the Negev, P.O.Box , Be'er Sheva, Israel

ABSTRACT. In the present work a couple of Argon jets were investigated as a heat source for temperature controlled brazing process. Local convective heat transfer coefficients were measured for a couple of Argon jets with a constant jet to jet spacing and jet to target spacing of 0.5 and 1 mm. The configurations were a couple of circular 4 mm diameter jets with a space of 10 mm between their centers. The target was two copper cylinders 6 mm diameter and 13 mm in high which were heated by the hot jets. The gas temperature was about 350 ^{o}C and Reynolds number was in the range of 3500 to 10000. The convective heat transfer coefficient was obtained from the calculation of the transient heating of copper cylinders and the assumption of lumped heat capacity and constant heat transfer coefficient during the process. The heat transfer coefficient values were calculated from the experimental time constant of the heating process.

It was found that the Nusselt number which was measured is much higher than reported value in the literature (about one order of magnitude at the same Reynolds number) due to the small jet to jet spacing (x/d=2.5) and the small target dimensions. A small effect was found of the jet to target spacing for the same Reynolds number. The experimental results were correlated to the next correlation:

$$Nu = 0.72\,\mathrm{Re}^{0.74}\,\mathrm{Pr}^{1/3}$$

INTRODUCTION

Impinging fluid jets are widely used for heating or cooling in engineering systems and processes. Those applications include the turbine blades cooling, cooling of electronic systems, metallurgic treatments of metals and drying systems. The use of jet impingement is due to the high convective heat transfer that can be achieved without increasing of the flow rate or the target surface.

Several investigators have measured the heat transfer characteristics of a single jet or jet array focusing on the heat transfer coefficient that obtained by that mechanism. In most of the works such as Friedman and Mueller [1], Gardon and Cobonpue [2] and Chance [3] the investigators tried to determine the influence of the cooling flow rate, fluid properties and system geometry on the convective heat transfer.

The metallurgic limitation of the gas turbine blade temperature motivate the investigators to focus their works on cooling the turbine blades in order to increase the maximum working temperature of the engine and the thermodynamic efficiency. Many works (experimental and/or numerical) focus on the prediction of jet impingement onto concave surface, a situation typically employed for the

E-mail address: jaharon@bgumail.bgu.ac.il

internal cooling of the leading edge of a blade. Measurements of the relevant flow have been reported by Kounadis [4] and Iacovides et al. [5] using an array of jets impinging onto the curved wall of semi-circular passage. Most of those works use air as the cooling fluid because of its availability in gas turbine. In studies which are investigating the quenching process of metals usually the cooling fluid is water (such as the work of Aharon et al. [6]) oil or any other inert gas in order to avoid oxidation of the quenched surface during the cooling process.

In the electronic industry the brazing process of circuit components is very common and the usual way to apply that process is by using a hot iron which heats the electronic component's terminals to the required temperature to get the melting of the solder. At that process the temperature of the component and the solder is usually uncontrolled which may cause damage to the component. It is also important to control the melting and solidification duration to get the required metallurgical structure of the solder for better brazing results. The use of hot inert gas jet for brazing process may result a more controlled temperature profile of the melting and solidification of the braze and a minimum heating of the electric component.

The purpose of the present study is to measure the local convective heat transfer coefficients for a couple of Argon jets with a constant jet to jet spacing and two values of the jet to target spacing. The measurement conducted during a heating of the target as a simulation of the brazing process

.

THE EXPERIMENTAL SET UP

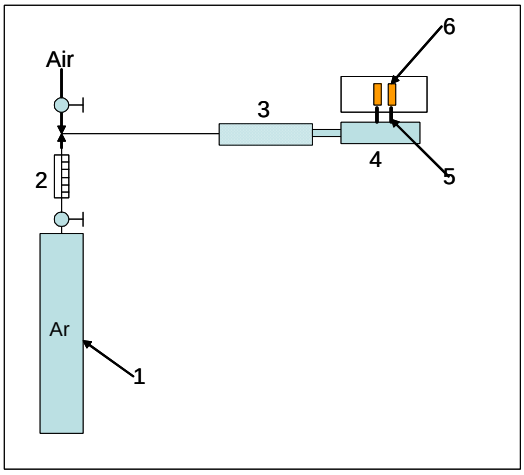
The test system is shown in Figure 1 (a) where detailed Figure of the nozzles and the target is presented in Figure 1 (b). The heating gas supplied from a gas vessel (1) thought a flow meter (2) to the system. At the inlet of the system the gas heated to the required temperature by using an electrical 1.5 kW heater (3). The power to the heater was controlled by AC transformer. The outlet temperature of the gas was measured by a thermocouple which was located at the exit of the heater. The hot gas flow from the heater to the jets plenum (5) and exit through two circular jets nozzles (6) to the target. The nozzles diameter was 4 mm and the space between them was 10 mm. Two other thermocouples measured the gas temperature at the plenum and at the nozzle for accurate evaluation of the exit gas temperature.

The heated target was two cupper cylinders 6 mm diameter and 13 mm in high which were heated by the hot gas. The target temperature was measured continuously during the heating process by a thermocouple which located inside a hole which was drilled in one of the cylinders. The using of cupper cylinder ensures an isotherm temperature profile in the target and a lumped heating process. The target was insolated from the surrounding to avoid heat losses. The spacing between the target and the nozzle outlet obtained by using suitable spacers (7) and locate them under the target block (8). Because of the high thermal capacity of the system, the initial heating of the nozzles and the plenum was done by using air as heating fluid.

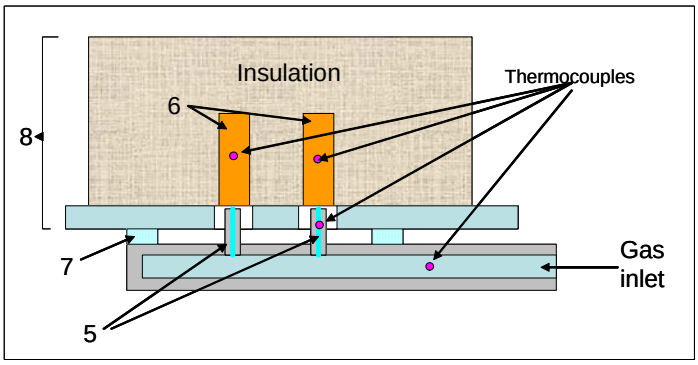
EXPERIMENTAL PROCEDURE

The experimental procedure consists of the following steps. In the first step the system was heating to a required temperature by using air as a heating fluid. The air valve opened and electric power was supplied to the heater. When the required outlet temperature of the air was achieved, the air valve was closed and the Argon valve was opened to get the required flow rate through the nozzles. The electric power to the heater was adjusted to keep the outlet Argon temperature. The required spacers were located above the nozzles plenum and the target block was placed above the spacers. Three leading rods were connected to the nozzles plenum to lead the target block and the

cupper cylinders above the nozzles exit A continuous measurement of the target temperature was made as well as the outlet gas temperature until reaching an asymptotical measured temperature value. The experiments matrix is presented in table 1. As it can be seen the outlet velocity and temperature were changed as a parameter for each jet to target spacing.



(a)



(b)

Figure 1. (a) The test system, (b) The nozzles and the target.

Table 1
Experiments matrix

Jet to target spacing [mm]	0.5	1
Outlet velocity [m/sec]	47	47
	70	70
	94	94
	117	117
	140	140

RESULTS AND DISCUSSION

Each run was terminated when an asymptotical measured target temperature value was achieved. A typical target temperature measurement is presented in Figure 2. That experiment was conducted with outlet Argon velocity of 47 m/sec and exit temperature of 350 ^{o}C. The volumetric measured flow rate increases at the outlet of the heater and the nozzles due to the heating of the gas. To

calculate the outlet velocity it was assumed that there is pressure drop between the flow meter and the nozzle and that the Argon acts as an ideal gas.

The normalized target temperature is presented for various jets velocities in Figure 3 and 4 for jet to target spacing of 0.5 and 1 mm respectively. It can be seen that the time to reach the asymptotic temperature value decreases with the jet velocity. In Figure 5 a comparison of the results from the experiments with the two jet to target spacing values is presented for jet velocity of 47, 70 and 94 m/sec. In that figure it can be seen that the cooling rate with the smallest spacing is lower than with the higher value.

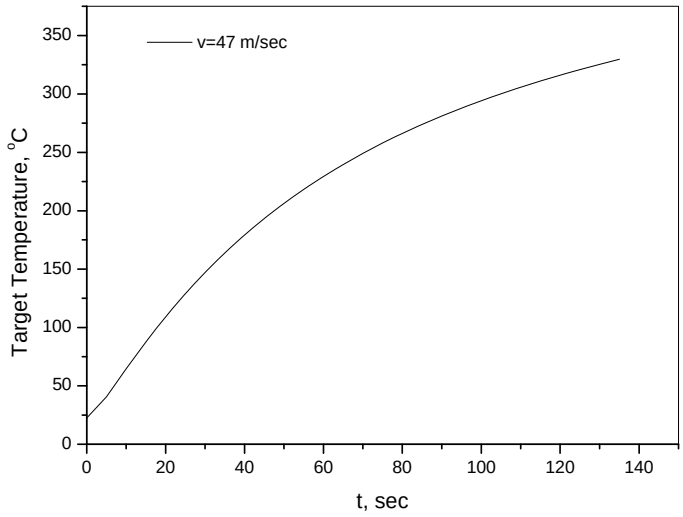


Figure 2. Typical target measured temperature during the experiment (v=47 m/sec).

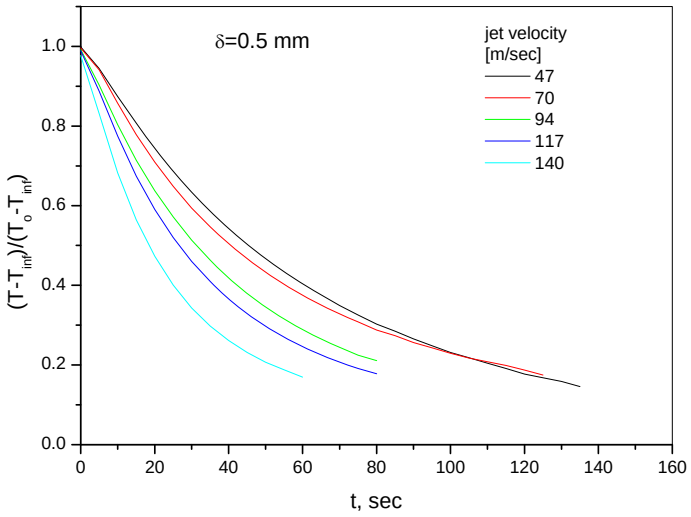

Figure 3. The normalized target temperature for various jets velocities (jet to target spacing of 0.5 mm).

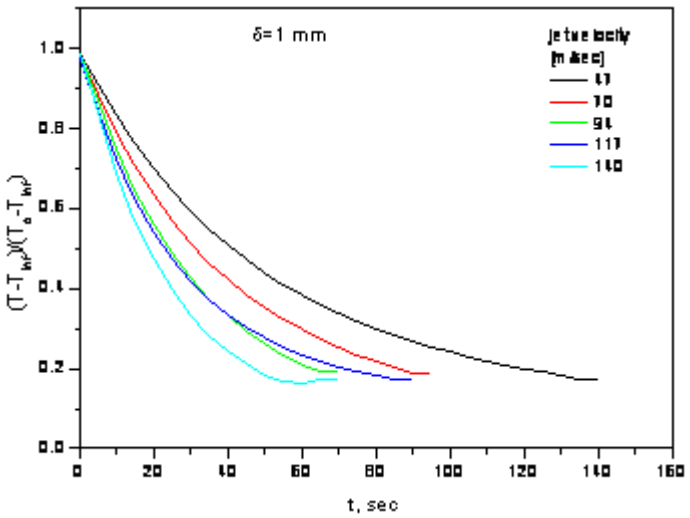

Figure 4. The normalized target temperature for various jets velocities (jet to target spacing of 1 mm).

The convective heat transfer coefficient was obtained by using the assumption of lumped heat capacity and constant heat transfer coefficient during the process. In that model the temperature change during the heating process can be presented by equation (1).

$$T(t) = (T_o - T_\infty) \cdot \exp(-hA/(\rho CV)_{Cu}) + T_o \qquad (1)$$

The time constant of the system at that process is $\tau = (\rho CV)_{Cu}/hA$ in which the system temperature difference ($T-T_\infty$) reaches a value of 36.8 percent of the initial difference (T_o-T_∞). The heat transfer coefficient values were calculated by using the experimental measured values of τ and the time constant definition.

The Nusselt number values which obtained from the experimental heat transfer coefficient results are presented in Figure 6 versus the Reynolds number. Bothe the Nusselt and the Reynolds numbers are based on the nozzle diameter and velocity and gas properties at 350 ^oC. The best fit for the experimental results can be presented by the correlation in equation (2).

$$Nu = 0.72\,\mathrm{Re}^{0.74}\,\mathrm{Pr}^{1/3} \qquad (2)$$

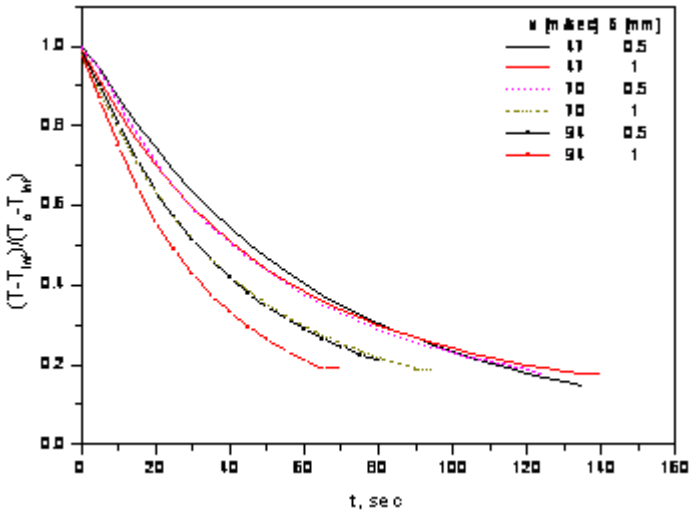

Figure 5: A comparison between the two jet to target spacing values results.

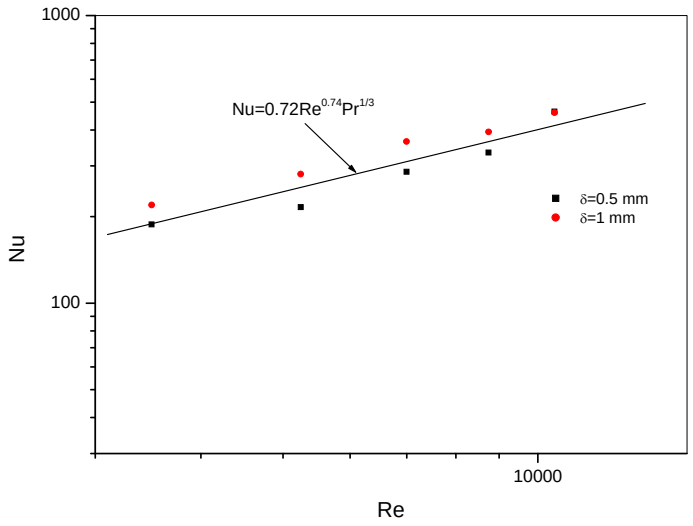

Figure 6: Experimental Nusselt number vs. Reynolds number.

CONCLUSIONS

1. The local convective heat transfer coefficient which was obtained from the experiments is much higher than the average values which are reported in the literature. That result is because of the small spacing between the jet and the target and the dimensions of the target.
2. The heat transfer coefficient increases with the spacing between the jet and the target. However the effect of the jet to target spacing is small.
3. The experimental results for the both jet to target spacing were correlated with the Reynolds number based on the exit velocity and the jets diameter.

ABSTRACT. The purpose of this study is to develop a micro steam generator using a tubular flame. The tubular flame is formed in a swirl flow field induced by injecting the air-fuel mixture tangentially into the cylindrical chamber. The tubular flame consists of an inner hot gas core of burning gas and an outer region of unburned mixture. By installing a water tube into the hot gas core of the tubular flame, the water tube is heated by the surrounding high-temperature burning gas with very low heat loss. The combustion test was carried out using 13A city gas. The vortex structure was weakly affected by the installed water tube, while the tubular flame becomes unstable by the excess cooling with the water tube at high air ratio. This paper focuses on the stability of the tubular flame with the heat absorption and related heat transfer characteristics of the water tube.

Keywords: *Tubular flame, Heat transfer, Flame stability, Steam generator*

INTRODUCTION

The tubular flame is formed in a swirl flow field induced by injecting the air-fuel mixture tangentially into the cylindrical chamber. Figure 1 shows the structure of the tubular flame. The circular luminous flame exists in the combustion chamber. The burning reaction occurs in radial direction, then, the outer region of the tubular flame remains unburned. The high-temperature burning gas flows through the center of the cylindrical chamber. This flame has some constructional advantages. First, the tubular flame is covered with the unburned low-temperature gas, thus the heat loss is extremely suppressed at low level. Second, the tubular flame is stable and suitable to achieve the lean combustion in a stretched and swirl flow field.

The tubular flame has been studied widely by S. Ishizuka et al [1-9]. They developed the tubular flame burner from 4 mm to 300 mm in inner diameter, and reported combustion characteristics on a variety of fuels such as methane, propane, bunker C and biomass [1-6]. These reports presented the structure of the tubular flame, effects of flame stretch, fuel concentration, temperature distribution and extinction limit. The flow field in the combustion chamber was reported in recent years [7-9]. They

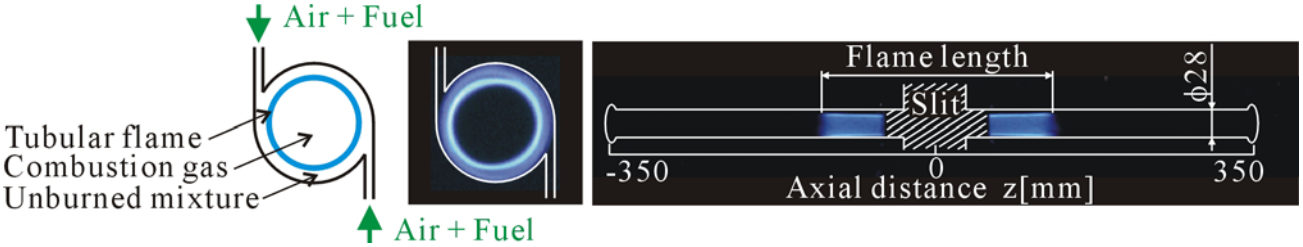

Figure 1 Tubular flame (Q =7 kW, λ =1.4).

developed the tubular flame burner with 150 kW output for industrial boiler and heating furnace applications.

By the way, increasing attentions has been given to a cooking method using superheated steam in considering the health maintenance through foods of good quality. The superheated steam generator (S-SG) for the cooking instruments should be compact for the household use. Considering a limitation of electric capacity of domestic use, the heat source for S-SG is preferably supplied through combustion of city gas. The combustion in the narrow space causes an incomplete combustion, thus the combustion technology suppressing the carbon monoxide CO is essential in the development of the S-SG for the household use. Iio et al. [10] developed the micro superheated steam generator using the partially-premixed burner with the internal exhaust-gas recirculation. Further miniaturization S-SG keeping the high output and the low-CO concentration, the new combustion technology should be developed for the S-SG.

In this study, the tubular flame is applied to the micro superheated steam generator. The conventional burner needs a relatively large space for the complete combustion. However, the tubular flame can be achieved stable and lean combustion in a small bore tube. By installing a water tube into the hot gas core of the tubular flame, the water tube is heated by the surrounding high-temperature burning gas. This concept means that the S-SG is constructed by integration of the heat exchanger into the tubular flame burner. The compact S-SG is thus achieved, and at the same time effective heat transfer is performed on the water tube by surrounding high-temperature gas. However, the excess cooling by the water tube brings the tubular flame unstable. Therefore, the heat transfer on the water tube is important to develop the efficient S-SG.

This report describes the first step of the research aiming at the development of the tubular-flame steam generator. The combustion test was carried out using 13A city gas, and the stability of the tubular flame is examined. The heat transfer characteristics on the water tube are investigated.

EXPERIMENTAL APPARATUS

The experimental apparatus is shown in Figure 2. The combustion chamber is a cylindrical tube with D=28 mm in inner diameter and L=700 mm in length. The middle position of the combustion chamber, the gas injection unit made of SUS304, was installed. The gas injection unit has two slits of 2 mm in thickness and 50 mm in width, through which fuel and air mixture was injected tangentially into the chamber. To observe the tubular flame, quartz glass tubes were used as the combustion chamber. To ensure the uniform velocity in the slits, the cylindrical plenum chambers were equipped at the slit inlets.

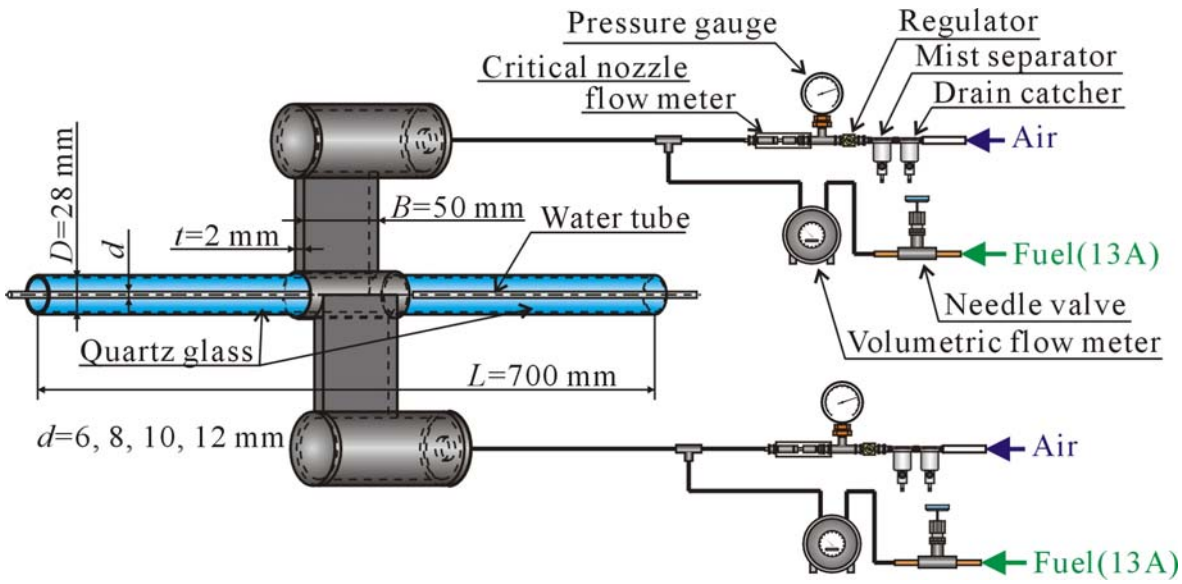

Figure 2 Experimental apparatus.

Each of the water tube of 6, 8, 10 and 12 mm in outer diameter of SUS304 tube, is inserted into the center of the combustion chamber. The wall thickness of the SUS tube is 0.5 mm. The flow rate of the water was measured by a rotameter and the bulk temperature was measured by K-type sheathed thermocouples of 1 mm in diameter. The water flow rate was kept enough high so as to avoid boiling in the water tube. The combustion chamber is set at 30 degree inclined from the horizon for smooth removal of bubbles, if any.

Fuel is 13A city gas consisting of 89 % of methane, 7 % of ethane, 3 % of propane and 1 % of butane. The low heating value is 40.4 MJ/m^3_N. The flow rate of the fuel gas was measured by a wet-type volumetric flow meter. Combustion air is supplied from the compressor, and the flow rate was regulated by means of the critical flow nozzle. Fuel and air were well-mixed and supplied to the combustor. The combustion rate was from 2 to 7 kW.

The combustion gas was sampled at the exit of the combustion chamber by using a water-cooled sampling probe, and was analyzed with the gas analyzer (Horiba Corp. PG-235). The CO, NOx and O_2 concentrations were measured by infrared adsorption, chemiluminescence, and zirconia oxygen sensor, respectively.

The swirl number, which represent the angler momentum relating to the axial momentum, is defined as follows [7];

$$S = \frac{G_w}{G_z \cdot R} = \frac{\int_0^R (u_\theta r)(\rho u_z)(2\pi r)\,dr}{\int_0^R \left(\rho u_z{}^2 + p\right)(2\pi r)\,dr \cdot R} \tag{1}$$

where G_w is the angular momentum, G_z is the axial momentum and R is the radius of the combustion chamber. The angular momentum G_w is assumed to be constant in the combustion chamber, $G_w = 2\{\rho(Btu_s)\,u_s\,D/2\}$, where u_s is the tangential velocity at the slit exit. The axial momentum is given by the mean axial velocity as $G_z = 2\left[\rho\left\{\left(\pi D^2/4\right)u_{z,ave}\right\}u_{z,ave}\right]$. The axial mean velocity $u_{z,ave}$ is a function of the velocity at the slit u_s, $Btu_s = \left(\pi D^2/4\right)u_{z,ave}$. Thus, the swirl number is simply expressed by Equation (2) when the axial pressure drop is neglected.

$$S = \frac{\pi D^2/4}{Bt} \tag{2}$$

Then the swirl number is determined from the dimensions of the combustion chamber. In the present experiment, the swirl number was 6.

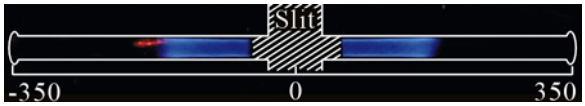
COMBUSTION CHARACTERISTICS OF TUBULAR FLAME WITH WATER TUBE

Figure 3 shows the flame pattern at the combustion rate Q=7 kW without the water tube. The flame was recorded with a digital video camera. Experiments were carried out for various air ratio λ at the constant heat release rate Q. The air ratio λ is defined as the ratio of air volume relative to the stoichiometric volume of air, i.e. the inverse of the equivalence ratio. In these figures, the center of the flame cannot be observed due to the gas injecting unit. As shown in Figure 3, the stable tubular flame was formed in the combustion chamber. The diameter of the flame is almost constant along the axis of the tubular flame. An increase in the air ratio λ results in an increase in the flame length. Shiraga et al. [11] reported that the burning velocity becomes lower with a decrease in the fuel concentration. To ensure the complete combustion, the long flame length, i.e. the large flame surface, is needed at high air ratio and high injecting velocity.

Even inserting the water tube into the tubular flame, the stable tubular flame was formed in the combustion chamber at the air ratio λ=1.3 and 1.4, as shown in Figure 4 (a) and (b). The shape of

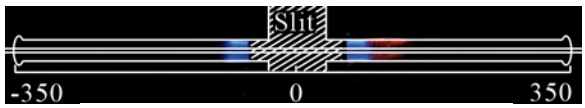
(a) Q=7 kW, λ=1.3, u_s=14.1 m/s

(b) Q=7 kW, λ=1.4, u_s=15.1 m/s

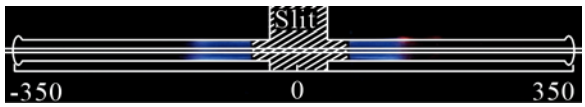


(c) Q=7 kW, λ=1.5, u_s=16.1 m/s

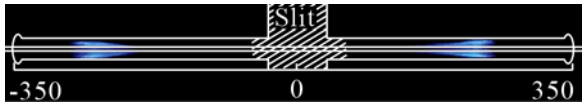
Figure 3 Flame pattern without water tube.



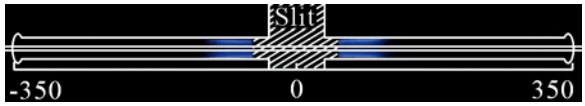
(a) Q=7 kW, λ=1.3, d=6 mm



(b) Q=7 kW, λ=1.4, d=6 mm



(c) Q=7 kW, λ=1.5, d=6 mm



(d) Q=7 kW, λ=1.5, d=6 mm

Figure 4 Flame pattern with water tube.

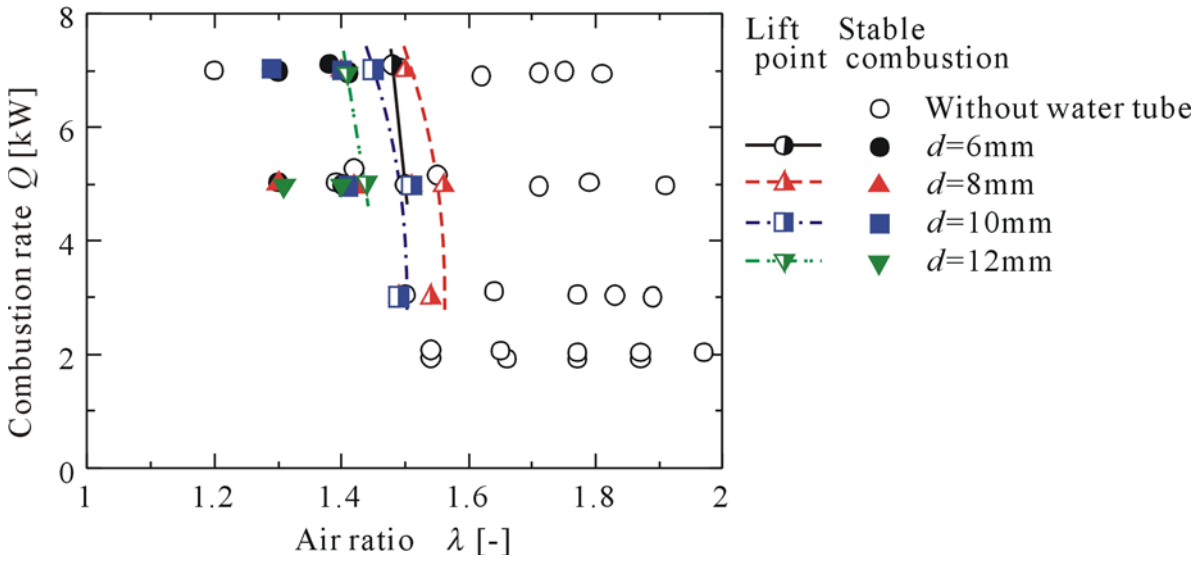


Figure 5 Flame lift point.

the tubular flame is almost the same with the case without water tube. At the air ratio λ =1.5, however, the tubular flame flickers, which is equivalent to the state of alternation flame lifting and holding, as shown in Figure 4 (c) and (d). When the air ratio is higher than λ =1.5, the tubular flame becomes extinct. In the case of Figure 4 (b), the water tube absorbs the heat from the hot burning gas about 1.6 kW, which corresponds to about 23 % of the heat release rate. The tubular flame becomes unstable combustion due to the excess cooling by the water tube. Thus the heat absorption rate, i.e. heat transfer characteristics is a key issue in achieving a stable combustion.

The stable combustion map and the equivalent flame lifting point are plotted in Figure 5. The open circles show the stable tubular flame without water tube. When the water tube is not equipped in the combustion chamber, the flame extinction is not observed even at high air ratio. At low combustion rate and low air ratio, the tubular flame cannot be observed due to the short flame. By applying the water tube into the combustion chamber, the stable combustion region is limited in the

region represented by the solid plots in Figure 5. The equivalent flame lifting occurs at around the air ratio λ=1.5. An increase in the water tube diameter d brings about the flame lifting point to be shifted toward low air ratio, except the water tube of 6 mm. An increase in the heat transfer area results in an increase in the heat absorption rate, which induces the unstable combustion. Thus, the stable combustion area becomes narrower with an increase in the water tube diameter.

HEAT TRANSFER CHARACTERISTICS ON THE WATER TUBE

To achieve the stable tubular flame with the heat absorption by the water tube, the heat transfer characteristics on the water tube is important. The local heat transfer coefficient on the water tube is evaluated from the temperature profiles of water and burning gas.

The heat exchange process in the combustion chamber with the water tube is considered as a double-tube type heat exchanger. The local heat flux q from the high temperature burning gas to the water tube is estimated by the sensible heat of water calculating from the temperature gradient of the water along the flow direction, as follow;

$$q = \frac{m_w c_w}{\pi d} \cdot \frac{dT_w}{dz}, \tag{3}$$

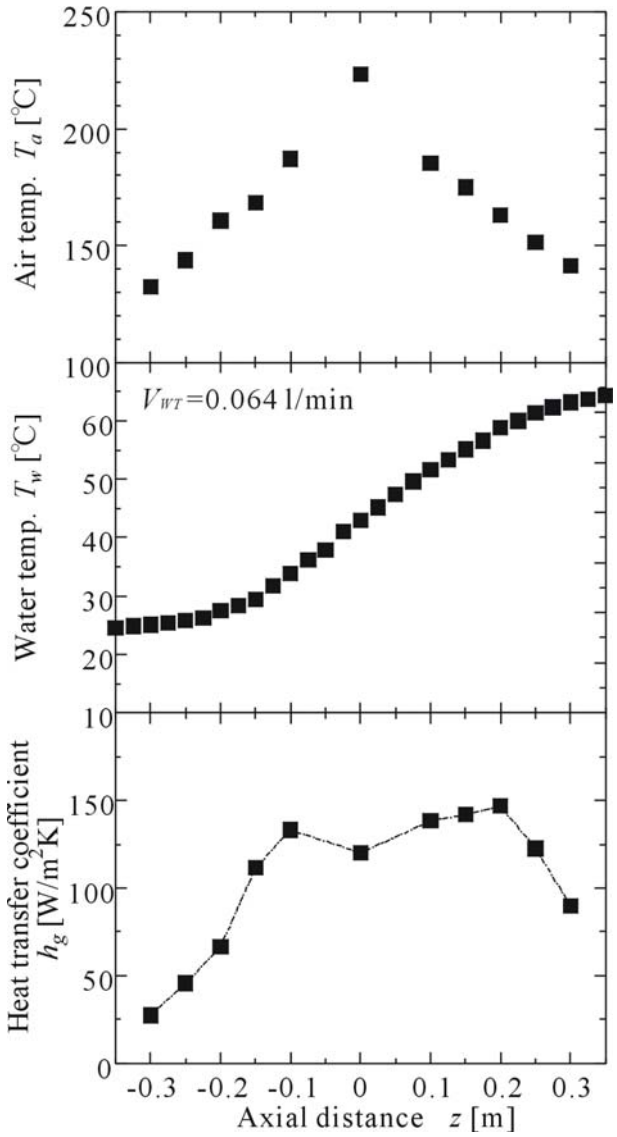

Figure 6 Distributions of temperature and heat transfer coefficient in the non-combustion case (D=28 mm, d=6 mm).

where m_w and c_w are mass flow rate and the specific heat of water, respectively. The thermal resistances of the SUS tube wall and the heat transfer on the water side are sufficiently low. Therefore, the local heat transfer coefficient h_g outside the water tube is calculated by Equation (4).

$$h_g = \frac{q}{T_g - T_w} \tag{4}$$

To ensure the measurement of heat transfer, the preliminary test was carried out in the non-combustion case. The electrically preheated air is used as the working fluid to simulate the combustion flow field. The preheated air flow rate is adjusted to as the combustion experiment (Q =7 kW, λ =1.4) of 9.94 m^3_N/h.

The temperature profiles of the non-combustion case are shown in Figure 6. The air temperature is 503 K at the inlet and decreases with the axial direction. The water temperature increases along the water flow direction from 298 K to 338 K, which corresponds to 178 W of heat absorption rate. The local temperature gradient of water is determined from the neighboring five temperature measurement points. Local heat transfer coefficient is shown in Figure 6 calculated by Equation (4). Relatively high heat transfer coefficient appears at z<±150 mm even in the low mean axial velocity of 4.3 m/s. The swirl flow induces the heat transfer enhancement in the middle of the combustion chamber. On the downstream, however, the heat transfer coefficient decreases due to the attenuation of the swirl effect. On the non-combustion test, the heat transfer coefficient can be estimated from the temperature profiles.

The measurement of the heat transfer coefficient on the combustion tests are carried out at the 5 and 7 kW with the water tube of 6 mm in outer diameter.

The combustion gas temperature was measured by a silica-coated R-type thermocouple of 200 μm in diameter. The representative temperature distributions in the radial direction of the combustion gas are shown in Figure 7 at 5 kW. r is the radial direction from the center of the combustion chamber. At z=0 mm, the temperature of the outside of the tubular flame is low due to the unburned gas mixture. The temperature increases rapidly at r=8 mm, reaches its maximum at of 1653 K at r=4 mm. The luminous flame zone is expected to be around at r=8 mm. At the combustion rate 5 kW with λ=1.4, the tubular flame has 140 mm in length, thus the combustion is completed at around z=±70 mm. Outside the combustion zone, the temperature distribution becomes flat as typically shown in the data at z=-100, -200 and -300 mm. Therefore, the bulk gas temperature T_g in Equation (4) can be estimated as the radial-averaged temperature of the combustion gas. At z=0 mm, T_g is averaged from r=4 to 8 mm of the burning gas temperature.

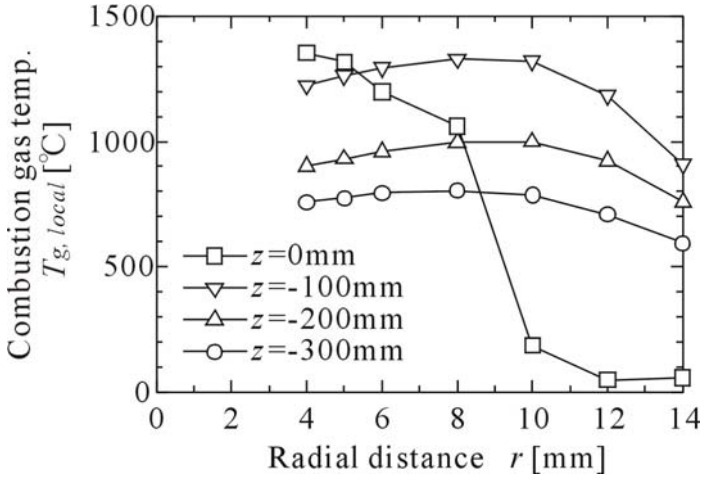

Figure 7 Temperature distributions of the burning gas in the radial direction (Q =5 kW, λ =1.4, d =6 mm).

Figure 8 shows temperature distributions of the radial-averaged combustion gas and the water at the combustion rate of 5 and 7 kW with air ratio λ=1.4. The gas temperature at z=0 mm is lower than the adiabatic flame temperature plotted by the cross plot, and the gas temperature at the end of the tubular flame shows almost the same with that at z=0 mm. In the combustion zone, the bulk temperature of the combustion gas is considered as an almost uniform profile in the axial direction, because the combustion reaction takes place together with the heat transfer inside of the tubular flame. Outside of the tubular flame, the gas temperature decreases along the axial direction.

Figure 8 also shows distributions of the local heat transfer coefficient. On the combustion experiments, the heat transfer coefficient reaches maximum at both ends of reaction zone, and is slightly lower at the center (z=0 mm). The combustion gas flow rate increases along the flow direction due to the combustion reaction. This causes the heat transfer maximum at the both ends of reaction zone. The heat transfer coefficient shows almost the same with distribution at the non-combustion case. This suggests that the radiant heat transfer is weak than the convective heat transfer in such a narrow flow area. Therefore, the heat absorption rate on the water tube in the tubular flame can be evaluated by the convective heat transfer of the combustion gas.

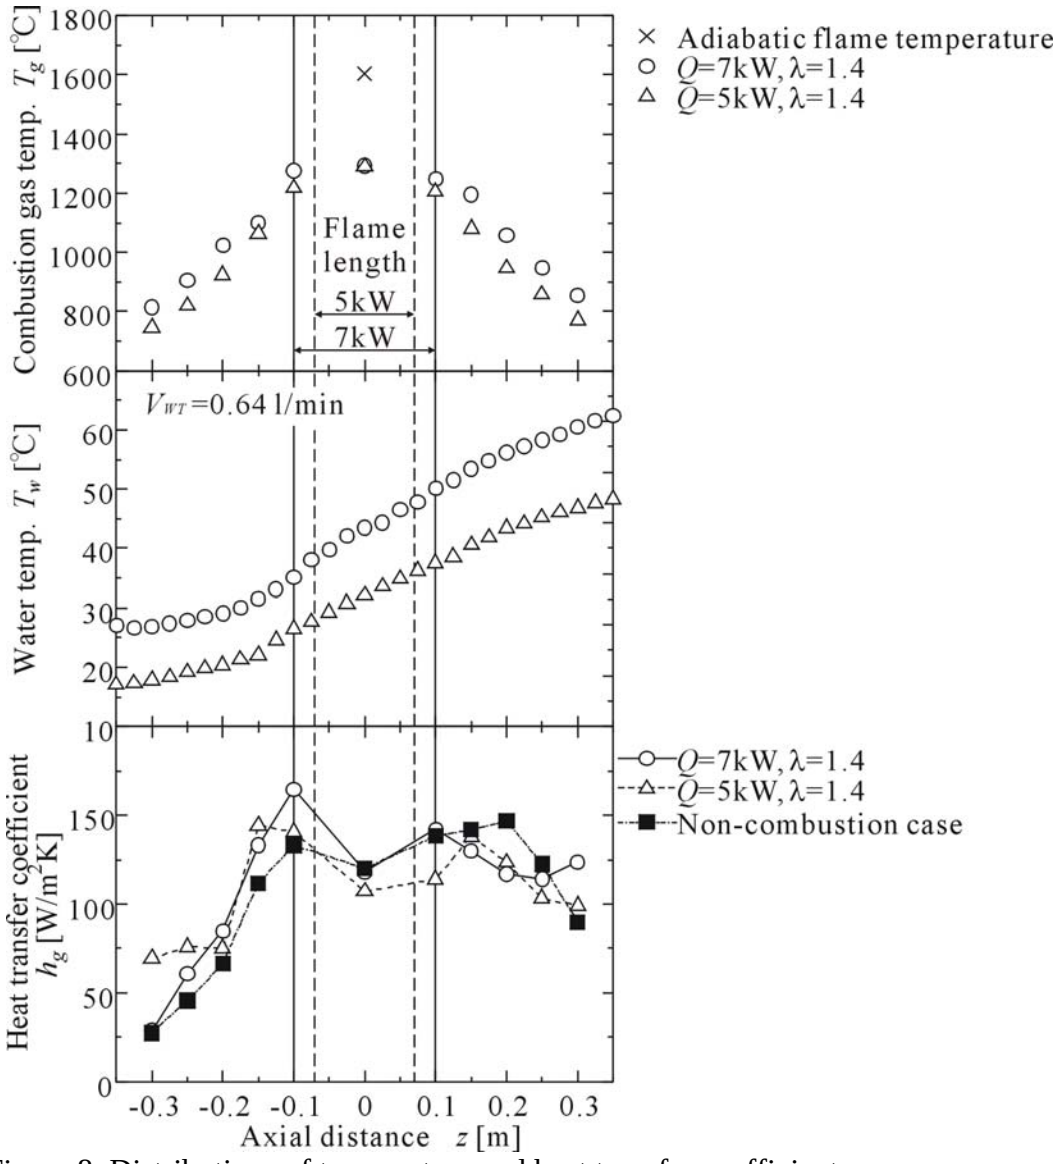

Figure 8 Distributions of temperature and heat transfer coefficient in the combustion case (D=28 mm, d=6 mm).

CONCLUSION

This study was conducted aiming at the development of the compact steam generator using the tubular flame. This paper describes the fundamental combustion characteristics of the tubular flame with water tube inserted into the center. Then, the heat transfer characteristics on the water tube surface was investigated. The results are summarized as follows:

(1) The stable tubular flame is formed even with the water tube in the hot gas core. By increasing the air ratio, however, the tubular flame becomes unstable due to the excess cooling by the water tube.

(2) The local heat transfer coefficient on the water tube surface is estimated. The heat transfer coefficient shows almost the same with distribution at the non-combustion case. The heat absorption rate on the water tube can be evaluated by the convective heat transfer of the combustion gas.

ABSTRACT. Scraped Surface Heat Exchangers (SSHE) are usually employed in presence of high viscosity fluids; the scraping is generally obtained by a mechanical agitation system. In this work results of an experimental campaign on a SSHE, used in a commercial machine for ice-cream production, are presented. The ice-cream mix, after the mixing with the air, goes into the SSHE, working as evaporator, where is cooled to obtain soft ice-cream. A particular difficulty in SSHE performance analysis arises from the non-Newtonian behaviour of the ice-cream mixture; for this reasons, some assumptions on rheological properties of ice-cream mix have been accepted. Experimental tests are carried out by varying ice-cream mass flowrate, liquid mix inlet temperature and agitator speed. Starting from correlations available in literature, dimensionless analysis has been applied to the experimental evidences to develop a heat transfer correlation. The predictions of proposed correlation show a good agreement with the experimental data.

Keywords: *SSHE, scraped, agitator, non-Newtonian.*

INTRODUCTION

Heat exchangers with mechanical systems of agitation and scraping (SSHE, Scraped-Surface Heat Exchangers) are widely used (many constructive geometries are available [1]) in presence of viscous or partially solid fluids. Agitators ensure the constant removal and replacement of stagnant fluid from exchanger surfaces that is very important when working temperatures are close to fluid solidification or evaporation conditions. Moreover, it is useful for heat transfer improvement, in order to reduce possible fouling problems and to induce a mixing improvement and, consequently, a rapid balance in the mass fluid temperature as well.
In this paper, starting from experimental test data and correlations available in literature, a heat transfer correlation for a particular SSHE, used as evaporator, has been developed.
The SSHE tested works in a soft ice-cream machine; the liquid ice-cream mixture, containing a variable quantity of air, goes into the heat exchanger where is whipped and cooled and, finally, goes out as ice-cream. This mixture behaves as a non-Newtonian fluid and is made up of various components (milkfat, water, sugar, egg yolk solids, flavor). Moreover, because some of those components may also change state or characteristics during the process, mixture physical quantities may strongly depend by temperature. In particular, the tested mixture shows a pseudoplastic behavior for temperatures higher than -2°C, whereas for lower temperatures (range of liquid-solid phase transition), it behaves as a plastic fluid, involving considerable problems of physical representation.
In a previous step of this activity, that aims to obtain a SSHE simulation tool useful for sizing and design purposes, we have already carried out some preliminary test sets using a mixture of water and propylene-glycol, instead of ice-cream mixture, to define some aspects of the machine behaviour [2].

In this paper, to estimate the overall heat transfer coefficient, all test data have been processed with a methodology proposed from Skelland [3, 4] and based on the dimensional analysis application. To conclude, the predictions of the achieved heat transfer correlation have been compared with experimental data.

EXPERIMENTAL FACILITY

Ice cream flows inside a cylindrical tube where the agitator (type "helical ribbon" and named beater for this application) is located; the cooling fluid (R404A) runs in counter-current flow inside a rectangular section coil that is helically wrapped on the cylinder external surface. Due to an industrial patent protection, below we can only provide its main geometrical characteristics (Table 1).

Table 1
SSHE geometrical characteristics

Exchanger tube i.d., D mm	85
Tube exchange length, L mm	250
Heat transfer area thickness, s mm	2.25
Rectangular coil size a×b, mm	10x6.5
Coil pitch, mm	12
Total coil lenght l, m	6.03

The experimental setup is a commercial soft ice-cream machine (figure 1) that is modified and instrumented in order to achieve the planned experimental test conditions. The use of two inverters, connected to the compressor and the agitator electric motors, allows a wider range of tests. All circuit points of interest in the process study are instrumented with pressure gauges and thermocouples; refrigerant mass flow-rate is detected using a Coriolis mass flow-meter, while some electrical power consumptions are also recorded.

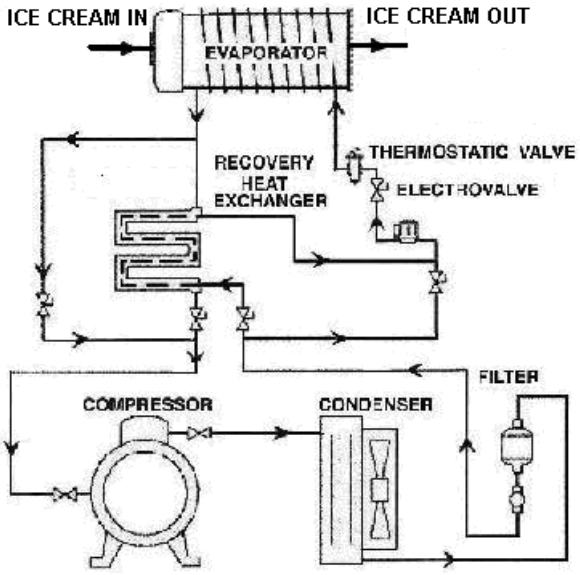

Figure 1. The experimental setup

The ice-cream mass flow-rate is calculated by the ratio between produced ice-cream weight and corresponding time of extraction. A specific and very important parameter to have comparable tests

is the ice-cream quality that stands for the "goodness" of ice-cream production; this is directly evaluated by soft ice-cream machine and shown by a number on the display (afterwards called ICQN).

TEST MATRIX

Five series of tests with different agitator speeds on the SSHE have been carried out, for a total of 152 runs. For each set, fixing the evaporator inlet ice cream temperature between -1 °C and +6 °C and accepting an ICQN range of 6 ÷ 9, the ice mass flow rate $\dot{M}$ (with a range of 8 ÷ 32 kg/h) and the agitator engine power consumption W_{agit} have been measured. Using a recovery heat exchanger with appropriate adjustments on the thermostatic valve, refrigerant conditions close to complete evaporation have been obtained; this test condition is essential to have useful tests for a further analysis on heat transfer coefficient [2]. Ranges of significant controlled parameters along with corresponding number of performed tests are indicated in Table 2.

EXPERIMENTAL INVESTIGATIONS

Experimental heat transfer coefficient

The evaporator overall heat transfer coefficient, U, can be obtained from the general equation

$$Q = U\ A\ \Delta T_{lm} \tag{1}$$

where A is the scraped surface area and ΔT_{lm} is logarithmic mean temperature difference; the amount of heat transferred per unit of time Q is given by

$$\dot{Q} = \dot{M}\left\{\frac{y}{100}\left[c_{pl}(T_{in} - T_{cc}) + \lambda + c_{ps}(T_{cc} - T_{ic})\right] + \left(\frac{100 - y}{100}\right)\left[c_{pl}(T_{in} - T_{ic})\right]\right\} + W_{agit} \tag{2}$$

where W_{agit} is a frictional thermal power transferred to the fluid by the agitator. The amount Q is determined experimentally since we are able to measure all involved quantities, including the power absorbed by agitator engine. On the other hand, the theoretical expression of the global coefficient U for a cylindrical surface yields:

$$\frac{1}{U} = \frac{1}{h_i} + \frac{\ln\left(\phi_e / \phi_i\right)\phi_i}{2k} + \frac{\phi_i}{\phi_e h_e} \tag{3}$$

where h_i and h_e are the ice-cream and two-phase refrigerant adduction heat transfer coefficients, respectively, k is the thermal conductivity of tube wall and ϕ_i , ϕ_e are inner and outer tube diameters, respectively. The coefficient h_e is calculated using the Schrock-Grossman's correlation [5] as modified by Nariai et al. [6], for predicting boiling heat transfer coefficient in a helically coiled tube. This correlation, modified with the introduction of a corrective factor, Fc, proposed by Kattan et al. [7] for the non-azeotropic behaviour of a refrigerant mixture (R404a), is defined as:

$$h_e = h_l \left[1.1 \left(\frac{1}{\chi_{tt}} \right)^{0.66} + 7400\, Bo \right] F_c \tag{4}$$

where χ_{tt} is the Martinelli parameter [7] and h_l represents the liquid heat transfer coefficient calculated with the well-known Dittus-Boelter correlation [8]. From previous correlations we can calculate the h_i coefficient, hereunder denoted with h_{iexp}, once evaporator geometry and conductivity of the material used are known.

Dimensional analysis to determine h_i

To describe thermal exchange in the SSHE, considering its particular working characteristics, we identified four meaningful dimensionless groups: Prandtl number (Pr), the ratio between the rotating device speed and fluid axial velocity, rotational Reynolds number (Re_r), and a group that defines the geometry of the heat exchanger. In our tests this last group is constant because we have tested only a SSHE so the functional relationship between the Nusselt number and the main dimensionless groups can be given in the form:

$$Nu = h_{i\,ad} \frac{D}{k} = \alpha \left(\frac{c_p \mu}{k} \right)^{\beta} \left(\frac{ND}{\nu} \right)^{\gamma} \left(\frac{\rho N D^2}{\mu} \right)^{\delta} \tag{5}$$

where α contains the constant value of geometrical group as well.

<u>*Method development.*</u> For a non-Newtonian fluid is more complex to calculate some physical properties, in particular the density (that is a temperature function) and viscosity (that depends on temperature and average shear rate γ_a).

In these tests, the mixture density has been calculated by experimental measures while the relationship between viscosity μ and shear rate γ_a is available thanks to laboratory rheological tests (fig 2). For helical ribbon agitators with low clearance "c", the average shear rate γ_a can be evaluated from the following equation [9,10]:

$$\gamma_a = \left[34 - 144 \left(c/D \right) \right] N \tag{6}$$

For the SSHE, having clearance ≈ 0, the term in square bracket in (6) reduce to 34. With the average shear rate so calculated and fig.2 data, it is possible to estimate ice-cream mixture viscosity.

To calculate the coefficients α, β, γ and δ in (5), we have carried out test series at constant values of Re_r and Pr. In this way it is possible to highlight a relationship between Nu and the dimensionless second group in (5) and, therefore, calculate its exponent γ. By way similar subsequent analysis we are able to define the other parameters. Physical properties have been evaluated at average bulk fluid temperature.

Hereafter, the various steps of the procedure are briefly described (some figures are not presented for paper length problems).

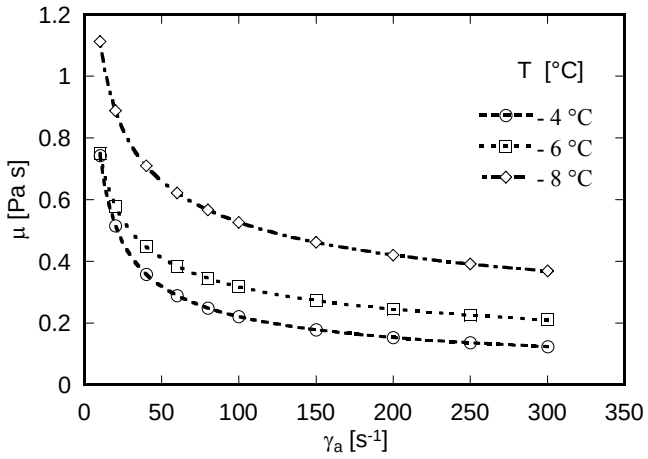

Figure 2. Viscosity vs shear rate, parameter temperature

γ exponent evaluation. Exponent γ is calculated using all test data that are reported in the log-log plot of $Nu_{exp} = h_{exp}D/k$ vs. DN/v dimensionless group, fig. 3. For better clarity, fig. 3 shows only some tests among those elaborated.

We can observe that the points at constant Re_r (in this step Pr is considered constant for all the tests even if, depending on the test execution difficulty, its values are in a short range) practically lay along straight lines. All the lines are almost parallel thus the mean slope, which is about -0.329, can be considered the exponent γ□□ value. This value will be revised later in a final plot. The calculated exponent is used in the following steps.

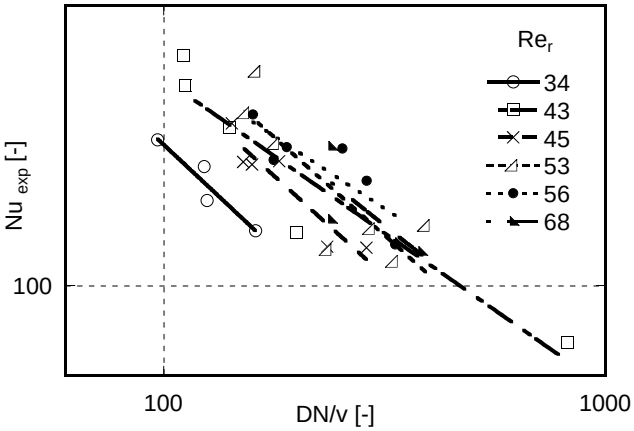

Figure 3. γ exponent evaluation

δ □exponent evaluation. In a preliminary assessment of this exponent, all tests are still used in the log-log plot of

$$Nu\left(\frac{ND}{\nu}\right)^{0.329} \; vs. \quad \frac{\rho ND^2}{\mu}$$

obtaining a situation similar to the previous one; δ value obtained is about 0.497.

β exponent evaluation. In this step, all data tests are used. In a log-log plot we compare

$$Nu\left(\frac{\rho ND^2}{\mu}\right)^{-0.497}\left(\frac{ND}{\nu}\right)^{0.329} vs.\ Pr$$

The slope for all data fits is about 0.546 and corresponds to the exponent β.

coefficient α evaluation and revised value for all exponents. A final plot of all the data against the *DN/v* dimensionless group is drawn to assess the coefficient α. Figure 4 shows a log-log plot of

$$Nu\left(\frac{c_p\mu}{k}\right)^{-0.546}\left(\frac{\rho N D^2}{\mu}\right)^{-0.497} \quad vs. \quad \frac{DN}{v}$$

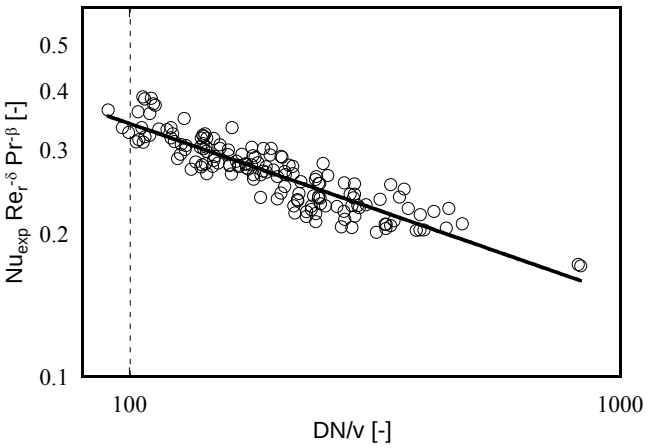

Figure 4. Coefficient α and new γ exponent evaluation

The intercept has a value of 4.55 and the slope of the line gives a revised value for γ equal to -0.344, which is slightly different to the first value calculated γ (-0.329). On the basis of previous experiences, we consider the convergence process acceptable when the difference between two consecutive γ values is less than 0.01, therefore we have repeated the procedure introducing this γ value in the second step *("δ exponent evaluation"*). Finally, at whole process convergence, the final correlation is:

$$Nu = h_{iad}\frac{D}{k} = 1.8\left(\frac{c_p\,\mu}{k}\right)^{0.671}\left(\frac{N\,D}{v}\right)^{-0.36}\left(\frac{\rho\,N\,D^2}{\mu}\right)^{0.568} \qquad (7)$$

Result evaluation

Differences between coefficient values h_{iad} obtained by (7) and experimental values h_{iexp} are shown in Fig. 5. Predictions are on average centred with errors between -14.8 and +17.5 % but a large part of points has lower error.

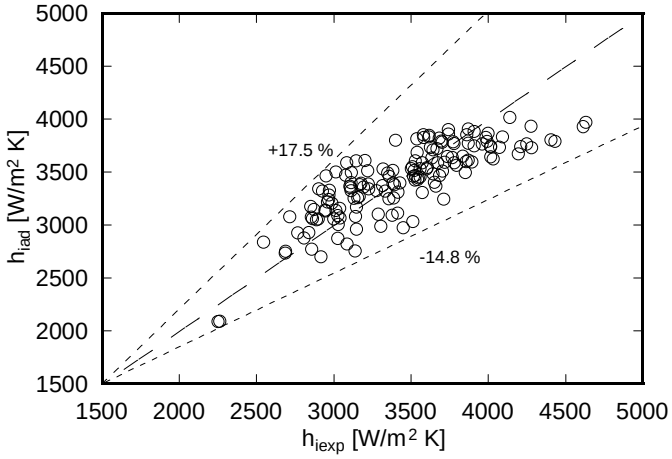

Figure 5. Correlation predictions h_{iad} vs h_{iexp}

If R_h and Δ indicate, respectively:

$$R_h = \frac{h_{iad}}{h_{i\,exp}} \qquad \Delta = R_h - R_m \tag{8}$$

with R_m all data mean (ideally equal to unit), it is possible to obtain normal distributions of such variables in terms of absolute errors, Δ [11]. The normal distribution is represented by a probability density function $P(\Delta)$

$$P(\Delta) = \frac{1}{\sqrt{2\pi}\ \sigma}\ e^{-\frac{\Delta^2}{2\sigma^2}} \tag{9}$$

where σ is the standard deviation of the same distribution. For current experimental data, σ is 0.0743. It is worthy pointing out here that the integral

$$\int_{-\Delta_1}^{+\Delta_1} P(\Delta)\, d\Delta = \int_{-\Delta_1}^{+\Delta_1} \frac{1}{\sqrt{2\pi}\ \sigma}\ e^{-\frac{\Delta^2}{2\sigma^2}}\, d\Delta \tag{10}$$

is the probability that result of a measurement, R_h, is affected by an error between $-\Delta$ and $+\Delta$.
Table 3 shows the probability that data obtained fall within some special ranges; we can note that there is a probability of approximately 70% that the submitted correlations predictions are affected by an error lower than ± 7.4%, and that only about 16% of data have an error greater than ±10.5%.

Table 3
Statistics values

Δ	$\int$	**probability**	$\Delta_{\%}$
0.674σ	0.5	50 %	±5
σ	0.684	68.4 %	±7.43
$\sigma\sqrt{2}$	0.842	84.2 %	±10.51
2σ	0.95	95%	±14.86

CONCLUSIONS

Before reading any conclusion it is necessary to premise some difficulties that are associated with tests.
The first one is the achievement of the same ice cream quality in every test (ICQN control). If the machine is operated under conditions far from commercial production, we noted that the torque-resistant might loose the simple relationship and be affected by test conditions.
Another problem depends on rheologic characteristics of process fluid and on difficulty to express physical properties by an average bulk fluid temperature only.
Finally, we have to remind the complexity to obtain refrigerant conditions close to complete evaporation that might involve little errors.
The main aim of the present study is the development of a heat transfer correlation for the SSHEs installed in the soft ice cream machine under consideration. We have developed a correlation based on Skelland [3, 4], looking for different dimensionless groups that allow a better representation of the SSHE design.
The results obtained allow thinking that the used methodology and the chosen dimensionless groups look appropriated for the development of a heat transfer correlation for the SSHE tested. This step is

crucial for the research planning therefore other geometries and different heat transfer conditions which will be considered.
As far as the correlation performance is concerned, despite unavoidable procedural difficulties, the results are encouraging, since most of its predictions have an acceptable error (Table 3).
Finally, this experimental research has confirmed, as on the other hand reported by many authors [1], the importance of the impeller geometrical characteristics for the research of a SSHE heat transfer correlation.

Nomenclature

c	clearance [m]
N	agitator revolution speed [s^{-1}]
U	overall heat transfer coeff [$Wm^{-2}K^{-1}$]
y	frozen water fraction in the final product [-]
λ	latent heat of evaporation [J kg^{-1}]
ϕ	diameter [m]
Re_r	rotational Reynolds number $\rho ND^2/\mu$ [-]

Subscripts

ad	adimensional
agit	agitator
cc	freezing start
e	external
exc	exchanged
exp	experimental
i	internal
ic	ice cream
s	shaft

BUBBLE FORMATION IN POOL BOILING OF NATURAL REFRIGERANTS ON HORIZONTAL TUBES

Andrea Luke*, Björn Müller, Yabai Wang
Institute of Thermodynamics, Leibniz University Hannover, 30167, Hannover, Germany

ABSTRACT. A general theory for boiling heat transfer could be developed in the future, if the heat transfer of a single bubble and the interaction between neighbouring bubbles are integrated in the evaluation modeling. The influence of microstructure of a heating surface and of the bubble formation on nucleate boiling heat transfer is investigated. The aim is to develop a correlation of the local and temporal activation of the potential nucleation sites, which can be statistically determined by the envelope area method based on the roughness measurements of the heating surface before the heat transfer measurements. The activation of nucleation sites, the bubble growth and departure and the sliding along the superheated wall of the test tube are observed by high speed video sequences.
The video sequences of nucleate boiling of natural refrigerants on a differently structured copper tube and a mild steel tube, respectively, are evaluated using a special evaluation program. The raw-data of the evaluation of the video sequences will be sorted and converted for the statistical analysis. The bubble departure diameter and frequency will be compared to existing empirical and semi-empirical correlations of literature. The bubbles are tracked along their way sliding in the superheated liquid. The characteristic behaviour of nucleation sites during nucleate boiling, for example the local and temporal distribution of the nucleation sites and frequency distribution of the distance to the next active nucleation site, will be also analyzed for different pressures.

Keywords: *pool boiling, natural refrigerants, active nucleation sites, bubble formation*

INTRODUCTION

The long term aim in design of modern evaporators is to find a correlation based on the phenomena of vapour bubble formation within the cavities of the microstructure of the heated surface. The essential thing to be found out is the activation and deactivation criteria for nucleation sites in which the micro and macro topography of the heated surface, material properties of wall and liquid, and operating conditions enter. This implies for the experimental studies of nucleate boiling heat transfer that detailed and precise information on the topography of the heated surface and of the bubble formation and motion are as important as the heat transfer results, and that all kind of data originate from the same experiment.
High speed video technique offers the possibility to get more detailed information of the bubble formation. The density of active nucleation sites is determined with semi-automatical evaluation methods of the high speed image sequencies. The paper will focus on the bubbble formation for an intermediate pressure from low to high heat fluxes of boiling propane on an horizontal copper tube with fine sandblasted surface and on an horizontal steel tube with drawn and polished surface (for the heat transfer results, cf also Luke and Müller [6]). The cavities within the measured topographies acting as potential nucleation sites are determined additionally and are discussed in form of standardized parameters and statistical ones [3],[9].

EXPERIMENTAL PROCEDURE FOR HEAT TRANSFER AND BUBBLE FORMATION

The heat transfer and the bubble formation are investigated during the same experiment in a so-called Standard Apparatus, [1], [2]. The main parts of the apparatus are

- the dc-heated hoziontal test tubes in the evaporator,
- evaporator and condenser combined to a natural circulation loop for the test fluid and placed in a conditioned chamber whose air temperature is adjusted to the saturation temperature T_S of the liquid in the evaporator.

The measurements are performed for boiling propane boiling on a horizontal copper tube with an outer diameter of D = 25.4 mm with a fine sandblasted surface and on a mild steel tube (D =19 mm) for a wide pressure and heat flux range [3]. Parallel to the heat transfer measurements, the bubble formation is examined by photographs and by high speed video technique with 1000 images/s for a resolution of 512x512pixel. The evaluation is performed by special semiautomatical programms to determine number, local position of the active nucleation sites and the size of the growing bubbles in each ms. The local distribution of the nucleation sites and of the bubble departure diameter and frequency on the entire heating surface and their total number are measured at a constant spatial resolution, by investigating several overlapping camera settings for one boiling condition (e.g. from the upper to the lower surface, s. Figure 1).The number of active sites have been counted on the area examinated and presented true to scale in Figure 2, by two typical examples of the bubble formation within ca. 5x5mm² of the test tube surface near the horizontal median line of the copper tube. The images represent two succeeding video images with "momentary", simultaneously active nucleation sites during 1ms, indicated by horizontal arrows in Figure 2, left. The result varies from ms to ms, demonstrated by two new dashed angular arrows in Figure 2 right, these sites are activated between the two images. The average number of momentary sites is approximately $N/A_M = 9$ /mm² during the total session of 500 ms (as seen in the right image in Figure 2).

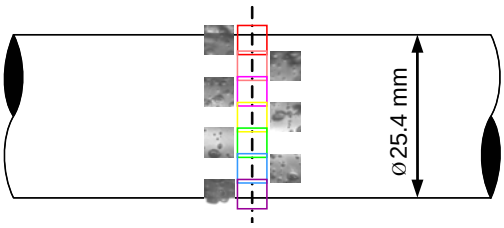

Figure 1. Sketch of the overlapping settings for one boiling condition on the fine sandblasted copper tube with D = 25.4 mm

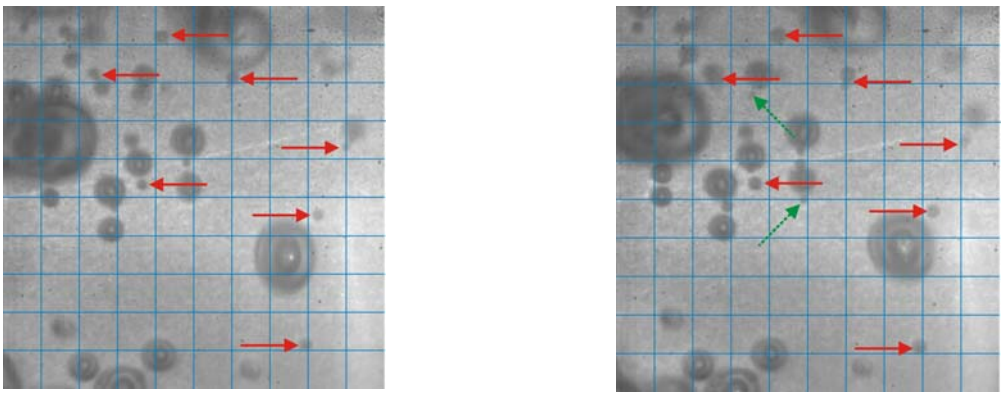

Figure 2. Bubble formation on the median line of the test tube for propane boiling at p* = 0.1, q = 20kW/m²: Selected images with typical momentary active nucleation sites (horizontal arrows) and activated one ms later, see the dashed angular arrows, right.

HEAT TRANSFER AND LOCAL ANALYSIS OF THE WALL SUPERHEAT

The results for the heat transfer are presented in Figure 3 (left) and for the steel tube in Figure 3 (right) as double logarithmic diagram of the heat transfer coefficient α versus the heat flux q with the saturation pressure reduced to the critical pressure, $p^* = p_s / p_c$ as parameter. α increases strongly in the regime of boiling with increasing pressure and heat flux and achieves values of 10^5 W/m²K. The variation of the local wall superheat ΔT with the azimuthal angle φ and heat flux q is represented in Fig. 4 for propane boiling $p^* = 0.1$ (top) and for the intermediate heat flux $q = 20$ kW/m² with the pressure as parameter (bottom). As known from recent experiments, the superheat of the tube wall varies significantly with the azimuthal position φ. The maximum variation of the superheat ΔT occurs at the intermediate heat flux $q = 20$kW/m² (or for superheats greater than 20 K). Similar variations of ΔT with φ are observed with differing pressures, see Figure 4 bottom. The relative effect is most pronounced at intermediate pressure $p^* = 0.1$ and it decreases to lower pressures and to higher ones, respectively. The local effect is on the rough surface the same as on the smooth one, the curves are only shifted to smaller superheats. These results may be explained by the corresponding variation of bubble formation and the roughness [5]. The heat transfer in the lower parts of the tube surface is enhanced at intermediate heat flux by the bubbles sliding along the superheated tube surface improving heat transfer by convective effects and additional evaporation. At high heat fluxes and pressures, i.e. high superheats, the importance of the sliding bubbles diminishes because the tube is entirely covered by bubbles growing at their nucleation sites. At very low heat fluxes only very few potential nucleation sites become active, so that only very few bubbles exist. The same explanation holds for the variation of $\Delta T(\varphi)$ with the reduced pressure p^*, because the active nucleation site density is much smaller at low and much greater at high reduced pressures than at intermediate. Further reasons are the smaller difference between the densities of vapour and liquid at high reduced pressures and the large bubble departure diameter at very low reduced pressures.

RESULTS FOR THE BUBBLE FORMATION

The average numbers of cumulative and momentary sites for all image sequences of video investigated for two pressures are shown in Figure 6 as function of the heat flux (left) and of the critical radius r_c for stable bubble nuclei (right). There is a large difference between the cumulative and momentary numbers of sites, e.g. the cumulative numbers of sites are for a factor 70 higher than the momentary for p* = 0.2 and q = 20 kW/m². The decreasing effect for the highest heat fluxes may be due to the difficulty to properly distinguish the single active sites for intensive boiling with turbulent bubble movement, and with interaction of the growing bubbles with those upstreaming along the heated surface. The local distributions of the cumulative nucleation sites near the flank of the horizontal tube are shown in Fig. 6, left, for a selected boiling condition (intermediate heat flux q = 10 kW/m²) and a selected sequence near the flank of the copper tube. Each area is subdivided in cells for better comparison with the size of the topographies investigated for the roughness analysis. The active sites show in some parts some agglomerations on the fine sandblasted surface, but mainly the tube surface is uniformly covered by active nucleation sites, see Fig. 7, left.

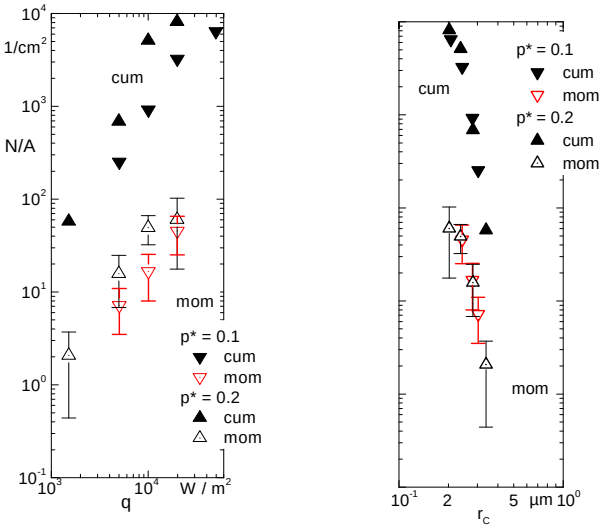

Figure 5. The number of active sites as function of q (left) and of the critical radius of a stable nucleus (right)

The contribution by upstreaming bubbles may be observed in the left and right part of the diagram in Fig. 6. An indication of the interaction between adjacent sites is the statistical analysis of their nearest distances such as the size distributions in Fig. 6, right. The histograms may be described by a modified Weibull function. The smallest distances are far away from the value of the critical radius of ca. $r_c \approx 0.25$ µm, but it is expected that the bubbles will coalesce during their growth, especially near the departure moment ($d_A \approx 0.25$mm on the flank of the test tube, see Figure 10) - if they are activated simultaneously. The numbers of momentary nucleation sites are not constant during the sequence of about 500 images = 500 ms. The temporal resolution of the activation is shown in Figure 7 for the same boiling conditions as in Figure 6. A cycle of activation is succeeded by one of deactivation with a regular fluctuation to the average value of $N/A_{M,m}$. The momentary active nucleation sites are distributed irregularly over the surface, see the crosses in Fig and the symbols in Figure. There are more active sites in this ms as in average, see Fig 7 and 8. In consequence, the model assumption of stable nucleation sites with constant frequence have to be checked. For fine sandblasted surfaces, the most of the nucleation sites are activated once during the entire sequence.

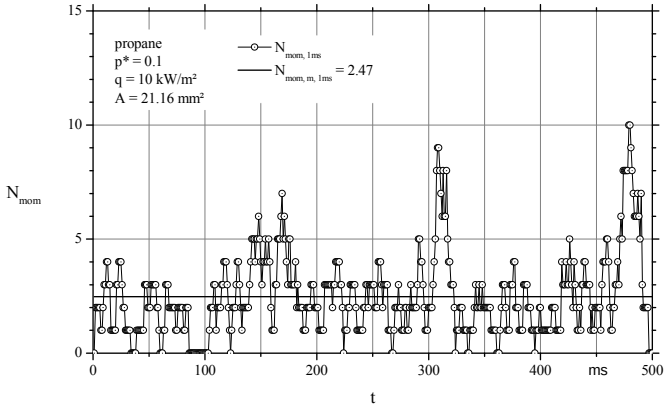

Figure 7. Temporal resolution of the activation with N/A_M as function of the evaluation time of the video sequence by different evaluation times

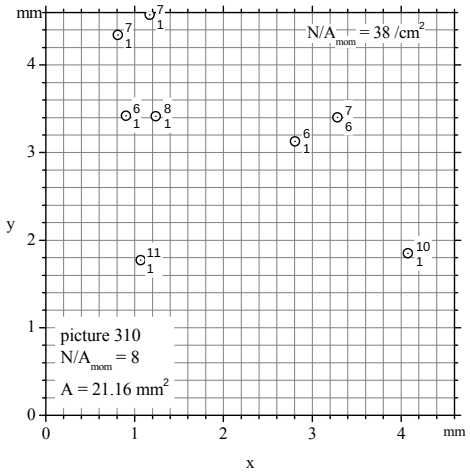

Figure 8. Local distribution of the active nucleation sites for p* = 0.1 and q = 10 kW/m² on the fine sandblasted surface of the copper tube

Most frequently bubbles are measured manually. Shortly after departing from the surface the bubbles are usually not spherical, but rather elliptical. In this case the largest horizontal and vertical diameter, d_x and d_y, is measured at this point in time. The departure diameter d_A is computed as an effective diameter according to

$$d_A = (d_x^2\, d_y)^{1/3} \qquad (4.1)$$

The bubble departure diameter is a function of the position of the active nucleation sites on the horizontal tubes, which is demonstrated in Figure 9 at p* = 0.1 and two different heat fluxes. The flank of the tube corresponds to 270° (s. also Fig). The size distribution of the bubble departure diameter is quite large, see the scatter of the data in Figure 9, right, while d_A seems to be influenced by the heat flux due to the increasing influence of the interaction of the bubbles. The measured values of d_A increase systematically from the flank of the tube (φ = 270) to the top or the bottom. This effect has also been found by Luke and Gorenflo [8] for propane on a smaller steel tube. The data $d_{A,min}$ at φ = 270° are characteristic for this part of the tube and are lower than acc. to calculation methods like those of Weckesser [7]. The relative increase of the calculation method of [8] are in good agreement with the new experimental data. The bubbles are larger at the bottom of the tube, where only a component of the gravitational acceleration is effective, and the larger bubbles on the top are caused by a higher superheat of the up streaming liquid and by separation and recirculation. This discussion shows that applying results on horizontal plates to horizontal tubes is questionable.

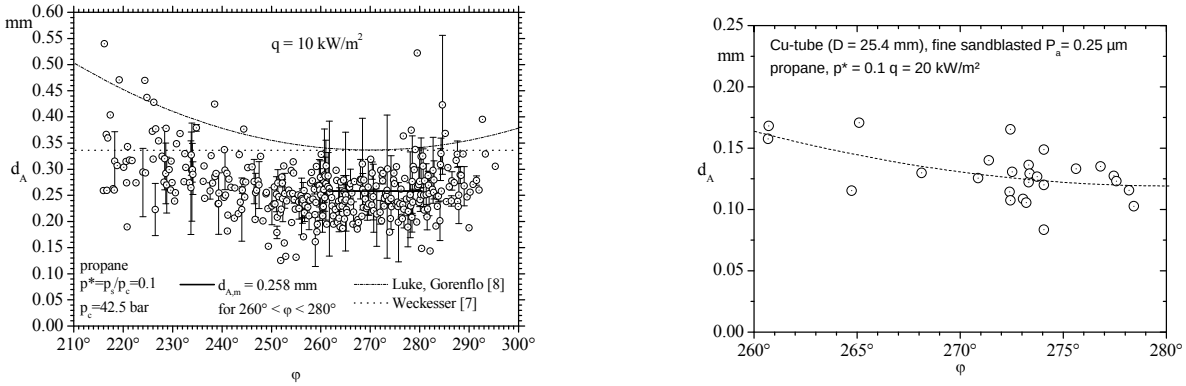

Figure 9. Bubble departure diameter as function of the azimuthal position and comparison with calculation methods of the literature for p* = 0.1 and two heat fluxes for boiling propane on a horizontal fine sandblasted copper tube (φ = 270° is near the flank of the tube).

The results of the evaluation of one sequence for propane boiling on a fine sandblasted copper tube surface with p* = 0.1 and a heat flux of q = 10 kW/m² near the median line of the tube is represented in Figure 11. The bubble No 707 is identified and tracked until it vanishes from the image (squares), cf also Figure 10. Bubbles smaller than d_B = 0.05 mm cannot be detected by this method due to the insufficient resolution in pixels. Shortly after activation the bubble is growing on its nucleation site to the departure diameter (d_A = 0.30 mm; closed squares). After departure, it still grows while it is streaming up along the superheated tube surface (open squares). The scatter within the data for the bubble diameter is due to the variation of the visible two-dimensional shape (the projection area) of the bubble, while the third dimension in direction of the tube surface cannot be evaluated. The bubble is only analysed from its top. The variation of the shape follows the influences caused by the movements of the liquid and the up-sliding bubbles. The uncertainties can be estimated to be in the order of 7% to 12% of the values of the bubble diameter. The growth of a bubble situated on another nucleation site (circles in Figure 11) is stronger and it departs with larger diameter from its site (d_A = 0.45 mm).

The sliding path of the bubbles No 707 and 748 along the tube surface is shown in Figure 11. The bubble No. 707 is drifted due to convective effects to the left side, while the way of No. 748 is quite irregular (Compare also the variation in the bubble diameter in Figure 9).

The sliding bubbles can be separated in different types: the first one still grows by contact with the superheated boundary layer during its movement upwards, see Figure 12. The diameter of the second type remains more or less constant because it is obviously far away from the superheated surface. The way of the bubble No. 60 is strictly upwards and undisturbed, see Fig 12, while the bubbles closer to the superheated surface as No 498 drift to the left side, see Figure 12.

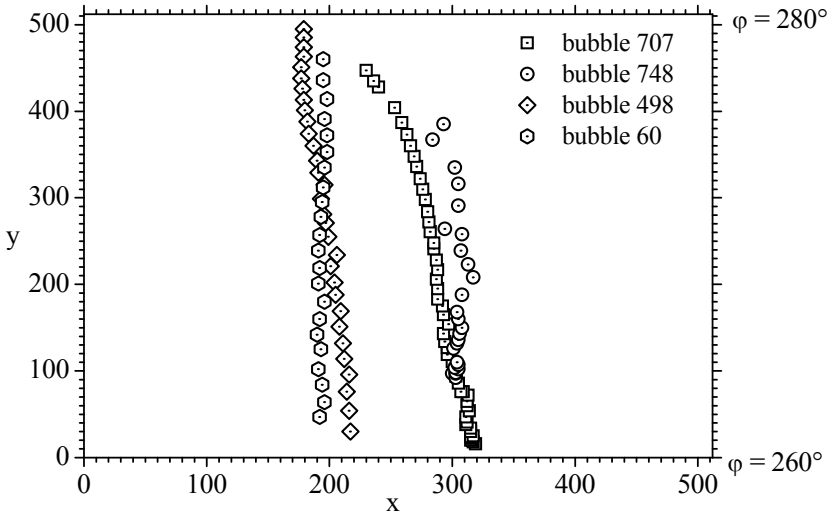

Figure 10. The sliding path of selected up streaming bubbles along the superheated boundary layer of the fine sandblasted copper tube for boiling propane (p* = 0.1 and q = 10 kW/m²).

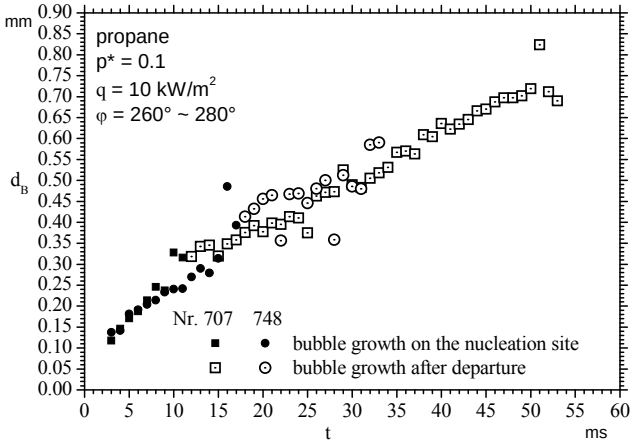

Figure 11. Two examples of bubbles growing on their nucleation sites and then sliding along the superheated surface

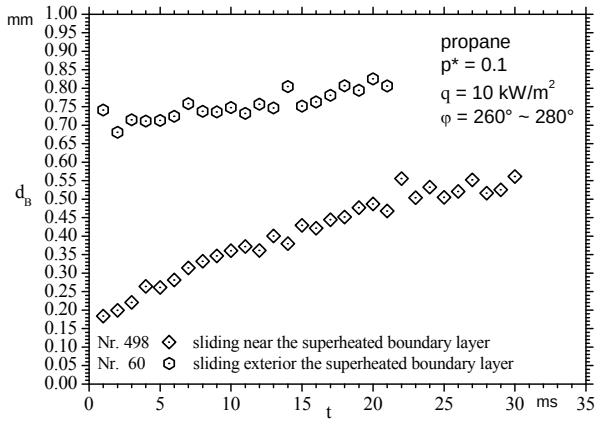

Figure 12. Examples of bubbles moving upwards and growing or which do not grow (bottom) by sliding along the superheated surface

CONCLUSIONS

The coherent new data of heat transfer, bubble formation and roughness from the same heated surface gives new idea for the activation of bubbles on the surface, their growth on the site and by sliding up and the manifold interaction between them. The evaluation of high speed video images offers the possibility to receive much more detailed information about the activation of bubbles and of the heated surface and its cavities, but it was very time consuming. Semi-automatic and automatic programs are developed to identify and track the individual bubbles. Some video sequences have been analysed previously for a few examples because of the large amount of data. The cumulative active nucleation sites are distributed statistically, especially for low heat fluxes agglomerations are observed over the median line of the horizontal test tube. The density distribution of the nearest distances between the adjacent sites shows that interaction of bubbles growing at their sites is possible if they are active simultaneously. The growth of the bubbles sliding-up along the superheated tube surface results in values nearly twice the bubble departure diameter. Their contribution to the vapour production in model assumptions has to be considered in future. The long-term aim is that the new results shall enable to interpret the fundamentals in boiling heat transfer and to establish new calculation methods using them.

MEAN FLOW AND THERMO-HYDRAULIC BEHAVIOUR IN INCLINED LOUVERED FINS

C. T'Joen[1,*], H. Huisseune[1], M. De Paepe[1]
[1]Department of Flow, Heat and Combustion Mechanics, Ghent University, Belgium

ABSTRACT. In this study a hybrid fin design, the inclined louvered fin, is considered. The aim of the design is to increase heat transfer at low Reynolds numbers compared to louvered fins. To study the flow field behaviour a series of flow visualisation experiments have been performed to measure the mean flow angle and to observe the transition to unsteady flow. The mean flow angle was determined using validated CFD simulations. Parallel a series of wind tunnel measurements were performed to determine the thermo-hydraulic characteristics. The impact of the fin pitch, fin angle and louver thickness were studied. A strong coupling was found between the flow behaviour and the thermo-hydraulics showing clear boundary layer driven flow.

Keywords: *compact heat exchanger, inclined louvered fins, flow behaviour*

INTRODUCTION

When exchanging heat with air, the main thermal resistance in a heat exchanger is located on the air-side. To increase the heat transfer rate, the exterior surface area is enlarged by adding fins. Manufacturers continuously seek to increase the fin performance in order to reduce the heat exchanger size and cost. Today, highly interrupted surfaces are widely used to enhance the thermal performance of compact heat exchangers. These interrupted fins exploit two mechanisms to provide a performance improvement compared to continuous fins: (1) interrupted surfaces restart the thermal boundary layer, and because the resulting average thermal boundary layer thickness is smaller for several short plates than for one long plate, the average convective heat transfer coefficient is higher for the interrupted surfaces; and (2) above a critical Reynolds number, interrupted surfaces can cause vortex shedding and the resulting mixing and flow unsteadiness result in an increased heat transfer. Two widely used interrupted fin designs are the offset strip or slit fin and the louvered fin. Both consist of arrays of flat plates. In slit fins these plates are aligned to the main flow, while in louvered fins the plates are set at an angle to the flow. The inclined louvered fin is a hybrid design of louvered and offset strip fins, as described by Shah *et al.* [1]. The plates are aligned with the main flow (Fig. 1) but are set out in a staggered layout, forming a stair like deflecting channel. In Fig. 1 the main geometric parameters are indicated: the fin pitch F_p, the louver pitch L_p, the fin thickness t, the fin angle φ and the number of louvers. Just as in louvered fins there are distinct inlet-, turnaround- and exit-louvers. Usually air-side heat transfer and pressure drop characteristics of a new fin type are determined from experimental data (using the Wilson plot measurement technique, see e.g. Rose [2]) on full scale heat exchangers. This method requires the manufacturing of complete exchangers and thus is expensive. An alternative is to study a scaled model of the novel fin type. This approach was selected at UGent to study the inclined louvered fin.

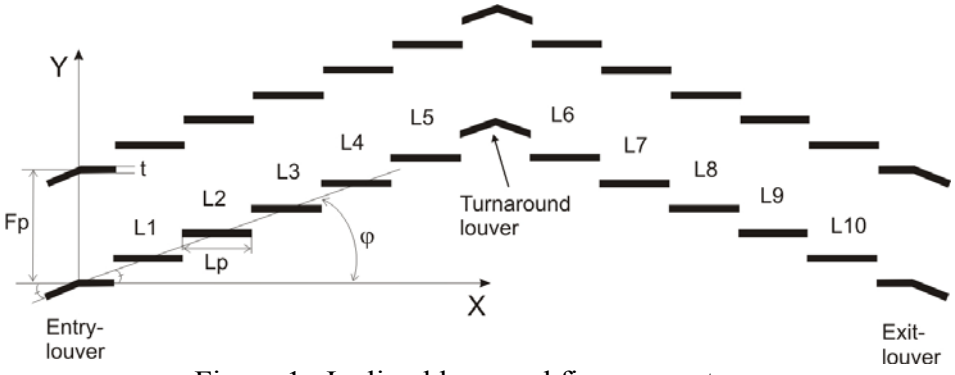

Figure 1. Inclined louvered fin: parameters.

Tanaka *et al.* [3] used a simple analytical model to study the flow in inclined louvered fins (with a nonzero louver angle – in this study the louver angle is kept constant at 0°) and concluded that a high average heat transfer coefficient could be realized provided that (1) the minimum traverse space to the adjacent louver is wide enough to include the boundary layers and (2) the longitudinal distance between the stream-wise louvers is wide enough to eliminate wakes. After a series of visualizations using large scale models, a single heat exchanger was built, tested and compared to a standard louvered fin. In the considered velocity range (1-5 m/s) the average heat transfer coefficient of the inclined louvered fin core was 16% higher and the pressure drop 21-27% lower compared to the standard louvered fin heat exchanger. This example clearly indicates the potential of this fin type.

MEAN FLOW BEHAVIOUR IN INCLINED LOUVERED FINS

Both in louvered fins and slit fins previous studies have shown a strong link between the thermo-hydraulic behaviour and the flow characteristics (slit fins: DeJong and Jacobi [4] – louvered fins: DeJong and Jacobi [5] and Achaichia and Cowell [6]). The interrupted surface breaks up the thermal boundary layer increasing the heat transfer coefficient, and the accumulation of flow perturbations due to the louvers results in a gradual transition to unsteady flow, as shown by Tafti and Zhang [7]. Using mass transfer measurements DeJong and Jacobi [4] showed that unsteady flow results in increased (local) heat transfer coefficients. In louvered fins an additional flow characteristic arises: at high Reynolds numbers the flow is deflected. Louvered fins show two different flow profiles, as shown by Cowell *et al.* [8]. At low Reynolds numbers the thick boundary layers block the passage between the louvers, forcing the flow between the different fins. This is referred to as 'duct oriented flow' in Fig. 2. As the Reynolds number increases the flow passages open up and 'louvered oriented flow' is created. This is indicated in Fig. 2. As is shown, the flow is deflected at high Reynolds numbers; extending its flow path throughout the fin array (the right side of Fig. 2 gives an impression of the modified flow path). For high Reynolds numbers the flow angle approaches the louver angle. This increases the heat transfer rate. But as the flow path is extended so is the frictional pressure drop. The degree of flow deflection is usually quantified using the concept 'flow efficiency' η. This is the ratio of the mean flow angle α to louver angle θ, Eq. (1). Achaichia and Cowell [6] found a strong link between the heat transfer rate of flat tube louvered fin heat exchangers and the mean flow behaviour, relating the Stanton number to η (Eq. (2)).

$$\eta = \frac{\alpha}{\vartheta} \tag{1}$$

$$St = 1.18 \cdot \eta \cdot \mathrm{Re}_{Lp}^{-0.58} \tag{2}$$

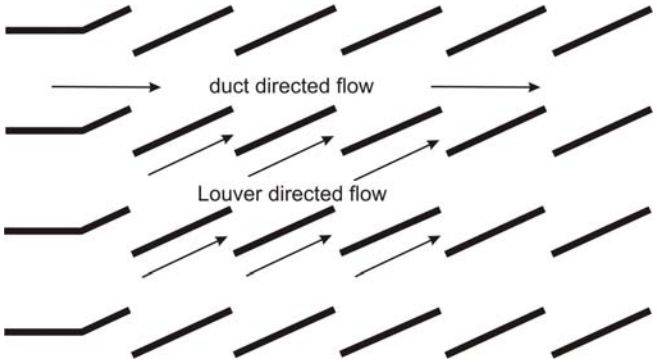

Figure 2. Duct directed flow versus louver directed flow.

Using a large database of validated two dimensional numerical CFD-simulations, Zhang and Tafti [9] determined a correlation for the flow efficiency of louvered fins. Results show that η is strongly dependent on geometrical parameters, especially at low Reynolds numbers. Flow efficiency increases with Re and louver angle, while decreasing with fin pitch and thickness ratio.

If the geometry of the inclined louvered fin (Fig. 1) is considered, *a priori* it is clear that similar phenomena as in louvered fins will occur. At low Re_{Lp} the thick boundary layers will block the passages between the louvers, forcing the flow to wind up and down. As Re_{Lp} increases, the flow passages will open up and the flow becomes more slit fin like, aligned with the louvers. To study the flow behaviour through the fin array and to determine at which Reynolds number the flow becomes unsteady, a series of water tunnel experiments were performed. In the closed loop water tunnel (located at the University of Illinois), the water is circulated using a frequency controlled pump through a plenum, followed by a contraction section, the test section and then finally a reservoir. To ensure a uniform flow at the inlet of the test section, two honeycomb flow straighteners are used in the contraction. The test section has a length of 0.4 m, a width of 0.3 m, a height of 0.3 m and is made of transparent plexiglass. A digital camera was used to record the images. The water temperature is measured using an E-type thermocouple. To determine the water velocity the time required for a single streakline to travel a given distance (0.25 m) was measured using a chronometer. To visualise the flow, dye is injected at a specific point just upstream of the test section, highlighting a single streakline. Scaled models (20:1) of the inclined louvered fin were placed in the test section. Six configurations with varying geometric parameters were studied (Table 1, L_p = 0.02 m). The scaling factor was selected in order to obtain sufficient spatial resolution, while maintaining a sufficiently large number of fin rows to ensure periodic flow behaviour. DeJong and Jacobi [10] showed that wall effects can result in a strong distortion of the measured mean flow angle. More details on the measurement setup and procedure can be found in T'Joen *et al.* [11].

Table 1. Geometric parameters of the studied inclined louvered fins

Fin parameters	Configuration 1	Configuration 2	Configuration 3
F_p	0.0340 m	0.0225 m	0.0340 m
φ	12.64°	12.64°	30.96°
t	0.002 m	0.002 m	0.002 m
Fin parameters	Configuration 4	Configuration 5	Configuration 6
F_p	0.0225 m	0.0276 m	0.0276 m
φ	30.96°	19.78°	19.78°
t	0.002 m	0.002 m	0.004 m

In order to quantify the flow behaviour in the inclined louvered fins, the 'fin angle alignment factor' ζ (defined in Eq. (3) as the ratio of the mean flow angle α to the fin angle φ) is introduced. Note that the definition is identical to that of the 'flow efficiency' η for standard louvered fins. For louvered fins, a high value of η corresponds to a flow almost parallel to the louvers, resulting in large heat transfer coefficients due to thin boundary layers. Thus high values of η are good from a heat transfer perspective, resulting in the term flow '*efficiency*' for η. For the inclined louvered fin array, high values of ζ indicate that the flow along the louver surface is dramatically reduced, and the local heat transfer coefficient can be expected to be reduced. This would make the term 'flow efficiency' misleading for inclined louvered fins, thus an alternate term is used, the 'fin angle alignment factor'.

$$\varsigma = \frac{\alpha}{\varphi} \approx \frac{\tan\alpha}{\tan\varphi} \tag{3}$$

For each of the six configurations images of the flow field were recorded at various Reynolds numbers. At each Re_{Lp} the dye injection point was varied over the channel width. This resulted in a series of images of various streaklines which, once combined, provide an overview of the total flow field at a given Reynolds number. For each of the images ζ can be determined graphically by using the approximation in Eq. (3). The images were imported into a graphical software package. The mean flow angle was determined between the point where the streakline enters the fin array and the midpoint of the turnaround louver. For each configuration a series of graphs can then be produced, one per Reynolds number, showing the local values of ζ set out against the injection location. This value represents the position of the injector relative to the fin passage and is scaled with the fin pitch, so it ranges from 0 (top of the fin passage) to 1 (bottom of the fin passage). An example is shown in Fig. 3 (filled symbols). The error bars are indicated. A detailed description of the uncertainty analysis can be found in T'Joen *et al.* [11]. There is clearly a strong variation depending on the injection location.

To determine a correct average value the gaps between the data points should be filled with additional data. To this end, a series of numerical simulations were undertaken. The flow through the fin configurations was simulated using Fluent©. Two dimensional cases were studied using unstructured quadrilateral meshes. A single louver row was simulated with an entry region (two fin pitches) and exit region (five fin pitches). The height of the computational domain is set to one fin pitch with periodic boundary conditions on the top and bottom of the domain. The double precision segregated solver was used with convergence criteria of 1e-8 for continuity and velocity components and 1e-6 for energy. A grid independence study was performed.

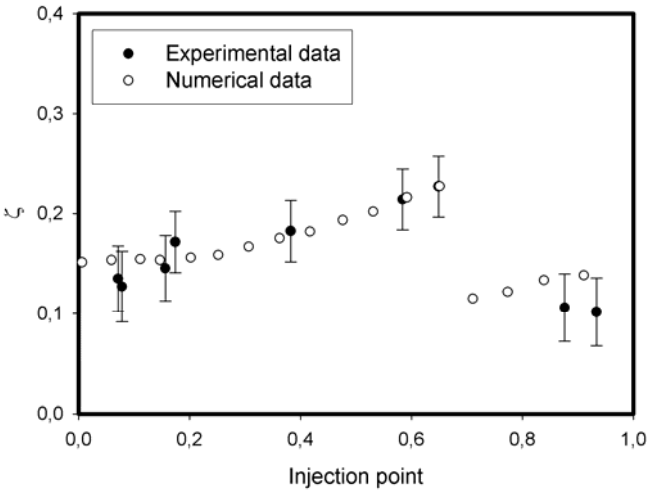

Figure 3. Comparison of the experimentally and numerically determined local ζ values set out against the injection point, configuration 5 - Re_{Lp} = 402.

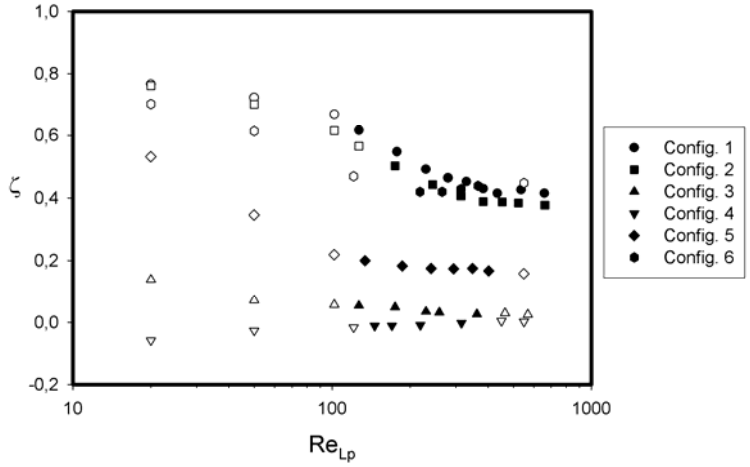

Figure 4. Averaged ζ values for the 6 different configurations over the studied Reynolds number range. The filled symbols represent validated numerical simulations. The open symbols are purely numerical cases without accompanying experimental data.

In order to determine ζ from the simulations, the same procedure was used as for the water tunnel experiments. The streamlines were visualized using the 'path lines' option and the resulting image was exported to the graphical software. This resulted in a set of numerical data points, spread out evenly over the fin spacing, as can be seen in Fig. 3. The agreement between the simulations and the experimental data is very good. Using the validated numerical data it is possible to determine a well defined average value for ζ. These values are shown in Fig. 4 for the different configurations. Compared to flow efficiency data of louvered fins, two key differences can be seen:

- The flow deflection is considerably lower than those found in standard louvered fins, Zhang and Tafti [9] reported η values between 0.5 and 0.95 in the same Re_{Lp} range. So it is clear that inclined louvered fins generate flow deflection, but that it is less pronounced.
- Figure 5 also shows that for most configurations (3 - 4 - 5 - 6) the flow deflection is nearly constant in the considered Reynolds range. This is a large difference with standard louvered fins, which show a sharp reduction in η (and thus become less effective) once Re_{Lp} drops below 300. The flow deflection also shows an opposite trend in inclined louvered fins, increasing as the Reynolds number decreases.

UNSTEADY FLOW IN INCLINED LOUVERED FINS

During the flow visualization experiments the transition from steady laminar flow to unsteady flow was studied as well. It was found that the initial instability appears in the wake of the exit louver. As the Reynolds number increases the flow instabilities move upstream into the fin array. The onset of unsteady flow occurred at low Reynolds numbers (200-300). The transition was triggered geometrically due to the recirculation zones present on top and underneath of the inlet, turnaround and exit louver. Figure 5 shows the Reynolds numbers at which the first unsteady flow patterns were detected at the inlet-, turnaround- and exit-louver for configurations 1-5. It can be seen that the fin pitch and fin angle both impact the transition to unsteady flow. The louver pitch L_p was used to make other length scales non dimensional. This is expressed by a superscript *, so the ratio of the fin pitch and louver pitch is noted as F_p^*. For comparison the transitional behaviour in 2 louvered fins (Tafti and Zhang [7]) and 1 slit fin (DeJong and Jacobi [4]) are shown as well. As can be seen the transition in inclined louvered fins occurs at much lower Reynolds numbers and also moves upstream much faster than in the louvered fin or slit fin. This is consistent with a transition that is purely geometrically triggered rather than due to the accumulation of flow disturbances.

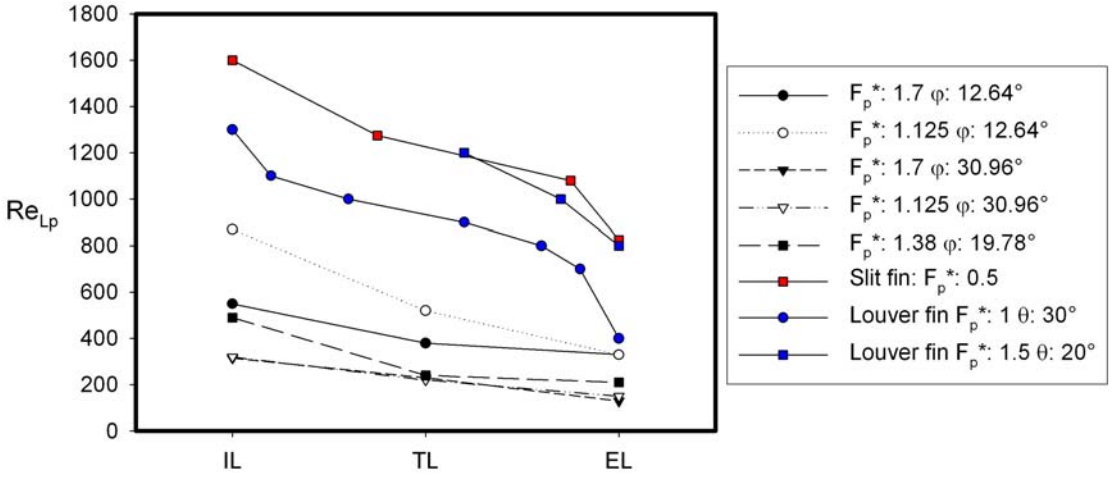

Figure 5. Reynolds number of the onset of unsteady flow at three locations in the inclined louvered fin configurations compared with similar data for louvered fins [7] and a slit fin [4].

THERMO-HYDRAULIC BEHAVIOUR OF INCLINED LOUVERED FINS

To determine the thermo-hydraulic characteristics of the inclined louvered fin, a series of wind tunnel experiments was performed on the scaled models. The air mass flow rate is measured using a calibrated orifice plate (ISO 5167). The fin parts are made out of printed circuit board material coated with a thin copper layer on both sides (2 mm thick). To provide heating (a uniform heat flux) a current is sent through the copper layer. The different louvers are connected in series to each other electrically using wires, ensuring the same heat flux is dissipated throughout the fin array. The test section and the downstream settling channel are insulated using 5 cm thick PUR foam in order to reduce the heat loss to the environment. The pressure drop over the test section is measured using a differential pressure transducer. These measurements were done without heating. The pressure taps were set along the sides of the channel. The air inlet temperature was measured using a thermocouple. To determine the heat transfer coefficient the local surface temperatures are measured using K-type thermocouples. A measurement louver was made using balsa wood. Nineteen thermocouples were inserted in the centre along the flow direction in order to measure the surface temperature change along the flow path. In the experiments the local heat flux q is imposed, and the local surface temperature is measured. Thus only a reference temperature T_{ref} is required to determine the local heat transfer coefficient, Eq. (4). To allow for easy comparison with other fin types the inlet temperature was used as a reference value. The resulting local heat transfer coefficients are averaged out over the fin surface area to determine the Colburn j factor. During the experiments it was found that a temperature difference was present between the top and the bottom of the measurement louver, due to the finite conduction of this louver. By measuring the thermal conductivity of the balsa wood (0.045 W/mK) the conductive flux q_{cond} could be determined. This flux through the louver is then added to or subtracted from the imposed heat flux boundary during the data reduction (Eq. (4)).

$$h = \frac{q \pm q_{cond}}{T_w - T_{ref}} \tag{4}$$

Figure 6 shows the parallels between ζ, the friction factor f and the Colburn j-factor for different configurations. As can be seen, there is a strong link between the mean flow behaviour and the resulting thermo-hydraulics: a strong change in ζ results in a transition in the friction factor curves away from the laminar flow solution (solid line). The same trends were found in the heat transfer

data. Increasing F_p^* lowers the friction factor. For the small fin angle cases the Colburn factor increases as F_p^* decreases due to increased fin compactness, while for the larger fin angle cases the reverse occurred. This is probably due to thermal wake interference. The small fin angle cases show two distinct transition points, one due to the change in ζ and the other due to the onset of unsteady flow. For the cases with a large fin angle only the transition due to unsteady flow can be found as the fin angle values are already low and extremely low Reynolds numbers would be required to detect the transition due to the sudden shift in ζ.

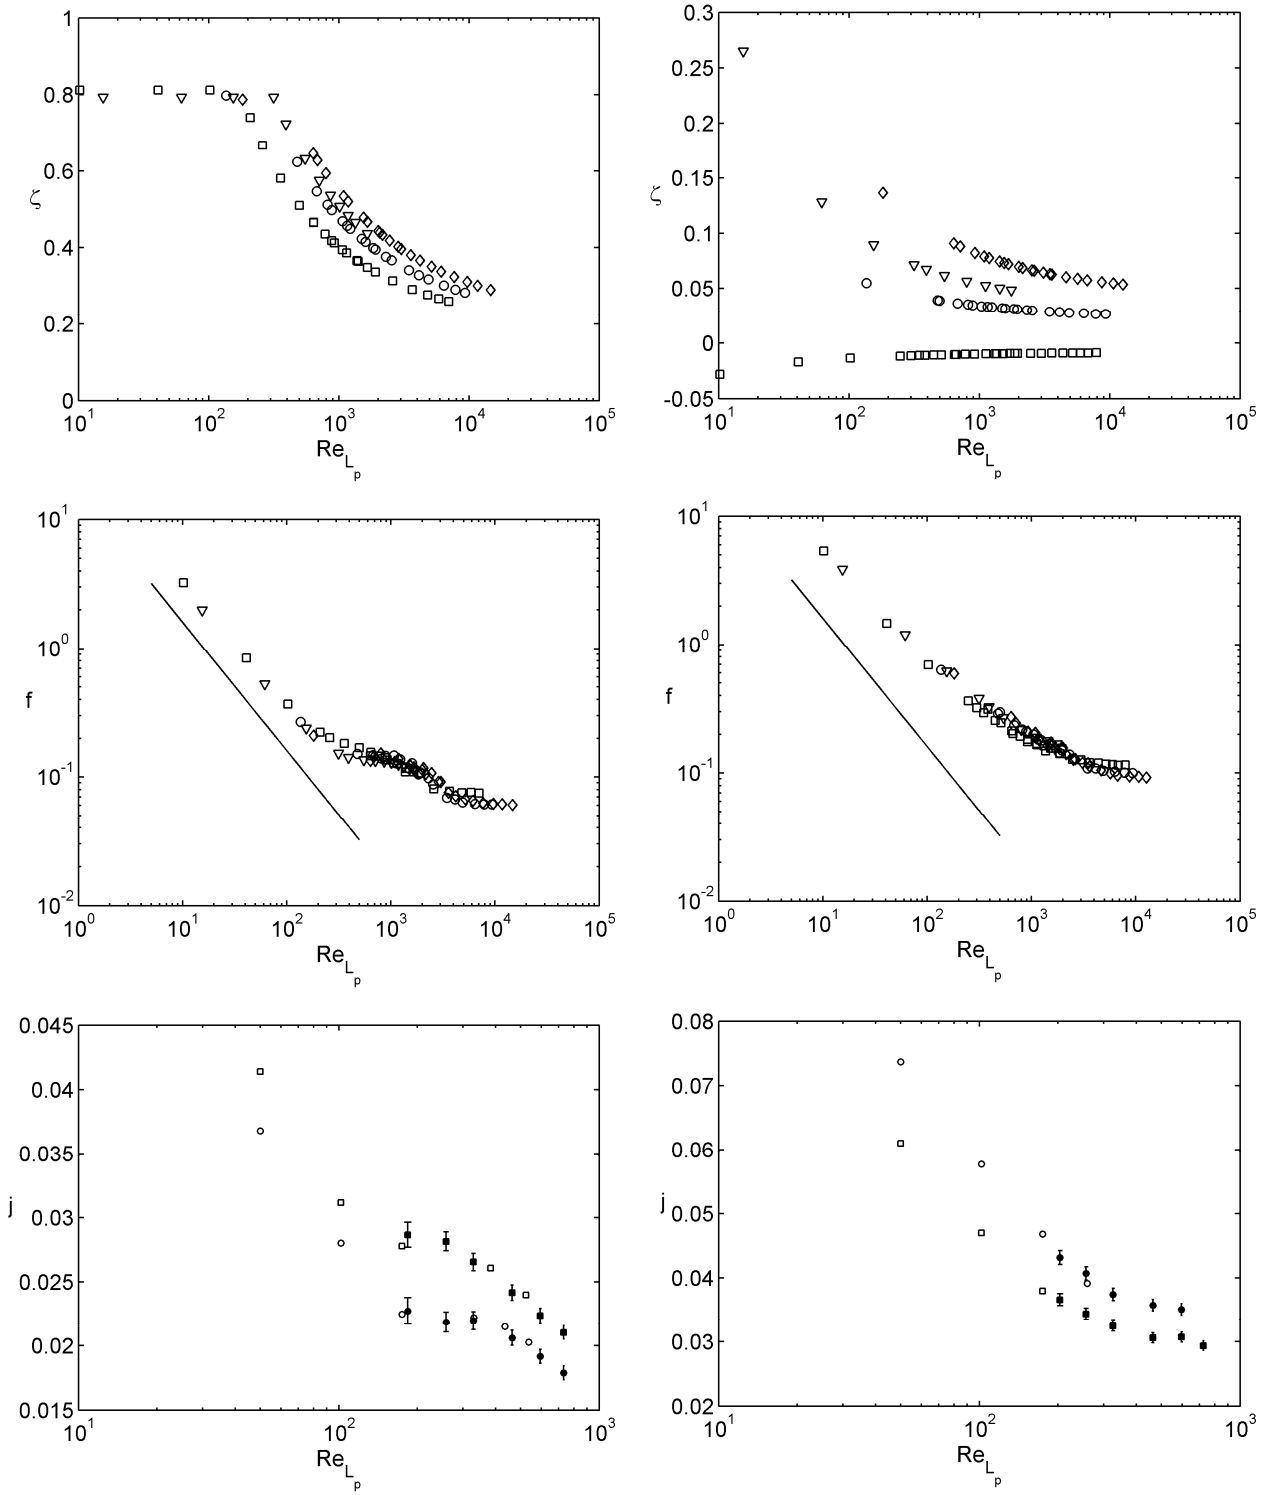

Figure 6. Fin angle alignment factor (top row), friction factor (middle row) and Colburn factor (bottom row) set out against Re_{Lp}. Left column: φ = 12.64°, right column: φ = 30.96°. Filled symbols: experimental data – open symbols: numerical data. Square symbols: $F_p^* = 1.125$, circle symbols: $F_p^* = 1.5$, triangle symbols: $F_p^* = 1.7$, diamond symbols: $F_p^* = 2$.

NOMENCLATURE

F_p	fin pitch [m]
L_p	louver pitch [m]
Re_{Lp}	Reynolds number based on the inlet velocity and the louver pitch [-]
q	heat flux [W/m²]
t	fin thickness [m]
α	mean flow angle [°]
ζ	fin angle alignment factor [-]
θ	louver angle [°]
φ	fin angle [°]

CONCLUSIONS

In this study the flow behaviour and thermo-hydraulic characteristics of a hybrid fin design, the inclined louvered fin, have been reported. Using a combination of experimental (water tunnel visualization) and numerical (CFD simulation) data the flow behaviour was quantified through the fin angle alignment factor ζ. At low Reynolds numbers the flow is deflected due to boundary layer growth. Comparison of the ζ curves with the j and f data set out against Re, revealed the strong link between the flow and j – f. A sharp decrease in ζ results in a rise of both j and f, as the flow becomes better aligned with the louvers. The onset of unsteady flow further increases j and f. During the visualization it was shown that unsteady flow occurs at low Reynolds numbers (~200-300) and that this transition is geometrically driven by recirculation zones on the inclined sections of the fin array. These findings could have significant impact for low Reynolds number applications.

HEAT TRANSFER FROM A HEMISPHERCAL CAVITY TO A SWIRL IMPINGING JET

V.I. Terekhov, Yu.M. Mshvidobadze
Kutateladze Institute of Thermophysics SB RAS, Novosibirsk, Russia

ABSTRACT. Experimental results on investigation of heat transfer at interaction of an air impact jet with a semi-spherical cavity are presented in this work. This research is continuation of investigations of turbulent jet interaction with complex surfaces and search for the method of heat transfer control. Experiments were carried out with fixed geometry of a semi-spherical cavity (D_C = 46 mm) and swirl parameter (R = 0; 0.58; 1.0; 2.74). The distance between the axisymmetrical nozzle and obstacle was 2÷10 sizes over the nozzle diameter, and the Reynolds number varied within $Re_0 = (1÷6)\cdot10^4$. It was found out that with an increase in swirling heat transfer intensity decreases because of fast mixing of the jet with ambient medium. In general, the pattern of swirl jet interaction with a concave surface is complex and multifactor

Keywords: *semi-spherical cavity, impinging swirl jet, heat transfer*

INTRODUCTION

Jets impinging onto heat-exchanging surfaces can be used in many technical apparatuses as very efficient heat-transfer intensifiers. Interest in this field was initiated many years ago, and since then ample data concerning this problem have been accumulated [1, 2]. Nonetheless, jets of interest still attract considerable attention, and extensive studies aimed at searching for new methods to control heat and mass transfer in such systems are presently under way. One strategy here implies modification of the surface onto which the jets impinge with obstacles. The authors of [3-5] examined heat transfer in narrow channels in which a system of jets impinging onto a surface modified with cavities was organized. It was shown that such systems exhibit good performance characteristics and can be used, in particular, for cooling turbine blades from inside. Yet, the physical reasons underlying the observed intensification of heat-transfer processes in the systems of interest have remained unveiled.

Cavities used as obstacles modifying the streamlined surfaces attract considerable interest as they proved capable of generating exotic self-oscillatory flow modes and intensifying heat transfer [6 - 9]. In the case of jets impinging onto heat-exchanging surfaces the interaction pattern of the jet flow with the surface is much more complicated compared to a flat surface. For instance, vortex formation processes and local flow separations induced by obstacles prepared in the form of cavities may give rise to a complex, unstable flow involving large-scale low-frequency oscillations, Taylor-Görtler vortices, etc. Under such conditions, accurate prediction of heat-transfer processes becomes problematic, although this problem was addressed in several publications.

The aerodynamic structure of the flow and the heat transfer from hemispherical cavity versus the jet Reynolds number and as functions of the distance from the nozzle exit to the heat-exchanging surface were examined in [10]. The jet flow was not swirling, and the cavity-to-nozzle diameter ratio was D_c/d_0 =5.4. The average heat transfer from the cavity surface was found to be decreased twice compared to the case of a flat surface, all other conditions being identical. With decreasing the nozzle diameter, the heat transfer grows in value and, according to [11], at D_c/d_0 = 44 its

intensity may become exceeding the same quantity for flat surface. Moreover, in the region outside the cavity the thermal interaction between the lateral flow and the jet rapidly degenerates, making the heat transfer almost vanishing here [10]. In the cavity, pronounced vortex formations arise. These formations, resembling Taylor-Görtler vortices, give rise to coherent structures that can be easily registered by heat flow microsensors.

In [12], local heat transfer in hemispherical cavity was examined as a function of cavity-to-nozzle diameter ratio in the range $D_C/d_0 = 11 \div 30$. Here, unlike in [11], increase in the nozzle diameter was found to suppress heat transfer throughout the whole examined range of Reynolds numbers, $Re_0 \sim 10^4$ to $5 \cdot 10^4$. Thus, the experimental data concerning the interaction of jet flows with curvilinear surfaces are still few in number and contradictory.

The problem becomes even more complicated if the jet flow impinging onto an obstacle has a rotational velocity component. So far, the heat transfer and the structure of flow between a swirling jet and a surface onto which this jet impinges remain poorly understood. Reported studies [13-17], also few in number, show the interaction of a swirling jet with an obstacle to be a complex many-factor process. An increase in jet pre-rotation intensity enhances mixing processes in the system; as a result, the heat transfer of the surface interacting with the jet at large nozzle-to-surface separations ($L/d_0 > 6$) turns out to be substantially reduced in comparison with non-swirling jets. At small nozzle-to-surface separations, $L/d_0 < 6$, the picture may be opposite, with additional maxima emerging in the radial distribution of heat-transfer intensity due to specific formation pattern of swirling jets with different pre-rotations, Reynolds numbers, and separations between the jet turning point and the surface onto which the jet impinges.

Expectedly, pre-rotation of the jet approaching a surface modified with a spherical cavity will complicate the problem. The fluid leaving the cavity will interact with the rotational jet flow impinging onto the obstacle, thus causing the formation of unsteady three-dimensional flows hard to predict numerically.

The purpose of the present study was to experimentally examine the time-average heat transfer from a surface with spherical cavity during impingement of a swirling jet onto this surface. Such flows are often encountered in low-temperature plasma generators and in power-plant cooling systems.

EXPERIMENTAL FACILITY AND PROCEDURE

The experiments were carried out on an experimental setup whose schematic diagram is shown in Fig. 1. This setup was described in detail elsewhere [18]. A room-temperature axisymmetric swirling air jet emanated out of the nozzle whose diameter was $d_0 = 8.5$ mm. The cavity diameter was fixed, equal to $D_C = 46$ mm, and the cavity depth was either $\Delta = 0$, 12, or 23 mm. The gas-flow velocity U_0 at the nozzle exit plane was varied in the range from 20 to 100 m/s, corresponding to Reynolds numbers $Re_0 = U_0 d_0/\nu = 10^4 \div 5 \cdot 10^4$.

The distribution of flow velocity over the nozzle outlet was almost uniform, the turbulence number being $Tu \cong 0.3\%$. The jet approached the obstacle normally, and the nozzle-to-surface separation S was varied from 0 to $10d_C$.

The jet flow was made swirling by pre-rotating it with a flat swirler with variable slit inclination angle. The jet pre-rotation parameter, defined as the momentum ratio between the circumferential component of the jet flow and the jet flow along the jet axis, was R = 0, 0.58, 1, or 2.74.

The test section, 50-mm thick and 190-mm in diameter, was prepared from copper. The desired temperature difference between the jet and the obstacle, about 40^0 in the majority of tests, was achieved with the help of an ohmic heater installed over the obstacle. The choice of copper, having a high value of thermal conductivity, as the obstacle material was motivated by the desire to organize the boundary condition $T_w \cong$ const at the obstacle surface. The temperature of the streamlined surface and the flow temperature were measured by chromel-copel thermocouples.

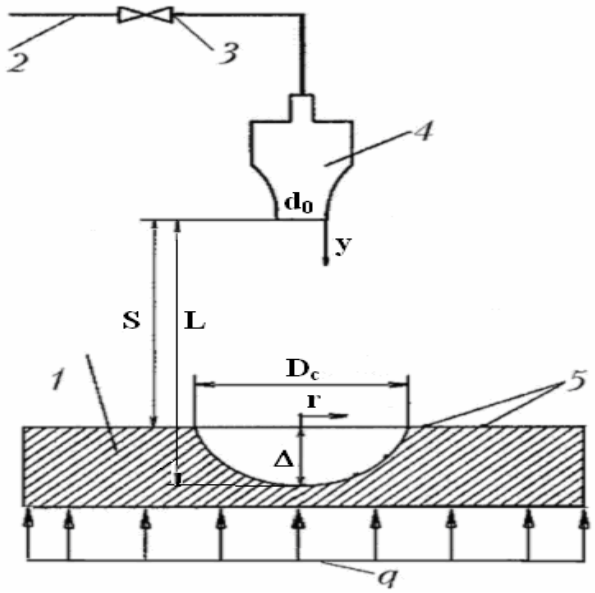

Figure 1. Experimental setup 1 – obstacle; 2 – air line; 3 – regulating valve; 4 - nozzle; 5 – heat-flux meters.

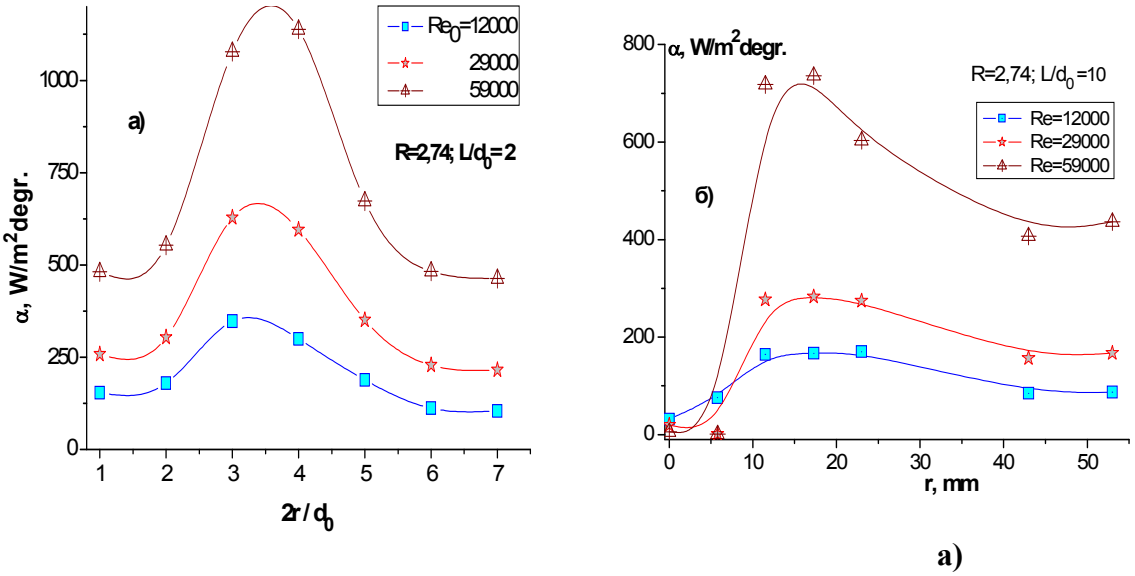
The heat fluxes were measured by gradient-type heat flow sensors glued onto the obstacle [19]. The characteristics of the sensors were as follows: in-plane dimensions - 2.5x2.5 mm (these dimensions were much smaller than the characteristic spatial scale of the flow under study), thickness - 0.2 mm, volt-watt sensitivity ≈ 10 mV/W, response time - 0.05 ms. In the course of measurements the arrays of instantaneous values of heat-flux densities were used to calculate the time-average heat fluxes, and also the heat-flow pulsations and spectra. The total number of realizations in one measurement was chosen to equal 10^4. The time in which one measurement was taken was varied from 10 to 90 s; it was found experimentally that this time affected measured data insignificantly. A tailored multi-channel unit was used to amplify the signals from the thermocouples and heat-flow sensors; then, the signals were fed to a computer to be processed there. The coefficient of heat transfer was defined as $\alpha_i = q_i / (T_w - T_0)$, where q_i is the local heat-flux density measured by sensor, and T_w and T_0 are respectively the temperature of the surface and the temperature of the air at the nozzle exit. An error analysis showed that the measurement inaccuracy for heat fluxes in our experiments was within 0.3÷10%. Simultaneously, the measurement inaccuracy for square-mean pulsations of heat fluxes was much greater, amounting to 30% for the obstacle with cavity. In processing the experimental data, experimentally determined losses of heat by radiation and free convection were taken into account.

Normally to the cavity surface and to the flat surface adjacent to the cavity, holes 0.5 mm in diameter were drilled; these holes were used to measure the radial distributions of pressure. In the tests, the average component of pressure was registered, and estimates of the intensity of pressure pulsations were made.

INTERACTION OF SWIRLING JET WITH A FLAT OBSTACLE

At the first stage of the study, we experimentally examined the heat transfer of flat obstacles interacting with eddying jets. A specific feature of such jets is their high ejective capacity due to which the jet divergence angle grew in value with increasing jet pre-rotation [14-16]. As a result, the heat-transfer maximum got displaced off the center (see Fig. 2). Depending on pre-rotation and nozzle-to-obstacle separation, this maximum could be either distinctly pronounced (Fig. 2a, $L/d_0 = 2$) or smooth (Fig. 2b, $L/d_0 = 10$). A similar tendency was also observed at other jet pre-rotations.

Importantly, in the majority of our experiments the radial distributions of local heat transfer behaved similarly, the heat transfer increasing with increasing the Reynolds number (see Fig. 2a).



a)

b)

Figure 2. Distributions of heat-transfer coefficients over the flat surface interacting with a swirling jet.

Effect of a swirling angle of a impinging jet on a local heat transfer is shown on Fig. 3. It is visible, that with increase swirling parameter of a jets intensity of heat transfer is considerably reduced. At large parameter (R = 2,74) external region of flow heat transfer practically is absent, that speaks about intensive mixing impinging jets with an environment media.

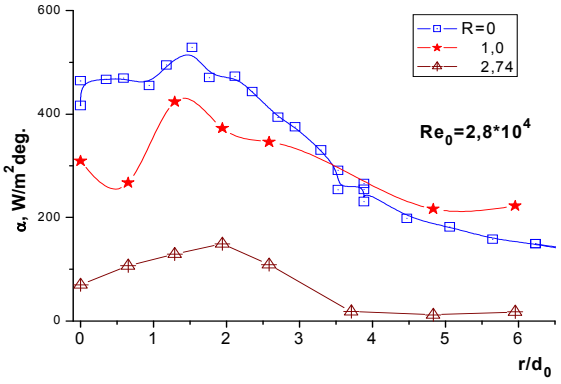


Figure 3. Effect of jet pre-rotation on the heat transfer from flat surface, $L/d_0 = 10$

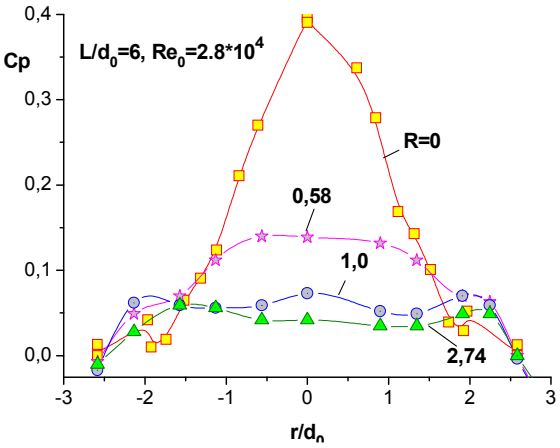

Figure.4. Pressure coefficient in the cavity onto which a swirling jet impinges

INTERACTION OF SWIRLING JET WITH HEMISPHERICAL CAVITY

PRESSURE PATTERN

The value of the pressure coefficient was found as the pressure drop between the surface and the atmosphere normalized to the dynamic pressure of the jet flow at the nozzle exit plane, $cp=2(p_i-p_a)/\rho_0 u_0^2$. A typical distribution of pressure coefficient over the radius of spherical cavity is exemplified in Fig. 4. Without pre-rotation (R=0) the pressure profile exhibits a distinct axial maximum. At the periphery, an inflection point brought about by the separation of the flow in this region is observed. The mechanism underlying the formation of flow in a cavity impinged by non-swirling jet was discussed in more detail in [10, 18].

With increasing the jet pre-rotation parameter the pressure level notably diminished due to the rapid expansion of the jet flow and the reduction of the jet momentum in the axial region. For instance, at R=2.74 the pressure coefficient is one order of magnitude smaller in comparison with non-swirling jet.

Another characteristic feature in the behavior of cavity pressure deserves mention. With swirling jets, the distributions of pressure in the peripheral region display no inflections. Moreover, a growth of pressure is observed in this zone due to the absence of flow separation and the action of centrifugal forces pressurizing the fluid here, as well as due to the influence of the surface curvature. Apparently, these factors will have influence on the formation of the temperature field in the system and on the heat- and mass-transfer processes proceeding there.

LOCAL AND AVERAGE HEAT TRANSFER IN CAVITY

The distribution of local heat-transfer coefficients in the radial direction is shown in Fig. 5. The rate of heat transfer is maximal in the absence of jet pre-rotation. As the jet pre-rotation parameter R grows in value, the Nusselt number starts exhibiting a non-monotonic behavior both along the radius, with the formation of additional maxima, and versus R. In the vicinity of the cavity the heat-transfer intensity for swirling jets turns out to be more than twice decreased. On the contrary, in the cavity the heat transfer from the swirling jet turns out to be enhanced in comparison with the case of non-swirling jets, the radial distribution of the heat-transfer coefficient being more uniform here.

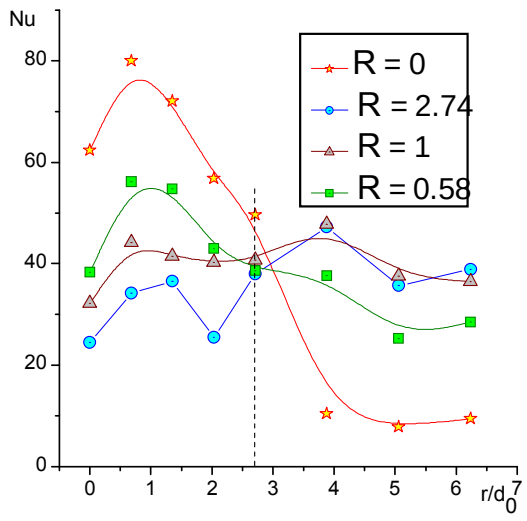

Figure 5. Local heat transfer for an obstacle with spherical cavity impinged by a jet. $Re_0=2.8\ 10^4$, $L/d_0 = 10$. The dashed line shows the cavity boundary.

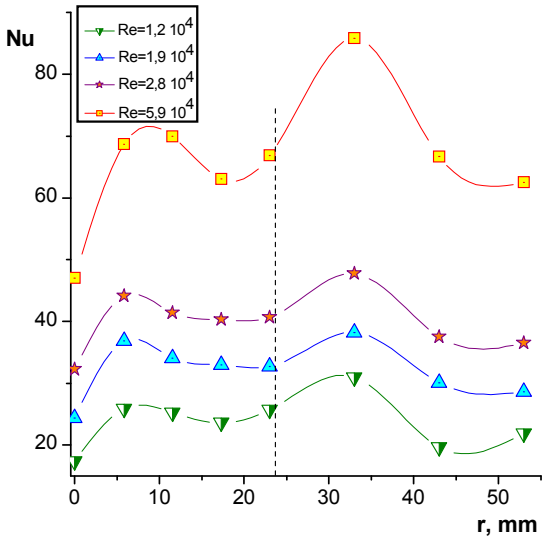

Figure 6 Effect of Reynolds number on the heat transfer of swirling jet. R =1, $L/d_0 = 10$

The latter points to a greater expansion angle of swirling jets, resulting in a growth of heat transfer in the region outside the cavity.

At fixed jet pre-rotation the heat-transfer data for different Reynolds numbers proved to be self-similar. This is evident from Fig. 6. Only at large Re_d numbers the heat-transfer maxima are pronounced more distinctly, with their position over the radius being quite stable.

An important characteristic of jets impinging onto surfaces is the heat transfer at the stagnation point. The experimental data $Nu_0 = f(Re_0)$ for various jet pre-rotations are shown in Fig. 7. Here, the most intense heat transfer is observed in the absence of pre-rotation (R=0), whereas the increase in the pre-rotation results in that the rate of heat transfer at the center of the cavity decreases. First of all, it is the formation of a complex aerodynamic structure during the interaction of jet with hemispherical cavity that underlies the complex behavior displayed by heat transfer.

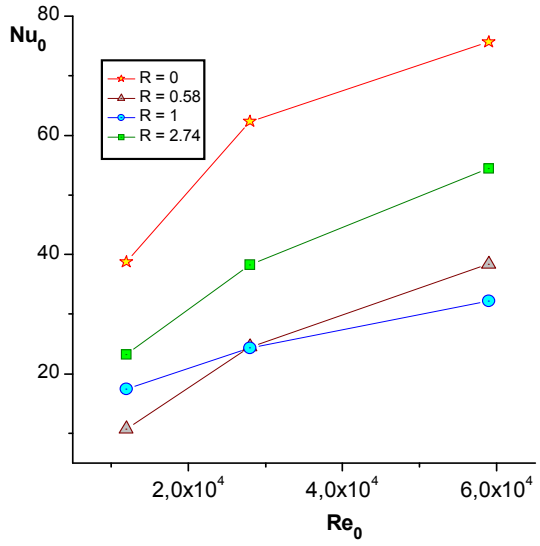

Figure 7. Distribution of Nusselt number Nu_0 at the stagnant point of the flow, $L/d_0 = 10$

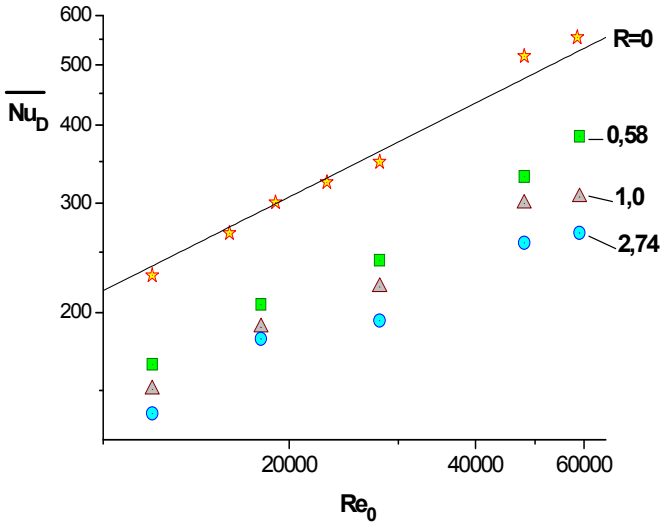

Figure 8. The Nusselt number $\overline{Nu}_D$ averaged over the cavity surface versus jet pre-rotation. $L/d_0 = 6.0$.

From the viewpoint of applications, a most important point in such complex problems is the deduction of correlation dependences for the average heat transfer versus Reynolds number and other governing parameters. In view of axial symmetry, in the present study the average value of the heat-transfer coefficient over the entire surface of cavity was obtained by integrating the local distributions over the radius. The average number $\overline{Nu}_D$ versus Re_0 at $L/d_c = 6$ for various jet pre-rotations is shown in Fig. 8. Here, the Nusselt number was calculated from the cavity diameter and from the mean value of the heat-transfer coefficient, $\overline{Nu}_D = \overline{\alpha} D_C/\lambda$. With increasing the jet pre-rotation at all other conditions kept unchanged the heat-transfer intensity decreases in value. For a non-swirling jet the experimental data obtained at $L/d_0 = 6$ can be fitted with the empirical relation

$$\overline{Nu}_D = 2.17 \cdot Re_0^{0.5}, \qquad (1)$$

typical of laminar heat-transfer mode. As a matter of fact, the flow in the cavity is turbulent; yet, the specific character of the formed flow pattern, namely, the involvement of reverse flows, curved flow streamlines, large-scale structures, etc., has resulted in the above relation for heat transfer. Apparently, relations of type (1) will undergo changes with distance to the heat-exchanging surface,

and for this evolution to be clarified additional tests or numerical experiments are required. Although the rate of heat transfer in the cavity proper decreases in the case of swirling jets, the total heat transfer, including the area adjacent to the cavity may be increased. For this possibility to check, here again additional studies are required.

SUMMARY

An experimental study of heat transfer during impingement of swirling jet onto hemispherical cavity was performed. It is shown that, following jet pre-rotation, additional maxima appear in the radial distribution of heat transfer, brought about by specific features of mixing processes of eddying jets with ambient air.

The intensity of heat transfer in cavity for swirling jets is substantially, by a factor of 2-3, reduced in comparison with non-swirling jets. On the contrary, outside the cavity the heat transfer for swirling jets is more intense. During variation of jet pre-rotation parameter the local Nusselt numbers vary non-monotonically both at the stagnant point and at different points over the radius, pointing to a complex mechanism of hydrodynamic and thermal processes in swirling jets impinging onto spherical cavities. At fixed distance to the plate and at jet pre-rotation parameter kept unchanged the distributions of heat transfer are self-similar if considered versus the Reynolds number.

HEAT CONVECTION AND FLOW REVERSALS IN A VERTICAL CHANNEL

J.-C. Tisserand[1,*], M. Creyssels[1], M. Gibert[2], B. Castaing[1], F. Chillà[1]

ABSTRACT. The main heat transport mechanism is convection. Convection occurs in many situations such as for example in natural situations : stars, planet's atmosphere or in half-natural situations : vertical access pit of an underground quarry [1]. The most popular configuration studied in laboratory is the Rayleigh-Benard one [2, 3, 4, 5]. However, the behaviour of a Rayleigh-Bénard's cell is mainly controlled by the neighbourhood of the horizontal plates, where convection vanishes. However for example in stars there are no such plates.

In order to understand how heat fluxes are carried in these situations [6, 7, 8, 9], we study it in a channel which links two chambers, the hot one at the lower end, and the cold one at the upper end. The channel is vertical. In this configuration, the flow in the channel is either globally ascending in the left part, and descending in the right one, or the opposite. Thus, flow reversals appear and they can be described by a characteristic time τ". It is worth noticing that reversals can be found in other situations such as for example with earth magnetic field [10]. In this study, we look at the dependence between τ" and the difference of temperature δT between the hot plate and the cold plate.

Keywords: *Convection, Channel, Flow, Reversals*

EXPERIMENTAL SET-UP

In order to do the experiments, the cell is filled with water, and is constituted of a classical Rayleigh-Bénard's cell with two horizontal plates : the upper is cold and the other is hot. The height of the cell is 40 cm and the section is 40×10 cm^2. The walls of the cell, twenty millimetres thick, are made with PMMA. As we can see on the figure 1, two honeycomb structures allow to prevent convection from appearing in about 50% of the cell. Between these structures, the channel has a cross section which is 10×10 cm^2 and his height is 20 cm. This channel is the zone of interest. Besides, a regulated water bath controls the temperature of the upper plate. The hot chamber is closed with a bottom plate which is heated by Joule effect thanks to resistors. Therefore, the difference of temperature δT is imposed by at once a power supply which heats the hot plate and a thermal bath which colds the upper plate.

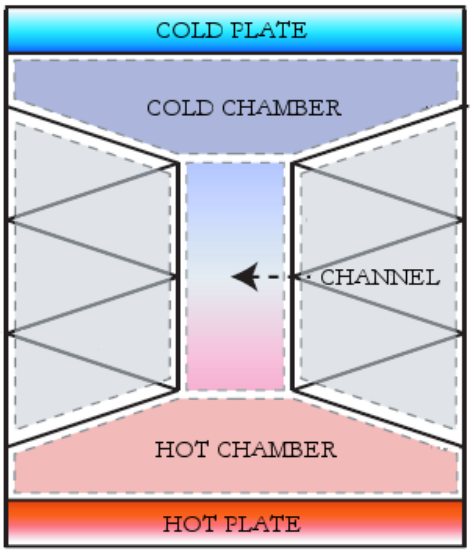

Figure 1. Picture of the cell

RESULTS

For our measurements, we use two resistive thermometers R_1 and R_2 inserted in the channel. Both thermometers are positioned on the same vertical line, each at the bottom end of a "L" structure. Moreover the vertical bars being made of two tubes, one sliding inside the other which allow to change the distance δz between the two thermistors. Resistances R_1 and R_2 are measured with two different Wheatstone bridges and we record both tension S_1 and S_2 thanks to an acquisition card. On each channel, signals S_1 and S_2 are turbulent time-correlated. We increase the space δz between R_1 and R_2 and for each time lag τ, we calculate the correlation C between S_1 and S_2 defined by

$$C(\delta z,\tau)=\frac{\left\langle \delta S_1(t+\tau)\delta S_2(t)\right\rangle}{\sqrt{\left\langle \delta S_1^2\right\rangle\left\langle \delta S_2^2\right\rangle}}$$

Where $\delta S_1(t)=S_1(t)-\langle S_1\rangle$ and $\delta S_2(t)=S_2(t)-\langle S_2\rangle$. As we can see on the Figure 2, except for the smallest distance, each curve presents two peaks. These peaks figure a delay between the two signals, the temperature perturbations travelling from one thermistor to the other.

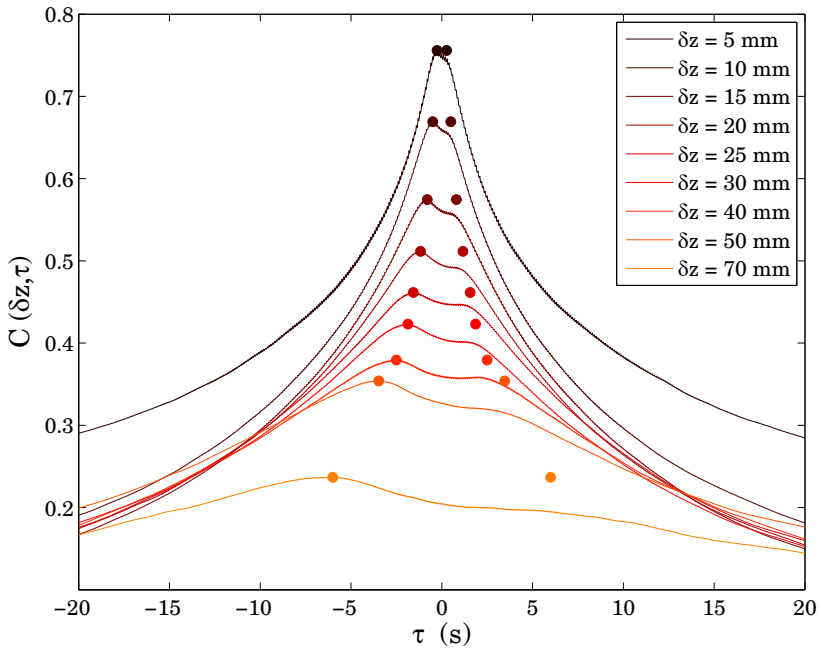

Figure 2. Correlation *C* versus time lag τ

On this figure, the presence of two maxima, approximately at symmetric times ±τ', seems to indicate that the flow undergoes reversals. Thanks to this maximum time lag τ', we can define a velocity *V*=δz/τ'. For instance, if the difference of temperature δT between the hot plate and the cold plate is 18°C and if the mean temperature in the channel is about 30°C, we can plot in the figure 3, the distance δz between the two thermistors versus τ'.

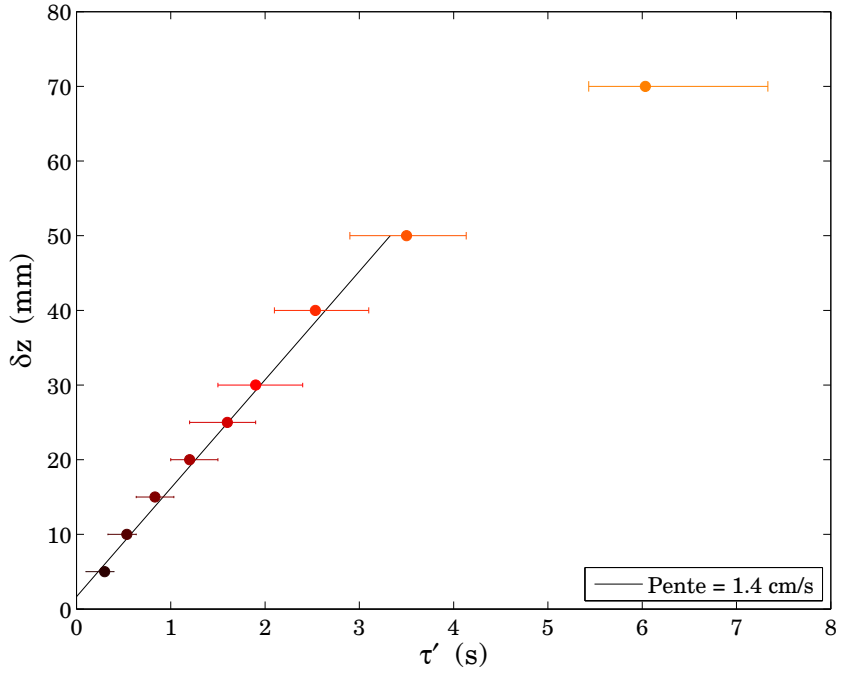

Figure 3. Distance δz versus maximum time lag τ'

In the Figure 3, the slope of the straight line, which stands for the velocity *V*, is about 1,4 cm.s^{-1}. It's worth noticing that the velocity *V* is close to the rms velocity V_{rms} measured with Particle Image Velocimetry in a previous study [11]. For example, with the same power, we obtained V_{rms}=1,23 cm/s. Furthermore, in the Figure 4, we plot, at once, the autocorrelation ϕ converted in distance and the correlation function *C*(δz,0) versus δz.

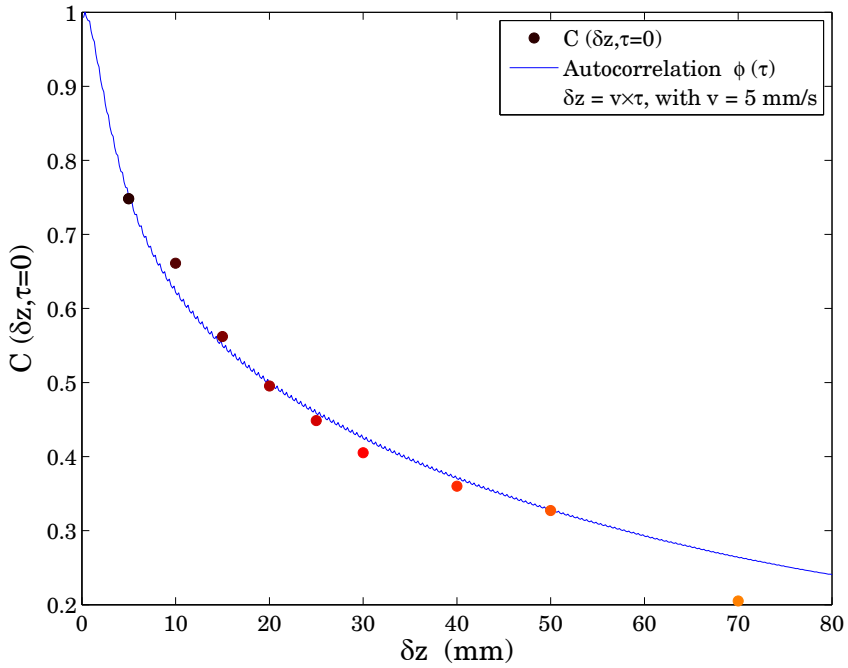

Figure 4. ϕ(δz) and *C*(δz,0) versus δz

We can notice that the ratio between the correlation length obtained with *C*(δz,0) and the correlation time obtained with the autocorrelation function ϕ give us a velocity v which is much smaller than the velocity *V*. This suggests a peculiar organisation for the coherent structures carrying the heat. Their travelling velocity as a whole is much smaller than the velocity occurring within the structure.

At last, with shadowgraph and thanks to a camera, we record image of the channel with a frequency of 1 Hz for three weeks for each measurements. Looking at the correlation between two successive images, we can deduce in real time if the flow in the channel is globally ascending in the left part, and descending in the right one, or the opposite. Therefore from then on, we can plot on the Figure 5 the characteristic time τ" versus the difference of temperature δT.

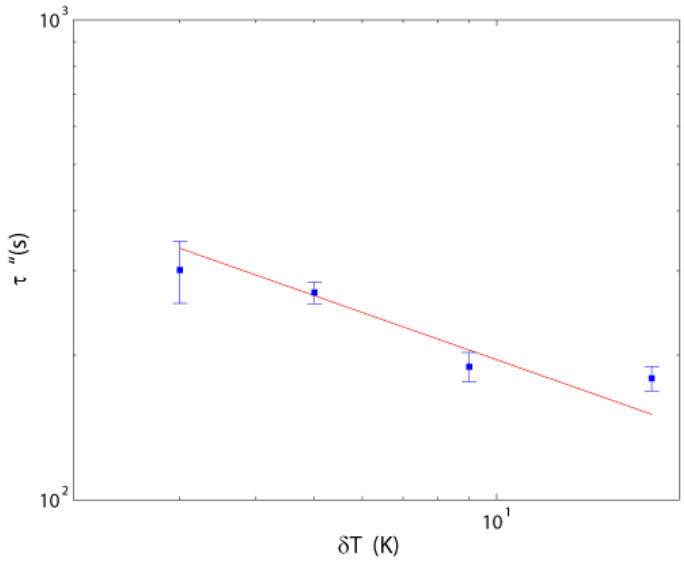

Figure 5. Characteristic time of flow reversals versus the difference of temperature

A simple model based on a previous experiment [11] is also developed and it predicts the relation between τ" and the difference of temperature δT.

AN EXPERIMENTAL INVESTIGATION OF THE INFLUENCE OF THERMAL EFFECTS ON INCEPTION OF CAVITATION IN SHARP-EDGED ORIFICES

M.G. De Giorgi [*], M. Tarantino, A. Ficarella
[2]University of Salento, Dep. Of Engineering for Innovation, Lecce, Italy

ABSTRACT. Cavitation remains a persistent problem for internal flow devices due to both performance reduction and the ability of cavitation bubbles to cause significant component surface damage during bubble collapse. The focus of this study is the experimental characterization of cavitation in a sharp-edged orifice in presence of thermal effects, considering water at different temperatures and cryogenic fluid, in particular nitrogen. The flow is investigated by means of visual observations and pressure signals. By means of high-frequency response pressure transducers strategically placed in the orifice cavitation could be sensed by the correlation of the power spectrum of the pressure signal measured with a cavitation index.

Keywords: *cavitation, two-phase flow , cryogenic, sharp-edged orifice, spectral analysis*

INTRODUCTION

Cavitation and boiling are very similar in the effects, but they are different in the mechanism of generation. These two processes can be distinguished by the fact that cavitation is the process of nucleation in a liquid when the pressure falls below the saturated vapor pressure, while the boiling is the process of nucleation that occurs when the temperature is higher than the saturated vapor temperature.
High performance hydraulic systems can operate at cavitating conditions leading to decreasing in the mass flow rate, and increased levels of dynamical structural loading in addition to the potential danger of cavitation erosion. Cavitation in hydraulic machinery can limit performance, lower efficiency, introduce severe structural vibration, generate acoustic noise, choke flow, and cause catastrophic damage. Any fluid handling device is vulnerable to cavitation once apposite hydrodynamic conditions are encountered. Cavitation in conventional orifices has been investigated by many researchers [1,2,3,4,5]. When the pressure downstream of the mechanical constriction such as venturi or orifice falls below the vapour pressure of the liquid a number of cavities are generated, which subsequently collapse with the recovery of pressure downstream of the mechanical constriction.
The nozzle discharge of cold fluid has been studied extensively over past several years, the main emphasis of the research in this area has been given to a variety of applications, such as fuel injector nozzles or high speed cutting jets [6,7,8,9,10]. In contrast the studies of hot and cryogenic fluid in orifice have been few. The discharge of a high-pressure hot fluid involves flashing of the liquid, while studies on the discharge of a cool fluid may focus on cavitation of the high-speed liquid flow within the nozzle. Clearly, there are similarities between these two-phase change processes. Cavitation is usually driven by the inertial growth of the vapour phase, while flash boiling can be thermally driven at the vapor–liquid interface. In the former case, the vapour pressure is quite low compared to the driving pressure and ample superheat is available in the liquid. In the latter case, the vapor pressure is

comparable to the driving pressure and the rate of mass transfer may be limited by the temperature of the surrounding liquid and possibly heat transport to the interface.
Acoustical noise, pressure fluctuations, and accelerometer readings have been interested to mostly mechanical engineers, who wish to understand investigators over a span of years to detect cavitation inception and to correlate developed cavitation with the cavitation number. The effect of cavitation on the energy spectra measured by various instruments are reported in [11,12,13,14]. In the past researchers [15, 16,17] used the accelerometer output as a criterion of defining cavitation inception and development in orifices and water valves.
In the present study visual observations and spectral analysis have been used to characterize of cavitation in flow through a sharp-edged orifice in presence of thermal effects, considering water at different temperatures and thermo-sensible fluid, in particular a cryogenic fluid, as nitrogen.

EXPERIMENTAL SETUP

Liquid nitrogen cavitation

A schematic illustration of the experimental set-up, used to investigate the internal nozzle flow, is shown in figure 1. The liquid nitrogen has been chosen as the cryogenic working fluid.
The set-up consists of a nitrogen supply tank, at a temperature of 82 K, two on-off valves and a flow visualization test section. The test section is an assembly of a central internal nozzle, in which the fluid flows; two vacuum chambers, for the thermal isolation and two flanges. In order to perform the continuous monitoring of cavitation phenomenon, four plexiglass plates are fitted between the assembly components. The supply tank is connected to the visualization chamber by a 2 m long pipe. The test section is a 15 mm-long rectangular orifice nozzle with a throat cross section 2 mm by 8 mm. After the visualization chamber, the nitrogen liquid is ejected in atmosphere as gas. The line is filled with pressurized cryogenic liquid at a pressure of 2 bar and flow immediately occurred when the first on-off valve after the nitrogen pressure tank is opened.
The cavitation phenomenon can be observed within the flow, at a certain flow rate, in the throat section. If the pressure is below the vapor pressure at the flow temperature, cavitation occurs.
The acquisition and data elaboration system is based on: three KULITE CT-190 cryogenic ruggedized pressure sensors, with a sensibility of 14.31 mV/bar and a temperature range of -195.5/120°C; a NI-4472 Dynamic Signal Acquisition Device for PCI up to 102.4 ks/s with two pole anti-alias lowpass filter for each input channel; a KISTLER 8702B100 accelerometer; a silicone diode temperature sensor (model 430, Scientific Instruments) coupled with cryogenic temperature monitor.
Observation of cavitation behavior has been made using a high-speed video camera system (CCD Kodak Motion Corder Analyzer FASTCAM-Super 10k). The imagines have been acquired at 2000 fps and then have been downloaded and stored on a pc to be subsequently processed digitally.
For the different test cases, the pressure and accelerometer signals have been acquired at a frequency of 102 kHz and 65000 samples, for a total data period of 0.637 s.
The acquisition programs were developed in-situ using the software Labview and the signal processing code was developed using Labview too.

Water cavitation

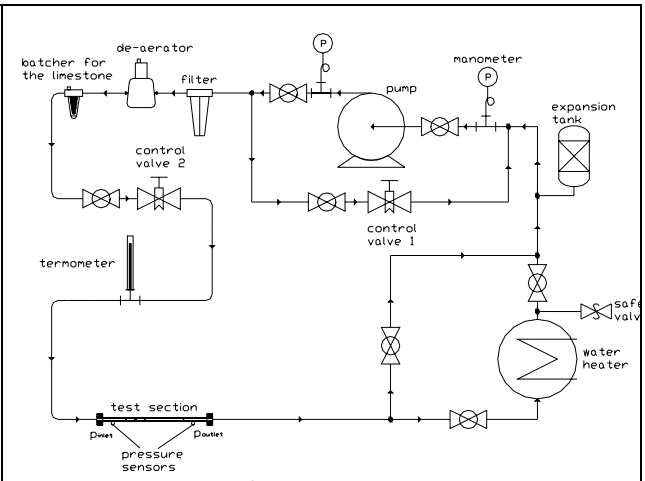
The experimental setup for water cavitation is showed in figure 1. The water flow is driven by a 1.10 kW centrifugal pump, capable of a maximum flow rate of $1.67 \cdot 10^{-3}$ m^3/s, located 1 m below the test section, in order to prevent cavitation in the pump. The mass flow rate through the test section, and then the pressure drop, has been varied by means of two calibrated control valves (control valve 1 and 2 in 5). In particular, a variable portion of the water flow was by-passed from the test section directly at the intake of the pump by means of the control valve 1; the control valve

2 was used to modify the inlet pressure further and therefore the pressure drop across the test section. The water was heated and maintained at the desired temperature by an electrical water heater, under the control of a thermostat.
Both circular and rectangular orifices were studied. The circular sharp-edge orifice is has an internal diameter of 3.5 mm and a length of 7.5 mm placed in a duct with an internal diameter of 11.2 mm. The rectangular orifice is the same used in nitrogen experiments.
The acquisition and data elaboration system is based on: two Kistler 4045A piezoresistive pressure sensors (for the upstream and downstream signals); a KISTLER 701A pressure quartz sensor (for the throath signal); a NI-4472 Dynamic Signal Acquisition Device for PCI up to 102.4 ks/s with two pole anti-alias lowpass filter for each input channel; a KISTLER 8702B100 accelerometer; a silicone diode temperature sensor (model 430, Scientific Instruments) coupled with cryogenic temperature monitor. The high speed video camera, the acquiring method and the software used for data elaboration are the same of nitrogen cavitation. For both, water and nitrogen fluids, the cavitation number is defined as follows:

$$\sigma = \frac{(P_u - P_v)}{(P_u - P_d)} \qquad (1)$$

where P_u, P_d and P_v are respectively the upstream, downstream and vapor pressures of the fluid.

Set-up for nitrogen cavitation



Set-up for water cavitation

Figure 1. Experimental set-up.

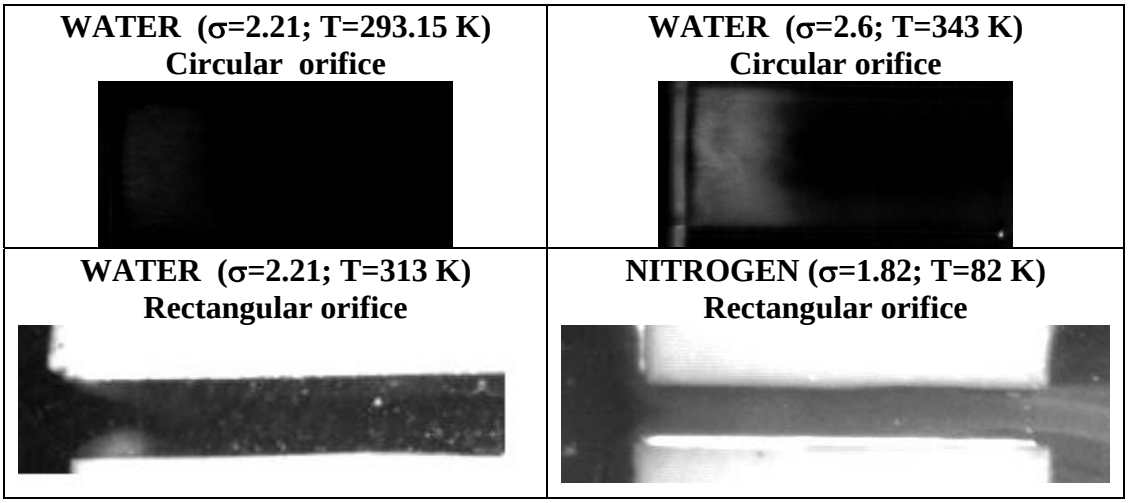


Figure 2. Visualization pictures of incipient cavitation in nitrogen and in water in the restricted area.

EXPERIMENTAL RESULTS AND DISCUSSION

Visual observations

The general visualization pictures of incipient cavitation are shown in figure 2 in the case of water at different temperature and nitrogen at 82 K. Looking to water experiments it is clear that cavitation appears at high cavitation number if the temperature increases. This is due to the fact that at high temperature smaller pressure variations are necessary to reach the phase change curve, due to the increase in vapour pressure. Comparing circular and rectangular orifices, it seems that the value of the cavitation number at the inception of the two-phase flow is not influenced by the cross section geometry. However the cross section influences the cavity shape.
The appearance of the cavitation structures is different for water and nitrogen. In the case of water a vapour cavity forms when cavitation starts, although the cavitation zone does not reach the outlet of the orifice, while in cryogenic fluids cavitation grows rapidly at the moment of the incipience.
Then in the case of nitrogen the cavitation starts at lower cavitation number than in water. An explanation is that the ratio between the liquid density and the vapour density of nitrogen is ten times smaller than the same ratio for water, so a greater mass transfer and a greater heat transfer are necessary to obtain the same vapour cavities, for the nitrogen than the water. As show in figure 3, in the case of water cavitation and circular orifice, cavitation starts at the upstream corner of the orifice restricted area. First, the length of cavitating zone keeps almost constant or slightly increases at higher cavitation number (subcavitation stage). Next the length begins to increase with the decrease in cavitation number (transition-cavitation stage). Then, it finally rapidly increases to occupy the whole part of the orifice throat (supercavitation stage). After this stage, as cavitation is further developed, the main cavitating area exceeds the orifice throat and a vapor pocket is created in the jet region (supercavitation regime). It appears that the length of the vapor pocket increases quickly with flow velocity. This is found also in the rectangular orifice (see figure 4 and figure 5). Comparing water and nitrogen experiments (figure 6) , a different cavitating behaviour is found. Looking to the fully developed cavitation in the case of cryogenic fluid, it presents a frothy appearance due to a much finer structure than in water under ambient conditions. The flow separation takes place at the exit of the restricted area. In this flow situation, the flow contains bubbles highly concentrate in the the separation shear layer, between the central core and near wall regions.
This behaviour is in accordance with previous observations of cavitation in helium, by Ishii [18].
The difference between water and cryogenic cavitation suggests that researchers must be careful to use experiments in hot water to study cryogenic cavitation by similarity.

The spectral analysis of cavitation

Flow observations show a more or less regular growth and shedding of vapour clouds that are convected downstream and take the form of horseshoe vortices before they collapse (see figure 7). Previous works have shown similar behaviour. In [19] periodic unsteady motion of separated vortex cavitation was experimentally investigated in a cylindrical orifice flow. A characteristic frequency, corresponding to the cavitation development as cloud shedding, can be observed in the power spectrum of the pressure. So in order to cope with many of the phenomena encountered in the study a number of signal analysis tools are employed. Of special interest is the ability to observe signal evolution in both time and frequency. Spectral analysis is one of the methods of examining the cavitation threshold. It enables observing the spectrum of the signal emitted from the cavitation area. The appearance of cavitation is manifested in the spectrum in the form of increasing of some frequency amplitude. In the process of cavitation inception, development and collapse, the bubble will experience volume expansion, compression, until collapse and vanishing. The pressure oscillations due to bubble growth and collapse can be identify by the power spectrum of the pressure signal measured at different nozzle positions. As in the visual observation, also the spectral analysis shows different cavitation regimes in water cavitation. In figure 8 the amplitude spectrum of the Fourier Transform of the downstream pressure is showed in the case of the circular orifice for water at different temperature are shown.
The first cavitation regime (no cavitating flow), occurs in the range of σ between the highest value tested and 2.2 at T = 293.15 K, and σ = 2.5 at T = 343.15 K. At the cavitation inception an evident increase of the peak amplitude of the first frequency components can be observed. A further reduction of the cavitation number brings to a sharp increase in the length of the cavitating zone (2nd regime). This cavitation regime is characterized by a sharp increase of the amplitude of the frequency spectrum, observed in the range from the critical values to σ = 1.7 at T = 308.15 K, and to σ = 2.1 at T = 343.15 K. As well as the cavitation volume increases to the outlet of the orifice (3rd cavitation regime), first a noticeable reduction of the amplitudes of the frequency spectrum can be noticed and then an increase in the amplitudes. These amplitudes tend to a rapid increase with a further reduction of the cavitation number below the cavitation number σ = 1.5 at T = 308.15 K, and σ = 1.9 at T = 343.15 K
The fourth stage of the cavitation phenomenon, that is revealed as the smallest values of the cavitation number are achieved, can be directly related to an evident increase of the amplitude of the first frequency component. This is confirmed by visual observations.

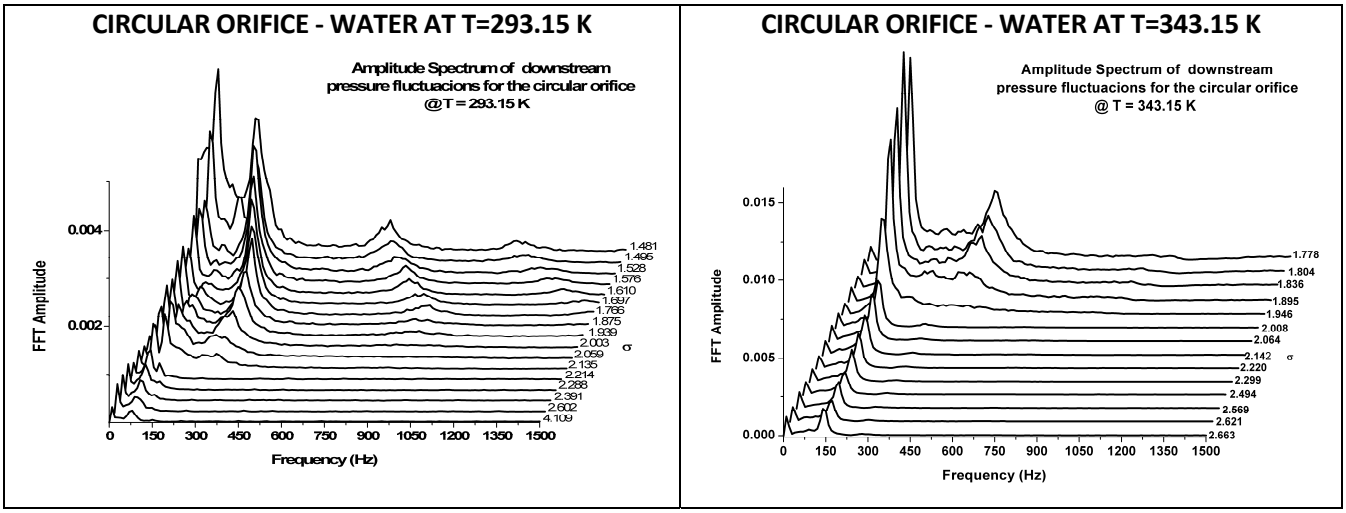

Figure 8. Amplitude Spectrum of the pressure oscillations measured in the case of circular sharp-edge orifice for water at T=293.15 K and at T=343.15K.

Figure 8 shows also that increasing the flow temperature the amplitudes of the spectrum in the range of low frequency increases. In figure 9 the amplitude spectra of the pressure oscillations measured in the case of nitrogen and of water in the rectangular orifice are shown. It is notable that the main pressure frequency content is in the range of lower frequencies for nitrogen, up to 70 Hz, especially for low cavitation number. Then the amplitude of the spectrum is highest in the downstream pressure fluctuations for water. The different between water and nitrogen is also evident looking to the temporal signals. In particular the standard deviation of the pressure vibration signals (figure 10) shows a higher oscillation for lower cavitation numbers in water cavitation. This is correlated to an increase in the activated nuclei density at low pressure and in water, that allows the bubble growing and collapsing, as confirmed by the increase of the standard deviation also for accelerometer signals.

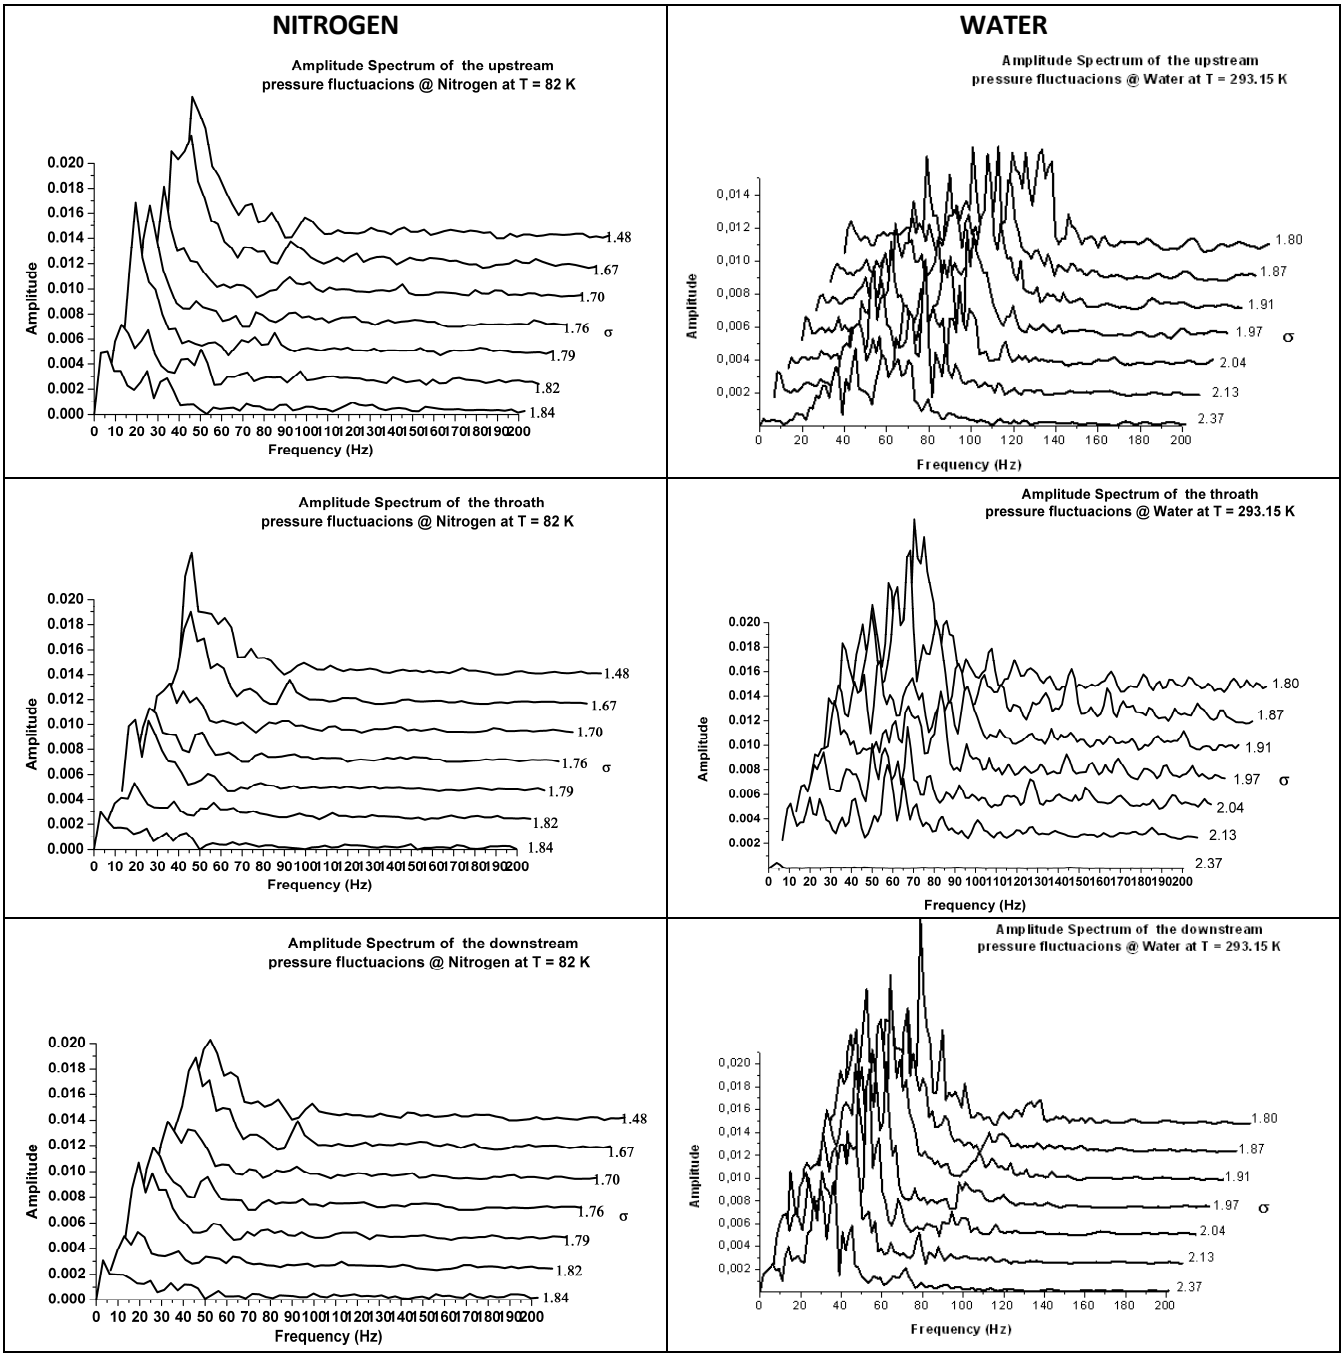

Figure 9. Amplitude Spectrum of the pressure oscillations in the rectangular sharp-edge orifice, nitrogen at constant temperature T = 82 K and water at T=293.15 K

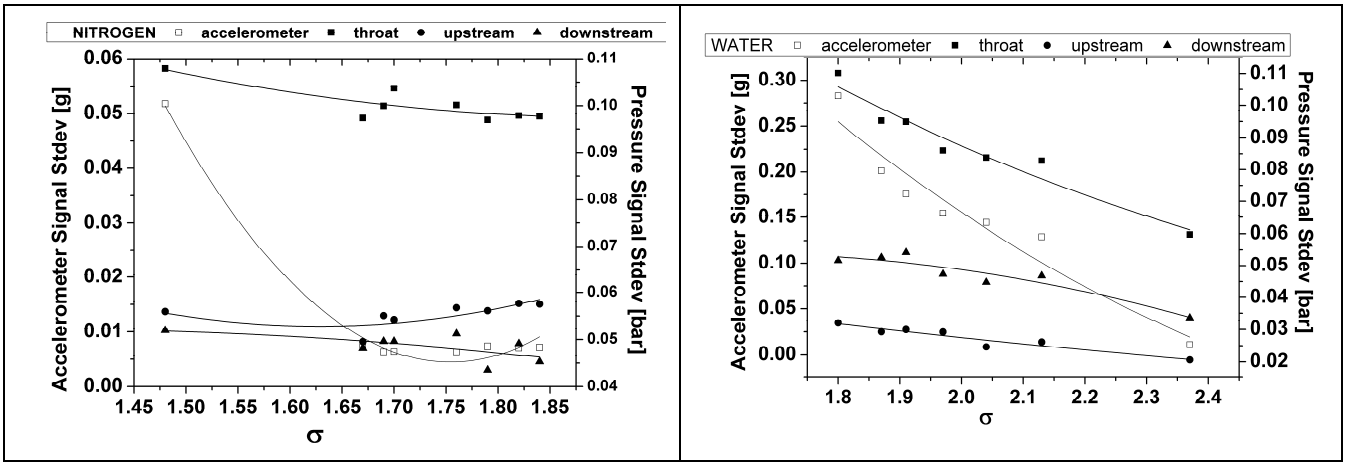

Figure 10. Standard deviation of the pressure signals measured in the case of the rectangular sharp-edge orifice for nitrogen at T=82 K and water at constant temperature T = 293.15 K

CONCLUSIONS

Some experimental studies on cavitation phenomena in both nitrogen and water flows at different temperature have been conducted by visual observation and pressure measurements. The conclusions are summarized as follows. Water cavitation appears at highest cavitation number if the temperature increases. This is due to the fact that at high temperature smaller pressure variations are necessary to reach the phase change curve, due to the increase in vapour pressure. Comparing circular and rectangular orifices, it seems that the value of the cavitation number at the inception of the two-phase flow is not influenced by the cross section geometry. However the cross section influences the cavity shape. The development of the cavitation structures is different for water and nitrogen. In the case of water a vapour cavity forms when cavitation starts, although the cavitation zone does not reach the outlet of the orifice, then as cavitation is further developed, the main cavitating area increases to occupy the whole part of the orifice throat (supercavitation stage). After this stage, as cavitation is further developed, the main cavitating area exceeds the orifice throat and a vapor pocket is created in the core of the jet region (supercavitation regime). In cryogenic fluids cavitation grows rapidly at the moment of the incipience and two-phase flow reaches the outlet, with bubbles highly concentrate in the separation shear layer, between the central core and near wall regions. Finally a good correlation is evident between the visual observations and the spectral analysis.

HYDRAULIC CHARACTERISTICS OF FLOW BOILING OF HYDROCARBON FLUIDS: EFFECT OF SUBCOOLED BOILING

V. V. Wadekar
HTFS, AspenTech Ltd, Reading, United Kingdom

ABSTRACT. Two-phase hydraulic characteristics, in terms of pressure drop and void fraction data, are reported for boiling of hydrocarbon fluids in vertical upflow. These data were obtained simultaneously with the boiling heat transfer measurements. The systematic trends of the measured pressure gradient with respect to vapour quality, mass flux and pressure are examined. This provides useful information in terms of the relative importance of the constituent parts of the two-phase pressure gradients and confirms the internal consistency of the measured data. These two-phase pressure drop data under flow boiling conditions are then compared with various correlations from the open literature and also with the HTFS correlation. Typical results of these comparisons are presented. It is noted that in the near zero vapour quality region the measured pressure gradient data may be lower than expected because of the effect of subcooled boiling. This effect is taken into account by the HTFS method when pressure drop is calculated for flow boiling.

Keywords: *two-phase, pressure drop, boiling, hydrocarbon, void fraction*

INTRODUCTION

The amount of information that exists in the published literature on flow boiling heat transfer to hydrocarbon fluids is rather limited. Even more limited is the information on two-phase pressure drop for boiling of hydrocarbon fluids. In previous papers some data were reported (Wadekar *et al*, 2008) for boiling of hydrocarbons, along with detailed analysis dealing with some apparently anomalous trends of void fraction at near dryout vapour qualities (Wadekar et al, 2007). The current paper carries forward this work by examining large amount of pressure drop data for single component hydrocarbon fluids, *n*-pentane and *iso*-octane and examines the possible effect of subcooled boiling.

Two-phase pressure drop can be measured for gas-liquid adiabatic flow or it can also be measured for vapour-liquid non-adiabatic, boiling or condensing flow. Because of ease and low cost of operation, laboratory measurements tend to be made with adiabatic gas-liquid flow e.g. air-water flow, rather than vapour-liquid flow with phase change. Two-phase pressure drop correlations are largely based on data for such adiabatic gas-liquid two-phase flow. On the other hand, two-phase heat transfer equipment, by default, will have boiling or condensing flows. It is generally accepted that the two-phase pressure drop and flow pattern characteristics for non-adiabatic flow could be similar to adiabatic gas-liquid flow. For example, Frankum et al (1997) have reported that the two-phase flow patterns for evaporating flows are similar to gas-liquid adiabatic two-phase flow. However, it is still desirable to carry out validation of pressure drop correlations for boiling hydrocarbons; such validation is especially relevant to oil and gas, and petroleum industry where a large number of process reboilers and vaporisers are used for hydrocarbon duties. Therefore, the paper also reports the results of validation of the proprietary HTFS pressure drop correlation used in the commercial heat exchanger design and simulation software.

State of the art thermal-hydraulic methods and correlations are developed by the Aspen HTFS Research Network, run by the Aspen Technology company, for modelling process heat exchange

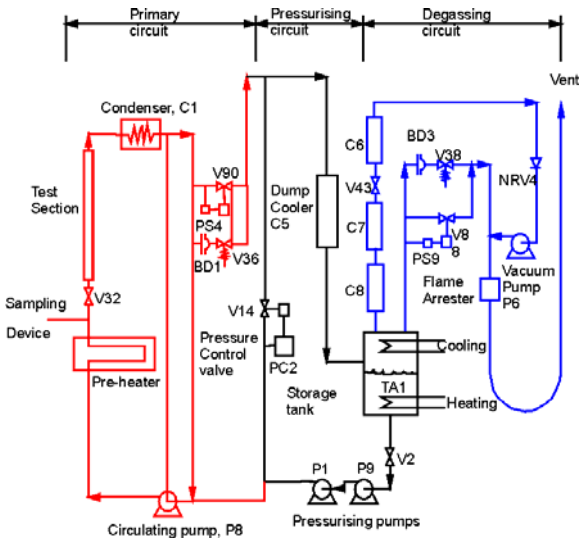

Figure 1. Rig circuit diagram for the HTFS HPBR facility

equipment. Methods and correlations developed by the HTFS Research Network are proprietary and are known as the HTFS methods or correlations.

EXPERIMENTAL DETAILS

The HTFS High Pressure Boiling Rig (HPBR) was used to obtain the heat transfer and pressure drop measurements. As shown in Figure 1, the HPBR had three distinct circuits: the primary circuit, the pressurising circuit and the de-gassing circuit. The primary circuit contained the test section, through which the test fluid was circulated at a fixed flow rate, inlet temperature and pressure. It also contained a circulating pump and condenser. The pressurising circuit generated a constant pressure in the primary circuit, with two pressurising pumps, arranged in series, and pumping against a partially closed valve, V14. Finally, the de-gassing circuit was used to remove dissolved gases from the test fluid, since these may affect its boiling characteristics. The circuit contained a fluid storage tank, TA1, to which vacuum could be applied to reduce the dissolved gas content.

The test section was a 8.68 m long 321 stainless steel tube, with an internal diameter of 25.4 mm and an outer diameter of 38.0 mm (a thickness of 6.3 mm). The long length of the test-section allowed a large number of simultaneous pressure drop measurements to be made, over a wide range of vapour qualities and flow regimes, as the flow passed from the single phase liquid inlet condition, through subcooled and saturated boiling to two-phase flow at the outlet. The test section was directly heated by passing electrical current (up to 4000 Ampere) at low voltage (up to 30 Volts), through the test-section wall. Heat transfer and pressure measurements were carried out along the test section. Details of the bulk fluid and wall temperature measurements are given by Urso et al (2002).

For each experimental run a total of 11 local pressure drop measurements were recorded along the test-section length, together with three absolute pressure measurements, at inlet, middle and outlet of the test-section, Figure 2. Each pressure drop measurement was across 0.75 m test-section length. Further details of pressure drop measurements are given by Kandlbinder (1997).

Test Procedure

After initial start-up of the rig, for each experimental test-run, the flowrate, pressure, inlet temperature etc. were set to the desired values and electric power was applied to the test section. Subsequently, the test conditions were monitored until steady state condition was achieved, and only then five consecutive scans of all measurements including temperatures, pressures and

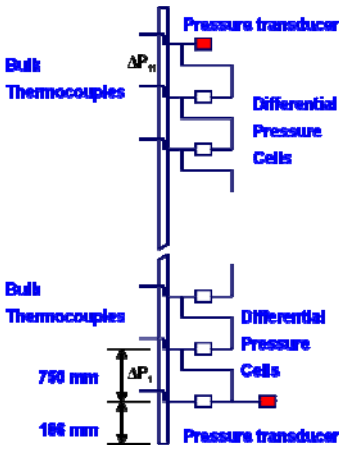

Figure 2. Details of test-section showing positions of pressure tapings

pressure drops were recorded. The experimental conditions were then altered and the process repeated. Each pressure drop measurement reported here, thus, corresponds to average of five consecutive scans.

Local vapour qualities along the length of the test-section were calculated from heat balance, assuming thermodynamic equilibrium between the vapour and liquid phases. As stated earlier, each pressure drop measurement was carried out across a 0.75 m test-section length. The vapour quality over this length would vary depending on the applied heat flux and flowrate. It was assumed that the measured pressure drop corresponded to the vapour quality occurring at the mid point between the differential pressure tapings. Single phase experiments were performed to check the heat balance accuracy. The typical errors associated with heat balance were less than 5%. The calibrations carried out for differential pressure cells indicated that typical errors associated with pressure drop measurements were around 5%.

MEASURED DATA

The pressure drop data, reported here, encompass a range of mass fluxes varying from 35 to 500 kg/m^{2}s, heat fluxes from 10 to 100 kW/m^2 (generally in increments of 10 kW/m^2), and pressures from 1.5 to 20 bar. These data were recorded simultaneously to the heat transfer measurements for flow boiling. In order to check the internal consistency of the data, they are plotted in Figures 3 to 5 as pressure gradient against vapour quality. In these graphs the experimental data are shown by various symbols and solid curves are, unless stated otherwise, predictions of the HTFS methods. These curves also highlight and illustrate the trends exhibited by the experimental data.

Effect of mass flux

Figure 3 shows the pressure gradient data at a fixed nominal pressure and heat flux, but varying mass fluxes, ranging from 70 to 410 kg/m²s. In addition to the data points, trend lines are also shown at different mass fluxes. The data at low mass fluxes, i.e. less than 210 kg/m²s, appear to be grouped together, and are reasonably well represented by a single monotonically decreasing curve. Here the contribution of the frictional component is small and the data are dominated by the gravitational component, and hence the apparent lack of mass flux dependence. These data, as discussed later, are useful in back calculating the void fraction. At high mass fluxes, however, the frictional component makes increasing contribution with increasing vapour quality and the data require different trend lines at three higher mass fluxes of 210, 310 and 410 kg/m²s.

Furthermore, at a given mass flux, the data also exhibit a characteristic minimum because, with increasing vapour quality, the two-phase gravity component decreases and the frictional component

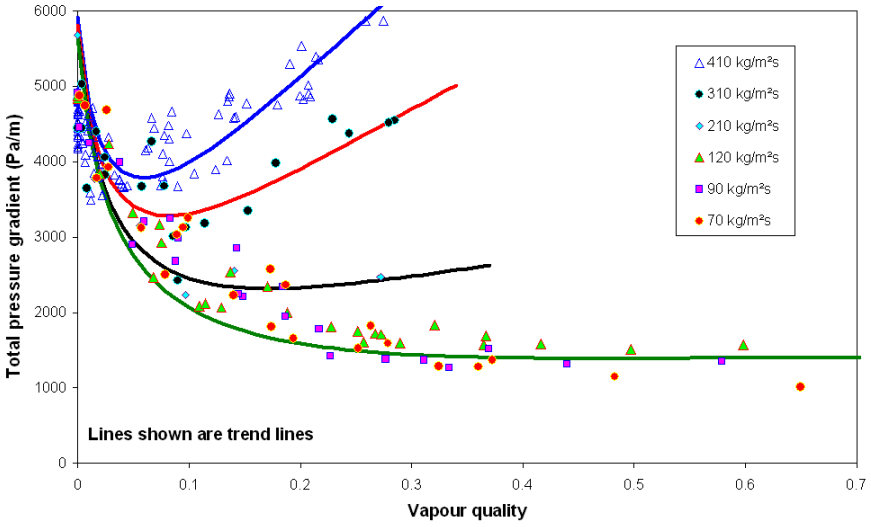

Figure 3. Effect of mass flux and vapour quality on measured pressure gradient

increases. The trend lines are rather difficult to draw in this area; they are shown to tentatively illustrate the trends. At low mass fluxes the frictional component increases with vapour quality rather slowly and, as a result, the characteristic minimum, seen at higher mass flux, is not exhibited in the range of vapour qualities covered here.

Effect of pressure

Figure 4 shows the measured pressure gradient data at a fixed mass flux and heat flux but varying pressures, ranging from 2.3 to 10 bar. With increasing pressure the vapour density increases. Therefore, at a given vapour quality, the two-phase frictional component decreases and the two-phase gravitational component increases with pressure. This is reflected in the data in two ways. At lower pressures of 2.3 and 3 bar the pressure gradient against vapour quality curve goes through a well defined minimum. At higher pressure of 10 bar, however, there is a monotonic decrease of the pressure gradient with the vapour quality.

Effect of heat flux

The effect of heat flux on the pressure gradient is examined in Figure 5 which shows some typical measured data. These data are plotted as the pressure gradient against the vapour quality at a fixed nominal mass flux and pressure. It can be seen that, there is some systematic variation of the

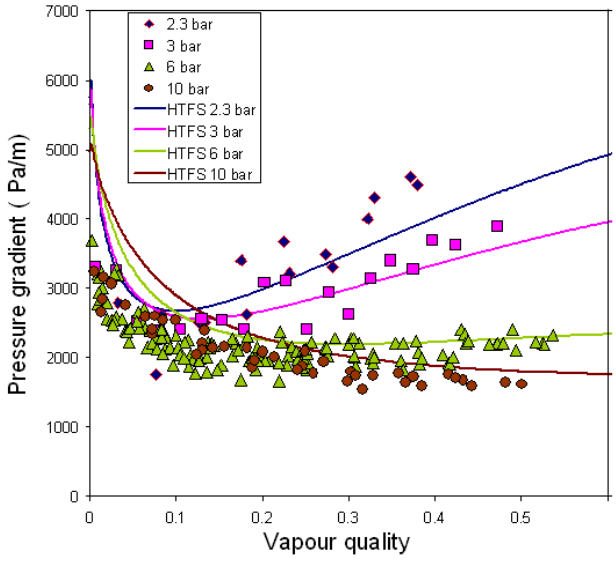

Figure 4. Systematic effect of pressure

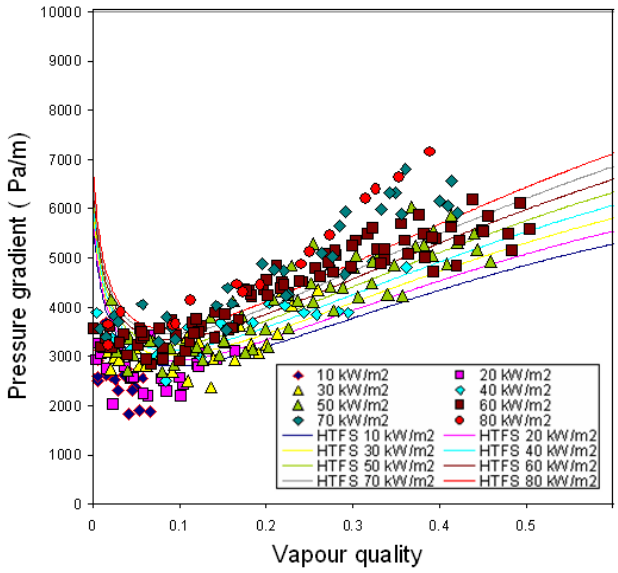

Figure 5. Systematic effect of heat flux

gradient with the applied heat flux. The calculations carried out using the HTFS method show that at the highest heat flux the contribution due to the acceleration component was around than 36%. Figure 5 appears to indicate that, in general, there is overprediction of the measured data at low vapour qualities and underprediction at high vapour qualities. Both these trends are examined in further detail after the brief discussion on void fraction.

Void fraction

Figure 6 shows the void fraction data that were back calculated from the measured pressure gradients. This back calculation was achieved by focussing on the pressure drop data dominated by the gravitational component, and relating that component to the void fraction. More details of the procedure followed are given by Wadekar et al (2007). Figure 6 confirms that the void fraction data are predicted reasonably well by the HTFS void fraction correlation; this is also corroborated by the average and RMS deviations shown in Table 1.

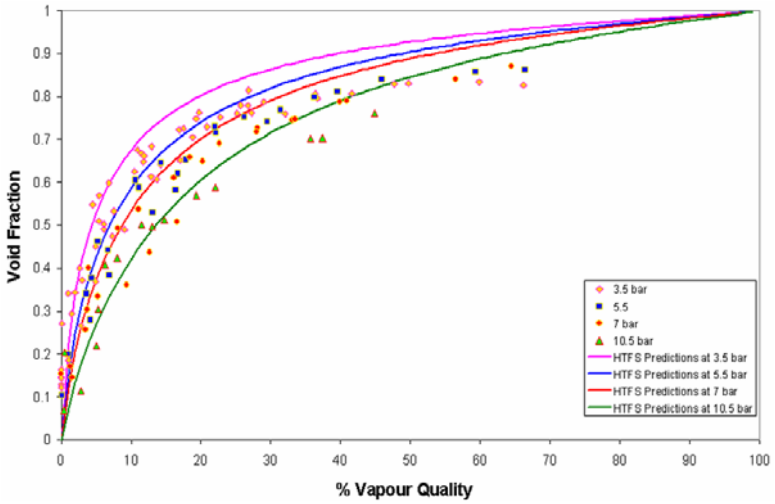

Figure 6. Comparison of experimental void fraction with HTFS predictions.

Table 1
Comparison of different predictive methods for void fraction data (115 points)

Void Fraction Method	RMS Deviation (%)	Average Deviation (%)
Chisholm (1973)	33.3	-12.8
Homogeneous	42.4	-32.1
HTFS	35.0	-6.3
Schrage *at al* (1998)	192.4	20.6
Zivi (1964)	42.4	-32.1

DATA AND PRESSURE DROP CORRELATIONS

The pressure drop data were compared with various correlations. Here comparison of the data with the Chisholm correlation and HTFS correlation are presented. Because the measured data contains the three components of the pressure gradient, namely, friction, gravity and acceleration, the predictions also consist of the sum total of all three components.

The gravitational pressure gradient is calculated from the following equation.

$$\frac{dp_g}{dz} = g\left[(1-\varepsilon)\rho_l + \varepsilon\rho_v\right] \tag{1}$$

The acceleration pressure gradient is calculated by the following equation.

$$\frac{dp_a}{dz} = \dot{m}^2 \frac{\left[\frac{x^2}{\varepsilon\rho_v} + \frac{(1-x)^2}{(1-\varepsilon)\rho_l}\right]_{in} - \left[\frac{x^2}{\varepsilon\rho_v} + \frac{(1-x)^2}{(1-\varepsilon)\rho_l}\right]_{out}}{\Delta z} \tag{2}$$

The length Δz is over which the calculations are carried out. As mentioned earlier the HTFS void fraction correlation was confirmed to perform well in predicting the measured void fraction data and therefore it was used to calculate the void fraction, ε, needed in Equations (1) and (2).

Chisholm correlation

Chisholm and co-workers (see, for example, Chisholm, 1973) formulated a two-phase frictional pressure drop correlation using the following ratio, Γ , similar to the Lokhart-Martinelli parameter

$$\Gamma^2 = \left(\frac{dp_f}{dz}\right)_{GO} \Big/ \left(\frac{dp_f}{dz}\right)_{LO} \tag{3}$$

Equation (3) shows that Γ^2 is the ratio of single phase gas (or vapour) to liquid phase frictional pressure gradient when the total flow is flowing as the respective phase.

The Chisholm correlation is one of the successful and well established two-phase pressure drop correlations. Figure 7 shows the results for the Chisholm correlation. Figure 7 and the subsequent Figure 8 also show the RMS and average errors. In general there appears to be a degree of overprediction of the data, reflected in the correspondingly high values of RMS and average errors.

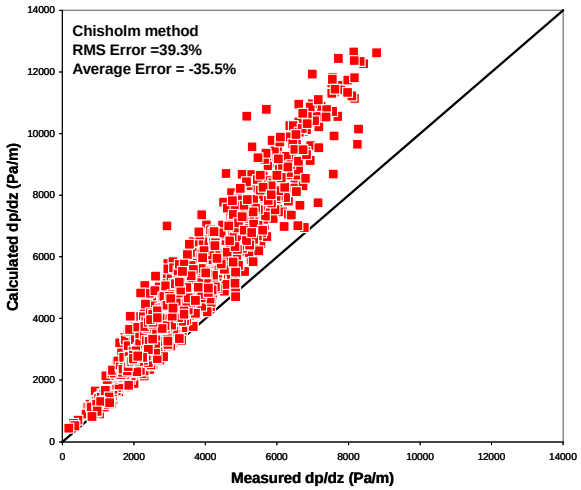

Figure 7. Comparison of measured data with the Chisholm correlation

HTFS correlation

The HTFS two-phase pressure drop correlation is a complex proprietary correlation developed using a large amount of measured data. In general Figures 4 and 5 show that the HTFS predictions largely follow the trends of the data over a range of parameters. Some instances of either over or underprediction of the data are, at least, partly due to the use of nominal rather than the actual

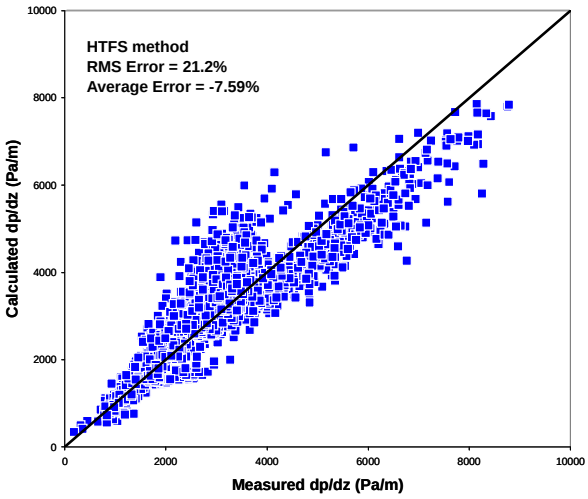

Figure 8. Comparison of measured data with HTFS correlation

conditions. In order to fully address this for all the data points, Figure 8 was prepared; it shows the entire data set of more than 2000 data points. Similar to Figure 7, the measured pressure drop data are compared with the sum total of the gravity, friction and acceleration components using the actual conditions of mass flux, heat flux, pressure and vapour quality. It can be seen from Figure 8 that the HTFS correlation predicts the data well with the RMS error of 21.2 % and the average error of -7.59%. This is particularly good considering that the data were obtained over a wide range of mass fluxes, pressures and vapour qualities for boiling hydrocarbon fluids.

EFFECT OF SUBCOOLED BOILING

It would be appropriate to make some observations about the possible effect of subcooled boiling on two-phase pressure drop. Further analysis indicated that subcooled boiling could indeed affect the pressure drop characteristics in the near zero vapour quality region. This is because of the higher void fraction (than expected from the thermodynamic equilibrium quality) in the subcooled boiling region. In addition to this direct effect, there is also carryover of increased actual, non-equilibrium vapour quality in the positive, near zero vapour quality region. Together, these two effects could cause lower than expected gravitational component, resulting in a total pressure gradient which is less than the calculated gradient in the low quality region. Comparison of measured data and the

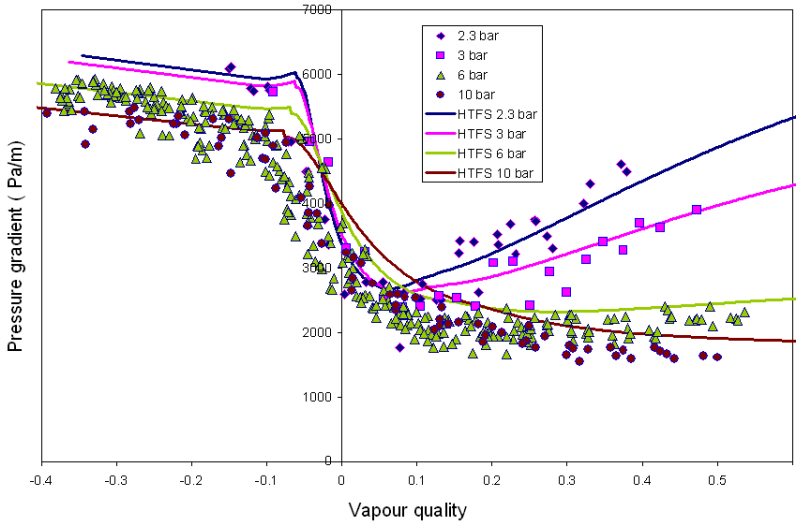

Figure 9. HTFS predictions of data including subcooled boiling effect

full HTFS correlation for flow boiling, which includes the effect of subcooled boiling, is shown in Figure 9. Note that Figure 9 uses the same data, as shown in Figure 4, in the positive quality region. A comparison of Figure 4 and 9 shows the improvement in predictions obtained by considering the effect of subcooled boiling in the positive, near zero quality region. Further results showing the detailed effect of subcooled boiling will be presented in a subsequent paper.

CONCLUSIONS AND FUTURE WORK

The HTFS correlation for calculation of pressure gradient, including two-phase friction, gravity and acceleration components, is validated for boiling hydrocarbon flow. It is demonstrated that the HTFS correlation performs, at least as well, and in some cases better, than other correlations, such as the Chisholm correlation in the open literature. The back calculated void fraction data, using the measured pressure drop data dominated by gravity component, confirm that the HTFS correlation for void fraction also performs well and also effect of subcooled boiling is taken into account appropriately.

An area of further work would be the boiling of mixtures. It is well known that boiling heat transfer for mixtures is affected by the mass transfer effects and this is confirmed by the data reported by Kandlbinder (1997). In general hydrodynamics of two-phase flow would not be affected by these effects. Nevertheless, it would be interesting to compare two-phase pressure gradients for mixtures and single component hydrocarbons.

ACKNOWLEDGEMENTS

The experimental work was performed by Drs M E D Urso and T. Kandlbinder using the HTFS High Pressure Boiling Rig Facility, as part of joint research projects between HTFS and Imperial College, London. Mr P Stepney provided the technician support. Thanks are due to Drs Y.S. Tian and K M Miller for the valuable assistance provided in data analysis. Author is grateful to HTFS, Aspen Technology for the permission given to publish the paper.

ABSTRACT**.** When a liquid falls from one horizontal tube to another below it, the flow may take the form of discrete droplets, jets, or a continuous sheet; the mode plays an important role in the wetting and heat transfer characteristics of the film. Experiments were carried to explore the effects of thermo physical properties like viscosity, surface tension, inertial, and gravitational effects and geometrical parameters on falling film mode transitions. Water, distilled water + n-heptanol (200 ppm) and SAE40 oil served as test liquids. Parameters like tube diameter, tube spacing, flow rate of the liquid were varied systematically. Depending on these parameters, the observed modes were droplet, droplet/column, column, column/sheet, and partial sheet. The complete sheet mode was not observed for SAE40 Oil. Based on experimental data flow charts were developed showing range of parameter for each flow pattern. The mode transitions for droplet- jet, droplet to column were in good agreement with reported literature, while the column/sheet to sheet mode occurs at higher values of Re_f. The regions of different flow patterns are shown in flow maps. The flow map indicates that when inertia effects dominate, the flow take the sheet mode. Gravity or surface tension effect dominated flows result in droplet mode. The formation of jets is apparently related to a complicated competition between these effects and viscous forces. Transitional Reynolds numbers can be correlated to modified Galileo numbers with reasonable accuracy in the current experimental range for all the transitions. Experimental correlations are suggested for the prediction of different flow patterns.

Keywords: *Falling film heat exchangers, Horizontal tube, Flow Pattern, Tube banks*

INTRODUCTION

Falling film heat exchangers with horizontal tube are used in the chemical, refrigeration, and petroleum and desalinization industries because they provide higher heat transfer coefficient and operate with smaller liquid inventories than flooded heat exchangers. When a liquid film flows from one horizontal tube to another below it, according to an increasing flow rate order, the flow may takes the form of droplets, circular jets or continuous sheet as shown in Figure 1.

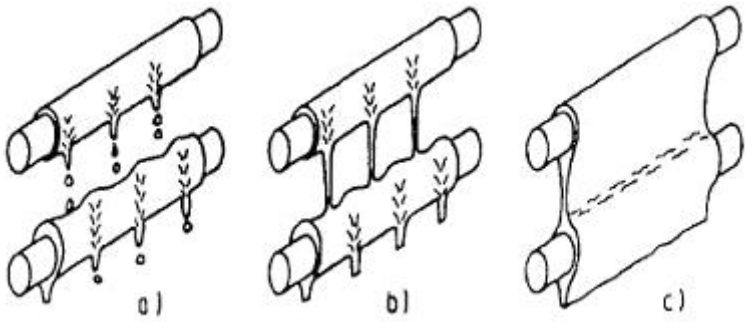

Figure 1. Schematic of three mode a) Droplet mode b) Column mode and c) Sheet mode [1].

Then, it tends to spread along the tube it flows in layer form around the periphery and falls off the bottom. As a result of this spreading tendency of the impinging columns or droplets along the tube overlapping waves are generated between adjacent columns. When inertia effects dominate, the flow will take the sheet mode. Gravity or surface tension dominated flows result in a droplet pattern. The formation of jets is apparently related to a complicated competition between these effects and viscous forces. Mixed modes representing combinations of two idealized modes existed at the intermediate flow rates so called droplet-jet and jet-sheet modes.

Based on the experimental results, Mitrovic [1] pointed out that the transition of flow modes depend on the flow rate, fluid thermo physical properties and the tube spacing. When liquid flow between adjacent tubes in the form of droplet trains or stationary columns. Ganic and Getachew [2], suggest that primary factor for changing the physical form of the liquid is the mass flow rate. Experimental observations by Ganic and Roppo [3] indicated that apart from the mass flow rate, the tube spacing and liquid viscosity also contribute to the physical form of the liquid. At low flow rate the liquid is usually in the form of droplets that are generated at a discrete point along the underside of a horizontal tube. As the flow rate increases the transition from droplet to column occur slowly over a range of flow rates. They observed that the droplet to column mode occur over a relatively large Reynolds number around 180, and it was affected by the tube spacing. While studying film condensation, Kutateladze et al., [4], suggested that the transition of flow mode was controlled by the modified Archimedes number based on the capillary constant. Armbruster and Mitrovic [5], modeled the mode transition among the droplet, jet and sheet modes, according to $Re = A\ Ga^{1/4}$, where A is an empirical constant. Re is Reynolds number and Ga is Galileo number. For sufficiently high stagnation pressure, they observed that the radial flows from adjacent jet collide and film surface is raised between the jets. The crests created at the top of the tube remain nearly unchanged around the tube, and forms the departure sites for jets leaving the tube. This flow mode is called staggered mode. In addition they found that the transition solely dependent on the liquid flow rate. Hu and Jacobi [6,7], suggested the flow modes, based on the observation of flow transition as droplet mode, droplet jet mode, an unsteady jet mode, the inline jet mode, the staggered jet mode, the jet sheet mode and the sheet mode. They found that, the flow modes are independent of geometric effect. The effect of gravitational, inertial, viscous and surface tension forces are correlated by using Reynolds number and modified Galileo number in $Re = AGa^{b}$, where A and b are empirical constant.

Researchers observed flow patterns and their transitions for different fluids and there is no agreements of dependency of flow transitions influenced by the diameter of the tube and its, spacing, surface roughness, mass flow rate of the fluid. Also empirical correlations proposed are different [5,6,7]. So there is need to verify the effects of these parameters on the mode of transitions.

So proposed work is to investigate the mode of transition and effects of parameters like wettability of tube, considering the effect of contact angle, departure site spacing, thermo-physical properties of fluid like water, distilled water + n-heptanol and SAE 40 oil.

EXPERIMENTAL METHOD

Test Rig

The test facility as is provided with a closed circuit forced circulation loop of test liquid its construction is explained in earlier paper on departure site spacing [ExHFT-7].

Experimental Procedure

Before starting a test, tubes with desired diameter were aligned in the test section at prescribed tube spacing. Since the falling film flow is gravity driven, a tube inclination would cause a non-uniform distribution of the flow. Therefore, the tubes were carefully leveled before test, and leveling was checked again after the liquid started circulating in the system. The test liquid was circulated

through the system for 15 to 30 minutes to ensure that the tubes were fully wetted and the piping system was free of air. Then the fluid flow rate was adjusted for different flow rates and the flow pattern and mode of transitions were observed by naked eye for increasing as well as decreasing flow rates. At each flow mode transition, flow rate was recorded. Similar test are carried for water, distilled water with n-heptanol (200 ppm) and SAE40 oil fluids with varying tube diameter and spacing. Some clipping and photographs were taken for different flow rates. All the experiments reported were conducted over adiabatic tubes at atmospheric pressure having temperature of the liquids were room temperature.

RESULTS AND DISCUSSION

Flow Patterns

Flow modes observed during increased and decreased flow rates of test liquids with varying tube diameter and its spacing are discussed. Also some images of the flow modes observed during testing these liquids are shown in Figures 2- 4. For each of these working fluids, the three modes were observed. Mixed modes representing combinations of two idealized modes were also observed: the droplet-jet and jet-sheet modes. Furthermore three distinct jet mode patterns were manifested, a distinction very rarely found in the literature. Because of these observations, and for other related reasons, a careful classification of the falling-film flow patterns was undertaken. At low flow rates, liquid dripped from regularly spaced sites along the bottom of the horizontal tubes, exhibiting the so-called droplet mode. The sites were not simultaneously active; droplets alternately fall from neighboring sites.

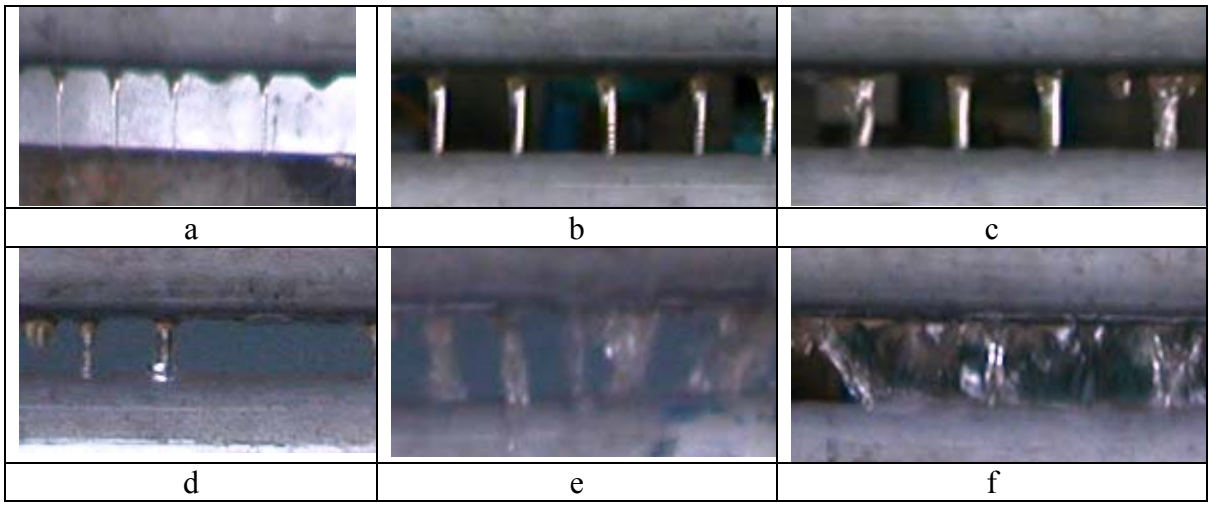

Figure 2. Photographs of observed flow modes for water are a) droplet b) droplet jet c) inline jet d) staggered jet e) jet sheet and f) sheet

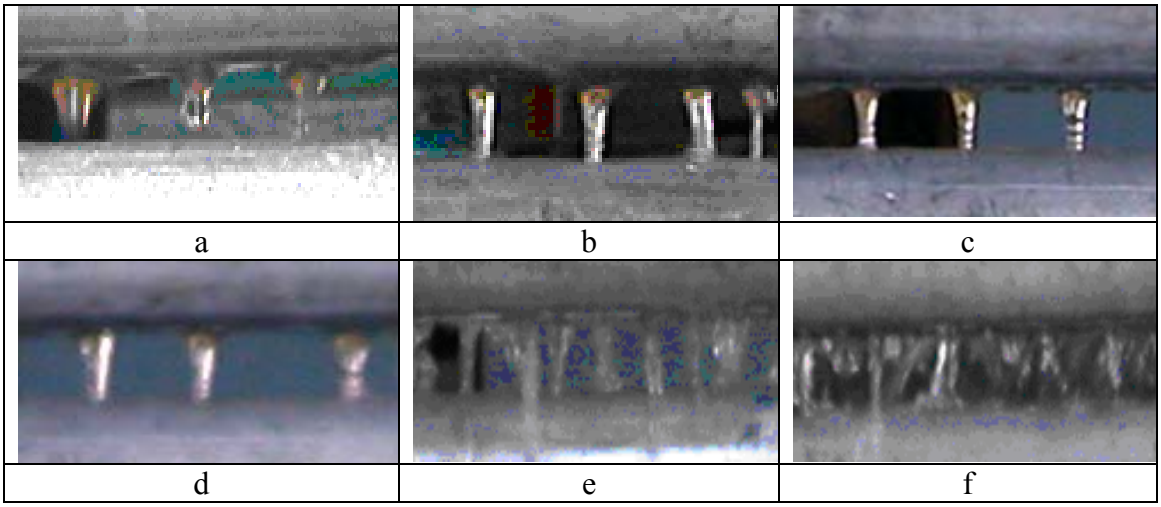

Figure 3. Photographs of flow modes for distilled water with n-heptanol a) droplet b) droplet jet

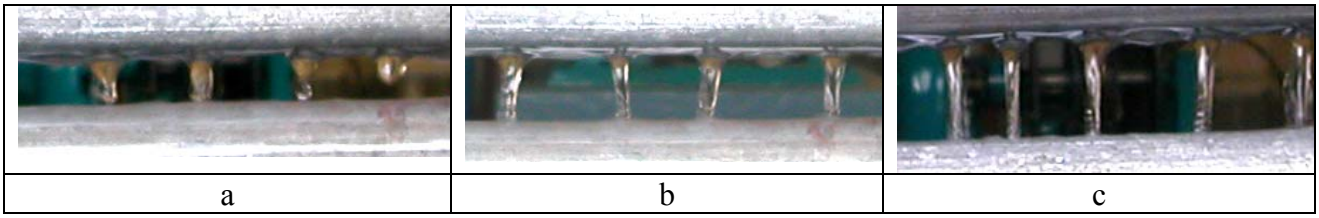
c) inline jet d) staggered jet e) jet sheet and f) sheet

The dripping frequency increased with an increase in flow rate, and all the sites became active simultaneously at a certain flow rate. A further increase in the flow rate eventually resulted in liquid departing from at least one site as a continuous jet. A flow with droplets and jets is called a droplet-jet mode, and such a transition is a droplet / droplet-jet transitions, in the reverse direction these conditions represent a droplet-jet / droplet transition (all backward transitions will be denoted in this way). From the droplet -jet mode, a sufficient increase in liquid flow rate caused liquid to falls continuously from every departure site on the bottom of the tube. The complete establishment of this flow pattern represents a droplet – jet / jet transition. Under some conditions the jet mode was established with departure sites directly beneath impingement sites; this pattern is inline jet mode.

a b c

Figure 4. Photographs of flow modes for SAE 40 oil are a) droplet jet b) inline jet c) Staggered jet

The diameter of the liquid jets increased with the flow rate and, eventually, the jets moved closer together and another discrete jet was added to the quasi-steady jet pattern. For some test conditions, a further increase in flow rate resulted in unsteadiness in the location of the jet departure sites. When the jet departure sites exhibited unsteady behavior, the flow was classified as an unsteady jet mode. From inline jet, staggered jets, or unsteady jets, a sufficient increase in the flow rate eventually resulted in jets merging to form a partial sheet. This flow pattern is called a jet-sheet mode and the transition with an increasing flow rate is denoted as jet/ jet sheet transition. Finally the flow exhibited a jet-sheet/sheet transition. When the final discrete jet merged to form a complete sheet of liquid the flow was said to be in the sheet mode under these conditions. Similar modes observed by Hu and Jacobi [9, 10].



a b c

Figure 5. The observed flow modes for distilled water at constant flow rate for same diameter of tube with different spacing.

Also there was no considerable effect of tube spacing on flow patterns were observed (Figure 5) Mode of Transitions : Armbruster and Mitrovic [5] and Hu and Jacobi [6] proposed flow pattern maps where the film modes were presented as functions of Re_f and of a modified Galileo number, Ga.

$$\mathrm{Re}_f = A.(Ga)^n \quad (1)$$

Where Reynolds number $\mathrm{Re}_f = 4\Gamma/\mu$ (2)

$$Ga = \sigma^3 \rho/(g\eta^4) \quad (3)$$

Based on the experimental data the following correlations were suggested for the mode transitions.

Transition Mode	Transition Criteria	RMS Deviation	
Droplet/Droplet-Jet	$Re_f = 0.276\ Ga^{0.389}$	1.98	(4)
Droplet-Jet/ Jet	$Re_f = 0.286\ Ga^{0.3093}$	2.04	(5)
Jet / Jet – sheet	$Re_f = 1.0956\ Ga^{0.2807}$	1.72	(6)
Jet-Sheet/Sheet	$Re_f = 2.68\ Ga^{0.2628}$	5.7	(7)

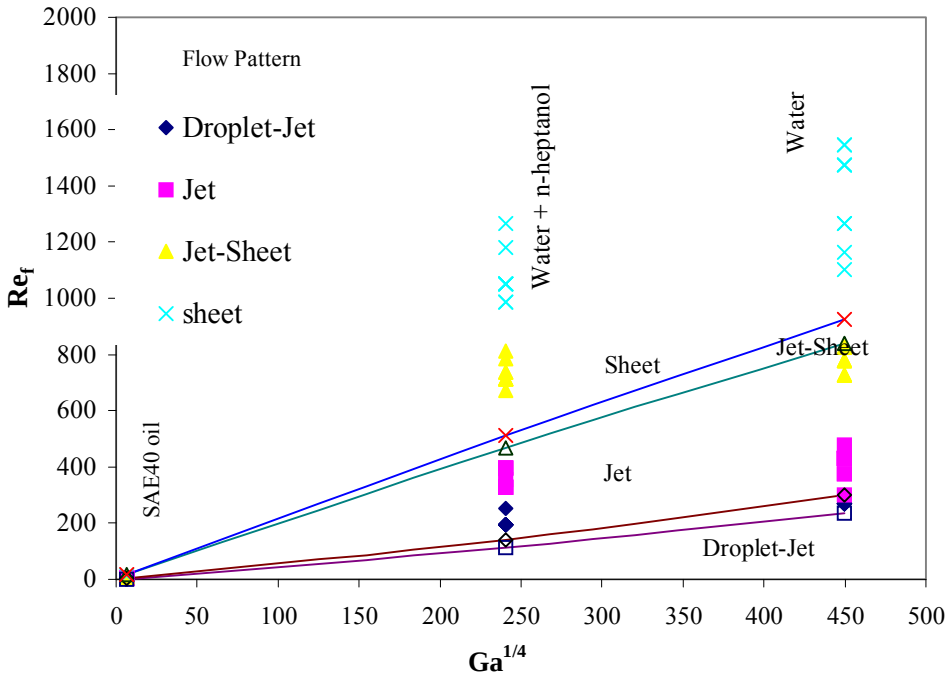


Figure 6. Flow regime map for the falling film mode transitions, comparison [6]

The straight lines indicate the correlation presented by Hu and Jacobi [6] and the points represents the experimental values. It is observed that for the same diameter flow transition changes as the spacing between tube increases.

Reynolds number represents ratio of inertia forces to viscous forces, a high Reynolds number flow is inertial dominated. The flow map provides a clear interpretation of physics of flow; Inertia dominated flows (Re tends to ∞) will results in the sheet modes. Modified Galileo number can be interpreted as ratio of gravitational force to viscous force. The flow map demonstrates that gravity dominated flows will takes the droplet mode.
The flow map implies that droplet mode occurs when surface tension effect dominates. The modified Galileo number reflects both gravitational and surface tension effects; both of the interpretations are intuitive, and there is more valid interpretation of physics reflected by flow regime map.

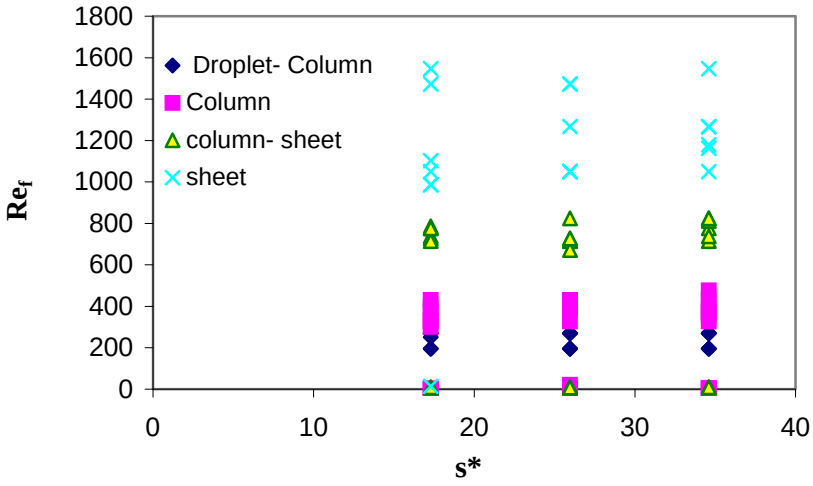

Figure 7. Effects of Tube Spacing on Transitional Reynolds Number

Tube Spacing

Figure 7 shows effects of tube spacing on transitional film Reynolds number. There is no considerable effect of tube spacing on transitional Film Reynolds number.

CONCLUSIONS

From the results of this study the following major conclusions are drawn.

The observed patterns were same as reported in literature like droplet, droplet/column, column, column/sheet, and sheet. The complete sheet mode was not observed for SAE40 Oil. The mode transitions for droplet- jet, droplet to column were in good agreement with Hu and Jacobi [9] (1998), while the column/sheet to sheet mode occurs at higher values of Re_f. The flow map indicates that when inertia effects dominate, the flow will take the sheet mode. Gravity or surface tension effect dominated flows result in droplet mode. The formation of jets is apparently related to a complicated competition between these effects and viscous forces. Transitional Reynolds numbers can be correlated to modified Galileo numbers with reasonable accuracy in the current experimental range for all the transitions. Equations 4 to 7 are suggested for the prediction of different flow patterns. There is no considerable effect of tube spacing on transitional Film Reynolds number.

These results provide deeper understanding of the falling film mode transitions and a useful tool for designing and modeling heat exchangers. Comparisons with existing models suggest that further work in this area is needed. Because falling film heat exchangers uses a range of fluids with concurrent and counter-current vapor flows, future work in this area should include vapor-shear effects with a wide range of fluid properties.

NOMENCLATURE

d - Diameter, mm
d* - Normalized tube diameter, d/a, dimensionless
Ga - Modified Galileo number, dimensionless
g - Gravitational acceleration, m /s^2
Re_f - Film Reynolds number, dimensionless
s - Tube spacing, mm
s* - Normalised tube spacing s/a dimensinless
Γ - Total liquid mass flow rate per unit length of tube, kg /ms
μ - Dynamic viscosity, N –s/m^2
ρ - Mass density, kg/m^3
σ - Surface tension at gas/liquid interface, N/m

ABSTRACT**.** The heat and mass transfer of the horizontal falling film heat exchangers are mainly depends on the wetting characteristics of the flow and the flow patterns between the tubes. The wetting characteristics of the flow over the tube are closely related to the departure-site spacing between the adjacent droplets/columns mode. Experiments were conducted exploring the effects of thermo physical properties like viscosity, surface tension, inertial, and gravitational effects and geometrical parameters on departure site spacing between the adjacent droplets/columns mode. Water, Distilled water with n-heptanol as surfactants and SAE40 oil served as test liquids. The effect of geometrical parameters like tube diameter and spacings between the consecutive tubes on the departure-site spacing was investigated for the smooth tubes. The flow modes and its behaviour over the tubes were observed visually and photographed with clippings by digital video camera. Measurements of departure-site spacing between the adjacent droplets/jets were reported for the test liquids. For the conditions of this study, departure-site spacing increased with decreasing Re_f for high - Ga fluids and was nearly independent of Re_f for low-Ga fluids. Departure site spacings increased slightly with tube diameters.

This paper aims to find the effect of various parameters on departure site spacing between the adjacent droplets/jets.

Keywords: *Falling film heat exchangers, Horizontal tube, Departures site spacing, Tube banks*

INTRODUCTION

Falling film heat exchangers with horizontal tubes, arranged one upon the other, thus forming a bundle have been used in chemical, refrigeration, petroleum, refining, desalination, and food industries. They provide higher heat transfer coefficients and operate with smaller liquid inventories than flooded heat exchangers. Also they offer advantages in dealing with liquid distribution, noncondensable gases, fouling and other problems. In a typical falling film heat exchanger, the liquid film is introduced at the top of the tube bank through nozzles or drip-tray distribution system. The liquid flows as a film around the tubes. It begins to extend from the underside of the tube and eventually detaches and falls freely until it impacts the top of the next tube. This process is repeated through the entire tube bank. The behavior of real films involves many complex interactions such as the waves and ripples generated by an impacting drop. When a liquid film falls from one horizontal tube to another below it, the flow may take the form of discrete droplets, jets, or a continuous sheet [1]. The mode plays an important role in the heat transfer. The flow pattern and wetting characteristics in the falling film heat exchangers have significant impact on the sensible and latent heat transfer.

The wetting characteristics and film complex over the tube depends upon distance between adjacent droplets/jets is so called departure site spacing λ (see Figure 1). The departure site spacing is considered to be an important parameter to understand the falling film flow behavior. This paper is aimed to analyze the effects of thermo physical properties like viscosity, surface tension, inertial, and gravitational effects and geometrical parameters on departure site spacing between the adjacent droplets/columns mode.

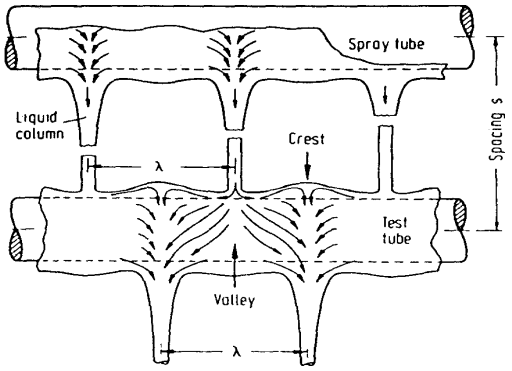

Figure 1. Stationary columns and flow of liquid on the tube.[2]

Departure Site Spacing

The average distance between the two adjacent droplets/columns can be explained with the Taylor instability theory

$$\lambda = 2\pi\sqrt{\frac{n\sigma}{\rho g}} \tag{1}$$

Where n is a factor ≥ 2. n was taken equal to 3, assumed to be thick films, n was taken equal to 2, assumed to be thin film.

The influence of inter tube spacing and flow rate on falling film heat transfer on horizontal plain tube bundles for subcooled liquid without evaporation was investigated by Mitrovic [2], for isopropanol and water. He measured the distance between the two adjacent columns from still photographs, obtaining a value of 22 mm for water at 25°C and 13.5 mm for iso propanol at 21.5°C. These values fall between the critical wavelength λ_{crit} and most dangerous wavelength λ_d. The departure site spacing can be calculated according to equations given by the Lienhard and Wang [3].

$$\lambda_c = 2\pi\sqrt{\left(\frac{g\left(\rho_L-\rho_g\right)}{\sigma}+\frac{2}{D^2}\right)^{-1}} \tag{2}$$

$$\lambda_d = \lambda_{cric}\sqrt{3} \tag{3}$$

Hu and Jacobi [4] experimentally investigated the effects of parameters like tube diameters, tube spacing and liquid flow rate on the film wavelength using four working fluids. They reported that the wavelength depends on flow rate and decreases for an increase in Re. A weak dependence on tube diameter was observed, with wavelength increasing with tube diameter. The dependence of wavelength on the tube spacing was also observed to be the weakest. They correlate the wavelength with Re, $Ga^{1/4}$ and tube diameter and provide a new widely applicable correlation.

$$\lambda = \left(0.863\frac{2\pi\sqrt{3}}{\sqrt{1+2\left(a/d_o\right)^2}} - 0.863\frac{\mathrm{Re}_f}{Ga^{1/4}}\right)a \tag{4}$$

Yung et al. [5], developed an equation to estimate the wavelength of low viscosity liquids like water, ethyl alcohol and ammonia. Ganic and Roppo [6], observed wavelength to be lower than predicted by the Taylor instability and unaffected by the flow rate and tube spacing for the jet mode. Armbruster and Mitrovic [7] provided a correlation for jet spacing; which was based on data with two fluids namely water and isopropyl alcohol. Using current nomenclature, the correlation can be written as

$$\lambda = \frac{2\pi\sqrt{2}}{\sqrt{\frac{g(\rho-\rho_v)}{\sigma}\left(1+\left(\frac{Re_f/2}{Ga^{1/4}}\right)^{0.8}\right)+\frac{2}{d^2}}} \tag{5}$$

This expression is somewhat unique, in that it explicitly accounts for a flow rate effects on the jet spacing. Siyoung et al [9], reported that, the departure site spacing is closer as the flow rate increases and the tube diameter decreases for smooth tube. They proposed a non dimensionalized departure site spacing relation with Reynolds number as

$$\lambda^* = \left(\frac{2\Pi\sqrt{3}}{\sqrt{1+\frac{3}{d^{*2}}}}\right)^{1.1} - 1.62\,Re^{0.22} \tag{6}$$

EXPERIMENTAL METHOD

Experimental Setup

The test facility as shown in Figure 2, is provided with a closed circuit forced circulation loop of test liquid. The purpose of liquid loop was to supply liquid medium to test section. The liquid circulation loop consisted of distributor, reservoir, flow pump and flow meter. The test liquid in reservoir was delivered by pump to distributor via flow meter then passed over the tubes assembly. In the experimental set up to damp the vibrations in the distributor, flow through the flow meter first passed to a circular tube having 2.5 mm diameter holes along its periphery.

At the bottom of distributor small holes of 1.57 mm diameter were drilled at 4 mm apart. The distance between bottom of distributor & top of first tube is kept 5 mm. Commercially available tubes of different diameters viz. 27, 32 and 42 mm with intertube spacing of 10, 15 and 20 mm were kept in the experiment. The arrangement of the tube side stands is made such that the spacing between the tubes can be changed easily.

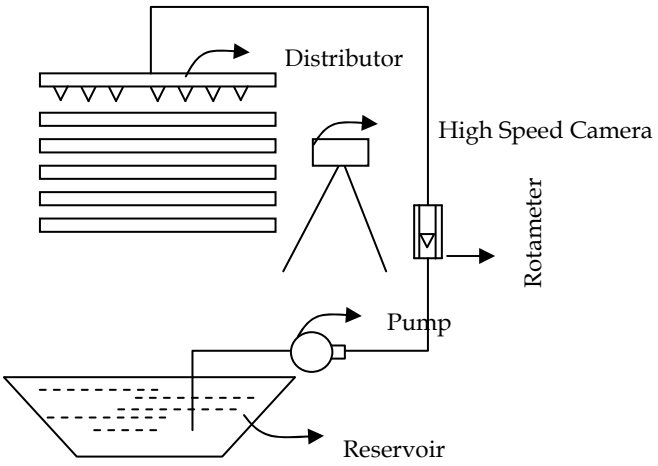

Figure 2. Schematic of experimental setup

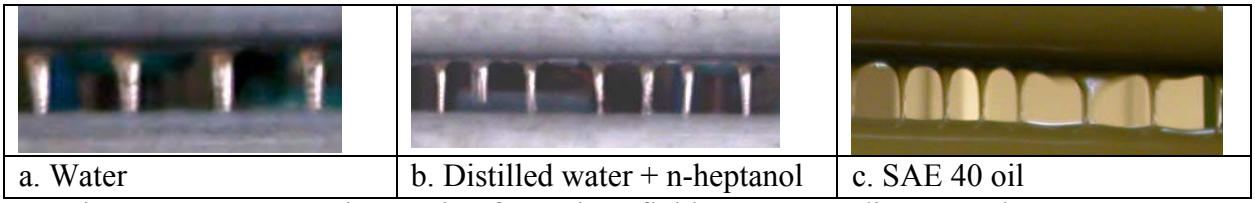
Experimental Procedure

Before test, tubes with desired diameter were aligned horizontally in the test section at prescribed tube spacing. As the falling film flow is gravity driven, a tube inclination would cause a non-uniform distribution of the flow. Also leveling was checked after the liquid started circulating in the system. The liquid flow rate was adjusted to obtain a jet mode, and the tubes were considered leveled if the jets fell at fixed sites without drifting toward either end of the test tube. The test liquid was circulated through the system for 15 to 30 minutes to ensure that the tubes were fully wetted and the piping system was free of air. Then the fluid flow rate was adjusted, mode existed was droplets/columns. Similar tests were carried for water, distilled water with n-heptanol (200 ppm) and SAE40 oil fluids with varying tube diameter and spacing. Some clippings and images were taken for different flow rates. All the experiments reported were conducted over adiabatic tubes at atmospheric pressure having temperature of the liquids were room 25°C.

RESULTS & DISCUSSION

Departure Site Spacing

The measurement of departure site spacing was carried out from the frames, which were excerpted from the Digital video camera for three different fluids viz. water, distilled water with n-heptanol and SAE40 oil. Software Adobe Photoshop 7.0 was used to measure the distance between the two adjacent droplets or columns.



a. Water	b. Distilled water + n-heptanol	c. SAE 40 oil

Figure 3. Departure site spacing for various fluids on 27 mm diameter tube

Figure 3 show the images of departure site spacing of test liquids. It shows that λ^* is higher for water and jets are higher diameter as compared to other test liquids. It might be due to higher surface tension of water as compared to others. Surface tension reduced due to presence of additive (n-heptanol) in water reduces jet diameter, film thickness and λ^*. Viscosity effect is more pronounced for oil film becomes thick and jet is thin and broader at the bottom of the tube. The decreased in Re results in increased in λ^*. Effect of tube diameter are more pronounced and λ^* increases with diameter.

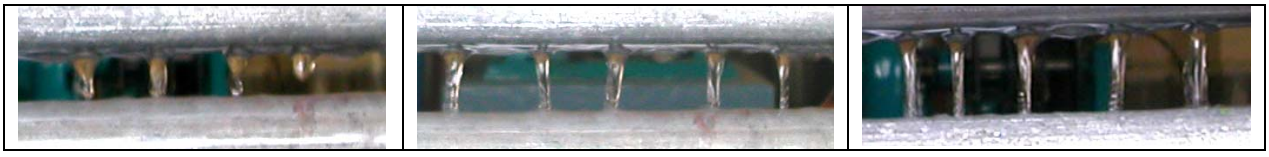


Figure 4. Liquid jet shapes for distilled water at 10mm, 15mm and 20 mm spacing

Figure 4 shows shapes of jet at different spacing between the tubes. For small values of spacing the jet appears to take a shape of pendent drop as increase in spacing, the jet becomes elongated, taking the shape of an inverted bell. For further increase in tube spacing results in jet shape like the upper frustum of cone.

Figures 5-7 show the dimensionless departure site spacing λ^* plotted against Re_f for varying tube diameter and intertube spacing for water, distilled water with n-heptanol and oil respectively.

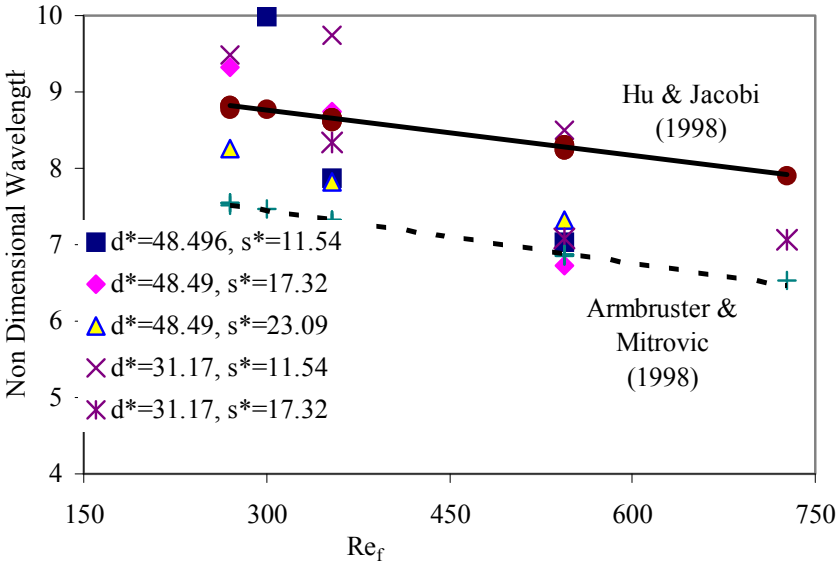

Figure 5. Departure site Spacing (Water)

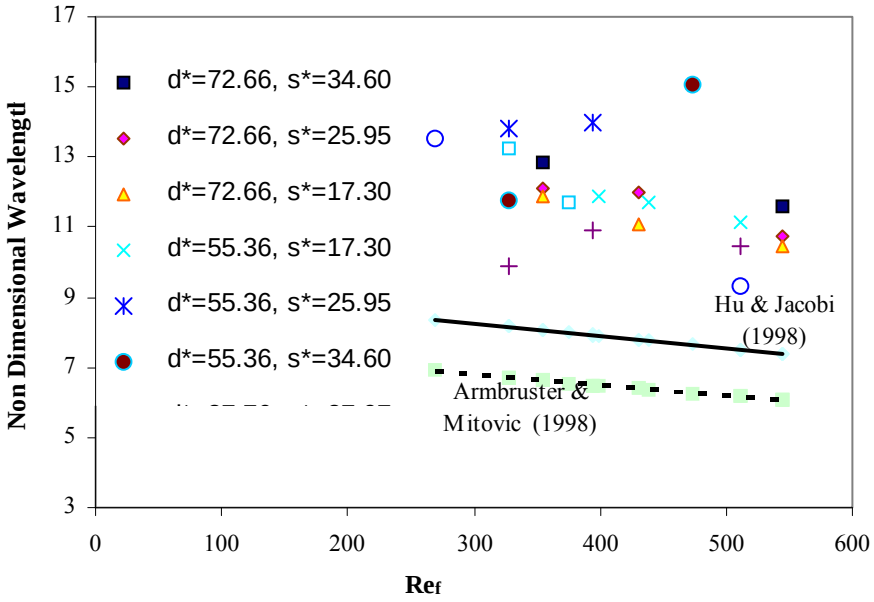

Figure 6. Departure site Spacing (Water + n-heptanol)

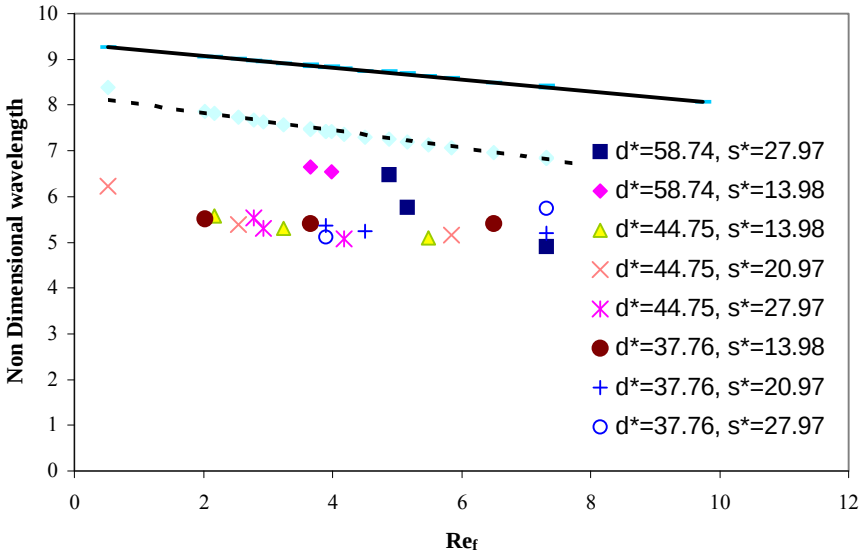

Figure 7. Departure site spacing (SAE 40 Oil)

Measured λ* are compared with Hu & Jacobi [4] and Armbruster & Mitrovic [7]. Figures 5-7 showed, for water results are good agreement with Hu & Jacobi [4] and Armbruster & Mitrovic [7] while water + n-heptanol it is higher side and SAE oil lower side for all test diameter and spacing. The data clearly show that λ^* depends on Re_f especially at low Re_f and high $Ga^{1/4}$. A decrease in Re_f is accompanied by increase in λ^*. At low $Ga^{1/4}$, λ^* appears to be insensitive to Re_f over a wide range. Irrespective of fluid, departure site spacing slightly increased with the increased in diameter of tube. Also it is observed that departure site spacing slightly decreased for water and SAE 40 oil with the increased in tube spacing.

CONCLUSIONS

From the results of this study the following major conclusions are drawn.
Departure-site depends on mass flow rate and decreases for increase in Re_f; this dependence is higher for fluids with a large $Ga^{1/4}$. Using Taylor's instability theory, departure-site spacing was under predicted for thick films and over predicted for thick films. In the experimental data, a weak dependence on tube diameter was observed, with λ^* increasing with tube diameter. The dependence of λ on tube spacing was observed to be the weakest. These results provide deeper understanding of the falling film mode transitions and a useful tool for designing and modeling heat exchangers. Comparisons with existing models suggest that further work in this area is needed.

NOMENCLATURE

d - Diameter, mm
d* - Normalized tube diameter, d/a, dimensionless
Ga - Modified Galileo number, dimensionless
g - Gravitational acceleration, m /s^2
Re_f - Film Reynolds number, dimensionless
s - Tube spacing, mm
λ - Departure-site Spacing
Γ - Total liquid mass flow rate per unit length of tube, kg /ms
λ* - Normalized departure-site spacing, dimensionless
μ - Dynamic viscosity, N –s/m^2
ρ - Mass density, kg/m^3
σ - Surface tension at gas/liquid interface, N/m

EXPERIMENTAL ANALYSIS OF BOILING IN SATURATED FC72 CONFINED POOLS:PRELIMINARY RESULTS

S. Filippeschi[1]
[1] Department of Energy,University of Pisa, Pisa, Italy

ABSTRACT. This paper deals with the analysis of the nucleate pool boiling regime in the case of a copper plate surface immersed in a FC72 fluid at saturation condition. The apparatus has been tested and calibrated by using water and by comparing the experimental data with four correlations. The minimum prediction error is 12,25%. After that the effect of the lateral confinement with FC72 has been studied by reducing the diameter of the vessel which contains the pool. The investigated diameters have been (72, 64, 52, 42, 34 mm). Besides for each diameter the effect of the immersion depth on the heat transfer coefficient has been evaluated. These first preliminary data shows that an enhancement of the theoretically expected heat transfer coefficient have been measured for each diameter except for the diameter 42 mm, where a drastic deterioration of the heat transfer has been observed. A dependence of the CHF on the immersion depth has been observed for little diameters.

Keywords: *Pool boiling, FC72, confined boiling, small liquid pools, immersion depth.*

INTRODUCTION

Boiling heat transfer regime aroused a great interest in the past since the 1900s. For the great number of its possible applications, the natural convective boiling or pool boiling, has been studied by a lot of researchers. Different fluids, different surfaces and materials, different orientations with respect to the gravity and low-gravity conditions have been analysed and experimented [1], [2]. Pool boiling regimes have found a large employment in a large number of technical fields.
The pool boiling regime, which had been studied in the past, is usually characterised by a surface immersed in a large pool of liquid where the sidewalls are far enough from the boiling surface. In compact two-phase devices with small pools of liquid when the boiling is employed as the main thermal control mechanism of a surface in a confined space, its behaviour can be very different to that of the boiling in a large liquid pool, [3],[4].
In 1986 Westwater et al. [5] presented a lot of experimental boiling data of circular flat surfaces (9 diameters from 6.4 to 304.8 mm) at atmospheric pressure with liquid nitrogen, Freon 116, and ethane.
They noted that boiling data depended strongly on the plate diameter when the diameter was small. They found a critical diameter, which made the heat transfer abruptly fall, and in the case of nucleate boiling it was about $2.5\lambda_D$, where λ_D is the most dangerous wavelength for Taylor instability, given by equation (1):

$$\lambda_D = 2\pi \cdot \sqrt{3} \cdot \sqrt{\frac{\sigma}{g \cdot (\rho_f - \rho_g)}}. \qquad (1)$$

In 1987 Elkassabgi and Lienhard [6] studied the effects of the sidewall and of the immersion depth on the critical heat flux (CHF) with methanol. They noted that the CHF decreased with a linear dependence on the ratio of the distance between the sidewall confinement and the diameter of the

* Corresponding author: Dr. S. Filippeschi

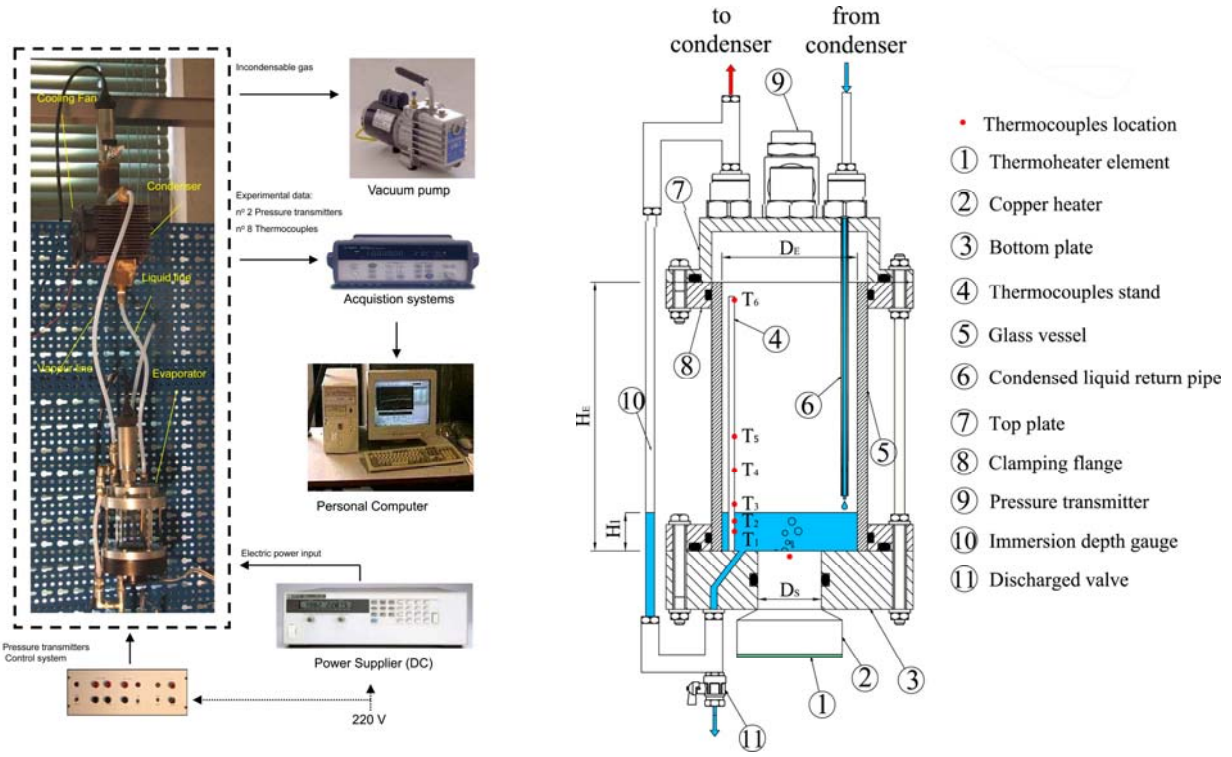
E-mail address: s.filippeschil@ing.unipi.it

heater. They showed that the effect of the immersion depth on the CHF was negligible for ratios higher than 14.78.
In 1998 Bonjour and Lallemand [7] experimentally studied the natural convective boiling of R-113 in a narrow rectangular vertical channel (confined space). The channel height was 120 mm and the gap-size ranges was from 0.5 to 2 mm. They observed, with a hot wire anemometer, three boiling regimes: nucleate boiling with isolated deformed bubbles, nucleate boiling with coalesced bubbles and partial dry-out. Both first two regimes result in a heat transfer enhancement whereas the latter implies a heat transfer deterioration.
In 1998 El Genk and Sauber [8] tested different correlations for uniformly-heated small liquid pools of water, ethanol, methanol, Dowtherm-A, R-11 and R-113 in small cylindrical enclosures. All correlations were within ±15% of most experimental data. The data covered a wide range of pool diameters (6÷37 mm) and heated pool heights (50÷800 mm).
In 2003 Zhao et al. [9] studied the confinement effect of a mesh screen on a horizontal surface. The gap range experimentally studied was 1-5.9 mm. A weak enhancement of the heat transfer coefficient was observed as the nucleate boiling is fully developed.
In 2004 Passos et al. [10] presented results for FC72 and FC87 on a downward facing surface and in confined spaces between a heated copper disk (diameter 12 mm and thickness 2 mm) and an unheated surface, for distances varying between 0.2 and 13 mm. They noted that a decrease in the distance between the plates causes an enhancement of the boiling. In 2008 Kang et al. [11] presented the last of several papers on the pool boiling heat transfer in a vertical annulus. They noted that there was a heat transfer deterioration as the gap size decreased.
This literature review shows that there are a wide number of vague statements and discrepant results in the study of confined boiling. If the gap space effect seem to enhance the heat transfer in particular configurations, in the other cases a deterioration has been observed. Especially in the case of small boiling pools of liquid the effect of the confinement is, at the moment, not so clear.
This paper presents a preliminary study on the small pools of boiling liquid. In particular it deals with the combined effect of the lateral sidewall (D_E) and of the immersion depth on the heat transfer coefficient of a circular plate surface (D_S=18.8 mm).The surface material is copper, the fluid is FC72 at saturation conditions. The investigated ratio D_S/D_E are within the range 1.8÷3.8. Preliminary results of these effects are shown.

EXPERIMENTAL ACTIVITY

Experimental facility

The experimental facility consists of a gravity assisted loop two-phase thermosyphon and a set of instruments and control systems. A photo of the two-phase thermosyphon is shown in Figure 1.a. The thermosyphon consists of an evaporator and a condenser which are connected between them with two flexible pipes. A mechanical sketch of the evaporator is shown in Figure 1.b. It consists of a glass tube closed at the bottom and at the top by two plates. The glass tube is 85 mm high, but it has different internal diameters D_E. (72, 64, 52, 42, 34 mm). The bottom plate is made of a phenolic resin named kite brand Tufnol (ρ= 1440 kg/m^3, k= 0.26 W/m K, c=1.5 kJ/kg K). The bottom plate holds the copper dissipator heated from the bottom by a mica thermofoil heater. The particular shape of the dissipator allows to enhance the heat flux up to 500 kW/m^2 about. The top circular surface of the dissipator (D_S=18.8 mm) is wetted by the working fluid.
A metallic stand for the thermocouples is anchored to the bottom plate. This rigid stand prevents the thermocouples from changing their positions during the tests, because of the convective motions of the working fluid. The 6 thermocouples, all K-type, are located at 6 different distances from the bottom plate 2, 5, 10, 20, 30 and 80 mm. These thermocouples are used to monitor a possible thermal stratification inside the pool. A further thermocouple has been located within the copper dissipater 1.5 mm under the upper surface of dissipator, in order to calculate the temperature of the wall T_W.



(a) (b)

Figure 1. The experimental facility and a scheme of the evaporation section

The top plate is made of aluminium. On the top plate have been placed: the connection with the vapour line, the connection with the return of the condensed liquid, a pressure transmitter and a valve connected with a vacuum pump. The return of the condensed liquid inside the evaporator is realised by a metallic pipe with an internal diameter of 2 mm. The position of this tube remains the same during all the tests. The outlet ending of the tube is locate at 16 mm over the heating surface in a lateral position and does not directly influence the fluid-dynamic close to the heating surface.

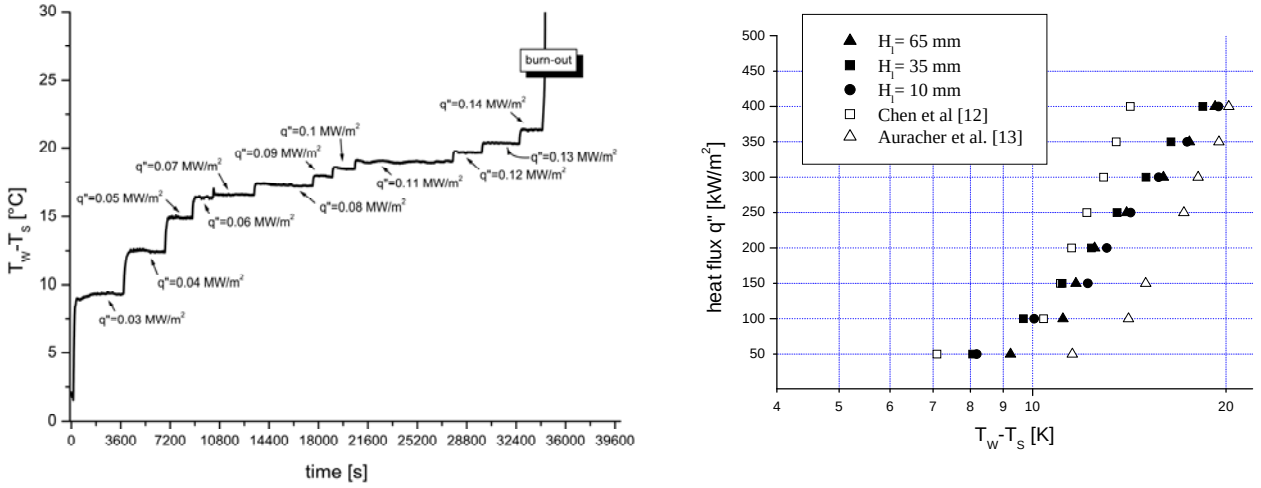
The remote condenser is made of copper. It consists of 4 copper tubes, 90 mm high, with an external diameter of 10 mm, which are connected with an inlet and an outlet manifold and which are covered with 16 copper fins interspaced by 5 mm. These fins are 0.5 mm thick and have a squared form of a side of 80 mm. The condenser is cooled by a centrifugal fan with an air flow rate of 50 m^3/h. The condenser has been designed to remove up to 150 W. In the upper part of the condenser has been place a vessel, to collect all the incondensable gases, and a pressure transmitter. In the upper vessel has been placed a valve connected with a vacuum pump. The condenser has been placed 0.6 m above the evaporator.

Instruments and procedures

The experimental apparatus which has been previously described, is equipped with some instruments and control systems. All the thermocouples used during the tests are K-type thermocouples, 0.5 mm thick, which are connected with a data acquisition switch unit Agilent 34970A. The accuracy specification is ±0.2 K on the differential measurement of two thermocouples. All the readings have been logged in a personal computer. The two pressure measurements are got with two absolutely pressure transmitters Druck PTX75/11 (±0.1% FS (±250 Pa)). The input power is supplied by a thermofoil heater which is electrically connected with a high performance DC power supplies Agilent 6574A.

For each test both the immersion depth and the diameter can change. The diameters D_E which are tested are 72, 64, 52, 42, 34 mm. For each diameter are carried out 5 tests at different immersion depths H_l (80, 60, 20, 10, 7 mm).

The procedure of a single test is here briefly described. The evaporation section is assembled with the glass cylinder of diameter D_E, the vacuum is realised within the loop and the evaporator is charged with a fixed volume of liquid. As soon as the wished immersion depth is reached, the vacuum pump is used again to drain off the incondensable gases.



(a) (b)

Figure 2. (a) Power increasing steps over time (b) Experimental data: water (D_E=72 mm; P=1 atm)

After that the input power is supplied to the thermo-heater starting from a heat flux of 30 kW/m^2 up to the CHF with a increasing step of 10 kW/m^2. For each power step a time necessary to reach the regime heat transfer conditions is waited. An example of the evolution over time of the wall superheat T_W-T_S in dependence on the power input step, is shown in Figure 2.a. Each test is repeated three times without discharge the liquid from the apparatus.

During the tests two different fluids are used: water and FC72. During the test with FC72 a further precaution is kept: an input power is supplied to the thermo-heater and a boiling regime is reached. The apparatus has been carried out for one hour at least and after all the incondensable gases, collected in the upper reservoir of the condenser, are removed with the vacuum pump. In such a way that a degassing of the FC72 is made.

Calibration tests and uncertainties -Water

Water has been used to calibrate the apparatus and to define the uncertainties, because there are a wide literature on the nucleate boiling of a copper plate surface with water at atmospheric pressure.

Figure 2.b shows the wall superheat measured during the experiments for each imposed heat flux for 3 different immersion depths (H_l= 10, 35 and 65 mm). The diameter D_E has been of 72 mm, in order to avoid any effect of the sidewall confinement. These data have been compared with the experimental data available in the literature. All the data in the literature are included within the range of data reported in [12] and [13]. The average wall superheat, experimentally obtained, show errors of about 25% with respect to the data in [12] and [13] for high heat fluxes, whereas they show errors lower than 15% for heat fluxes lower than 200 kW/m^2.

The same data have been compared with the most used nucleate boiling correlations. The first correlation which has been used is that of Stephan and Abdelsalam [14]. They reported, in the case of water, a correlation obtained with a mean absolute deviation between the predictions of the correlation and experimental data of about 11.3%. The applicable correlation for water is the equation (2):

$$\frac{h_{SA}\cdot D_b}{k_f} = 0.246\cdot 10^7 \cdot \left(\frac{q''\cdot D_b}{k_f}\right)^{0.673} \cdot \left(\frac{h_{fg}\cdot {D_b}^2}{{k_f}^2}\right)^{-1.58} \cdot \left(\frac{c\cdot T_s\cdot D_b}{\alpha_f}\right)^{1.26} \qquad (2)$$

where D_b is the bubble diameter expressed by the Fritz correlation by using a contact angle of 45° in the case of water [2]. The second correlation which has been used is that of Rosenhow et al. [1] reported in equation (3):

$$\frac{c \cdot \Delta T_{WS}}{h_{fg}} = C_{sf} \cdot \left[\frac{q''}{\mu \cdot h_{fg}} \sqrt{\frac{\sigma}{g(\rho_f - \rho_g)}} \right]^{0.33} \cdot \left(\frac{c \cdot \mu_f}{k_f} \right)^n \tag{3}$$

In [15] Rosenhow et al compared the accuracy of six well-known nucleate pool-boiling correlations against the reliable experimental databases. They noted that in the case of water and copper surface the correlation with the highest accuracy is that of Rosenhow [1] with a root mean square accuracy of 14% if C_{sf}=0.17 and n=0.76.

In addition to these two classic correlations has been used the Kutateladze correlation [15] which has been developed for predicting the pool boiling regime in two-phase thermosyphons. It is reported in equation (4):

$$h_{Ku} = 6.95 \cdot 10^{-4} \cdot \frac{k_l}{\sqrt{\frac{\sigma}{g \cdot (\rho_f - \rho_g)}}} \cdot \mathrm{Pr}^{0.35} \cdot \left(\frac{q'' \cdot L^*}{\rho_g h_{fg} \nu_f} \right)^{0.7} \cdot \left(\frac{p \cdot L^*}{\sigma} \right)^{0.7} . \tag{4}$$

The Kutateladze correlation has been corrected in the case of small pool liquid uniformly heated, by El-Genk and Saber [8] The El Genk and Sauber correlation is expressed by equation (5)

$$h_{EL} = (1.0 + 4.95) \cdot \psi) \cdot h_{Ku} ; \tag{5}$$

where the term ψ is the mixing coefficient which is given by the equation (6)

$$\psi = \left(\frac{\rho_g}{\rho_f} \right)^{0.4} \cdot \left[\frac{p \cdot \nu_f}{\sigma} \cdot \left(\frac{\rho_f^2}{\sigma \cdot g \cdot (\rho_f - \rho_g)} \right)^{0.25} \right]^{0.25} ; \tag{6}$$

it reflects for the contribution of mixing by sliding and rising bubbles to the nucleate boiling heat transfer in small liquid pools.

Figure 3 shows the comparison between the correlations (2)÷(6) and the experimental data which has been got with water and large diameter liquid pools (D_E=72 mm) at three different immersion depths. Table 1 shows the comparison between the average value of the experimental heat transfer coefficient and those theoretically calculated together to their relative prediction errors.

Figure 3 and Table 1 shows that the Rosenhow correlation has the best accordance with the presented experimental data for heat fluxes lower than 250 kW/m^2. For high heat fluxes the best accordance is given by the El Genk and Sauber correlation. The maximum prediction error is 13.16% and 12.25% for Rosenhow and El Genk and Sauber correlations, respectively.

RESULTS

Sidewall confinement effect

The experimental activity has been carried out with FC72 (C6F14) in saturation condition at atmospheric pressure. As described above, for each experimental condition (diameter and immersion depth) the test have been repeated three times, both without change the fluid and by changing the fluid every time. Every time which the fluid was changed, the boiling copper surface was cleaned with acetone. All the results have shown a good repeatability, except for the case of 42 mm where a sensible difference between the test with a clean or a dirty surface has been observed.

Figure 4 shows the boiling curves in the cases of different confinement diameters and different immersion depths. The bold black line represents the Rosenhow correlation by using the coefficients suggested by Pioro et al. in [15] for the refrigerant fluids and copper surfaces.

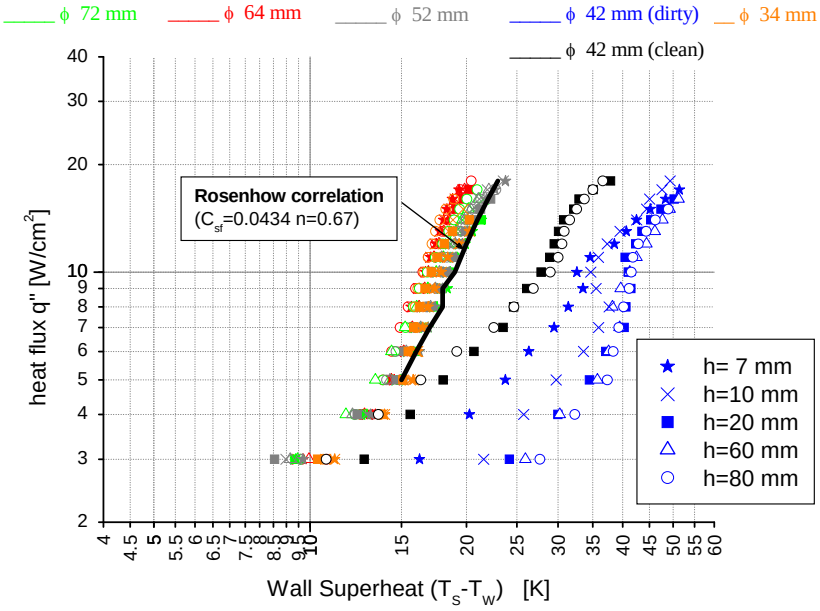

Figure 4: Boiling data of FC72 for different parameters D_E and H_l

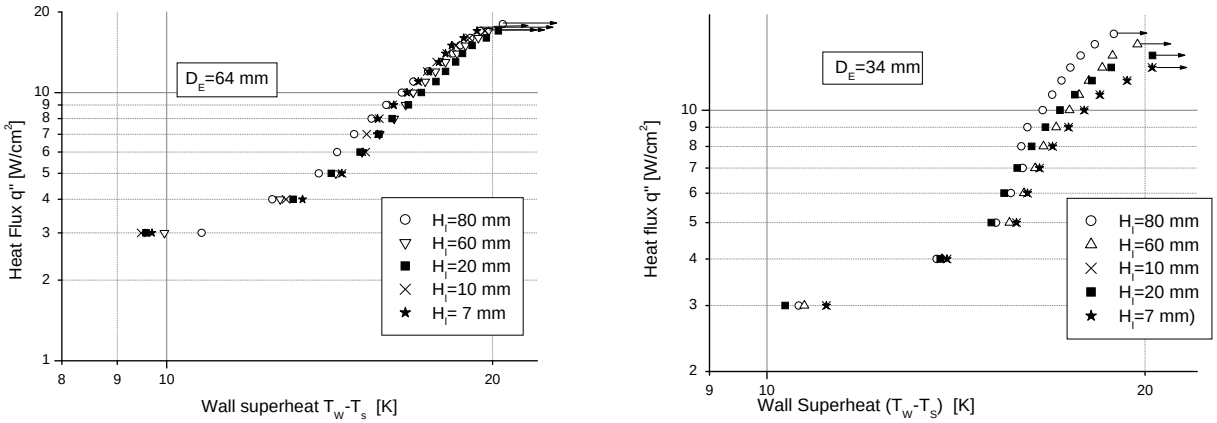
An enhancement of the heat transfer coefficient is observed with respect to that theoretically expected for all the diameters except for the case of 42 mm. In this case a wide spread of experimental data has been observed, but a drastic deterioration of the heat transfer coefficient has been however measured for each test. The results of this diameter are very influenced by the fluid and the surface cleanness, especially for low heat fluxes.This kind of behaviour is very strange and hardly predictable. In 1986 Westwater et al. [5] found that boiling data depended strongly on the plate and vessel diameter when the diameter is small and a critical value of this parameter was determined. For diameter lower than the critical one the heat transfer coefficient abruptly falls.

For nucleate boiling the critical plate diameter was judged to be about $2.5\lambda_D$. In the case of FC72 the Taylor instability length λ_D, given by equation (1), is approximately 8.62 mm, so that the critical diameter should be 21.55 mm about. These data shows that the critical diameter has been found in the value of 42 mm ($4.8\lambda_D$ about), but in the case of diameters (34 mm) lower than the critical value, the heat transfer coefficient increases and not decreases. In the case of very small pools of liquid or very little gap space sizes, an enhancement of the heat transfer coefficient has been reported in the literature[8]-[11]. The behaviour observed during the test could not be in contrast with the literature. Besides Westwater et al. did not present experimental data for diameter lower than the critical one and therefore, a further increase in the heat transfer coefficient, could be measured in that experiment also. Another possible explanation could be provide by the roughness effect.



(a) (b)

Figure 5. Experimental data at different H_l in the case of (a) 64 mm and (b) 34 mm

An excessive cleaning of the surface could have made a real coating of oxidation dust over the boiling surface, by decreasing the nucleation sites number. A further experimental activity focus on the fouling effect of the long time tests could explain this behaviour.

Immersion depth effect

The experiments have been carried out by changing the immersion depth of the small pool of liquid for each diameter. Figure 4 shows that the influence of the immersion depth on the boiling regime is very little. For diameters higher than 34 mm, the influence of the immersion depth on the heat transfer coefficient is low (±5%) as show the case of 64 mm reported in Figure 5.a.

As shown in Figure 5.b, in the case of D_E=34 mm, the immersion depth does not influence the heat transfer during a natural convective regime but in a fully developed regime. The heat transfer coefficient decreases as the immersion depth decreases for heat fluxes close to the CHF above all.

Besides Figure 5.b shows that a linear decrease in CHF value is observed as the immersion depth decrease. These preliminary results seems to confirm the results presented in [6], but a more accurate analysis must be made. A major effect of the immersion depth has been observed in the case of dirty surface. A further experimental activity can better explain this preliminary observation.

CONCLUSIONS

This paper deals with the experimental analysis of the boiling heat transfer regime in case of small pools of liquid. A new experimentally facility has been presented and tested by using water as working fluid. The experimental boiling data are in accordance with the data and the pool boiling correlations reported in the literature. In particular the El Genk and Sauber correlation has shown the best agreement with the experimental data with a maximum prediction error measured of 12%.

By using the new apparatus the effect of the lateral confinement and the effect of the immersion depth on the boiling regimes have been investigated, by observing the phenomena in small pools of FC72 in saturation condition. These preliminary results have shown that an enhancement of the heat transfer coefficient with respect of that predicted by Rosenhow correlation has been observed for all the tube diameters tested (72, 64, 52 and 34 mm) and for each immersion depth (80, 60, 20 ,10 and 7 mm). Just only in the case of the 42 mm diameter the heat transfer coefficient abruptly falls. Some preliminary results on the effect of the immersion depth on CHF have been presented.

CONSTRUCTAL HEAT TRANSFER IN THE ENTRANCE REGION OF PARALLEL PLATE CHANNELS AND DUCTS

T. Bello-Ochende[1*], J. P. Meyer[1] and A. Bejan[2]

[1]Department of Mechanical and Aeronautical Engineering, University of Pretoria, Pretoria, 0002, South Africa

ABSTRACT. This paper reports an increase in the heat transfer rate density by using the entrance regions in parallel plate channel and ducts with laminar flow. The heat transfer rate density is increased by taking advantage of the presence of relatively isothermal fluid at the entrance regions, in order to stimulate a more complete thermal interaction between walls and fluid. Two new methods are studied; the first part of this work consists of numerical simulation in a large number of flow configurations, one differing slightly from the next to determine the optimum plate spacing, and the maximum heat transfer rate density. In the subsequent stages, smaller plates are inserted in the centre plane between two adjacent (optimized space) longer plates in the entranced region where the boundary layer is thin and a core of unused fluid exists. The heat transfer rate density is further increased by progressively inserting shorter plates between the longer plates and then optimizing the whole structure. The resulting structures are optimized multi-scale structures with horizontal equidistant heated plates of decreasing length scales. In the second parts of this report, the ducts square entrances are wrinkled on the perimeter, at the one-third and the two-third positions. The new structure has two degrees of freedom. The fluid flow through the ducts is by the imposed pressure difference across the ducts. Numerical simulations were conducted studying the effects of the dimensionless pressure drop on the optimized configurations which show an increase of between eight to seventeen percent enhancement in heat transfer rate density.

Keywords: *Constructal, Maximum heat transfer density, Multi-scale, Entrance region, Optimal*

INTRODUCTION

Compactness and miniaturisation are driven by the need to remove more and more heat transfer from a given volume. The figure of merit is the heat transfer density. A recent trend in heat transfer research has been the focus on the generation of optimal flow architecture, as a mechanism by which the system achieves its maximal heat transfer density objective under certain constraints [1-3].The strategy is to endow the flow configuration with the freedom to morph, and to examine systematically many of the eligible design configurations. Strategy and systematic search mean that architectural features that have been found to be beneficial in the past can be refined and incorporated into more complex systems of the present. A similar idea has also been pursued and implemented by Dirker and co-workers [4-6] in the cooling of power electronics by embedded solids.

One class of flow features that aid the achievement of high-heat transfer density is the optimal spacings that have been reported for forced convection [7-9]. The progress in this area has been reviewed in [10-14]. Optimal spacings have been determined for parallel plate channels, cylinders in cross-flow, staggered parallel plates, and pin fin arrays with impinging flow. In each configuration, the optimal spacing is a single-length scale that is distributed throughout the available volume.

The optimal spacing idea was taken theoretically and numerically one step further in [1, 7, 15], where the flow structure had not one but several optimal-length scales. These were distributed non-uniformly through the flow space with more and smaller plates in the entrance region of the available volume. The

reason is that the boundary layers were thinner at the entrance and more plates could be fitted together optimally.

In this paper, we evaluated this design approach numerically, by considering forced convection cooling of a volume filled by stacks of parallel plates that generate heat. The plates are modelled three dimensionally which represents the actual geometry in space and the limitations of the result obtained using two-dimensional parallel plates [1] are eliminated. The flow and heat transfer are simulated numerically for a wide range of flow configurations. Each numerical simulation shows that the entrance region of every parallel plate channel has a core of unused (isothermal) fluid. In this wedge-shaped region, we progressively inserted smaller heat-generating plates, and then we optimised the multi-scale assembly. The maximisation of heat transfer density is pursued geometrically, by varying more and more degrees of freedom. The result is a class of progressively better flow structures with multiple-length scales that are distributed non-uniformly through the flow**.**

In the second part of this paper we propose a new concept to improve the constructal design for the cooling of a duct. We start with a square packing of channels, Fig 1. The size of the square ducts is to be selected numerically subject by fixing the pressure drop across the packing. The entranced regions of the duct do not participate fully in the heat transfer enterprise, because of the presence of relatively isothermal (cold) fluid that has not interacted thermally with the walls. Next, the duct entrance is wrinkled to stimulate a more complete thermal interaction between walls and fluid. The new structure has two degrees of freedom: the length of the wrinkled entrance, and the length or the spacing of the square ducts. These geometric features are optimized for maximum volumetric heat transfer density.

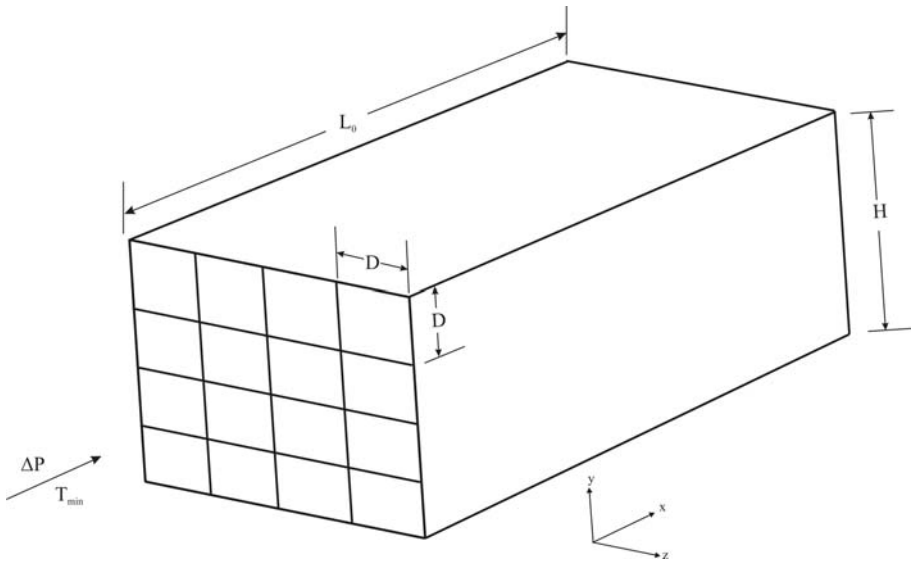

Figure 1. Packing of channels with square cross-sections

ENTRANCE REGIONS WITH WRINKLED ENTRANCES

Consider the three dimensional configuration of a channel with a wrinkled perimeter around a square cross-section. Figure 2 shows the entrance of one square channel after each side was wrinkled at the one-third and two-thirds positions. The walls of the channels (including the wrinkled portions) are maintained at the temperature T_{max}. The channel is cooled by a single-phase fluid at T_{min}, which is forced into the channel by a specified pressure difference (ΔP). The coolant is modelled as a Newtonian fluid with constant properties. The dimensionless equations for the steady-state flow of mass, momentum and energy are

$$\frac{\partial \tilde{u}}{\partial \tilde{x}} + \frac{\partial \tilde{v}}{\partial \tilde{y}} + \frac{\partial \tilde{w}}{\partial \tilde{z}} = 0 \tag{1}$$

$$\frac{Be}{Pr}\left(\tilde{u}\frac{\partial \tilde{u}}{\partial \tilde{x}} + \tilde{v}\frac{\partial \tilde{u}}{\partial \tilde{y}} + \tilde{w}\frac{\partial \tilde{u}}{\partial \tilde{z}} \right) = -\frac{\partial \tilde{P}}{\partial \tilde{x}} + \nabla^2 \tilde{u} \tag{2}$$

$$\frac{Be}{Pr}\left(\tilde{u}\frac{\partial\tilde{v}}{\partial\tilde{x}}+\tilde{v}\frac{\partial\tilde{v}}{\partial\tilde{y}}+\tilde{w}\frac{\partial\tilde{v}}{\partial\tilde{z}}\right)=-\frac{\partial\tilde{P}}{\partial\tilde{y}}+\nabla^2\tilde{v} \tag{3}$$

$$\frac{Be}{Pr}\left(\tilde{u}\frac{\partial\tilde{w}}{\partial\tilde{x}}+\tilde{v}\frac{\partial\tilde{w}}{\partial\tilde{y}}+\tilde{w}\frac{\partial\tilde{w}}{\partial\tilde{z}}\right)=-\frac{d\tilde{P}}{d\tilde{z}}+\nabla^2\tilde{w} \tag{4}$$

$$Be\left(\tilde{u}\frac{\partial\tilde{T}}{\partial\tilde{x}}+\tilde{v}\frac{\partial\tilde{T}}{\partial\tilde{y}}+\tilde{w}\frac{\partial\tilde{T}}{\partial\tilde{z}}\right)=\nabla^2\tilde{T} \tag{5}$$

where $\nabla^2=\partial^2/\partial\tilde{x}^2+\partial^2/\partial\tilde{y}^2+\partial^2/\partial\tilde{z}^2$, and the dimensionless pressure difference is defined as [16, 17]:

$$Be=\frac{\Delta P L_0^2}{\mu\alpha} \tag{6}$$

The non-dimensionalization of the governing equations is based on defining the variables

$$\tilde{x},\tilde{y},\tilde{z}=\frac{(x,y,z)}{L_0},\quad \tilde{P}=\frac{P}{\Delta P} \tag{7}$$

$$(\tilde{u},\tilde{v},\tilde{w},\tilde{U})=\frac{(u,v,w,U)}{\Delta P L_0/\mu},\quad \tilde{T}=\frac{T-T_{min}}{T_{wall}-T_{min}} \tag{8}$$

The boundary conditions are

$$\tilde{P}=1,\quad \tilde{v}=\tilde{w}=0,\quad \tilde{T}=0 \text{ at } \tilde{x}=0 \tag{9}$$

$$\tilde{u}=\tilde{v}=\tilde{w}=0,\quad \tilde{T}=1 \text{ on the walls} \tag{10}$$

$$\tilde{P}=\frac{\partial\tilde{u}}{\partial\tilde{x}}=\frac{\partial\tilde{v}}{\partial\tilde{x}}=\frac{\partial\tilde{w}}{\partial\tilde{x}}=\frac{\partial\tilde{T}}{\partial\tilde{x}}=0 \text{ at } \tilde{x}=\tilde{L}_0 \tag{11}$$

$$\tilde{D}=\frac{D}{L_0},\quad \tilde{L}_1=\frac{L_1}{L_0} \tag{12}$$

We are interested in the geometric arrangement of the wrinkled packing for which the overall heat transfer rate per unit of flow volume is a maximum:

$$q'''=\frac{\text{total heat transfer rate from walls to stream}}{\text{volume of one duct}}=\frac{q}{L_0D^2} \tag{13}$$

In dimensionless form, the above definition can be rewritten as

$$\tilde{q}=\frac{qL_0}{k(T_w-T_\infty)D^2} \tag{14}$$

Numerical method

We solved Eqs. (2) - (5) by using a commercial finite volume code [18, 19]. The domain was discretized using tetrahedral elements, and the governing equations were integrated on every control volume. Second order schemes were used for the diffusive terms. The pressure-velocity coupling was performed with the SIMPLE procedure. Convergence was obtained when the normalized residuals for the mass and momentum equations were smaller than 10^{-4}, and the residual of the energy equation became smaller than 10^{-8}. To obtain accurate numerical results, several mesh refinement tests were conducted. The monitored quantity was the overall heat transfer rate density, which was computed with Eq. (14). Convergence was established based on the criterion

$$\gamma=\left|\tilde{q}_j-\tilde{q}_{j-1}\right|\Big/\left|\tilde{q}_j\right|\le 0.02 \tag{15}$$

where j is the mesh iteration index, such that j increases when the mesh is more refined. When the criterion is satisfied, the j −1 mesh is selected as the converged mesh. A mesh size of 0.005 per unit length in the y and z directions, and a mesh size of 0.01 per unit length in the axial direction were found to satisfy the criterion chosen in Eq. (15).

Packing of wrinkled ducts

We started the optimization procedure by considering the case in which the mouth of the square channel is smooth, without wrinkles. In this case the only degree of freedom is the duct size, $\tilde{D}$. Figure 2 shows the selection of the channel size and the heat transfer rate density, and indicates that an optimal size exists for a channel with a square packing. In the second phase of this study we considered a modified type of wrinkling which allows us to pack the wrinkled entrances into a larger assembly, as shown in figures 2 and 3. The number of degrees of freedom of the geometry is two.

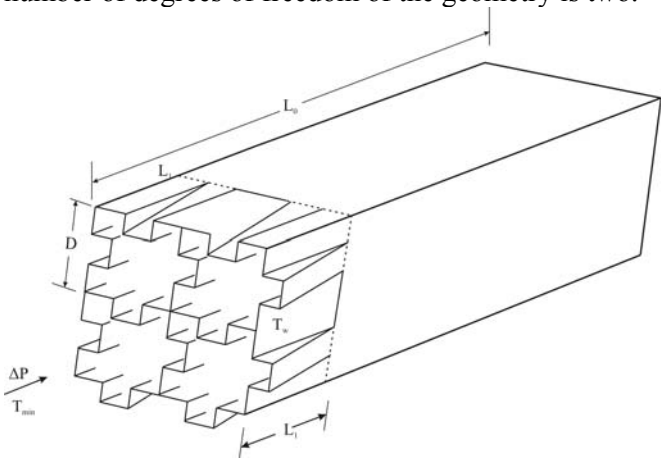

Figure 2. Packing of channels with wrinkled square cross-sections

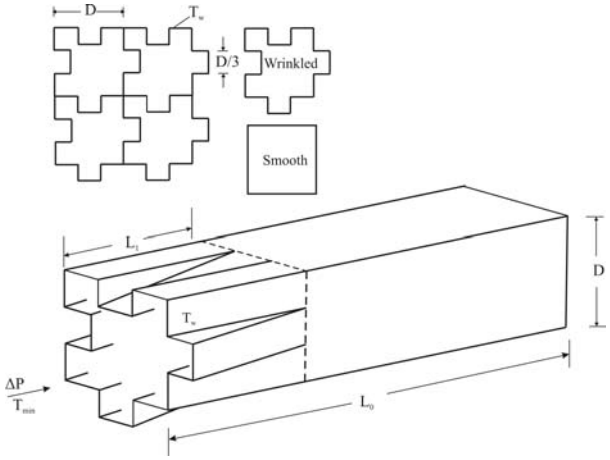

Figure 3. Packing of wrinkled square entrances showing an elemental computational unit of a square channel with wrinkled entrances

The depth of the wrinkled section is kept fixed at $\tilde{D}/6$, in order for the total volume of the new design to be same as that of smooth ducts, and to prevent the wrinkled walls from touching. These modifications prevent numerical instabilities and allow the flow to fill the entrance. Any changes in the position ($\tilde{D}/6$) results in increases or decreases in the total volume when compared with the total volume of a smooth tube of comparable size. The numerical procedure for flow simulation and geometry optimization was the same as the procedure describe in numerical method. As shown in the example of Figure 4, the Be number was fixed, and many configurations of ($\tilde{D}$, $\tilde{L}_1$) were simulated in search of the configuration with the highest heat transfer density $\tilde{q}$. This procedure was then repeated over the range $10^5 \leq$ Be $\leq 10^8$. The results for the new wrinkled duct are reported in Figore 5. Its shows how the new optimized square cross-section, the optimized length of the fold and the maximized performances vary with the dimensionless pressure difference. The optimal length of the fold ($\tilde{L}_{1,opt}$) shows little variation with Be. The optimal duct size decreases as Be increases which is consistence with other constructal studies.

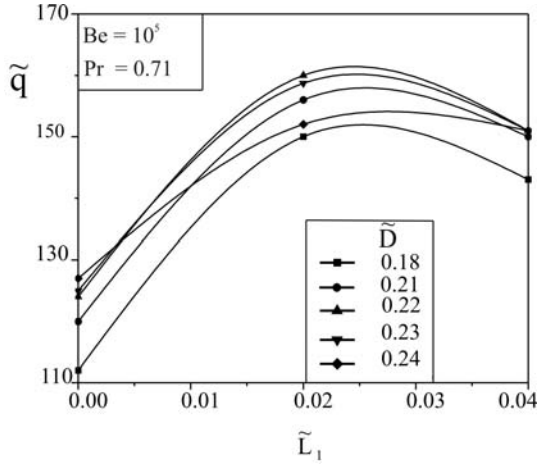

Figure 4. The effect of $\tilde{L}_1$ and $\tilde{D}$ (wrinkled) on the heat transfer density in the assembly of Fig. 3

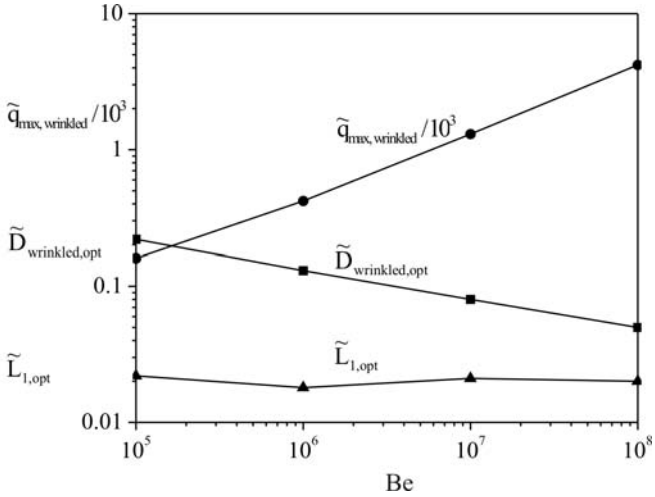

Figure 5. The effect of dimensionless pressure difference on the optimized length scales and on the heat transfer rate density on the assembly of Fig. 3.

ENTRANCE REGIONS WITH PLATE INSERT

Consider a stack of three-dimensional heat-generating parallel plates that form a channel in space as shown in Figures 6, 8 and 9. The plates are modelled as isothermal with temperature $T = T_w$. A stream of coolant with temperature $T = T_{min}$ is forced through the channels that is formed by the plates. The problem consists of maximising the heat transfer rate between the coolant and the heat-generating plates. The governing equations are the continuity, momentum and energy equations (1-5). The assumptions are the same as those of the wrinkled ducts, the boundary conditions are:

$$\tilde{P} = 1, \quad \tilde{v} = \tilde{w} = 0, \text{ and } \tilde{T} = 0 \text{ at } \tilde{x} = 0 \tag{16}$$

$$\tilde{u} = \tilde{v} = \tilde{w} = \frac{\partial \tilde{T}}{\partial \tilde{z}} = 0, \text{ at } \tilde{z} = 0 \text{ and } \tilde{z} = \tilde{W} \tag{17}$$

$$\frac{\partial \tilde{u}}{\partial \tilde{y}} = \frac{\partial \tilde{w}}{\partial \tilde{y}} = v = 0 \quad \text{at } \tilde{y} = 0 \text{ and } \tilde{y} = \tilde{D}_0 + \tilde{t} \tag{18}$$

$$\tilde{u} = \tilde{v} = \tilde{w} = 0, \quad \tilde{T} = 1 \text{ on the surface of the plates} \tag{19}$$

$$\tilde{P} = \frac{\partial \tilde{u}}{\partial \tilde{x}} = \frac{\partial \tilde{v}}{\partial \tilde{x}} = \frac{\partial \tilde{w}}{\partial \tilde{x}} = \frac{\partial \tilde{T}}{\partial \tilde{x}} = 0 \quad \text{at } \tilde{x} = (\tilde{L}_0 + \tilde{L}_u + \tilde{L}_d) \tag{20}$$

The dimensionless overall heat transfer density based on the total fluid volume is

$$\tilde{q} = \frac{qL_0}{k(T_w - T_\infty)WD_0} \tag{21}$$

Channels with plates insert

In the first phase of this study, we simulated numerically the heat and fluid flow fields for Figure 6 in the laminar range represented by $10^5 \leq Be \leq 10^7$, plate thickness $0.01 \leq \tilde{t} \leq 0.05$ and width $\tilde{W} = 1$, for several geometries in search of the optimal spacing. The optimisation of the stack of parallel plate channels has one degree of freedom, the spacing between the plates. This was optimised for a given Be and Pr and a fixed plate thickness. The results are shown in Figure 7. Comparison between the theoretical results, $\tilde{D}_0 = 2.7 Be_{L_0}^{-1/4}$ and numerical results shows the same trend.

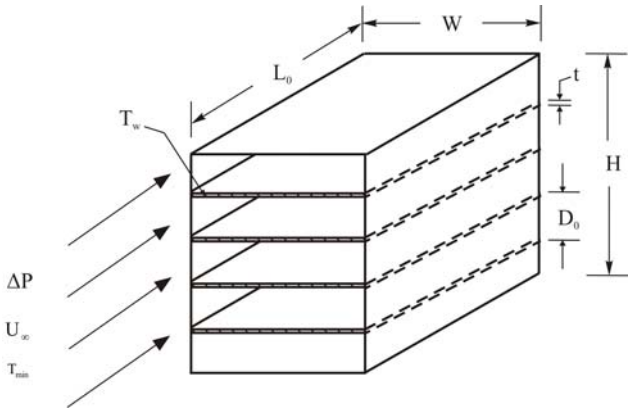

Figure 6. Stack of parallel plate channels

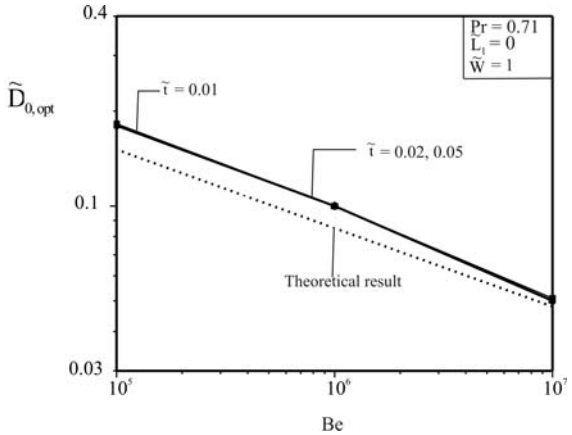

Figure 7. The maximised total heat transfer rate from a plate with finite thickness as a function of dimensionless pressure drop number.

In the sequence of increasing more complex structures and utilising the fluid wedge between two parallel plates, a small $\tilde{L}_1$-long plate with plate thickness $0.5\tilde{t}$ was inserted between the plates with thickness $\tilde{t}$ as shown in Figure 8.

To determine the contribution of the $\tilde{L}_1$-long plate, we fixed $\tilde{D}_{0,\,opt}$ at the values determined previously (Figure 7) so that the already optimised structure stays the same. The spacing between the plates becomes $\tilde{D}_{opt} = 2\,\tilde{D}_{1,opt}$. The thickness of the plates was set at $\tilde{t} = 0.01$, as the maximised $\tilde{q}$ is insensitive to changes in $\tilde{t}$ as previously determined. We now optimized $\tilde{L}_1$ by varying its length until we obtained an optimal length that corresponded to the new maximised $\tilde{q}$. The procedure stated above was repeated for several Bejan number in the range $10^5 \le Be \le 10^7$ and Pr = 0.71, for the ratio of $\tilde{D}_{0,opt}/\tilde{D}_{1,opt} = 2$. The results are shown in Figure 10.

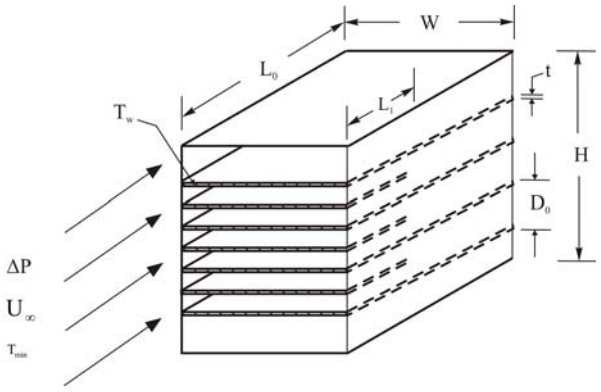

Figure 8. Stacks of parallel plates, with small plate insert

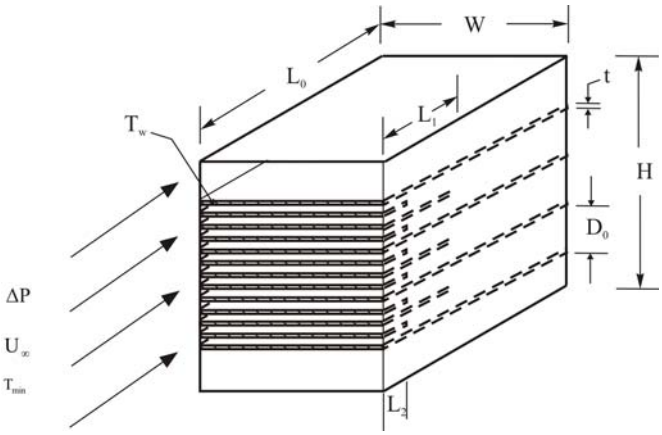

Figure 9. Three-dimensional stacks of parallel plate channels with smaller plate inserts

In the sequence of constructing a multi-scale assembly, and determining the contribution brought about by enduring the flow structure with more degrees of freedom, we inserted a second plate, $\tilde{L}_2$ (see Figure 9) in the channels formed between the L_0 and $\tilde{L}_{1,opt}$ channel, while still retaining the optimal spacing $D_{0,opt}$ obtained without plate insert. We now varied the length of the second plate until an optimal length, $\tilde{L}_{2,opt}$ of the plate that maximises the heat transfer rate density is obtained.

Figure 10 show the contribution of the second plate inserts to the heat transfer rate density is not significant. So inserting more plate to the structure is not beneficial to the heat transfer rate density. It was therefore decided to keep the number of plate inserts to two. Figure 11 shows that as the pressure number increases, the plate length increases. This is due to the fact that the slenderness of the plates also increases with the pressure drop number. Note that $\tilde{D}_{opt} = 2\,\tilde{D}_{1,opt} = 4\,\tilde{D}_{2,opt}$.

Figure 12 shows the comparisons of the theoretical heat transfer prediction, Eq. (22) and the results obtained from numerical analysis. It was observed that the general trend is the same and the agreement is acceptable. Figure 12 shows that the maximised heat transfer rate density increases in proportion to $Be^{1/2}$. This confirms the analytical result Bejan and Fautrelle [20] which can be rewritten in the notation employed in this paper for asymmetric plate inserts:

$$\tilde{q} = 0.36 Be^{1/2}\left(1+\frac{m}{2}\right)^{1/2} \qquad (22)$$

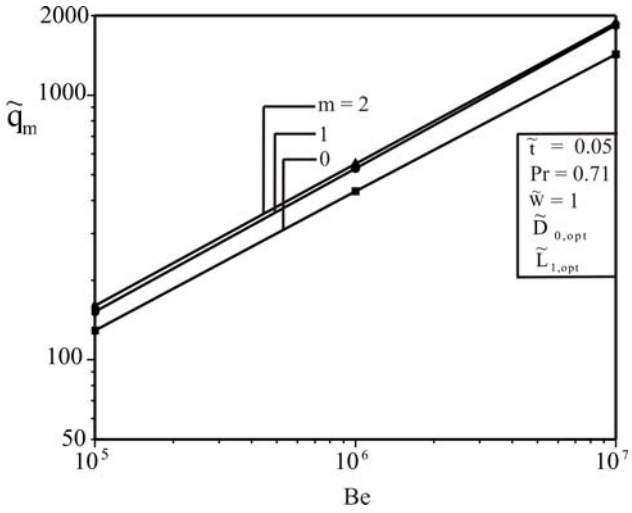

Figure 10. The maximized heat transfer density of the flow structure with three plates

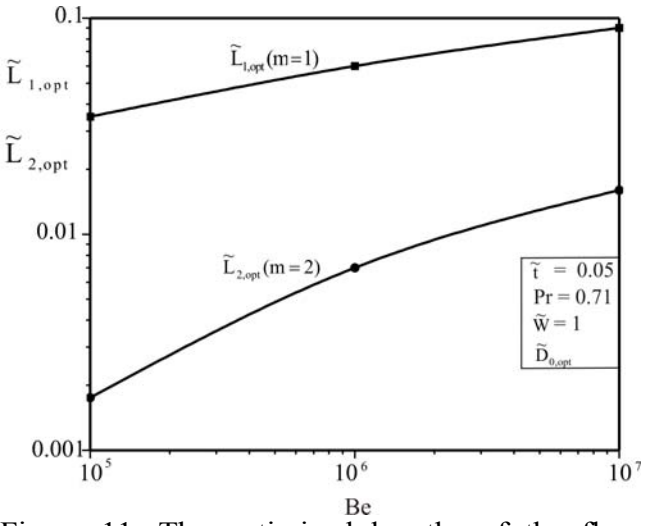

Figure 11. The optimized lengths of the flow structure with two length scales for the ratio $\tilde{D}_{o,opt}=2\tilde{D}_{1,opt}=4\tilde{D}_{2,opt}$.

Parameter m is the number of new (inserted) plate lengths, for example when m = 1, 2 as in Figure 12. The prediction is that the heat transfer rate density increases in progressively smaller steps as the number of length scales increases. This is confirmed by the numerical result shown in Fig. 12. Using the relationship obtained from Bejan and Fautrelle [20].

$$2^{4m}\left(1+\frac{m}{2}\right) = \frac{Be}{10^3} \tag{23}$$

and solving for m for Be in the range 10^5 to 10^8, one find that the realistic cut off (smallest) length scales below which the boundary layer are no longer distinct and where the sequence of generating optimal length scale ends is approximately m = 2, which also correspond to our numerical results.

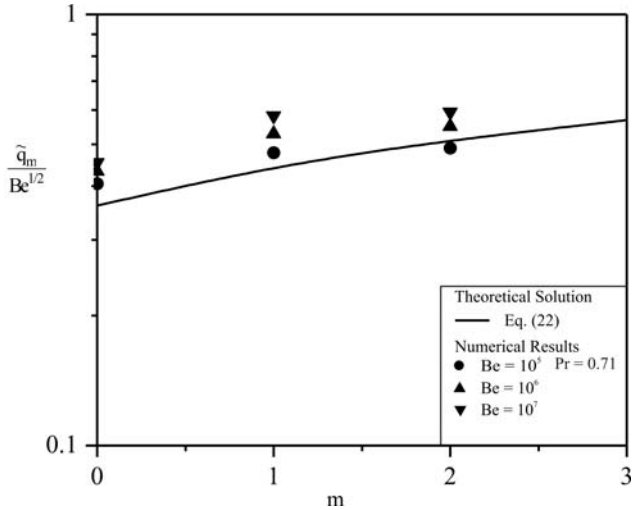

Figure 12. Comparison between the theoretical maximum heat transfer and the numerical results obtained from this study versus number of plates inserted.

CONCLUSION

In the first part of this paper, we described a new design for increasing the heat transfer rate density by using wrinkled entrance regions in ducts with laminar forced convection. The method consists of wrinkling the perimeter of square entrances, and by extending these deformations gradually downstream to a length ($\tilde{L}_1$) that is optimized. This new geometry allows a more complete heat transfer interaction between the walls and the fluid. The results show that the heat transfer rate density increases with the imposed pressure difference. In the second part of the paper, we illustrated the emergence of a multi-scale forced convection flow

structure for maximal heat transfer rate density for three-dimensional parallel plates installed in a fixed volume, and ducts wrinkled at the entrances. The objective was achieved by inserting smaller plates in the entrance region formed between successive plates. This technique utilises to the fullest the fluid surrounding the two tips of two neighbourhood plates where the boundary layers are the thinnest. The optimised spacing was fixed with each new (smaller) plate that is inserted into the entrance region of each channel. Optimal spacings were found numerically for structures with one length scale. Performance increases as complexity increases. The number of plate-length scales is limited by the validity of the boundary layer assumption. The smallest plate is the one where the plate length is comparable with the boundary layer thickness. The fundamental value of this study is that multi-scale flow structures are applicable to every sector of heat exchanger design. This approach promises the development of new and unconventional internal flow structures for heat exchangers and cooled electronic.

NOMENCLATURE

Be	dimensionless pressure number,
d	spacing between two-dimensional parallel plates, m
D	sides of duct cross-section, m
D_0	spacing between two plates, m
D_1	spacing between the L_0 and L_1 plates when L_1 plate is inserted, m
H	stack height, m
j	mesh interation index
k	thermal conductivity, W/mK
L_u	length of control volume before the plate, m
L_0	plate length in the flow direction, m
L_1	flow length of the first plate insert and flow length of the wrinkled section, m
L_2	flow length of the second plate insert, m
L_d	length of control volume downstream after the plate, m
m	number of new inserted plates
n	number of plates

LOCAL HEAT TRANSFER FROM MICRO IMPINGING JET ARRAYS

T. Lupton[1], A. Robinson[1], D. Murray[1]
[1]CTVR (Centre for Telecommunications Value-Chain Research)
Department of Mechanical and Manufacturing Engineering, Trinity College Dublin, Ireland

ABSTRACT. Much research has been carried out into the area of large scale impinging jet heat transfer but smaller scale jets are relatively unexplored in comparison. In this study 620 μm diameter confined air jets impinge normally onto an ohmically heated flat surface. The resulting surface temperature distributions, from a 3 x 3 in-line jet array, are recorded with an infrared camera with a spatial resolution of 47.5 μm. The inter jet spacing was kept constant at 4 jet diameters and the jet-to-target spacing was varied from 0.42 to 3.35 jet diameters. Tests were carried out at jet Reynolds numbers of 3000 and 6300 corresponding to Mach numbers of approximately 0.21 and 0.43. Results are presented in terms of local heat transfer coefficient distribution. The results indicate that small scale jet impingement heat transfer is fundamentally different than its larger scale counterpart. The effects of entraining warm fluid into the pre-impact jet are thought to considerably affect the heat transfer behaviour of the jets.

Keywords: *microscale, jet impinging, convective heat transfer, heated thin foil method, infrared thermography*

INTRODUCTION

Impinging jet flows are capable of achieving high heat transfer due to the very thin boundary layers resulting from them. A comprehensive literature review exists for macro scale impinging jet heat transfer, Martin [1], Webb and Ma [2] and Garimella [3]. However, the potential use of jets in thermal management of electronic devices has generated an interest in micro scale jet heat transfer. Garimella and Rice [4] noted that the effect of nozzle diameter on heat transfer is not always captured by conventional Nusselt number correlations. San et al. [5] noted similar effects for jet diameters smaller than 6 mm. Pence et al. [6] noted that direct scaling of macro scale heat transfer equations, as correlated by Martin [1], to the micro scale is improper as the fluid flow is dynamically different. Moderate Reynolds number jet flows can correspond to high Mach numbers in micro scale jets since the small characteristic lengths result in high jet velocities. The goal of this study is to investigate how parameters such as Reynolds number and nozzle-to-impingement surface spacing influence the heat transfer mechanisms for multiple micro-sized jets.

EXPERIMENTAL SET-UP

This study looks at a 3 x 3 in-line jet array with 620 μm diameter orifices, as depicted in figure 1. Several geometric and flow parameters are known to affect the local heat transfer resulting from such an array. Tests were carried out at a fixed inter jet spacing of S/D = 4, two Reynolds numbers were tested, Re = 3000 and Re = 6300 and the nozzle-to-impingement surface spacing was varied in increments from 0.42 to 3.35 jet diameters.

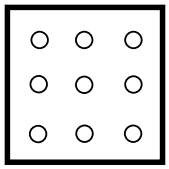

Figure 1. Test nozzle configuration for the 3 x 3 in-line array

The experimental facility used is illustrated in figure 2. The air flow to the test section was controlled with a MKS type 1179A mass flow controller (0-20 LPM ± 1% F.S). Air enters a plenum chamber where the stagnation temperature is monitored with a 1.5 mm diameter type-K thermocouple. The air inside the plenum then passes through a pipe nozzle with a development length, L_{dev}, of 20 jet diameters. This is sufficiently long to ensure a fully developed velocity profile at the exit of the nozzle, Incropera [7]. The nozzle surface is subject to heating from the foil beneath it. In order to maintain both the temperature of the air in the plenum and the temperature of the nozzle surface at ambient conditions, cooling channels were embedded into the nozzle plate. The coolant, water, is maintained at ambient temperature by passing it through a cross flow heat exchanger. Both the heated foil and nozzle plate had widths greater than 40 jet diameters as San et al. [5] demonstrated that stagnation Nusselt numbers varied with the width of the heated surface for $W/D < 40$. The heater assembly consisted of a 25 μm thick stainless steel foil (AISI 321 - Fe/Cr18/Ni9/Ti) which was heated ohmically by a Lambda DC power supply capable of supplying 200 A at 6V. The potential difference across the foil was measured from voltage taps attached to the foil. Construction of the impingement surface involved bonding the 80 mm by 28 mm foil to two copper bus bars with an electrically conductive, silver loaded epoxy. One bus bar was then fixed to a rigid stand whilst the other was mounted to a section of the stand which could traverse linearly along a pair of guidance rods. After the foil was cured, springs, located along the guidance rod, were adjusted to tension the foil. This tensioning system ensured that the foil remained continuously taut with varying system temperature.

The jets impinged onto the upper surface of the foil, however, as the metallic foil is so thin, calculations of the Biot number showed that the temperature drop across the thickness of the foil was negligible. Therefore, by cooling the upper surface with impinging jets it is possible to indirectly and non-intrusively record the resulting upper surface temperature distribution from the lower surface of the foil via infra red thermography. To facilitate accurate temperature measurement, the exposed underside area of the foil was covered with a thin layer of matt black paint with an emissivity $\varepsilon = 0.95$. Utilizing a FLIR ThermoCam A40 fitted with a close focus lens, IR thermal images were captured to record the temperature distribution of the foil. The total camera viewing area was 15.2 mm by 11.4 mm with a spatial resolution of 47.5 μm and a frame rate up to 50 Hz. The nozzle exit to impingement surface spacing, H, was set by zeroing the system through placing the jet exit surface in contact with the impinging surface. Subsequent to zeroing a traversing stage fitted with micrometers was used to accurately position the plenum relative to the foil.

DATA REDUCTION AND EXPERIMENTAL UNCERTAINTY

As some tests were carried out at large Mach numbers, $M = 0.43$, for which compressibility effects were significant, Re and M were calculate from an iterative approach outlined by Goodro et al. [8]. Goldstein et al. [9] determined that impinging high speed jets caused non-uniform temperature profiles on the adiabatic surface. This variation in temperature was accounted for by using the adiabatic wall temperature as the reference temperature in the calculation of the local heat transfer coefficients, equation 1.

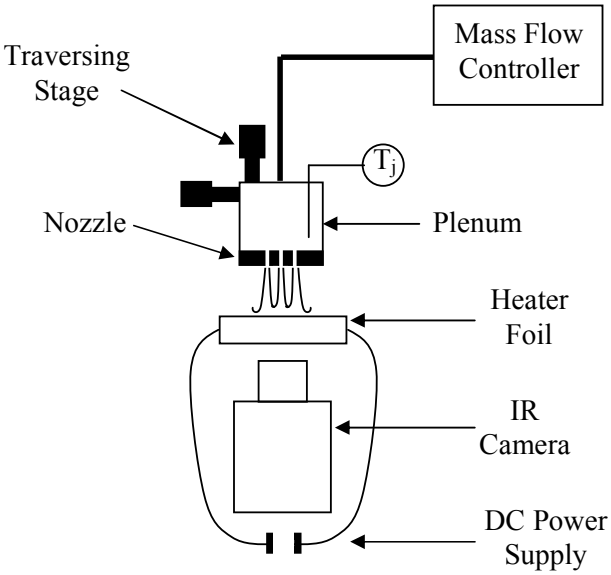

Figure 2. Experimental facility.

$$h = \frac{q''_{conv,jet}}{(T_{h,w} - T_{a,w})} \tag{1}$$

The adiabatic wall temperature, $T_{a,w}$, and the heated wall temperature, $T_{h,w}$, were obtained by recording the temperature distribution resulting from the 9 jets impinging onto first an unheated and subsequently a heated impingement surface, figure 3. The heat flux due to forced convection, $q''_{conv,jet}$, was calculated from an energy balance, equation 2.

$$q''_{conv,jet} = q''_{gen} - q''_{rad} + q''_{lc} \tag{2}$$

The largest term on the r.h.s. of equation 2 is q''_{gen}, the heat flux generated in the foil. The heat flux due to radiation, q''_{rad}, is relatively small however the heat flux due to lateral conduction, q''_{lc}, which is negligible in a macro scale system, is of the same order of magnitude as the generated heat flux. Calculating q''_{lc} required numerically approximating the 2nd spatial derivatives of heated temperature distribution. These derivatives were achieved by using finite difference approximations, however spatial fluctuations in the temperature field have a severe impact on numerical approximations of the 2nd spatial derivatives of temperature. To overcome this, a Wiener filter is used to smooth the data, Rainieri et al. [10].

In order to quantify the level of uncertainty in the lateral conduction component a Monte Carlo technique was implemented for each Reynolds number tested. For the purpose of uncertainty calculation, each measurement is denoted by x_i and the uncertainty in the measurement w_i. The result of a calculation using these measurements is denoted Z and the uncertainty in the calculated result is denoted by w_z. The uncertainty w_z is calculated from the method of Kline and McClintock [11] using the following equation:

$$w_z = \sqrt{\left(\sum_{i=1}^{n} \left[\frac{\partial Z}{\partial x_i} w_i \right]^2 \right)} \tag{3}$$

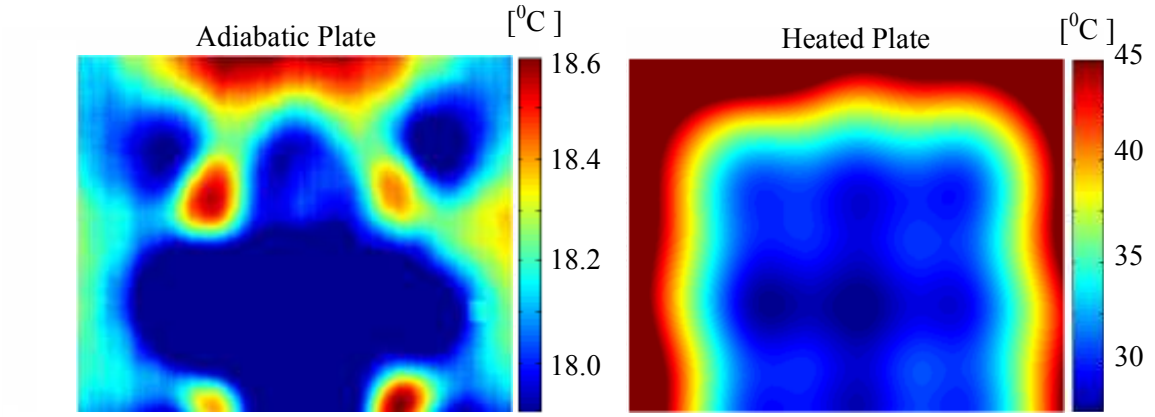

Figure 3. Temperature distributions resulting from a 3 by 3 inline jet array impinging onto a cold and a hot surface at H/D = 2.1 & Re = 6300.

The maximum experimental uncertainties are summarized in table 1.

Table 1
Calculated uncertainty

		Re		q''_{lc} (W/m^2)		h (W/m^2 K)

±7%	±10%	±4%	±8%	±12%	±9%	±12.5%	±9.5%

RESULTS AND DISCUSSION

Hubar and Viskanta [12] studied a 6.35 mm diameter 3 by 3 square jet array and found varying nozzle to target spacing from 1 to 6 jet diameters has little effect on the resulting Nusselt Numbers. However Garimella and Schroeder [13] later showed, for a similar shaped 1.59 mm diameter array, that decreasing nozzle to target spacing increased heat transfer. Similar results were seen for the tests carried out in this investigation, as illustrated in figure 4. Behbahani and Goldstein [14] attributed these findings to increasing turbulent intensity found at decreasing H/D values due to increased mixing caused by spent fluid from neighbouring jets. Another phenomenon that affects heat transfer and depends on nozzle to impingement spacing is entrainment. Azar et. al. [15] describes how entrainment can modify a jet's pre-impact temperature and Striegl and Diller [15] showed that the entrainment of warm air decreases with decreasing H/D.

In all test for H/D < 3, the central jet of a nine-jet array had considerable larger stagnation region heat transfer than its peripheral jets, figure 4, which is consistent with findings of Garimella and Schroeder [13]. This could be caused by the effects of turbulence intensity and entrainment. The central jet is surrounded by eight jets so it is expected that the temperature of the entrained fluid is lower in the central jet than in the fluid entrained by the peripheral jets. The increase in the stagnation heat transfer for the central jet compared to the peripheral jets is more pronounced at large Reynolds numbers which can be clearly seen at the bottom of figure 4.

Figure 5 shows the local heat transfer at values of H/D = 0.42, 1.68 & 2.94 and Re = 3000 & 6300. The images show the heat transfer between the stagnation zones. The central zone between any 4 adjacent jets demonstrates local minima in heat transfer. However, the linear zones located between

2 adjacent jets demonstrated relatively high heat transfer which has been associated with inter jet interaction. The interaction zones between the centre jet and adjacent peripheral jets demonstrated higher heat transfer than the interaction zones between purely peripheral jets.

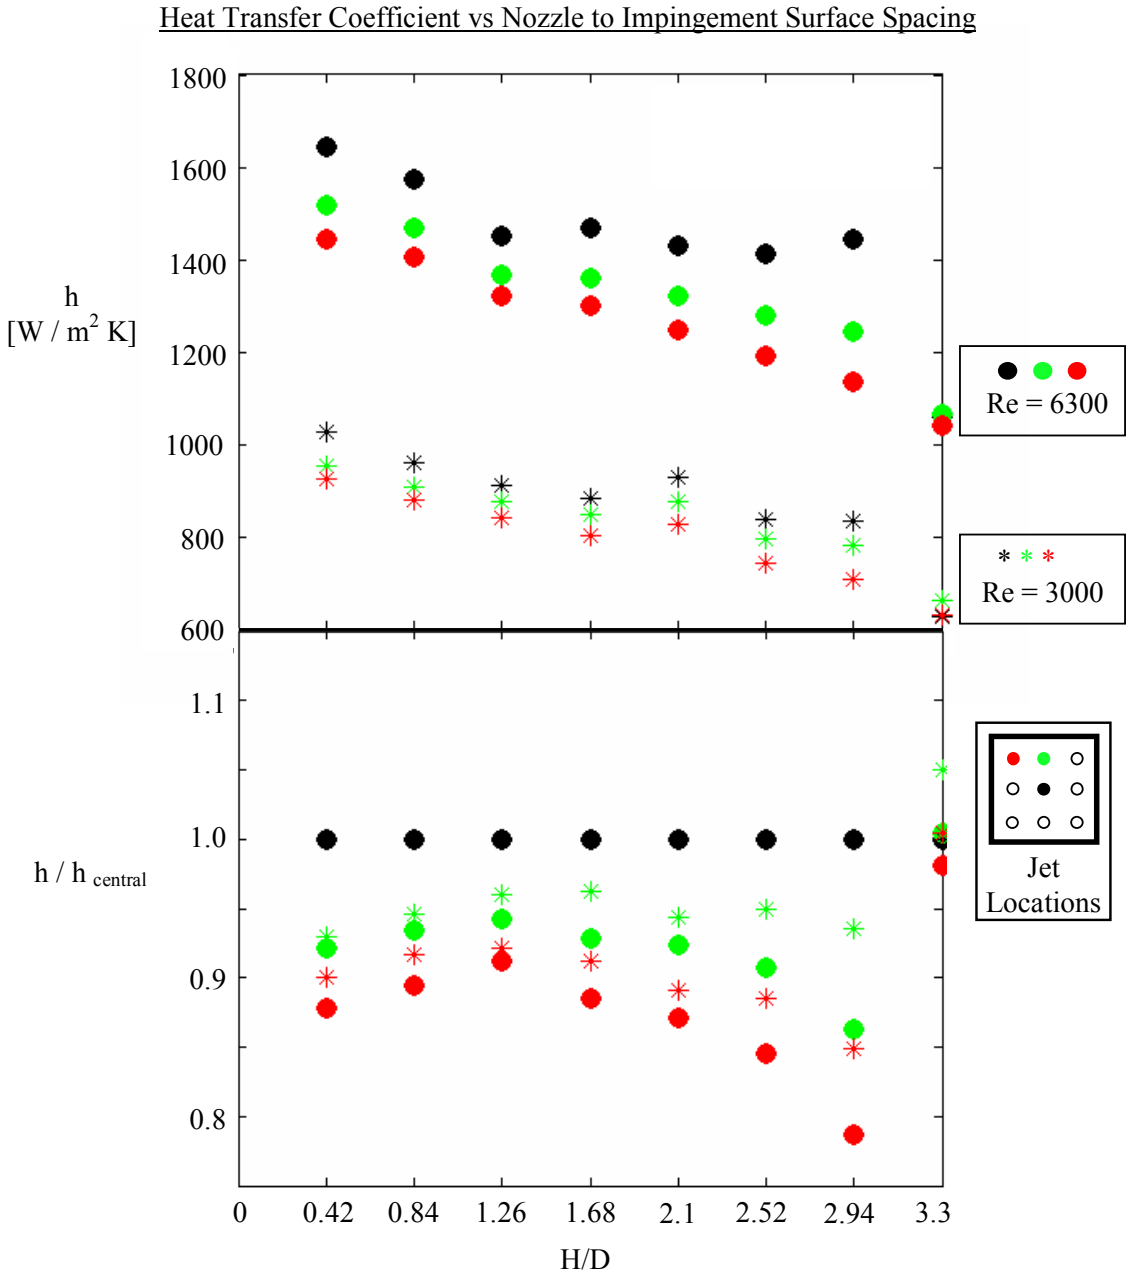

Figure 4. Stagnation point heat transfer coefficients at different nozzle to impingement surface spacings, for 3 individual jets found in a 3 x 3 inline jet array.

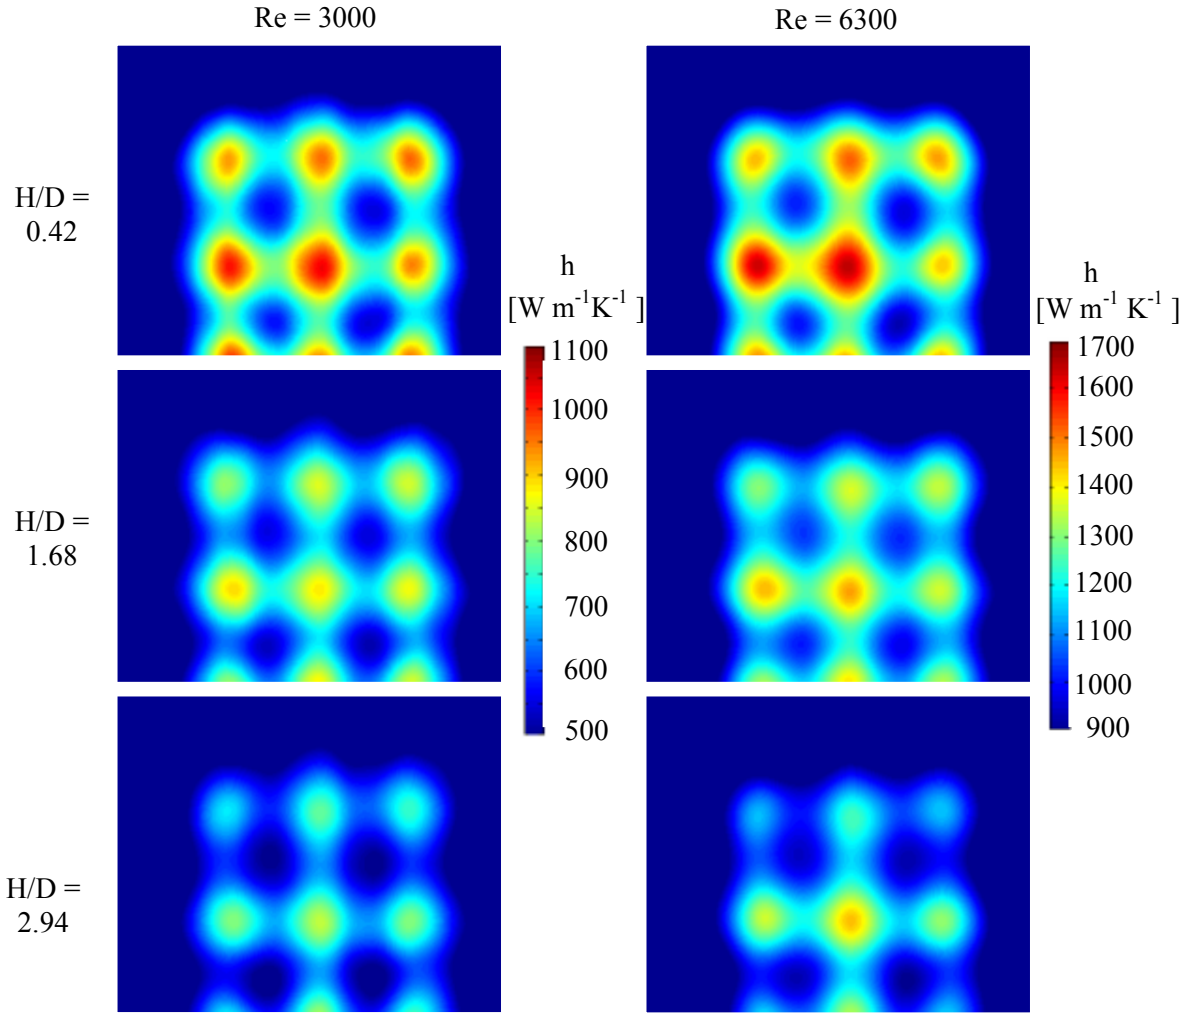

Figure 5. Local heat transfer distributions resulting from a 3 x 3 inline jet array impinging at H/D values of 0.42, 1.68 & 2.94 and at Reynolds numbers of 3000 & 6300.
Each image is 10 mm by 13 mm.

CONCLUSIONS

Micro jet heat transfer for a 3 x 3 array of 620 μm diameter jets was investigated experimentally. Experiments were performed using a heated thin foil and infrared thermography at a interjet spacing, S/D, of 4 and Reynolds number of 3000 & 6300; nozzle to impingement surface spacing was varied from 0.42 to 3.35 jet diameters.

The small length scale associated with micro jets suggests that Reynolds number scaling from the macroscale to the microscale is inappropriate, due to the high velocities associated with relatively low Reynolds numbers. These velocities result in high subsonic Mach numbers making compressibility a factor. It is thought that entrainment effects and turbulence intensity are vastly more significant at smaller scale.

The microjets studied demonstrated increasing heat transfer, both local and area averaged, with an increased Reynolds number. Heat transfer was also found to increase with decreasing nozzle to impingement surface spacings. Post-impact jet interactions lead to increased heat transfer in regions found between adjacent jets. The highest heat transfer was found to be in the stagnation zone associated with the central jet.

PERFORMANCE OF THREE DIFFERENT EVAPORATIVE COOLING SYSTEMS

E. Velasco[1] *, F. J. Rey[1] , A. Tejero[1], F. E. Flores.[2]
[1]University of Valladolid, Valladolid, Spain
[2]University of Quintana Roo, Quintana Roo, Mexico

ABSTRACT. This paper aims to describe three different evaporative cooling systems. The first is an indirect evaporative cooling system, which operates as an aluminium plate exchanger. It has two independent air streams. The supply air stream needs to be cooled, while the exhaust air is in direct contact with a water flow in order to improve heat transfer to the primary air. The second case is a semi-indirect evaporative cooling system which consists of a bank of porous ceramic pipes arranged vertically. The supply air circulates outside the pipes, while the return air is in contact with the water which circulates inside to allow heat and mass transfer and thus cool the primary air flow. The third system is also semi-indirect and has been manufactured with hollow bricks. It is fed by the primary air stream used for cooling, which comes into direct contact with the porous humid surface of the outer walls of the bricks, thus facilitating heat and mass transfer. This work compares the performance of these systems, considering heat transfer surfaces of approximately $2m^2$.

Keywords: Evaporative cooling, heat recovery, cooling capacity

INTRODUCTION

Nowadays, the availability of energy is essential for everyday life and welfare all over the world, even though energy consumption in wealthy countries is much higher. Therefore, population and economic growth is expected to involve a faster increase in energy consumption, despite the rise in fossil fuel prices.

Taking this into account, many problems such as dependency on sources, increased cost or the environmental impact of energy use and transformation are to be faced. Thus, new legislation to ensure sustainable energy provision at an affordable price is needed. In this context, evaporative cooling systems are of increasing interest to reduce thermal energy demand in buildings, since it is easier to cool with cold water than with hot air [1]. In fact, it has been demonstrated that these systems are more efficient and profitable than those cooled by air. Moreover, this technology can be both mechanical and healthy (Legionnaire's disease) if due maintenance is provided.

In this paper, an indirect evaporative cooling system and two different semi-indirect evaporative cooling systems are analysed. The comparative study has been developed in terms of effectiveness and cooling capacity considering heat transfer surfaces of $2m^2$ in every case. When designing the two semi-indirect systems, some technological criteria have been taken into account to avoid the risks of aerosols which might disperse legionnaire's bacteria [2] or other pathogen elements [3]. This objective has been achieved because humidification is produced through a porous surface, thus avoiding generating aerosols, whose pore diameter is too small to allow it to act as a filter for the

E-mail address: eloy@eis.uva.es

bacteria [4]. Moreover, working with relative air humidity below 70% reduces the risk of this kind of disease.

DESCRIPTION OF THE THREE EVAPORATIVE COOLING SYSTEMS

Three systems were designed and constructed in the thermal engineering department of the University of Valladolid. An experimental study was then performed to characterise their behaviour. As mentioned previously, these systems were an indirect evaporative cooler (IEC), a semi-indirect evaporative cooler made with ceramic pipes (SIECCP) and a semi-indirect evaporative cooler made with hollow bricks (SIECHB).

The first equipment, shown in figure 1, is made of aluminium plates. The supply air which we are to cool circulates on one side of the plates, while the other is in contact with water previously cooled with air from the room, which has a higher cooling capacity than that of the outside air.

The main characteristic of this system is that it consists of a plate heat exchanger, so that the water does not come into contact with the supply air. Thus, it avoids the proliferation of legionnaire's bacteria on the primary air. However, it also implies a lower effect of the evaporative cooling in the supply air.

The geometric characteristics of this equipment are shown in table 1.

Figure 1. Indirect Evaporative Cooler (IEC)

Table 1
Geometric Characteristics of the IEC

Thickness	3×10^{-3} m
Length	0.3 m
Number of plates	25
Geometry	Flat plates
Area	2.25 m^2

The second equipment consists of a bank of tubes arranged vertically [5], which can behave either as an indirect or direct cooler depending on the outside air temperature and relative humidity. In the first case, it works in a heat-recovery mode, using the pipes as a heat exchanger. In the other, humidification of the outside air is permitted, as water is capillary transported through the ceramic

wall. The supply air that has to be cooled circulates outside the pipes, while the return air and the cooled water circulate inside.

The pores of the ceramic pipes have such a small diameter that they act as a filter between the two streams of air, avoiding contamination of the supply air from the contaminants in the return air. Furthermore, this material shows a high corrosion and oxidization resistance, as well as high porosity. The geometric characteristics of the SIECCP are shown in table 2.

The left image shown in figure 2 is a detail of one of the pipes that make up the system. The one in the middle provides a vertical pipe arrangement, while the one on the right is a general view of the equipment installation.

The evaporative cooling system designed and constructed with hollow bricks is semi-indirect so that it is made with porous material. It has been installed in a heat-recovery system to cool a climate chamber equipped with an extra heat pump which helps it to reach thermal comfort conditions [6].

Number of pipes	49

Figure 2. Different views of the installation of the SECCP.

The SIECHB works with a primary air stream cooled when coming into direct contact with the humid porous surface of the bricks, allowing heat and mass exchange.

Depending on the permeability of the surface, there is a higher or lower diffusion of water from the pores to the air stream, the specific humidity of the supply air being the parameter which controls this mass exchange process. For this reason, the process is called semi-indirect.

Figure 3 shows, from left to right, a detail of a hollow brick similar to the ones used, a view of the evaporative cooler and the system installed in a heat-recovery mode. The dimensions of the hollow bricks are shown in table 3.

Since humidification occurs through a porous surface, as with the system previously described, the presence of aerosols that might disperse the legionnaire bacteria is prevented.

All the phenomenon described can be observed in any semi-indirect system. For that reason, there is a combined heat and mass exchange, increasing the cooling effect and optimizing the thermal process [7].

Figure 3. Semi-indirect Ceramic Evaporative Cooler (hollow bricks).

EXPERIMENTAL RESULTS OF SOME TESTS

Due to the limits established by each experimental device, it has only been possible to compare tests setting a 120 m^3/h volume flow for the indirect cooler, while 140 m^3/h and 240 m^3/h have been set for the semi-indirect evaporative ceramic pipe and hollow brick coolers respectively. All the tests

have been developed for the minimum level of relative humidity given by the outdoor air conditions. The entire process has been developed maintaining the comfort conditions inside the climate chamber.

Different levels of temperature have been tested in each case ranging from 24ºC to 44ºC for the level of inlet air volume flow fixed, corresponding to summer conditions. Inlet and return air temperature and relative humidity were subsequently measured to calculate specific humidity, wet bulb temperature, thermal and wet-bulb thermal efficiency, as well as cooling capacity.

The thermal efficiency is defined by equation (1).

$$\varepsilon_T = \frac{T_1 - T_2}{T_1 - T_3} \tag{1}$$

whereas wet bulb thermal efficiency [8] is given by the equation (2).

$$\varepsilon_{WBT} = \frac{T_1 - T_2}{T_1 - T_{3WB}} \tag{2}$$

The cooling capacity is defined by equation (3).

$$E_{CC} = \dot{m} \cdot (h_1 - h_2) \tag{3}$$

The results and graphs of some tests performed on the evaporative cooling systems are shown in tables 4 - 6, and graphs of figures 4 - 6.

CONCLUSIONS

For the air volume flow levels permitted by the experimental device and low relative air humidity, results evidence that every system could be properly used for cooling outdoor air.

However, the efficiency of these systems is especially interesting in those climates characterised by a high outside air temperature and low relative humidity. This fact is validated by the experimental results, which show an increase in the evaporative capacity of the air, and thus a higher cooling capacity, associated to the increase in supply air temperature.

As can be seen in figure 4, inlet air temperature is proportionally related to return air temperature in the three cases, the indirect system providing the lowest temperatures. This is due both to the use of a lower air volume flow and the characteristics of the material with which it was constructed, as aluminium has a higher conductivity than the ceramic materials used in the other two systems.

By contrast, thermal efficiency diminishes as temperature increases. However, the phenomenon of evaporative cooling allows a lower cooling temperature than that of the output air, values given thus being over 1 in many cases, which would be the maximum obtainable by using a conventional heat-recovery system. Evaporative cooling systems can thus improve cooling capacity in conventional heat-recovery systems working in dry climates.

As the air volume flow is smaller in the case of the indirect system, wet-bulb thermal efficiency obtained in this case is over 60%, while for the semi-indirect systems this efficiency is around 60%, which is enough to ensure that the supply air from the systems is not saturated.

Moreover, the semi-indirect systems, which take advantage of the evaporative cooling capacity of outdoor air, allow supply air temperatures below 30ºC when working with inlet air temperatures of 40ºC. Therefore, this kind of device also provides high cooling power for high levels of air volume flow.

Of the three systems, the SIECHB provides a better cooling capacity for high temperatures. Furthermore, the materials used for its construction are hollow bricks, very common in the building sector, meaning the system has the highest porosity and is the cheapest, an advantage for its use as a commercial system. It can also be combined easily with passive cooling systems.

An increase in the level of the air volume flow involves a lower thermal leap as well as lower levels of relative humidity output when working with evaporative systems. It is possible, therefore, to vary the air volume flow which circulates through these systems in order to control the relative humidity in the supply air so that it is low enough to avoid problems such as the risk of producing aerosols or condensations in the coldest areas of the premises.

Improvements in semi-indirect evaporative cooling systems focus on the use of thinner walls, which might not only increase water flow through the ceramic material but also reduce thermal resistance to heat exchange, as this kind of material is characterised by low thermal conductivity. This would entail an increase in the cooling capacity of the system, although it should be taken into account that such a reduction in wall thickness must not weaken the system's frame.

NOMENCLATURE

ε_T	thermal efficiency	T_{3WB}	return air wet bulb temperature (ºC).
ε_{WBT}	wet bulb thermal efficiency	$\dot{m}$	primary airflow (kg/s).
E_{CC}	cooling capacity (W)	h_1	enthalpy (primary airflow) at the entrance of the device (kJ/kg).
x_1	absolute humidity (g/kg)		
T_1	outdoor air dry temperature (ºC).	h_2	enthalpy (primary airflow) outside the device (kJ/kg).
T_2	inlet air dry temperature (ºC).		
T_3	return air dry temperature (ºC).

Mechanical Engineering Dep.

ABSTRACT. An experimental study was performed to investigate the heat transfer characteristics of the convection flow through a rectangular air duct with aspect ratio of 10 (a/b=10) which is filled with metallic porous materials. All four walls of the duct are subjected to a constant and uniform heat flux. The Reynolds number based on the hydraulic diameter has been kept between 500-2000 in order to ensure the laminar flow through the duct. The effect of different parameters such as variable porosity and density of porous layers have been investigated. For different porous layers configuration, heat flux at the walls, wall temperatures and air mass flow rate has been measured and the Nusselt number has been calculated. The results are compared with the clear flow case where no porous material was used. it can be concluded that higher heat transfer rates can be achieved in porous media flow case at the expense of a reasonable pressure drop. Based on the experimental data new empirical correlations for both Nusselt number and friction factor have also been developed for such air duct, which gives a good agreement between predicted values and experimental values of Nusselt number and friction factor.

Keywords: *Heat transfer enhancement, Pressure drop, Porous media*

INTRODUCTION

Theoretical and applied research in flow and heat transfer in porous media has received more attention during the past three decades. This is due to the importance of this research area in many engineering applications such as solid matrix heat exchangers, heat pipes, drying efficiency, electronic cooling, enhanced heat transfer by surface modification, nuclear reactors using gaseous coolants flowing through radioactive pellets, dehumidifying, Porous preheaters and flame stabilizers, oil and gas flow in reservoirs, catalytic converter for air pollution reduction of combustion products, etc.
Kays and London [1] pointed out that an effective way to increase the performance of a heat exchanger is to increase its surface area to volume ratio. Kim et al. [2] established correlations for friction factor and overall heat transfer coefficient for metal foam channel heat exchangers via experimental techniques. Hsu et al. [3] and Hsu and Fu [4] measured the velocity and the pressure drop for both steady and oscillating flows across porous columns packed from wire screens. Varshney and Saini [5] have experimentally investigated the heat transfer and the fluid flow characteristics of a solar air heater having its duct packed with wire mesh screen matrices (air flowing parallel to matrix planes). Lee and Vafai [6] developed an analytical solution for temperature distribution within a channel filled with a porous medium and subject to a constant heat flux boundary condition. They established an analytical relationship for Nusselt number as a function of solid and fluid effective thermal conductivities and solid–fluid interfacial characteristics utilizing local thermal non-equilibrium model.

Open cell porous matrix such as an unconsolidated bed of small particles, woven metal screens, or foam matrixes provides excellent heat-transfer characteristics due to its large surface area to volume ratio. Woven metal screens have other advantages include easy arrangement, high permeability and relatively small deviation of the pore size from the mean value.

Present experimental study includes the heat transfer and pressure drop investigations of the flow passing through a rectangular channel in which different porous media are located. All four walls of the channel are heated by uniform heat flux about 174 W/m². The experiments were carried out for Reynolds numbers (based on the hydraulic diameter) between 500-2000, and 3 different porous media, which their porosities varied between 95.0% and 97.9%, were examined. The maximum increase in the length-averaged value of the Nusselt number of about 4.9 times in comparison with the clear flow case was achieved with a porous medium fully filled the duct (porosity 97.9% and a Reynolds number of about 2000). Using experimental data, two correlations have been developed for predicting the Nusselt number and friction factor for such rectangular air ducts. Comparison of the empirical correlations with experimental data in open literature validated the empirical correlations.

EXPERIMENTAL STUDY

Setup and procedure

The schematic diagram of test setup is shown in Figure 1. The setup includes the test section, flat heater, centrifugal fan and instrumentations for measuring mass flow rate of air, pressure drop, temperature and voltage for heating the test section. Air from the quiescent laboratory room is driven into the operators by means of a downstream-positioned fan (8). The air enters a long hydrodynamic development length (1.2 m), (1) and (2), in order to establish a well-defined velocity profile at its downstream end. The downstream end of the development section is mated to the inlet of the test section (3). The test section is a rectangular duct with cross-sectional aspect ratio of 10, filled with a metallic porous matrix. The length of the test section in the flow direction is 0.5 m. The downstream end of the test section is mated to the exit section (4) that is an extension of the test section walls, but without the porous medium. The inlet of the exit section was equipped with honeycomb straighter for uniforming the flow field. The exit section was followed by a mixing ...

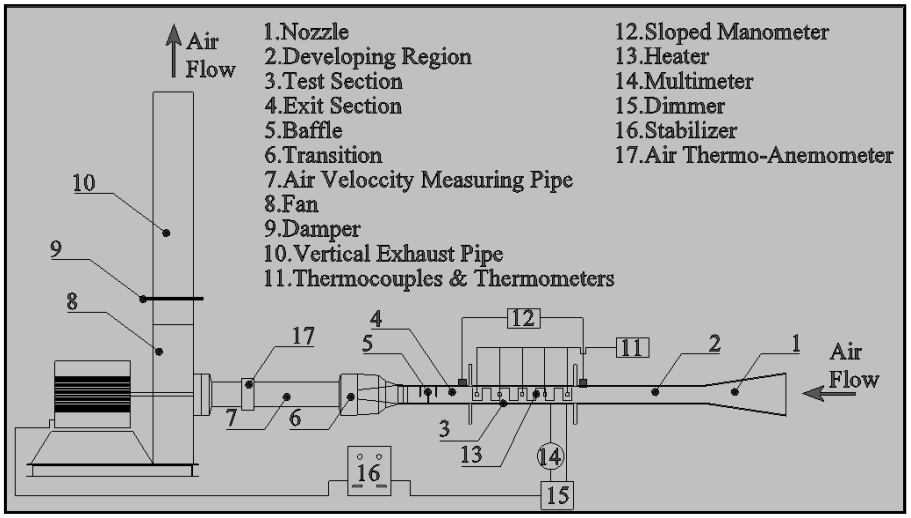

Figure 1. Experimental setup

device (5), namely baffles for mixing the air. The mixing device enabled measurement of the bulk mean temperature at the outlet of the test section. The length of the exit section was 0.35 m and its cross section area matched with that of the test duct. Three equally spaced baffle plates which spread over 0.0425 m length beyond the exit section were provided for the purpose of mixing the hot air coming out of the test section to obtain a uniform temperature of the air at the outlet. The mixing section was connected to the pipe fitting (7) through a transition piece and flexible pipes (6). At the far end of the air velocity measurement pipe, an isolation device was installed to decouple any possible blower-motor vibration.

Heating of test section was accomplished on all of its bounding surfaces by means of a flat heater. The heater plates consist of asbestos sheet, mica and nichrome wires. The wires were fixed on asbestos sheet covered with strips of mica to keep the uniform distance between the wires. The heater was fabricated to produce about 2000 W/m^2 heat energy. With the help of a voltage regulator, a voltage of 65 V across the wires having total resistance of 54 Ω was maintained. Corresponding to this voltage of 65 V and resistance of 54 Ω, about 78 W of energy over a surface area of 0.45 m^2 was obtained. All of the outer bounding surfaces of heater and exit section were carefully wrapped with a 0.038 m thick rock wool (k = 0.03 W/m K) as insulating material to minimize the extraneous heat losses.

Temperatures were measured by thermocouples deployed along the centre span of the walls of the test section and its upstream and downstream extensions. The thermocouples (Type J, 0.3-mm-diameter) had been specifically calibrated after their installation (±0.1℃). At all thermocouple locations, the thermocouple junctions were pressed tightly against the outer surface of the respective walls. Using 20 thermocouples, temperatures of all four surfaces of the test section, at five axial positions (0.020, 0.135, 0.250, 0.365 and 0.480 m) were measured. In addition, three thermocouples were used to measure the fluid bulk temperature, respectively positioned upstream and (among the baffles of) downstream of the heated test section. The thermocouples out puts were displayed in ℃, by Hanyoung- ED6 temperature meters.

The pressure drop across the test section has been measured by a sloped manometer having 0.01 mm accuracy. The liquid having density of 784 kg/m^3 at 29℃ has been used in manometer to increase the accuracy further.

For the measurement of the mass flow rate, a dedicated instrumented section (7), situated downstream of the exit section, was used. The instrumented section had been previously calibrated against a rotameter.

The porous media used for experiments were manufactured from commercial steel screens (wire diameter 0.45×10^{-3} m, density 7830 kg/m^3, thermal conductivity 64 W/mK) which cut into a rectangular shape with dimension of 0.4×0.04 m^2 are packed layer by layer in the 0.5 m long test section. Three different porous media, whose properties are presented in Table 1, were obtained by varying the distance between two adjacent screens L.

Table 1
Porous medium characteristics

Porous medium	Screen Dimension (mm)²	L (mm)	ε (%)	K (m²)	F	D_p	$Da = \frac{K}{(H/2)^2}$
(1)	40×400	2	95.0	2.88×10^{-7}	4.69×10^{-2}	2.45×10^{-3}	7.20×10^{-4}
(2)	40×400	4	97.0	3.23×10^{-7}	2.81×10^{-2}	2.45×10^{-3}	8.07×10^{-4}
(3)	40×400	6	97.9	4.13×10^{-7}	2.01×10^{-2}	2.45×10^{-3}	1.03×10^{-4}

All joints of duct, inlet section, test section, exit section, transition and pipes are thoroughly checked up for any leakage before starting the experiment every time. All the measuring equipments were checked up before starting the experiment. Usually an initial period of approximately 3–4 h was required before reaching steady-state conditions (considered to be attained, when the temperatures indicated by the thermocouples did not vary with more than ±0.3°C within a period of about 20 min). Following parameters were measured for each set of readings: pressure drop across the test section, temperatures of the test section walls, the fluid bulk temperature at inlet and outlet of the test section, voltage and electric current supplied to heater, air velocity and temperature at the air velocity measurement pipe, to measure the air flow rates. After collecting a set of data at steady-state conditions, the mass flow rate of air was increased so that the next value of the Re number differed from the previous one by about 250 units. A new set of data was collected when steady-state conditions were reached again, usually within a period of approximately 40 min. That is, the mass flow rate of air was increased progressively until a maximum value of Re ~ 2000 was reached.

In order to verify the validity of the experimental setup the values of Nusselt number and friction factor were compared with the values obtained from correlations available in the literature for smooth duct namely Shah and London set of equations [7] and modified Blasius equation [7]. The Nusselt numbers have a maximum deviation of 5.86% while the maximum deviation of the friction factor is 2.63% from the predicted values by the Shah and London and Blasius equations, respectively.

Data reduction

The experimental data was used to determine the desired parameters as given below. All the properties of air, viz. density, viscosity, specific heat used in the calculation, were evaluated at the arithmetic mean of the inlet and the outlet temperature of air. The heat transfer rate, Q_{air} to the air can be determined as:

$$Q_{air} = \dot{m} c_p (T_{out} - T_{in}) \tag{1}$$

The local heat flux from the wall to the flowing fluid, q (assumed uniform on all surfaces which bound the porous medium) obtained from:

$$q = Q_{air} / A_s \tag{2}$$

where A_s is the heat transfer area m^2.

The average Nusselt number based on the hydraulic diameter $\overline{Nu}_{D_h}$ was evaluated in accordance with the following equation:

$$\overline{Nu}_{D_h} = \frac{qD_h}{(\overline{T}_s - T_m)k_{air}} \tag{3}$$

where hydraulic diameter D_h is,

$$D_h = \frac{4A_c}{P} \tag{4}$$

and the average surface temperature $\overline{T}_s$ can be calculated from the 20 points of the local surface temperatures, which can be expressed as

$$\overline{T_s} = \frac{\sum T_s}{20} \tag{5}$$

and the average air temperature T_m is given by,

$$T_m = \frac{T_{out} + T_{in}}{2} \tag{6}$$

The modified fanning friction factor f_{D_p} (the ratio of the wall shear stress at channel to the flow kinetic energy) and the modified Reynolds number Re_{D_p} [8] are defined as

$$f_{D_p} = \frac{\Delta p}{L_0}\frac{D_p}{\rho u^2}\frac{\varepsilon^3}{(1-\varepsilon)} \tag{7}$$

$$\frac{\mathrm{Re}_{D_p}}{1-\varepsilon} = \frac{D_p \rho u}{\mu} \tag{8}$$

where the equivalent spherical diameter D_p, is the characteristic length of woven metal screens (shown in table 1) and defined as $D_p = 6/S_V$ (S_V, is the surface area per unit volume of solid phase).

RESULT AND DISCUSSION

Average Nusselt number results

The variation of the average Nusselt number ($\overline{Nu}_{D_h}$) versus the Reynolds number (Re_{D_h}) for three studied porous medium, is shown in Figure 2. It was observed that the value of average Nusselt number increased with the increase in Reynolds number. It can also be observed that the effect of ...

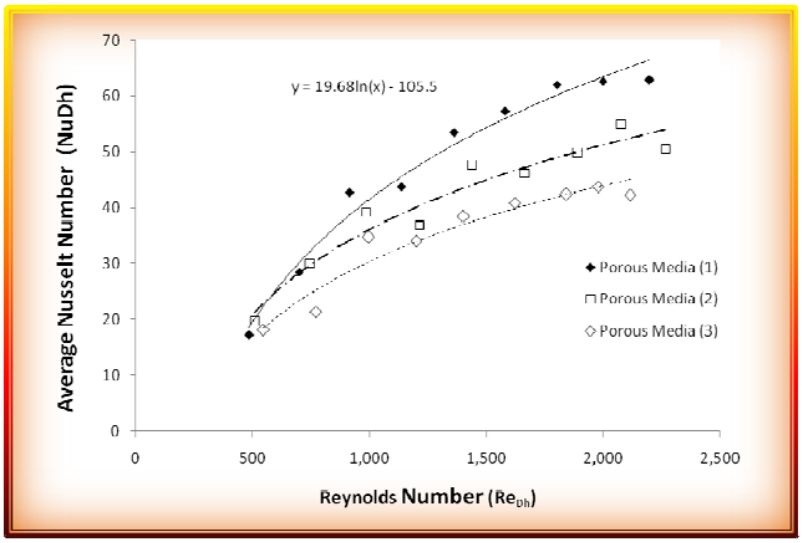

Figure 2. Effects of Reynolds number on average Nusselt number for 3 studied porous medium.

Reynolds number on Nusselt number decreases, at higher Reynolds numbers. As seen in the Figure 2, the effect of Reynolds number (Re_{D_h}) on average Nusselt number decreases for third porous medium when Re reaches the value of 2100, and a similar trend occurs for second and first porous medium when Re reaches the value of 1900. Another aspect demonstrated in Figure 2 is that the porosity has an important influence on the average Nusselt number. If the porosity decreases from 0.98 to 0.97, the average Nusselt number increases between 13% and 37% depending on Reynolds number. However, average Nusselt number increases up to 70% when the porosity is decreased from 0.98 to 0.95. This appears to be due to a higher level of turbulence created in the flow as the porosity decreased and the flow passages become more tortuous and narrower with a higher solidity of such matrices.

Pressure drop results

The variation of the pressure drop (Δp) versus the Reynolds number (Re_{D_h}) for three studied porous medium, is shown in Figure 3. It was observed that the higher the Reynolds number, the higher the pressure drop. It can also be observed from Figure 3 that the value of pressure drop increased monotonically with a decrease in porosity. If the porosity decreases from 0.98 to 0.97, the pressure drop (Δp) increases between 50% and 150% depending on Reynolds number. However, pressure drop (Δp) increases up to 200% when the porosity is decreased from 0.98 to 0.95.

Development of correlation

The modified fanning friction factors f_{D_p} of the three porous medium used in this study were determined following the definition given in equation (7) and plotted as functions of $Re/(1-\varepsilon)$ in Figure 4. In this figure, it is noted that f_{D_p} decreases with the increase of $Re/(1-\varepsilon)$. It should also be noted that the data for the three porous medium fell well into a single curve.

Jones et al. [9] analyzed the pressure drop characteristics of granular porous materials. The equation is given below:

$$f_{D_p} = 150\frac{1-\varepsilon}{Re_{D_p}} + 3.89\left(\frac{1-\varepsilon}{Re_{D_p}}\right)^{0.13} \tag{9}$$

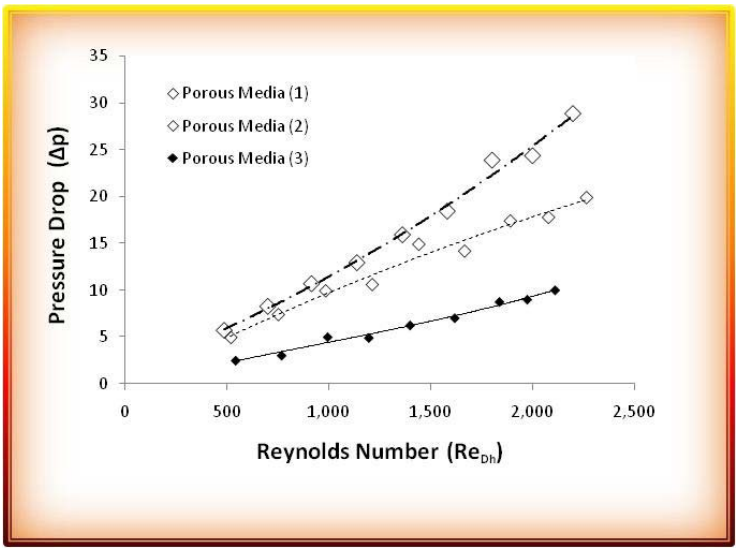

Figure 3. Effects of Reynolds number on pressure drop for 3 studied porous medium.

Table 2
Properties of metal screens

Dimension of screen (m)	Mass of a single screen (kg)	Thickness of a single screen (m)	Diameter of warp wire (m)	D_P (m)	Woven density (wires/in.)
0.4×0.04	23.77×10^{-3}	0.85×10^{-3}	0.45×10^{-3}	2.45×10^{-3}	17

In order to develop a correlation for pressure drop characteristic of flow through woven metal screens (Table 2), this study adopts a general equation in the form of equation (9), given below in equation (10).

$$f_{D_p} = \alpha \frac{1-\varepsilon}{Re_{D_p}} + \beta \left(\frac{1-\varepsilon}{Re_{D_p}}\right)^{\gamma} \tag{10}$$

A series of experiments were conducted to determine the coefficients α, β, and γ of equation (10). Based on the measured pressure drops of three woven metal matrices, present study developed an empirical equation of friction characteristic for woven metal screens. As shown in Figure 4, the correlation for the three porous medium was determined to be

$$f_{D_p} = 0.006 \frac{1-\varepsilon}{Re_{D_p}} + 0.39 \left(\frac{1-\varepsilon}{Re_{D_p}}\right)^{0.81} \tag{11}$$

Figure 5 shows the comparison of equation (11) with the experimental data (obtained from this study) of the metal screens of the plain square type. Figure 5 shows that data from present study all fall within ±25% of equation (11).

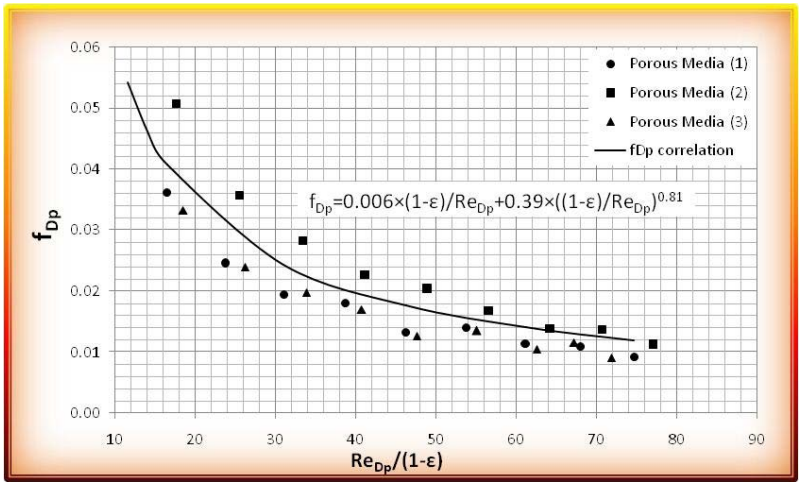

Figure 4. Correlation between f_{D_p} and $Re_{D_p}/(1-\varepsilon)$.

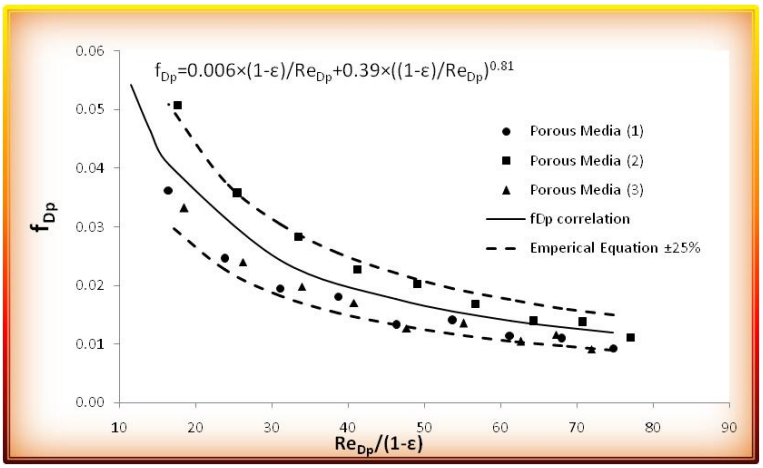

Figure 5. Deviation between experimental data and the correlation.

CONCLUSIONS

In this study, an experimental setup was established for data collection on heat transfer and fluid flow characteristics of air through woven metal screens. It is shown that higher heat transfer rates are achieved when using porous inserts at the expense of a reasonable pressure drop, which depends on the permeability of the porous media.

Based on the measured pressure drops of three porous matrices, this study developed an empirical equation of friction characteristic for plain-square-type metal screens. The empirical equation is:

$$f_{D_p} = 0.006\frac{1-\varepsilon}{Re_{D_p}} + 0.39\left(\frac{1-\varepsilon}{Re_{D_p}}\right)^{0.81}$$

where

$$f_{D_p} = \frac{\Delta p}{L_0}\frac{D_p}{\rho u^2}\frac{\varepsilon^3}{(1-\varepsilon)}, \qquad \frac{\mathrm{Re}_{D_p}}{1-\varepsilon} = \frac{D_p \rho u}{\mu} \qquad \text{and} \qquad D_p = 6/S_V$$

DISTRIBUTION AND HEAT TRANSFER CHARACTERISTICS OF CO_2 IN A MULTI MICRO-CHANNEL TUBE EVAPORATOR

Siyoung Jeong *, Dae-hwan Kim
Dept. of Mechanical Engineering, Sogang Univ., Seoul, Republic of Korea

ABSTRACT. In this study, the distribution and heat transfer characteristics of CO_2 are experimentally investigated for an evaporator composed of 10 extruded aluminum tubes. The 1000 mm long tube has six micro-channels with a diameter of 0.8 mm. The distribution of CO_2 into each tube and the heat transfer characteristics are investigated by measuring the wall temperature along the tubes. The temperature differences are greater at upper tubes (pass #9 and 10) and at longer distance from the inlet. It is thought that less refrigerant is supplied to upper tubes because of the mal-distribution due to the gravity. Further investigation is required on these phenomena with more experimental data.

Keywords: *Refrigerant distribution, Evaporator, Carbon dioxide, Micro-channel tube*

INTRODUCTION

Because of the restriction on using ozone depleting substances, a natural working fluid CO_2 is a good candidate for a refrigerant of vapour compression refrigeration systems. Because of high operating pressure of CO_2 refrigeration systems, micro-channel tubes made of extruded aluminum are suitable for evaporators. In designing the micro-channel evaporator of a CO_2 refrigeration system, one of the issues is the refrigerant distribution in evaporators as Pettersen et al. [1] pointed out.

Some studies [2, 3] have been carried out for various micro-channel evaporators. However, since the properties of CO_2 is quite different from those of conventional refrigerants, two-phase flow pattern and heat transfer characteristics of CO_2 is quite different from other refrigerants. Moreover, researches on CO_2 are very limited [4, 5]. Therefore, the refrigerant distribution characteristics studies on CO_2 are needed to be investigated extensively considering the geometry of the evaporators and various operating conditions such as mass flux and heat flux.

In our research, the flow distribution characteristics of a parallel-flow micro-channel evaporator will be investigated considering the evaporator position, inlet and exit location, and various operating conditions. Some preliminary experimental results are presented in this paper.

EXPERIMENT

Experimental apparatus

Since direct measurement of liquid distribution is difficult, heat transfer tube wall temperatures were used as an indirect indicator. Regions with little or no liquid will have poor internal heat transfer, resulting in high tube -wall temperatures.

Figure 1 shows the schematic diagram of the experimental apparatus. The sub-cooled liquid state CO_2 is circulated by a magnetic gear pump, and the mass flow rate is measured by a mass flow meter using Coriolis' effect. A pre-heater is installed to make CO_2 at the test section inlet a saturated liquid state. The state of the refrigerant flow is observed at two sight glasses installed at the inlet and exit of the test section. The inlet refrigerant pressure is detected by an absolute

E-mail address: syjeong@sogang.ac.kr

pressure transmitter (A.P.T.). A differential pressure transmitter (D.P.T.) measures the pressure difference between the inlet and outlet of the test section. In the test section consisting of ten parallel extruded aluminium tubes (Figure 2), liquid state carbon dioxide is heated and evaporated by the Joule heat of the heating wire winding the micro-channel tube. The inlet and exit header have three connecting pipes respectively to test the effect of the inlet and exit location. In the present study, the inlet is the bottom of the header and the exit is the top of the header. The length of the tube is 1000mm, and it has 6 circular micro-channels of which the diameter is 0.8mm (Figure 3). Figure 4 shows a cross section of header and the tube arrangement. The inner diameter of header is 15mm, and ten tubes are installed at the interval of 15mm. The tubes are inserted 5 mm into the header.

Calibrated T-type thermocouples were attached at the tube wall to measure the outer wall temperature. The thermocouples are checked to have the accuracy of 0.2K by flowing liquid-phase CO_2. Temperatures were measured at 5 locations per tube (6, 248, 490, 732, and 974 mm from the inlet of the test section). The details of the heating wire and the thermocouple arrangement are shown in Figure 5. The temperature and pressure data were recorded in a data acquisition board. In order to condense the evaporated CO_2, a thermostat and a counter flow heat exchanger was installed. The liquefied CO_2 refrigerant, which is separated in the accumulator, is supplied to the gear pump. A relief valve was installed to secure the system from overpressure. The entire system including the test section is well insulated. Before charging the system with CO_2 refrigerant, the system was evacuated by a vacuum pump. The charging amount was measured with an electronic scale. For each experimental condition, the data were collected for 2 minutes when the system reached steady state.

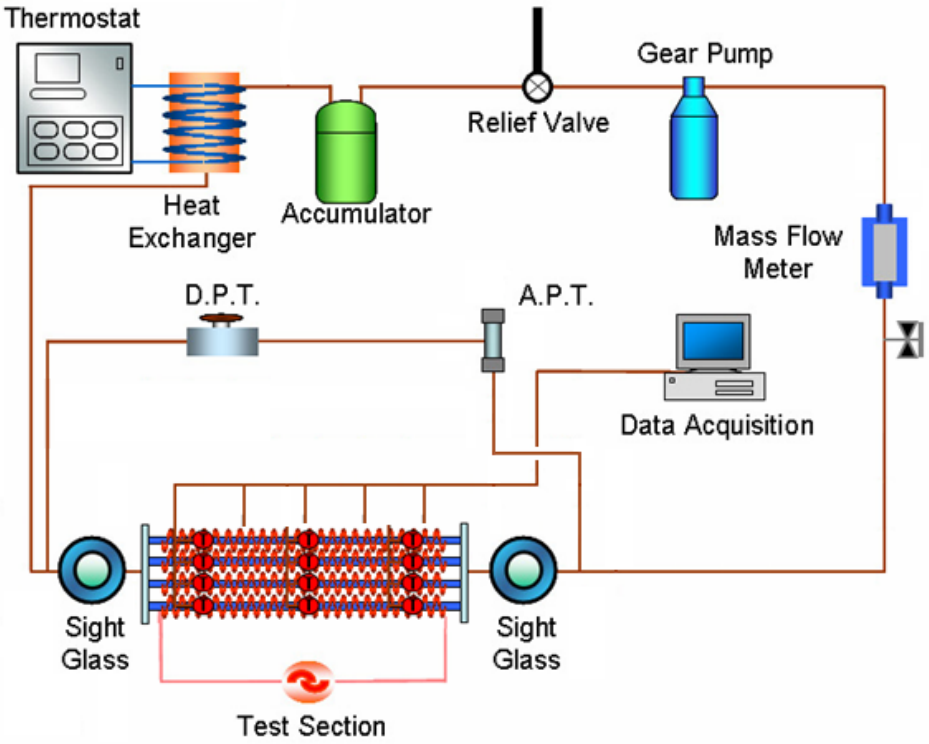

Figure 1. Experimental apparatus

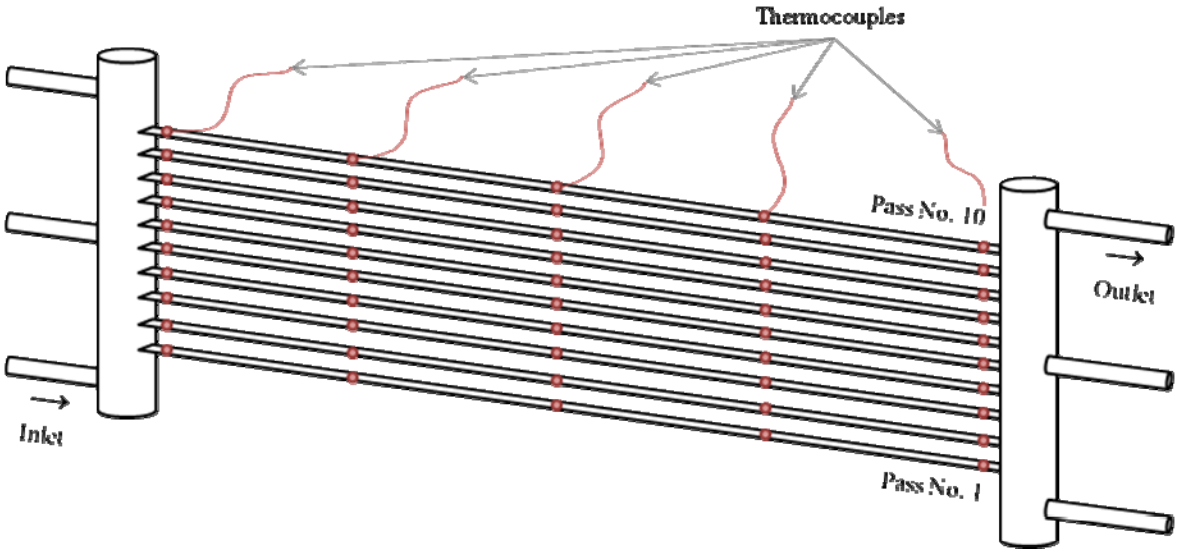

Figure 2. Test section

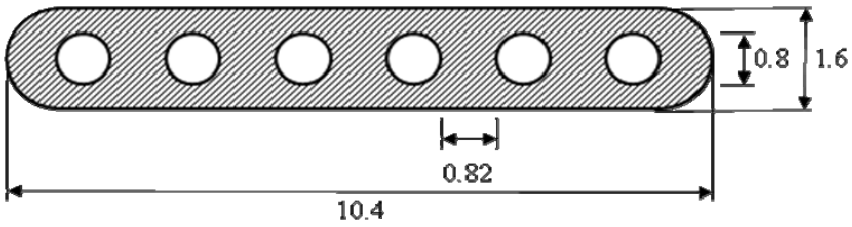

Figure 3. Cross section of the micro-channel tube (unit: mm)

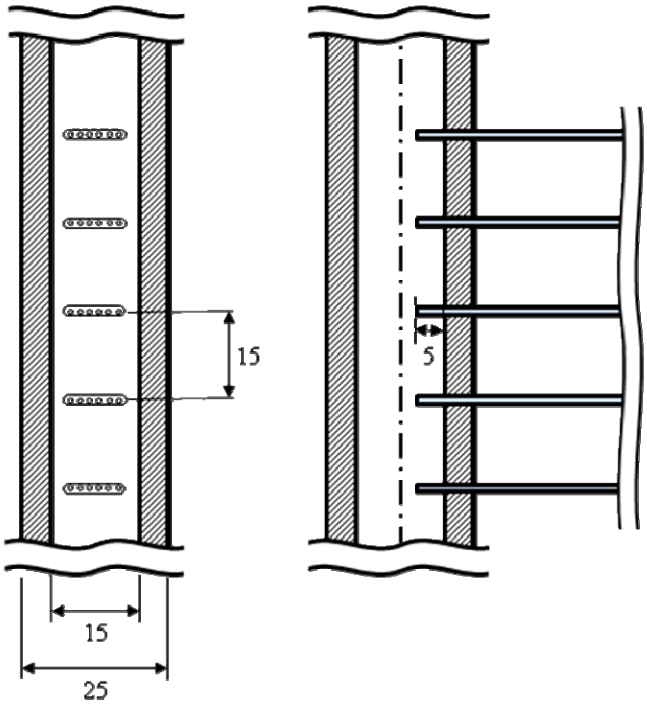

Figure 4. Cross section of the header (unit: mm)

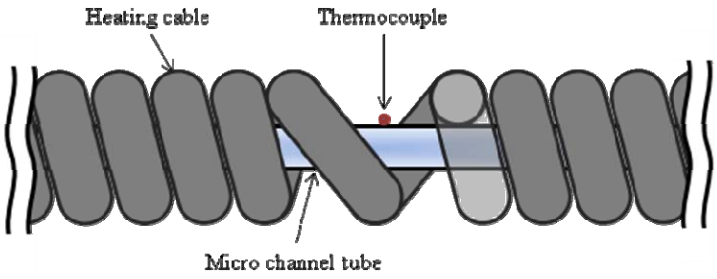

Figure 5. Arrangement of the heating wire and the thermocouple

The heat flux is calculated by the electric current and resistance of the test section.

$$q'' = \frac{I^2 R}{A} \tag{1}$$

The saturation temperature of CO_2 is determined from the property relation of CO_2. The properties of CO_2 were calculated with REFPROP version 6.01.

$$P_{sat} = P_{sat.in} - \Delta P \frac{l}{L} \tag{2}$$

$$T_{sat} = f\left(P_{sat}\right) \tag{3}$$

Temperature difference between the outer wall temperature and the saturation temperature of is an indirect indicator of the flow distribution.

$$\Delta T = T_{wo} - T_{sat} \tag{4}$$

RESULT AND DISCUSSION

Figure 6 shows the temperature difference at the mass flow rates of the refrigerant were 160, 200, and 400 kg/m^{2}s. All of them are under the same heat flux condition of 8kW/m^2. The evaporation temperature of the refrigerant is 5^{o}C. Because of its similarity, the temperatures at pass 2, 3, 4 and 6 are not plotted on the graph.

In spite of the mass flow variation, the temperature distribution of other passes than pass #10, do not change considerably. Temperature differences are about 10 K regardless of the mass flux and the distance from the inlet. The difference among the passes becomes remarkable at lower mass fluxes. At the mass flux of 200 kg/m^{2}s it is observed that the temperature differences are higher at upper tubes (pass #9 and10). Especially, the top pass (pass #10) shows much higher temperature difference at the distance of 732 and 974 mm. It is thought that less refrigerant is supplied to upper tubes because of the mal-distribution due to the gravity. It seems that the dry-out of CO_2 causes a high temperature difference. It implies that the mal-distribution of the refrigerant can be a serious problem for upper tubes at lower mass fluxes.

Figure 7 shows the pressure drop across the test section. If the tubes are not heated, the pressure drop is increased almost in proportion to the mass flow rate. At the heat flux of 8kW/m^2, the pressure drop increases by about 30 % comparing with no heat flux condition.

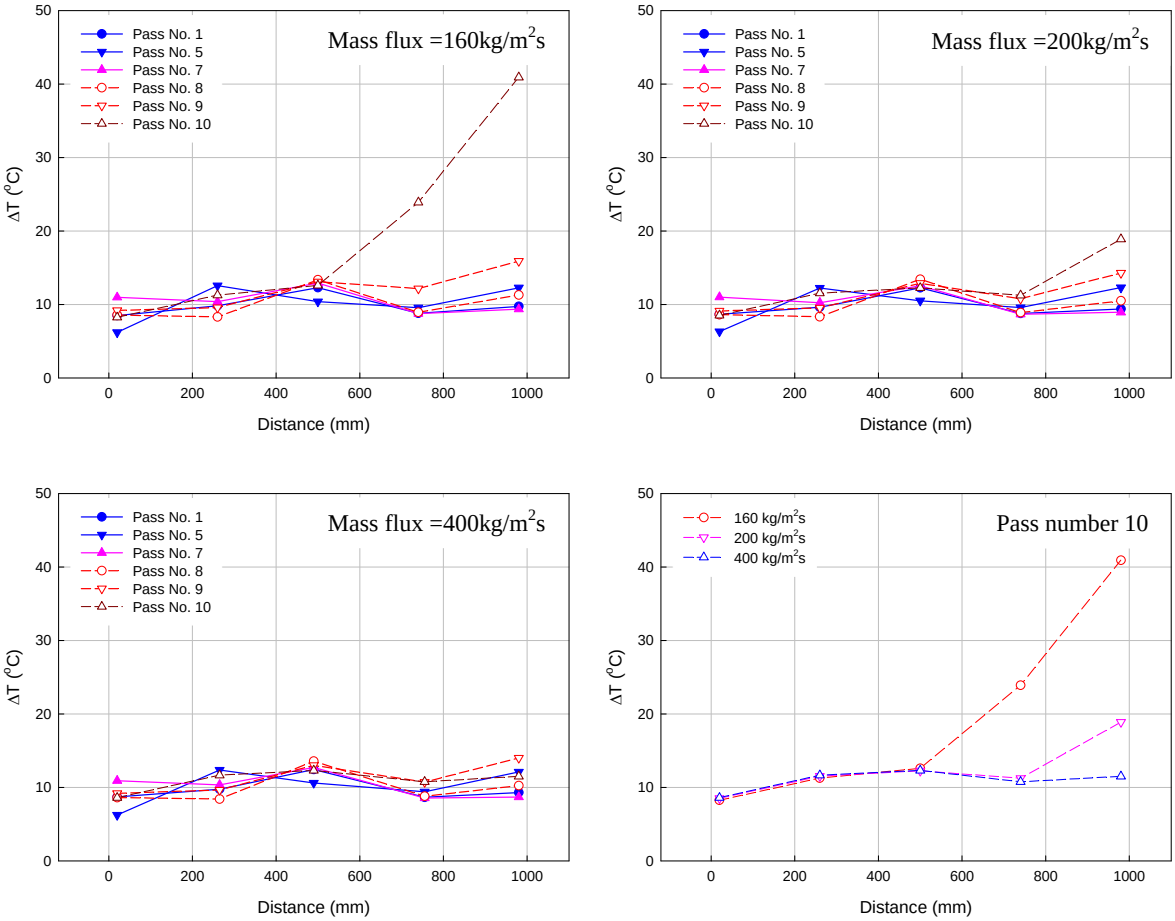

Figure 6 Effect of mass flux on temperature difference (T=5°C, q'' =8kW/m^2)

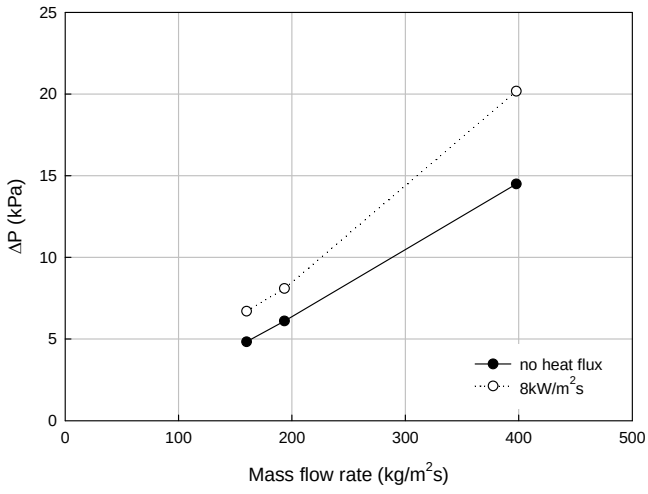

Figure 7 Effect of mass flux on pressure drop (T=5°C, q'' =8kW/m^2)

CONCLUSION

In this paper, the flow distribution characteristics of a multi-port parallel-flow CO_2 evaporator using micro-channel tubes are studied, and the following preliminary results are obtained.

- The inlet and exit part of the tube indicate higher temperature difference than the middle of the tube.
- The temperature differences are higher at upper tubes (pass #9 and10). Especially, the top pass (pass #10) shows much higher temperature difference than other passes. It is thought that less refrigerant is supplied to upper tubes because of the mal-distribution due to the gravity.
- Especially at the top pass(pass #10), this tendency is observed more clearly at the end of the channel, if the mass flux is lower,.

Further investigation is required on these phenomena with more experimental data.

HEAT TRANSFER HYSTERESIS FOR SUDDEN GROWTH HEAT FLUX

T.M. Wójcik
Kielce University of Technology, Kielce, Poland

ABSTRACT. The paper presents results of experimental investigations of boiling heat transfer in metal, fibrous capillary porous structures. Boiling curves were determined in terms of dynamic changes of heat flux. The measurements in these terms confirmed the existence of type II hysteresis. All the ranges of boiling curve designated for slow changes of the heat flux are shown at the curve in terms of dynamic changes of heat flux. The phenomenon of hysteresis type II is independent of the supply of heat, and models developed for type II hysteresis can be transferred to the actual conditions of acceptance of electronic systems in the heat.

Keywords: porous covering, boiling, hysteresis

INTRODUCTION

Capillary porous structures (CPSs) intensify heat transfer in boiling. Boiling heat transfer on surfaces with CPSs is a complex thermodynamic process combining phase change, heat transfer as well as the motion of liquid and vapor. Due to incomplete understanding of the boiling process inside the porous structures, the formulae defining the heat flux or heat transfer coefficients are mostly empirical or based on the similarity theory. Until now, no general view has been formed on the causes behind the increase in the heat transfer coefficient and the decrease in superheating of the heating surface which initiates the boiling process on porous surfaces.

Heat transfer hysteresis manifests much more clearly when the heating surface is covered with CPS than in boiling on a smooth surface.

One of the least frequently presented types of boiling heat transfer hysteresis is *II type hysteresis*, also called *simple hysteresis loop*. It is characterized by the heat transfer coefficient increase at the heat flux diminishing, prior to the heat flux reaching the maximum value. Hysteresis of this type was only presented by Tehver [1] - Figure 1, Kravčenko [2] - Figure 2, Wójcik and Poniewski [3,4]. Figure 3 presents the characteristic experimental boiling curve for *type II hysteresis* observed by Wójcik and Poniewski. The heat transfer coefficient increases as the heat flux diminishes, prior to the latter reaching the maximum density. The change in the value of the heat transfer coefficient is attributed to the change in the number of active boiling centres. *II type hysteresis* might be caused by the fact that the centres once activated remain so when the heat flux decreases.

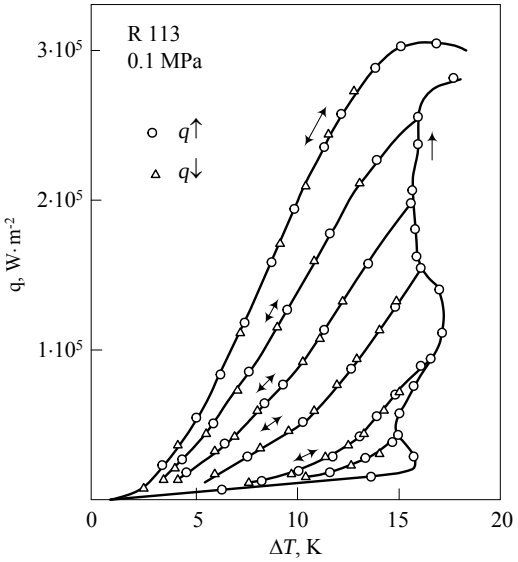

Figure 1. II type hysteresis presented by Tehver [1], plasma-sprayed surface.

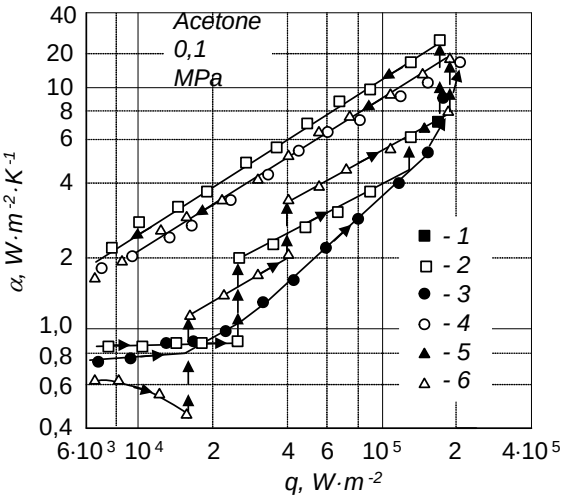

Figure 2. II type hysteresis presented by Kravčenko [2], gas-thermally porous surfaces.

Hysteresis is observed after the heat flux is decreased in range ***b***, Fig.3. Phenomenon was determined for the liquids of the contact angle smaller than that of water, i.e. R-113, R-123, ethanol and for copper, fibrous coverings of small thickness ($\delta \leq 0.6$ mm). The typical phenomena presented in this figure were also observed for ethanol or refrigerants, for other coverings. At boiling of ethanol, refrigerants R 113 and R 123, for samples of small covering thickness, the II type hysteresis phenomena were observed in the whole range of porosity changes.

MECHANISMS OF BOILING HYSTERESIS

The analysis of experimental results for type II hysteresis helped to determine the characteristic ranges of boiling curves.

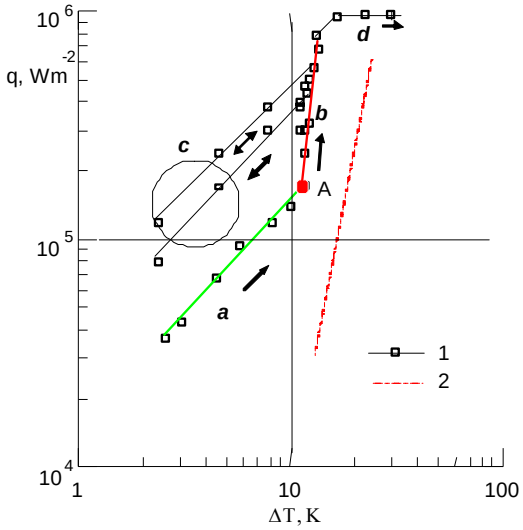

Figure 3. II type hysteresis observed by Wójcik and Poniewski [3,4].

An explicit nucleate boiling was observed in range ***a,*** Fig.3. It was assumed that the boiling initiates on the porous covering external surface. The character of the boiling curve, - $q \sim \Delta T^{1...2}$, in part ***a*** indicates a constant or slightly increasing value of a heat transfer coefficient. The number of active nucleation sites is either constant or slightly increasing. The occurrence of such a mechanism is fostered by porous covering characteristics. High value of skeleton heat conductivity of the structure ($\lambda_s \sim 70$ $Wm^{-1}K^{-1}$) and its small thickness result in slight temperature drops on the covering thickness.

In the structure of non-homogeneous pore size distribution, gradual activation of nuclei of smaller and smaller diameter D_a takes place, when the heating surface temperature increases.

The heat transfer mechanism in the range ***a*** is presented in Figure 4.

Along with increasing the heat flux, in point ***"A"*** (Fig.3) there is a change in boiling curve slope into - $q \sim \Delta T^{4...9}$, which confirms a change in heat transfer mechanism. In point ***"A"*** pores activation inside the structure takes place, and it is a delayed activation (in terms of higher superheating value ΔT than this coming from nucleation superheating dependence, formula (1)). The phenomena is fostered by physical parameters of heat-carrying agent, specially a low value of contact angle, causing the "flooding" of potential nucleation sites inside the structure.

A sudden change in the boiling curve in range ***b*** indicates that along with the increasing heat flux, the number of nucleation sites also increases. Activation of new sites is more violent than for technically smooth surface, for which $q \sim \Delta T^{3.3}$.

Hysteresis occurs after the heat flux has been diminished in range ***b.*** It means that after the activation of nucleation sites inside the structure and after diminishing the heat flux they are still active. The heat transfer mechanism in the range ***b*** is presented in Figure 5.

Boiling curve segments in range ***c*** are stable in temperature ranges presented in Fig.3, with increasing and diminishing heat flux. In range ***c*** moving to the curve located above is possible through curve ***b.*** A lower heat flux value for the same temperature difference (lower curve from ranges ***c*** or curve ***a***) is possible to obtain only when the boiling is stopped.

Ranges ***b*** and ***c*** are especially important for the mechanism of type II hysteresis forming.

EXPERIMENTAL SET-UP AND METHODOLOGY OF INVESTIGATIONS

The objective of the present study was to investigate whether the heat flux supply has an impact on the hysteresis phenomenon and determine the shape of the curve with boiling hysteresis in terms of dynamic changes of heat flux. The diagram of the measurement stand and its basic module is presented in Figure 6.

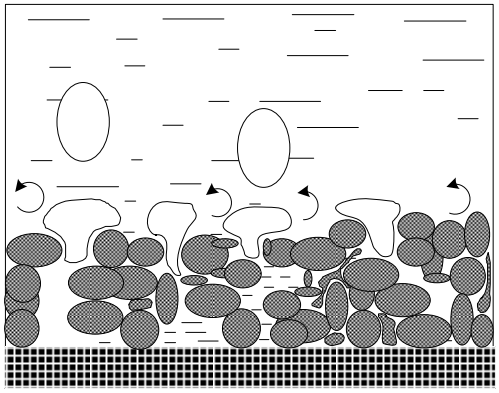

Figure 4. Heat transfer mechanism in range **a** boiling curve with type II hysteresis.

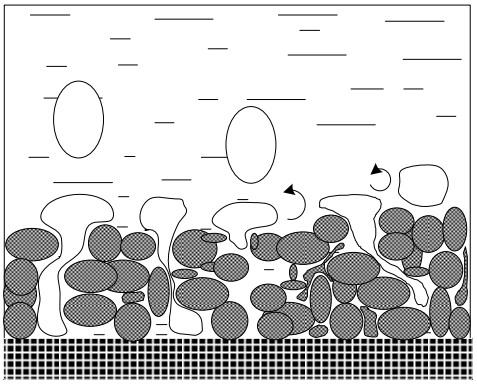

Figure 5. Heat transfer mechanism in range **b** boiling curve with type II hysteresis.

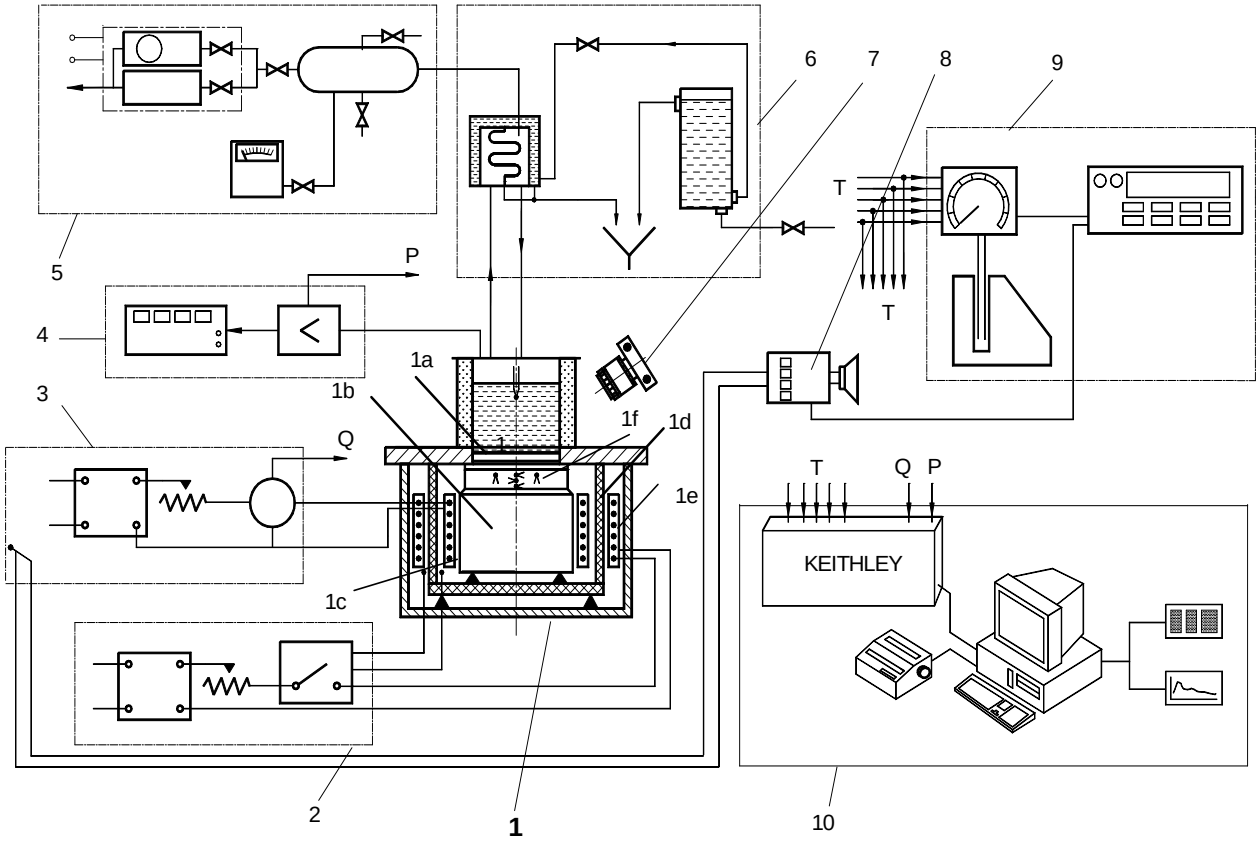

Figure 6. Diagram of the experimental stand and auxiliary systems: 1 - basic module; 2- heat loss compensation system; 3 - heating module with input power reading ; 4 - measurement of pressure in liquid tank; 5 - low pressure generating and measuring module; 6 - vapor cooling and condensate recovering module; 7 - digital high speed camera; 8 - excessive temperature signaling module; 9 - temperature measuring module; 10 - data collecting and processing module; p - pressure; Q- electric power; T- temperature.

A specimen (1a, Fig. 6) with a porous covering was mounted on a copper cylinder (1b). A heater wound around the cylinder (1c) was charged via autotransformer. The cylinder was thermally isolated with a ceramic pipe (1d) and insulation fillings. A compensation heater (1e) mounted on the exterior of the ceramic pipe (1d) provided additional protection against heat loss. Type K thermocouples (1f) were mounted underneath the specimen, on the axis of the cylinder and in the boiling liquid. The temperature of the heating surface was determined by extrapolating to it temperatures measured along the axis of the cylinder.

The measurement error was 9% for temperature differences and 12% for the heat flux.

Metal, fibrous capillary-porous covering of the heating surface is a layer of sprinkled wires, sintered to one another and to the heating surface, Fig. 8. The main structural parameters of the covering, made most often of copper or steel, are as follows: wire diameter d_w, wire length l_w , layer porosity Π, layer thickness δ. They range: d_w = 10 - 100 μm, l_w = 1 - 10 mm, Π = 40 – 85%, δ = 0.2 – 2 mm. For metal, fibrous coverings, unlike in other methods, e.g. thermal spray technique, we can plan the parameters that want to obtain.

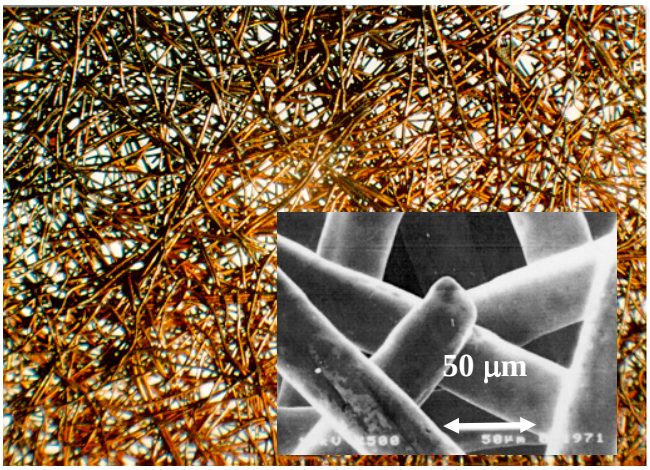

Figure 8. Metal, fibrous porous structure.

The advantages fibrous, porous coverings have over structures manufactured with other methods have been well recognised. Those coverings are characterised by high skeleton conductivity as well as only open porosity and simple manufacturing. Other advantages include the possibility of porous coverings deposition over the base surfaces of complex shapes and, which is the most important, a high value of the heat transfer coefficient. The latter was confirmed by many experimental investigations.

The basic investigation of boiling heat transfer on a heating surface covered with a porous layer was preceded by testing measurements of the stand. The test consisted in determining the boiling curve for the smooth reference surface and comparing it with data provided in literature. The results of heat transfer measurements for nucleate boiling on a copper reference surface were in the range of results obtained by other authors.

The investigation of heat transfer on horizontal heating surfaces covered with porous layers was carried out for ethanol, R – 113 and R - 123 boiling, at atmospheric pressure.

Prior to the experiment, the CPSs were submitted to a preparatory procedure that included wiping them with acetone, rinsing in ethanol, and drying. Specimens mounted to the heating cylinder were left in the liquid for approximately 24 hours. The proper experiments were preceded by intense nucleate

boiling for approximately half an hour. The power of the main heater was then decreased, until boiling subsided.

The applied experimental procedure, Figure 9, was as follows: first, the heater power was increased. Once the target heat flux q_1, Fig. 9a, was attained, it was reduced to a value at which nucleate boiling did not subside. The procedure was repeated by increasing the heat flux to the new value of q_2, Fig. 9b, which was bigger than the previous one, and once more decreased. These steps were repeated until the maximum heat flux q_{max} was reached, Fig. 9c. It was not always possible to obtain the maximum heat flux for a certain porous structure. Figure 3 presents the characteristic experimental boiling curve obtained for this procedure.

The aim of this study was to investigate whether the heat flux supply has an impact on the hysteresis phenomenon and determine the shape of the curve with boiling hysteresis in terms of dynamic changes of heat flux. The procedure was as follows: after the system has reached the balance, under the conditions of stable nucleate heating (q_{min}), the heater power increased to q_{max}, Fig. 9d (1), which resulted in a systematic increase specimen temperature. Once the maximum allowed temperature measured inside the heating cylinder was attained, the heat flux was decreased until boiling subsided, Fig. 9d (1).

Thermocouples were mounted underneath the specimen, on the axis of the heating cylinder and in the boiling liquid. Temperatures were recorded every 0.5 seconds through a data acquisition system. The heat flux density was determined by a gradient method. The temperature of the heating surface was determined by extrapolating to it the temperatures measured along the axis of the cylinder.

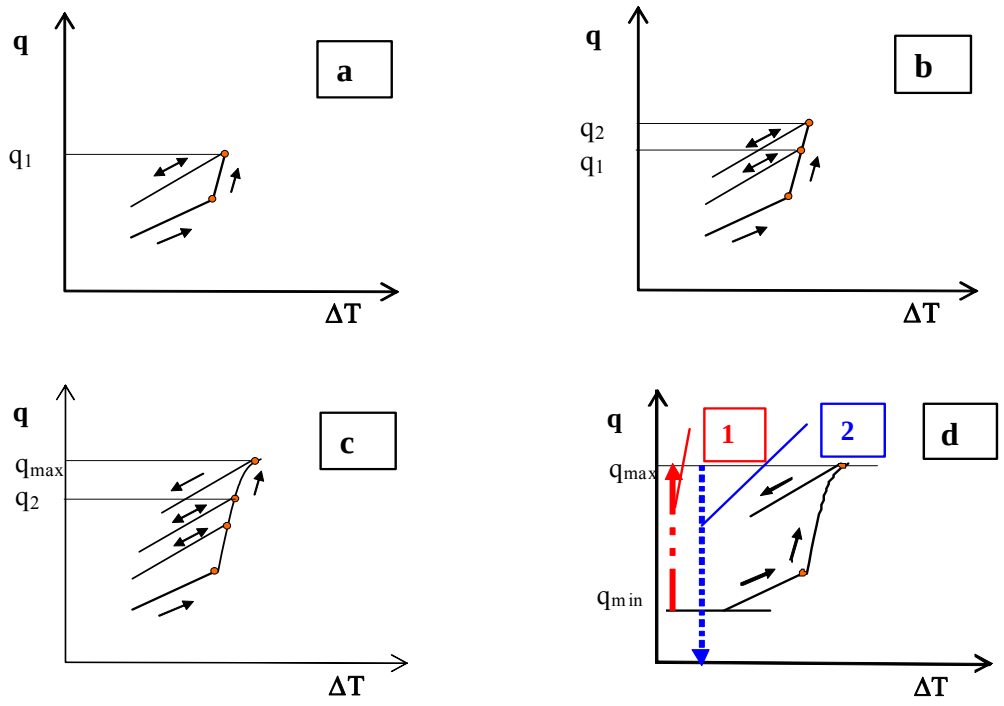

Figure 9. Procedure of determining the boiling curve *(curves **a**, **b** and **c** apply to hysteresis occurring before q_{max} is attained, and curve **d** hysteresis for sudden growth heat flux)*

RESULTS

Figure 10 shows the results of the measurements for the thin-layer covering of copper, fibrous CPS. The measurements and calculations confirmed the existence of *type II hysteresis* in terms of dynamic changes of heat flux. The ranges of *a, b, c* and *d* are shown at boiling curve, just as in Figure 3. As planned, the method of the heat flux supply does not affect the type II heat transfer hysteresis, confirms the physical mechanisms of the phenomenon.

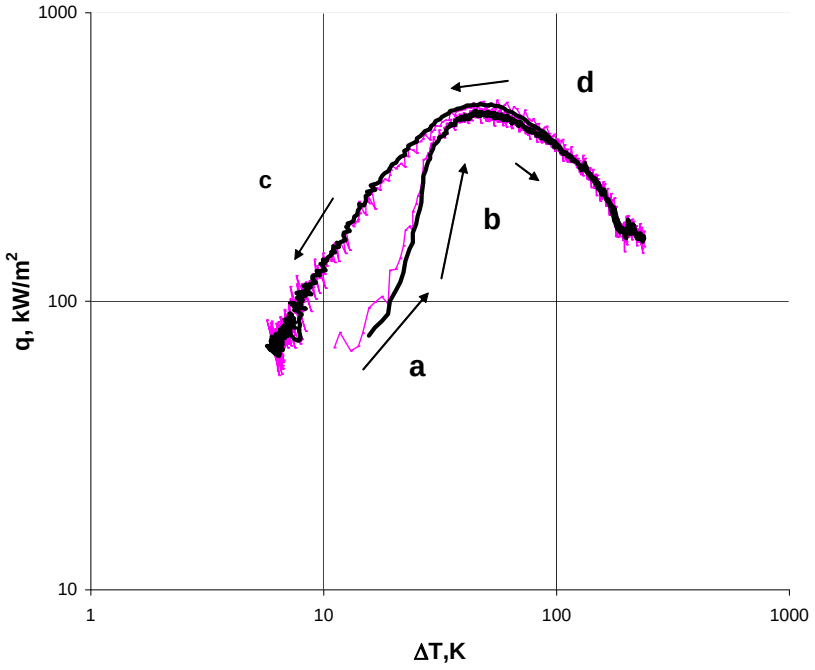

Figure 10. Results of experimental research for R - 123, copper, fibrous, CPS, δ = 0.6 mm, Π= 85%, atmospheric pressure

CONCLUSIONS

The aim of this paper was to investigate whether the heat flux supply has an impact on the hysteresis phenomenon and to determine the shape of the curve with boiling hysteresis in terms of dynamic changes of heat flux.

The measurements and calculations confirmed the existence of type II hysteresis in these terms.

All the ranges shown of boiling curve designated for slow changes of the feat flux are shown at curve in terms of dynamic changes of heat flux.

This means that the type II hysteresis phenomenon is independent of the supply of heat and models developed for type II hysteresis can be transferred to the actual conditions of reception of heat, for example rapid changes in the load of electronic circuits.

AN EXPERIMENTAL STUDY ON PERFORMANCE OF POLYMER HEAT EXCHANGER FOR EXHAUST HEAT RECOVERY IN VENTILATION SYSTEM

S. Y. Yoo, K. H. Han*, J. H. Kim
BK21 Mechatronics Group in Chungnam National University, Daejeon, Korea

ABSTRACT. The purpose of this research is to develop high efficiency polymer plate heat exchangers which can be substituted for aluminium plate heat exchangers and applied directly to the conventional ventilation system. Since thermal conductivity of polymer is much smaller than that of aluminium, enhancement techniques for convective heat transfer are adopted to compensate conduction resistance. Square dimple type and hexagon dimple type heat exchangers are developed and compared with square plate type and hexagon plate type heat exchangers used as reference model. Thermal performance and pressure drop for each polymer heat exchanger are measured in various operation conditions and compared each other. From the experimental results, correlations for the heat transfer coefficient and friction factor are obtained. Effectiveness of the square dimple type and hexagon dimple type is improved about 100% and 50% at air velocity of 2.5m/sec compared to the square plate type and the hexagon plate type, respectively.

Keywords: *polymer heat exchanger, ventilation system, heat transfer enhancement, pressure drop, effectiveness*

INTRODUCTION

Heat recovery units have been widely used for energy saving and it usually recovers around 60~80% of wasted thermal energy which improves about 20~30% of total system efficiency. Conventional HVAC systems have commonly adopted the rotary-wheel type, and the aluminium plate type heat exchangers. However, they have been used only for limited industrial applications such as buildings because of high cost and lack of concern of people in practical fields like HVAC systems in housing. An integrated unit that consists of air filters, heat exchangers, and an air-conditioning system not only makes a pleasant environment also saves lots of energy in cooling and heating.

The aluminium plate heat exchangers have been used widely for ventilation heat recovery in the air-conditioning system, and various non-metallic materials such as pulp, Teflon, and polymer have been adopted as a material of heat exchangers for the same usage. Among those non-metallic materials, polymer is one of the most promised materials because of its competitive mechanical advantages: low cost, light weight, easy processing, high corrosion-resistance, and so forth. [1]

The principal aim of this research is to develop high efficiency polymer plate heat exchangers which can be substituted for aluminium plate heat exchangers. Typical plate type heat exchangers have smooth flat-plate surfaces or finned-flat-plate surfaces. Since these kinds of surface structures demonstrate a low heat transfer coefficient, typically passive ways, which are to increase surface area or the number of plates per unit volume, have been applied for heat exchanger designs.[2] Thus, these heat exchangers have a bigger volume and a low efficiency. In order to obtain competitive polymer

* Corresponding author: K. H. Han

E-mail address: khhan@cnu.ac.kr

plate heat exchangers, various heat transfer enhancement techniques should be studied and applied to overcome the extremely low thermal conductivity.

Heat transfer enhancement techniques can be classified as passive, which manipulate the plate surface, and active which manage working fluid inside of heat exchangers. In this research, various passive enhancement techniques are applied to develop polymer plate heat exchangers. Since thermal conductivity of polymer is far smaller than that of aluminium, various heat transfer enhancement techniques are applied to design the surface of polymer plates.

DESIGN OF POLYMER HEAT EXCHANGERS

Existing polymer heat exchangers for exhaust heat recovery have a plate-fin-type structure which has great manufacturing advantages by being pressed in the forming process. In this study, four different prototypes of heat exchangers are designed and manufactured.(dimple square type, dimple hexagon type, square plate type and hexagon plate type) PP and PVC that have thickness 4mm are chosen for material of polymer heat exchanger because of its competitive mechanical characteristics. Both show high resistance to heat and chemical elements. Moreover, it is easy to fabricate on any complex surface geometry.

Heat exchangers have been initially developed using square flat, and the hexagon flat type heat exchanger can be used as of reference model to evaluate how much heat transfer performance increases. As shown in Figure 1, square and hexagon plate type heat exchangers are fabricated without manipulation of heat transfer area. The square plate type heat exchanger has a 4mm height and 230mm width of inflow. The flame to divide the flow is constructed with acrylic that has a 5mm width of both side, 2mm width of central side. The hexagon flat type is fabricated with hexagonal heat transfer area that satisfies the structure of flow of cross and counter in both. It has a 160mm width of inflow, and 4mm height of each channel.

In this study, enhanced heat transfer techniques are applied to develop the square dimple type and hexagon dimple type. Figure 2 depicts the surface and configuration of plates. Two different sizes of dimples, a hemisphere shape of a 4mm diameter and a 1mm diameter, are placed alternately with 25mm distance in between each of them. The bigger dimples not only increase the heat transfer area and generate vortexes and turbulence but also support the plates. Thus, any supporting frame is not required between plates. The outside of the dimples act as vortex generators, and secondary flows inside of the dimples promote heat transfer. The square dimple and hexagon dimple type heat exchangers are expected to produce higher overall heat transfer performance and pressure drop than simple plate type since it has a complex surface geometry compared to that of the simple plate type. The inflow width of each type is 210mm in dimple square type and 160mm in dimple hexagon type.

Figure 2. (a) Square dimple type and (b) hexagon dimple type polymer heat exchanger

EXPERIMENTAL APPARATUS AND METHODS

Experimental apparatus

A test apparatus for polymer plate heat exchanger is designed, and Figure 3 shows the schematic of the performance test facility. In order to minimize heat loss to surroundings, whole ducts are well insulated. Each fan is set up at the end of both outlets of a heat exchanger, and they operate as suction pumps which can eliminate disturbances in measuring. Nozzles are used as flow meters and placed at the outlets of fans. A hot water bath and a cold water bath are used for maintaining constant inlet air temperature. Inflow airs to cold side and hot side pass fin-tube-type heat exchangers in which hot water

…: pressure measuring, —: temperature measuring

Figure 3. Schematic of performance test facility

and cold water are circulated. Pressure drop in heat exchanger and flow rate are measured using micro-manometer and scanning box simultaneously. Because multi-sampling provides high precision results 14 pressure-measuring tabs are installed at inlet/outlet of heat exchanger and nozzles: two tabs are located at the upper side and the lower side of duct for each inlet/outlet of heat exchanger, and three tabs are set at each nozzle. In order to eliminate the influence of dynamic pressure on measuring flow rate, pressure-measuring tabs have a 2mm diameter less than recommended 3.2mm in ASHRAE standards. Calibrated T-type thermocouples are inserted on the duct wall for monitoring interaction between the duct sides and surroundings.[3]

Experimental methods

System performance can be described by heat transfer efficiency and pressure loss. Thus, in this study, performance tests are carried out on both of them. Pressure losses between the inlet and outlet of the heat exchanger are measured according to different flow rates, 0.3 ~ 3 m/sec. Heat transfer performance tests and pressure loss tests are performed under the same condition simultaneously. It is required to eliminate heat interaction between the flow air and duct wall before the performance test. Therefore, 1 hour pre-running at the initial condition of the test keeps all conditions a steady state inside of the apparatus. After the system reaches a steady state, another pre-running period is necessary to obtain steady state at given flow rate and it takes around 5 minutes to come to the steady state. The results of the last two minutes are taken from the 10 minutes running at given operation conditions.

RESULTS AND DISCUSSION

Pressure loss

Figure 4 provides the measured pressure loss of each heat exchanger model at various air velocities. Pressure loss tends to increase with the square of the velocity. The square plate type which has the simplest structure of flow channels shows the lowest pressure loss compared to other heat exchangers. Both dimple type has the similar pressure drop and show higher results than both plate type. In the case of hexagon plate type, there is no manipulation of heat transfer area like square plate type, but pressure loss is higher than square plate type because of existing separation zone of flow.

The friction factor f is a dimensionless number that is used for the quantitative comparison of the pressure losses of heat exchangers, and Reynolds number is used as a dimensionless number for air velocity. Figure 5 shows friction factors of each heat exchanger model according to various Reynolds number. Friction factor and Reynolds number are defined in equation (1) and (2)

$$f = \frac{\Delta P}{\frac{1}{2}\rho V^2} \cdot \frac{D_h}{L} \tag{1}$$

$$\mathrm{Re} = \frac{VD_h}{\upsilon} \tag{2}$$

Here, the parameter L is the channel length of heat exchanger V is the face velocity and D_h is the hydraulic diameter of a channel. Both dimple type show higher friction factors than both plate type. Friction factors of the square dimple type are prone to decrease gradually with increasing Reynolds number, while friction factors of the square plate type drop rapidly. The principle reason of this trend is that main pressure loss is occurring inside of the channels of former heat exchangers, but it happens at the face of heat exchanger for the latter model. This indicates that pressure loss in the low Reynolds number range, and pressure loss inside of channels increases as flow rate increases. Thus, Figure 5 illustrates well about this phenomenon nicely. Unlikely, friction factors of hexagon type heat exchangers decrease with similar tenderness. Since, the hexagon type is less number of

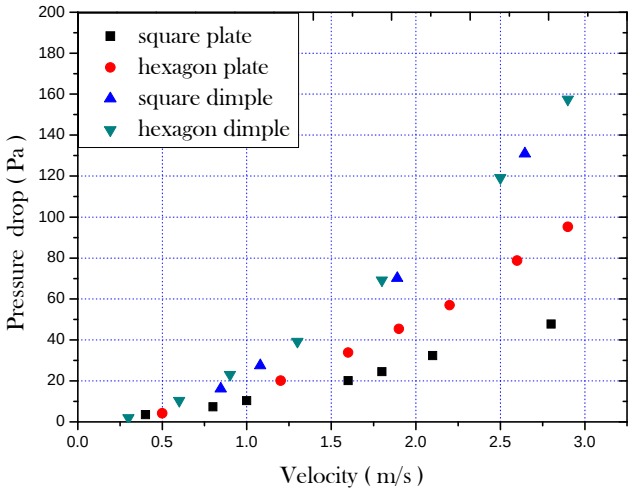

Figure 4. Comparison of pressure loss at various air velocities

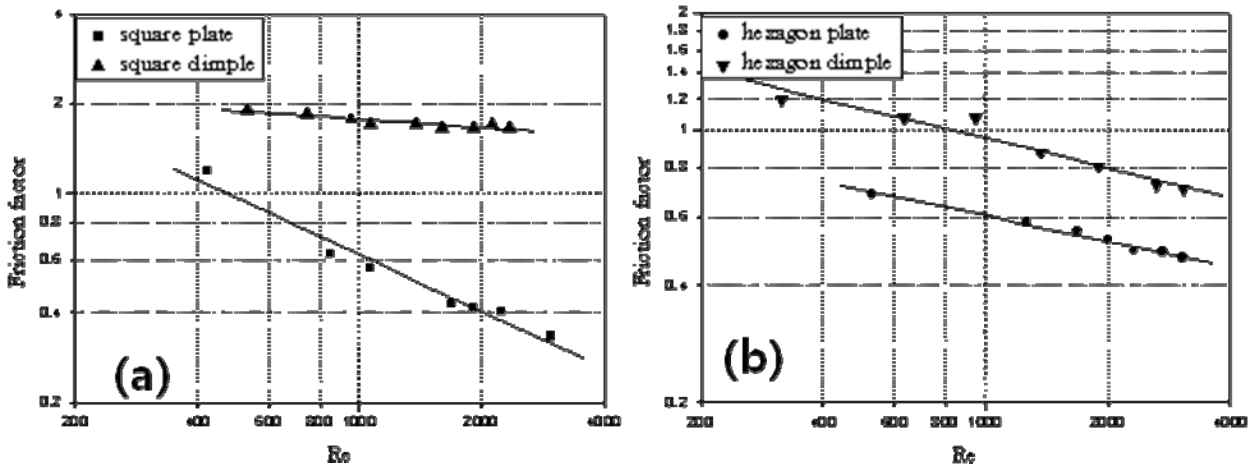

Figure 5. Comparison of dependence of friction factor on Reynolds number of (a) square shape (b) hexagon shape.

dimple than square dimple type, the rate of pressure losses of both hexagon type heat exchanger are considered as similar.

As a result, the correlation equation that need to calculate the power of heat exchanger in ventilation system can be obtained from Figure 5.

$$\text{Square plate type} : \quad f = 47.6\,\mathrm{Re}^{-0.627} \tag{3}$$

$$\text{Hexagon plate type} : \quad f = 2.71\,\mathrm{Re}^{-0.217} \tag{4}$$

$$\text{Square dimple type} : \quad f = 3.38\,\mathrm{Re}^{-0.093} \tag{5}$$

$$\text{Hexagon dimple type} : \quad f = 5.41\,\mathrm{Re}^{-0.261} \tag{6}$$

Heat transfer performance

If there are no heat losses, the heat transfer rate in heat exchangers from the hot air should be equal to the heat transfer rate to the cold air based on the first law of thermodynamics. The overall heat transfer rate for an air-to-air heat exchanger can be expressed as by Newton's law of cooling, and it can be modified for cross-flow heat exchangers, adopting the correlation factors as

$$\dot{Q} = UAF\Delta T_m \tag{7}$$

where $\dot{Q}$ is the heat transfer rate, U is the overall heat transfer rate, A is the heat transfer area, F is the correction factor, and ΔT_m is the log mean temperature difference. The maximum error of the heat transfer rate balance between the cold side and the hot side is less than 5%, and the error becomes less than 2% over the air velocity 1.5 m/sec. Thus, average values of two heat transfer rates are taken as the representative heat transfer rate. Heat transfer capacity of heat exchangers can be expressed in terms of the value of UAF, and Figure 6 provides the value of UAF of each model at various velocities. Both dimple type also has higher value of UAF than that of both models as in the pressure loss comparison, but the square dimple type shows higher values of UAF than the values of the dimple hexagon model.

The average heat transfer coefficient can be obtained using the value of UAF based on energy balance equations. Nusselt number is used as a dimensionless number of the heat transfer coefficient. Figure 7 shows the comparison of the dependence of Nusselt number on Reynolds number of each model. The correlation equations about Nusselt number on Reynolds number of each models represent as

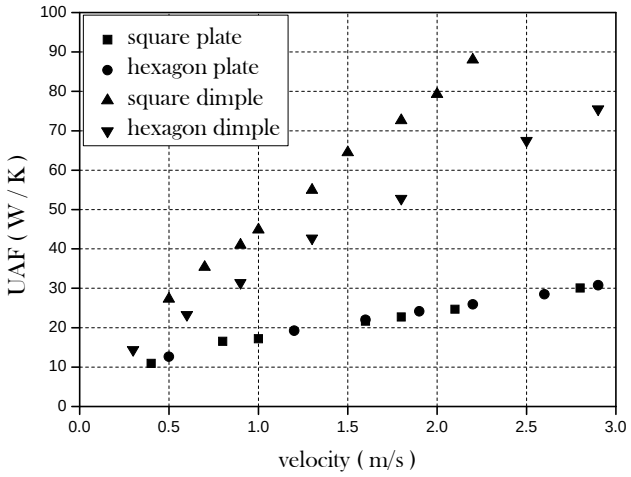

Figure 6. Comparison of UAF at various air velocities

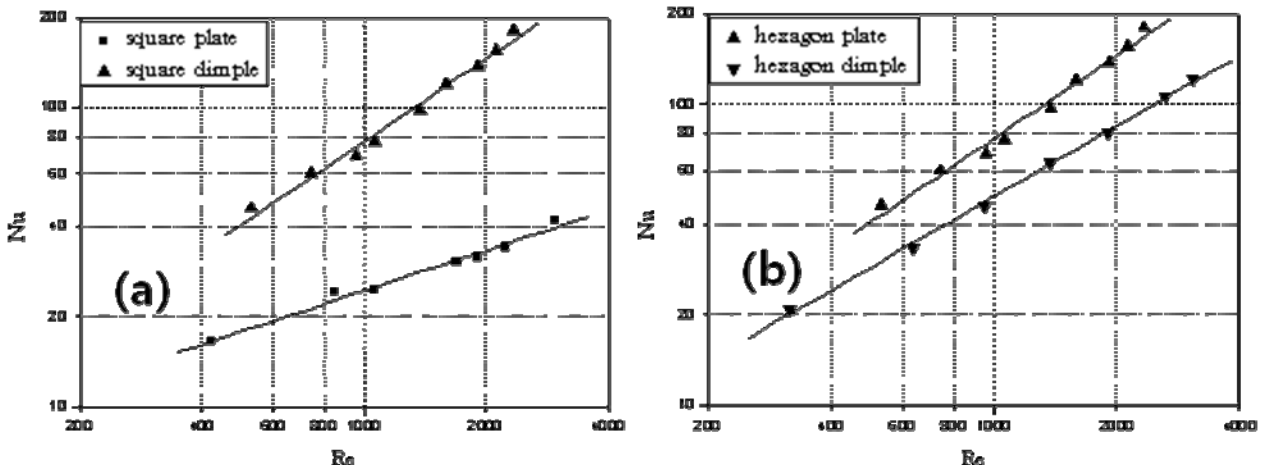

Figure 7. Comparison of dependence of Nusselt number on Reynolds number of (a) square shape (b) hexagon shape.

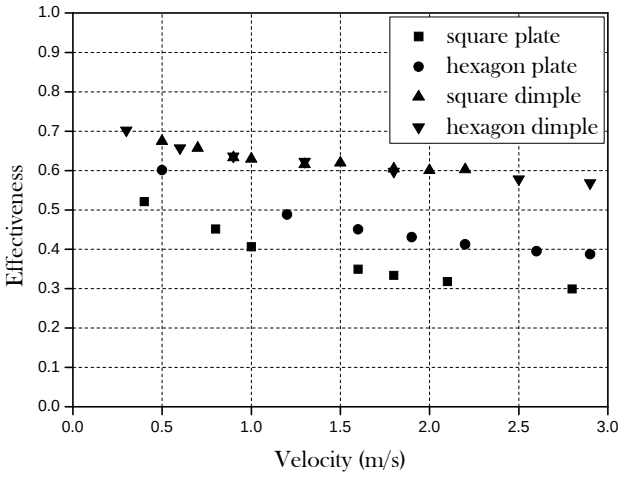

Figure 8. Comparison of effectiveness at various air velocities

$$\text{Square plate type} \quad : \quad Nu = 0.478\,\mathrm{Re}^{0.971} \tag{8}$$

$$\text{Hexagon plate type} \quad : \quad Nu = 0.512\,\mathrm{Re}^{0.928} \tag{9}$$

$$\text{Square dimple type} \quad : \quad Nu = 0.389\,\mathrm{Re}^{1.435} \tag{10}$$

$$\text{Hexagon dimple type} \quad : \quad Nu = 0.368\,\mathrm{Re}^{1.384} \tag{11}$$

Another way to investigate the performance of heat exchangers is based on a dimensionless value called the heat transfer effectiveness ε defined as

$$\varepsilon = \frac{\dot{Q}_{actual}}{\dot{Q}_{\max}} \tag{12}$$

Figure 8 provides the comparison of effectiveness at various velocities. The square dimple and hexagon dimple type show very similar results through whole ranges of velocity, and hexagon plate type is somewhat better than the square plate type. The effectiveness of the square dimple type and the hexagon dimple type are improved about 100% and 50% at air velocity 2.5m/sec. Effectiveness tends to decrease as velocity increases

Performance at equivalent fan power

The allowed fan capacity and the pressure loss should be considered in heat exchanger design. Pressure losses inside of heat exchangers can be converted to electrical input power to the fans. Enhanced overall performance of heat exchangers is obtained by the difference in the amount of improved heat transfer rate as a gain and pressure loss as a loss under same condition. Figure 9 shows possible heat transfer capacities of each model at the same fan power, and this comparison allows evaluating overall performance improvement and input power simultaneously. The square dimple type shows slightly higher overall performance than the hexagon dimple type.

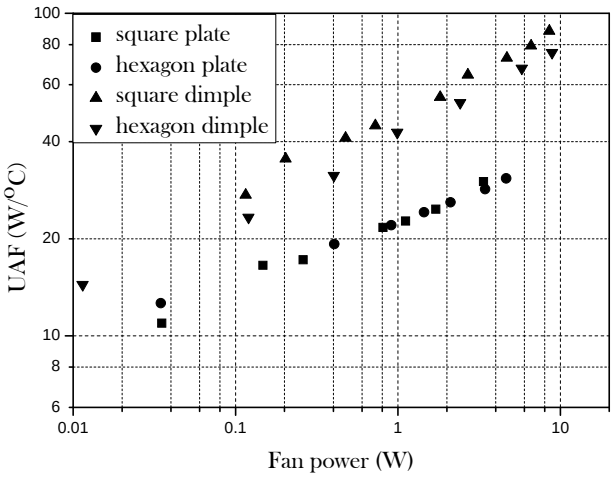

Figure 9. Comparison of UAF at equivalent fan power

CONCLUSION

Four types of the polymer plate heat exchanger are designed and manufactured, that is, the square plate type, hexagon plate type, square dimple type, hexagon dimple type. Thermal performance and pressure loss of the polymer plate heat exchanger are measured and compared in various operating conditions. The major results of this study are as follows.

[1] Friction factor of the square dimple type and hexagon dimple type increase about 350%, 60% respectively compare to the square plate type and the hexagon plate type heat exchanger at Reynolds number 2,000

[2] Effectiveness of the square dimple type and hexagon dimple type is improved about 100% and 50% at air velocity of 2.5m/sec compared to the square plate type and the hexagon plate type, respectively.

ACKNOWLEDGEMENT

ABSTRACT. The natural convection regime present within a simulated aircraft wing leading edge enclosure containing a horizontal isothermal cylinder is presented in this paper. A number of different ventilation configurations are investigated and compared to an unventilated case. A mixing ventilation regime with a single vent located on the lower surface of the enclosure exhibited very little difference in the thermal distribution within the enclosure compared to the unventilated case. This highlights the poor performance of mixing ventilation in such a configuration. Moving to a displacement ventilation configuration showed a significant reduction in the enclosure temperatures, with the greatest reduction seen with the vent openings placed on the upper and lower enclosure surfaces respectively. Placing the two ventilation openings on the lower enclosure surface saw a reduction of 70% in the mass flow rate across the vent boundary compared to the vents located on the upper and lower surfaces. As a result a significant increase in the average enclosure temperature was recorded.

Keywords: *Natural convection, Enclosure, Ventilation.*

INTRODUCTION

Natural convection plays an important role in many engineering disciplines such as electronics cooling, nuclear reactors and aircraft heat transfer. The convective regime present depends on enclosure geometry, the position and type of thermal boundary conditions along with the material and fluid properties within the enclosure. In natural convection, a coupling of the thermal and velocity fields is present within an enclosure. This means that a slight change in the operating conditions may have a significant impact on the enclosure thermal distribution, altering the convective regime considerably. This effect needs top be fully appreciated in order to limit the exposure of thermally sensitive equipment operating within to high heat loads.

During normal operations, particularly in high ambient temperature environments during turnaround, an aircraft stationary on the tarmac may be subjected to significant heating effects. Solar loading on the upper skin surface coupled with ground reflection heating the lower surface can result in an aggressive thermal environment for the aircraft to operate in. This is especially true in the wing leading edge where the presence of an engine bleed duct transporting high temperature fluid to the main fuselage through the leading edge also contributes to this thermal environment. The overall influence of both these contributions to heat transfer in a wing leading edge must be understood for effective thermal management.

Differentially heated enclosures have been the subject of numerous investigations in the literature including studies on the effect of aspect ratio [1-3], thermal boundary conditions [4,5], and enclosure geometries [6-8]. The convective regime present within is found to be highly sensitive to enclosure

conditions often with complex flow patterns induced, even for simple geometrical and thermal boundary conditions. Convective instabilities may also be increased when deviating away from a simple square or rectangular enclosure to a more complex shape [7]

The introduction of a discrete source into such an enclosure has a marked effect on natural convection within. For a heated object within an isothermal or adiabatic enclosure, the flow regime is driven solely by the heat source and is primarily determined by position [9] and Rayleigh number. A much more complex system is present when the heat source is coupled with external boundary conditions (e.g. a differentially heated enclosure). In this case the interaction between the two systems produce a regime that is much more complex than for each contribution seen separately, which may be difficult to predict without some insight into the flow phenomenon present. To the best of the authors' knowledge, research in this area has not received considerable attention compared to the previous cases, especially in non-standard geometries.

In many engineering applications however, simple natural convection alone may not be enough to provide adequate enclosure cooling, especially if subjected to a high thermal load. In such cases, effective enclosure ventilation is required with a view to reducing the aggressive thermal environment. Typical enclosure ventilation consists of one of two mechanisms: mixing ventilation and displacement ventilation. Mixing ventilation occurs when both the inlet and outlet ventilation flow pass through the same opening in an enclosure. A transfer to displacement ventilation occurs when a second ventilation opening exists in an enclosure, allowing for a separate opening for inlet and outlet ventilation flow. Haslavsky *et al* [10] study the effect of changing from mixing to displacement ventilation on a heated surface within an enclosure. They found that a significant reduction in ΔT between the component and its surroundings is possible, highlighting the effectiveness of displacement over mixing ventilation. Enclosure aspect ratio is also important with respect to enclosure ventilation. Bilgen & Yanange [11] found that a tall or wide enclosure can tend to choke the natural convection flow within, reducing the ventilation performance. This lead to a 50% drop in the Nusselt No. compared to the optimum configuration with an aspect ratio of 1.

This paper details an investigation into the effect of enclosure geometrical configuration upon the ventilation of a simulated aircraft wing leading edge compartment. The configuration and boundary conditions represent a stationary aircraft subjected to direct solar loading from above and ground reflection from below. A horizontal heated cylinder representing an engine bleed duct is also present within the enclosure. In order to reduce any aggressive thermal environment which may be present in the enclosure, ventilation openings are placed on the upper and lower wing skin surfaces. Different ventilation regimes are investigated, both mixing and displacement types and are compared to an unventilated enclosure to assess their performance.

DATA REDUCTION

The temperature, horizontal and vertical positioning were non-dimensionalised using the following transformations:

$$T^* = \frac{T - T_C}{T_H - T_C}, \quad X^* = \frac{x}{L}, \quad Y^* = \frac{y}{H}$$

where the subscripts C and H denote the coldest and hottest surface temperature respectively. The Rayleigh number based on cylinder diameter (d) is defined as:

$$Ra = \frac{g\beta(\Delta T)d^3}{\nu\alpha}$$

The fluid velocity normal to the vent boundaries are obtained from the expression

$$N = U_i Cos\theta + V_j Sin\theta$$

where θ is the angle of inclination of the vent. The mass flow rate is defined as

$$\dot{m} = \int \rho NA$$

where A is the unit area taken across the vent surface.

EXPERIMENTATION

Experimental temperature and velocity measurements were recorded within a ventilated leading edge enclosure. The enclosure dimensions are 300mm (H) x 550mm (L) x 600mm (D). The rear wall and leading edge surfaces were constructed from 10mm and 3mm thick respictively. An aluminium horizontal cylinder of diameter 50mm, length 580mm and wall thickness 3mm is present at location A of Figure 1. A glass window is present at the front of the enclosure for optical access, with the back of the enclosure sealed with a polycarbonate sheet. A polycarbonate window is also present in the rear wall of the enclosure to allow for laser sheet illumination in the enclosure.

Thermal boundary conditions are applied to the enclosure surfaces using Elemex thin film rubber backed heater mat with a 500W mat attached to the upper and lower surfaces of the enclosure and a 250W mat attached to the cylinder surface. Each heater mat is connected to a Eurotherm 2216e PID controller, which provided isothermal conditions on the enclosure surfaces, verified by thermocouples in contact with the enclosure surfaces. All other surfaces of the enclosure are assumed to be adiabatic with approximately 50mm of fibreglass insulation placed over the exterior surfaces to eliminate any heat loss to the environment. Ventilation openings 1 – 3 are placed in the enclosure as shown in Figure 1. These are 50mm in width and have a wire mesh placed over the openings, which constitute a 60% open ventilation area.

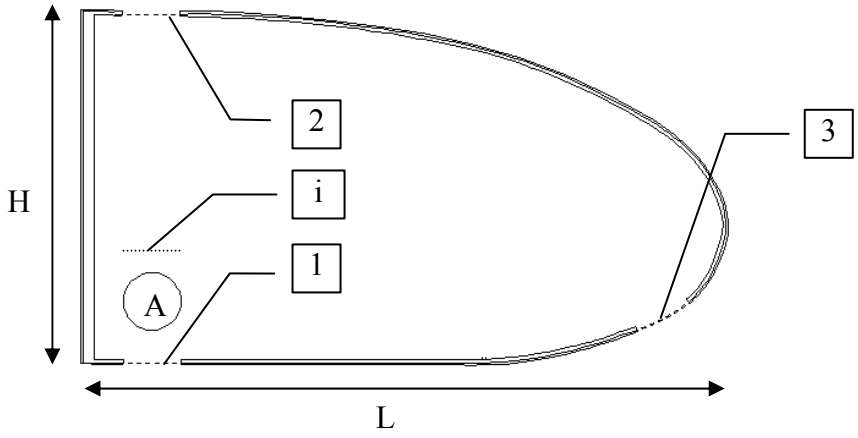

Figure 1 Enclosure Configuration Parameters

A number of different configurations within the leading edge enclosure are investigated. The enclosure geometrical configurations for Cases 1 – 4 are outlined in Table 1 in conjunction with Figure 1. Cases 1-4 represent the different ventilation configurations; an unventilated enclosure (Case 1), mixing ventilation (Case 2) and displacement ventilation (Case 3 & 4). All cases are subjected to identical

thermal boundary conditions, with the upper surface, lower surface and cylinder heated to 373K, 343K and 408K respectively. This results in a Rayleigh number based on the cylinder diameter of 6.5×10^5. All fluid properties are taken at the film temperature.

Table 1
Enclosure Geometrical Configurations Case 1 - 4

	Case 1	Case 2	Case 3	Case 4
Vent Openings	-	1	1 & 2	1 & 3

Temperature measurements are taken within the enclosure using calibrated K-type thermocouples placed along the interior surfaces and the horizontal and vertical centreline within the enclosure. The temperatures are recorded using a Stanford Research Systems SR630 16 Channel Thermocouple Reader. All temperature measurements are recorded at steady-state conditions which are defined as no greater than ±0.5°C change per hour. A maximum uncertainty in T* is found to be 1.3% during experimentation.

Velocity measurements within the enclosure are obtained by employing Particle Image Velocimetery (PIV). The flow was seeded using incense smoke, its particle diameter of typically 0.1-0.5μm [13, 14] deemed sufficiently small to accurately follow the flow field within the enclosure. In order to allow the seeding particles to reach neutral buoyancy, an external enclosure of 1.2m (H) x 1.2m (W) x 0.6m (D) was constructed, with the leading edge placed centrally within the enclosure. The incense smoke was then introduced into the outer enclosure with testing commencing after 30 minutes. Image acquisition was controlled by the TSI Insight 3G software package connected to a 2 Megapixel Powerview 2M Plus CCD Camera. The camera has a resolution of 1600 x 1200 and records at 30Hz. A AF Micro Nikkor 50mm f/1.2 D lens was attached to the camera which operated at an aperture of 1/2.8. The flow field was illuminated using a double pulsed 400mJ Nd-Yag laser (532nm) with a maximum operating frequency of 90Hz. Laser optics produce a 1.5mm laser sheet focused 500mm from the lens. The time between pulses is based upon a calculation of

$$t \leq \frac{8Sd_{pixel}}{v_{\max}}$$

where S is the image scale factor, d_{pixel} is the camera pixel pitch and v_{max} is the maximum fluid velocity expected in the test region.

RESULTS

For a simple heated ventilated enclosure, the external temperature boundary conditions are the sole drivers of the convective flow within. The presence of an isothermal cylinder adds complexity to the system with interaction between the enclosure and the buoyant cylinder plume significantly changing the resultant velocity and thermal distribution within the enclosure. Entrained exterior air will also interact with the enclosure flow and so the position and sizing of ventilation openings will be important with regard to the final enclosure conditions.

With these factors in mind, this section will describe the effect of different enclosure configurations, as outlined in Table 1, on the natural convection regime within the leading edge. The effect of ventilation orientation is also analysed, with unventilated, mixing and displacement ventilation systems investigated.

Ventilation configuration

The enclosure temperature distributions for Cases 1 – 4 are presented in Figure 2. A marked difference in the thermal environment within the leading edge can be seen depending on the ventilation configuration. As expected, the highest enclosure temperatures are seen for the unventilated enclosure in Case 1. A constant T* of 0.6 is seen along the horizontal centreline in Figure 2 (a), with a slight increase to 0.67 at X* = 0.1 due to the presence of the heated cylinder plume in this region. An approximately linear increase in T* from 0.54 to 0.61 along the vertical centreline in Figure 2 (b) suggesting a stably stratified fluid is present within the enclosure for this configuration. The mixing ventilation configuration in Case 2 exhibits an almost identical temperature distribution in the enclosure to that seen for Case 1. This demonstrates the ineffectiveness of a single vent located at the bottom surface of an enclosure. There is very little influx of cooler exterior air into the enclosure to aid in reducing the interior temperatures. This is mainly attributed to the choking of the ventilation flow at the vent boundary as for a mixing ventilation scenario, both the inflow and outflow must occur at the same opening in the enclosure. In Case 2 the opening is relatively small (50mm) and this severely reduces the ability of cooler exterior air to be entrained into the enclosure. A small recirculation zone is present at the vent boundary, with very little penetration into the enclosure. The rear wall temperatures seen in Figure 2 (c) are also almost identical between Case 1 and Case 2, again illustrating the ineffectiveness of this ventilation regime for the system under investigation.

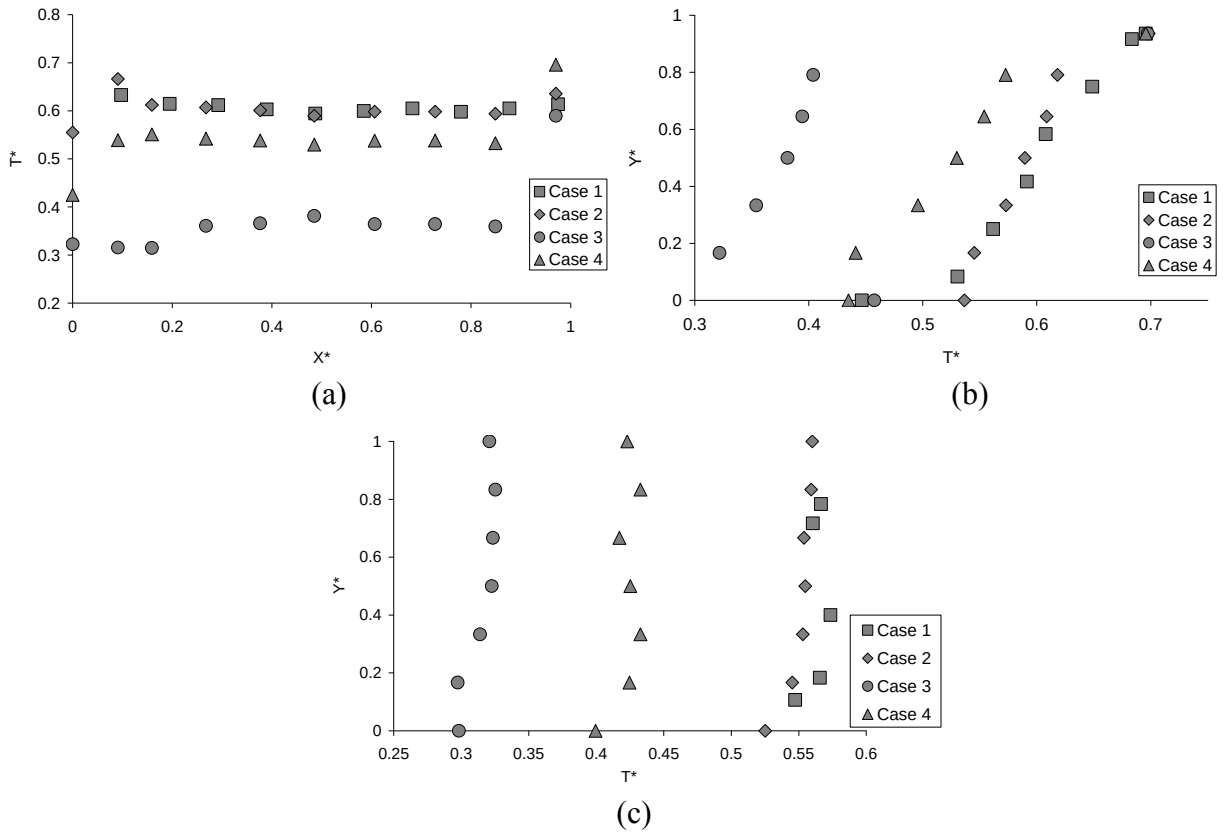

Figure 2 Enclosure Temperature Distributions for the Different Ventilation configurations in Cases 1 – 4 : (a) profile along horizontal centreline, (b) profile taken along vertical centreline, (c) profile taken along vertical centreline

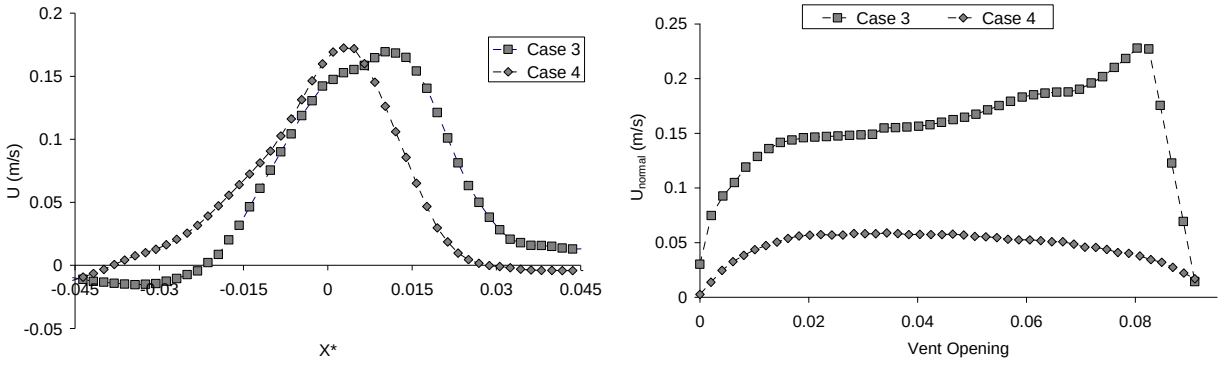
Transferring to a displacement ventilation regime in Case 3 & Case 4 shows a significant reduction in both the interior fluid and rear wall temperatures compared to the previous cases. The lowest enclosure

temperatures are seen in Case 3 with the vent openings located on the upper and lower enclosure surfaces. An approximate T* of 0.35 along the horizontal centreline is 40% lower than Case 2 and 35% lower than for Case 4. A similar trend in seen along the vertical centreline in Figure 2 (b), with the temperatures seen in Case 3 40% and 30% lower than Case 2 & Case 4 respectively. The temperature distribution along vertical centreline in Figure 2 (b) suggests the presence of large thermal gradients along both the upper and lower surface of the enclosure ($0<Y^*<0.19$ and $0.8<Y^*<1$). This indicates regions of high heat transfer along the interior enclosure surfaces in Case 3. This effect is not seen to the same extent for the other cases presented, particularly along the lower enclosure surface. This phenomenon may be present, but the spatial resolution of the thermocouple distribution used may not be sufficiently fine to capture any such effect.

The temperature profiles along the rear wall of the enclosure again show a large variation depending on the ventilation configuration. As noted previously, T* is identical along the wall height for the unventilated and mixing ventilation regimes in Case 1 & Case 2. The lowest wall temperatures are again seen in Case 3, which are up to 40% lower than Case 1 & Case 2. This occurs due to the ventilation path passing adjacent to the rear wall as it travels from the inlet to exit vent, helping to reduce the temperatures along the enclosure rear wall. The rear wall temperature reduction is much greater compared to the reduction in the interior fluid temperatures within the enclosure in Case 4. This is primarily as a result of a change in the cylinder plume orientation. For Case 1 & Case 2, the plume was found to attach to the rear wall surface with its heating effect contributing significantly to the temperature of the surface. In Case 4, the plume is found not to attach to the rear wall of the enclosure, but is orientated towards the centre of the compartment. This sets up an anticlockwise recirculation in the rear of the enclosure, resulting in a negative buoyant flow along the rear wall, producing the decrease in T* of 25% in Case 4 compared to Case 1 & Case 2. All of the T* profiles for the four cases under investigation show an approximately constant temperature along the rear wall height. This suggests that the rear wall is thermally isolated from the rest of the enclosure, with conduction between the rear wall and upper and lower enclosure surfaces inhibited.



(a) (b)

Figure 3 Velocity profile comparison between the two displacement ventilation regimes under investigation: (a) Cylinder plume structure taken along line (i) in Figure 1, (b) Exit vent flow taken normal to opening (2) for Case 3 and opening (3) for Case 4

The ventilation strategy used in Case 3 is found to be optimal as it allows for the entrainment of cool exterior air to be entrained into the enclosure from below and the hotter, more buoyant fluid to exit through the vent opening in the upper surface of the enclosure. This allows a direct path for the ventilation flow to enter the enclosure, interact within, and then exit through the upper vent. Case 4 show a moderate reduction in the horizontal centreline temperature from 0.6 to 0.55, with the largest

influence seen in the vertical centreline, particularly along the lower enclosure surface in this configuration. This suggests that the ventilation path in Case 4 is mainly limited to the lower surface of the enclosure, as it is entrained into the enclosure at the rear vent and passes towards the front vent opening with very little interaction with the remainder of the enclosure. All the temperature profiles exhibit a similar trend along both centrelines, with approximately constant temperatures along the horizontal centreline and linearly increasing temperatures along the vertical centreline. Very little difference in the cylinder plume structures in Figure 3 (a) is noted between Case 3 and Case 4, with Case 4 deflecting towards the centre of the enclosure to a greater degree, with its point of maximum velocity found at X* = 0.011 compared to X* = 0.003 in Case 4.

Table 2
Mass Flow Rates (kg/m) along the Vent Boundary & Average enclosure temperature

	Case 3	Case 4
Exit Vent	0.0184	0.00559
Average Enclosure T*	0.356	0.53

A large difference can be seen in the velocity profile at the exit vent of the enclosure in Figure 3 (b), with Case 3 showing a maximum velocity of 0.23 m/s whilst Case 4 has a maximum velocity at the outlet of 0.056 m/s. This results in a significant reduction in the mass flow rate of air exiting the enclosure from 0.0184 kg/s to 0.00559 kg/s with a corresponding increase in the average enclosure temperature as shown in Table 2. The main benefit of the ventilation regime in Case 3 is that both the buoyant cylinder plume and the enclosure surface flow can exit at the upper surface enclosure opening. In Case 4, the exit flow is comprised mainly of the air travelling along the lower surface of the enclosure, with very little contribution from the cylinder plume.

Whilst Case 3 is found to be the most effective method of reducing the temperature distributions within the enclosure, it may be very impractical from a wing design perspective, with the introduction of a ventilation opening on the upper skin surface incurring a significant drag penalty onto the wing. A more practical solution may be the configuration presented in Case 4 due to possible ventilation locations already present along the lower wing skin surface.

CONCLUSIONS

A comparison between a number of different ventilation configurations is presented in this paper. It was found that a single vent located on the lower surface of the enclosure in Case 2 is highly inefficient at reducing the enclosure temperatures, with an identical thermal distribution present to an unventilated enclosure seen in Case 1. This is primarily due to the choking of the ventilation flow at the vent boundary with little overall entrainment into the enclosure due to the small vent size.

Moving to a displacement ventilation regime in Case 3 shows a significant reduction in the interior temperature distributions with the provision of a separate opening for both the inlet and exit flow. This allowed for more effective removal of heat from the enclosure and an elimination of any recirculation at the vent boundary restricting entrainment into the enclosure. This however, does not represent an adequate ventilation solution as due to design constraints in the leading edge ventilation openings are limited to the lower enclosure surface.

Restricting the ventilation openings to the lower surface in Case 4 saw a rise in the temperatures in the enclosure compared to Case 3. In this case the ventilation path is restricted to the lower enclosure surface as air is entrained into the enclosure at the rear vent and exits the enclosure at the front vent, with little interaction with the core fluid.

Case 4 shows a significant drop of approximately 70% in the mass flow rate of air crossing the exit vent boundary compared to Case 3. In Case 3 there is a contribution from both the buoyant cylinder plume as well as the heated surface flow combining to cross the vent boundary, whereas in Case 4 this is reduced to the flow traveling along the heated lower surface only exiting at the front vent, with little contribution from the cylinder plume.

In Case 4 the rear wall temperatures exhibit a larger drop than the enclosure fluid temperatures when comparing them to the unventilated and mixing ventilated enclosure. This is as a result in a change in the cylinder plume orientation. For Case 1 and Case 2, the cylinder plume is attached to the enclosure rear wall, helping to increase is temperature whereas in Case 4, the plume travels towards the centre of the enclosure. This reduces its heating effect upon the rear wall, whilst at the same time helping to increase the overall enclosure fluid temperature due to strong mixing of the plume flow within the core region.

NATURAL CONVECTION REGIME WITHIN A WING LEADING EDGE ENCLOSURE. PART 2: EFFECTS OF ENCLOSURE PARTITIONING

D. Moore[1*], V. Egan[1], D. Newport[1], V. Lacarac[2]
[1]Department of Mechanical & Aeronautical Engineering, University of Limerick, Limerick, Ireland
[2]Airbus, Filton, Bristol BS99, 7AR, United Kingdom

ABSTRACT. The natural convection regime present within a ventilated enclosure containing a horizontal isothermal cylinder is investigated in this paper. The introduction of a dividing partition into the enclosure saw a marked change in the flow structure present, with the ventilation path between inlet and outlet vent blocked by the partition. Cylinder positioning within the partitioned enclosure is investigated, with a large difference noted the temperature profiles within the interior enclosure fluid and along the enclosure rear wall. The natural convection regime is found to be highly sensitive to the effect of cylinder positioning within the enclosure. A significant reduction in the mass flow rate of air leaving the enclosure is found upon partitioning the enclosure with a pure displacement ventilation regime no longer present for the partitioned cases. This is due to the presence of a region of backflow into the enclosure at the exit vent boundary reducing the overall ventilation effectiveness.

Keywords: *Natural convection, Enclosure, Ventilation, Partitioning*

INTRODUCTION

An understanding of the natural convection regime present within an enclosure is vital in order to provide sufficient provision for component cooling within the enclosure. As the resultant thermal and flow structures are a product of the external boundary conditions, they can be sensitive to the enclosure geometry, orientation and location of heat sources within the enclosure along with the fluid and material properties. In many scenarios, the resultant regime may be highly complex with a strong interaction between the thermal and velocity fields, where a slight change in one can have a marked effect on the other. This means that it can be difficult to quantify the enclosure conditions present without extensive investigation beforehand. One such scenario occurs in the leading edge enclosure of aircraft wings.

As aircraft operations have spread through the world, the range of thermal environments which they encounter varies can vary from arctic to hot dry desert conditions. In these high ambient temperature environments, there may be significant thermal loading present on the leading edge enclosure. This is as a result of direct solar radiation onto the upper enclosure skin and reflection from the ground tarmac heating the lower surface of the enclosure. This differentially heated enclosure is coupled with the presence of a heated horizontal cylinder travelling through the leading edge. This represents an engine bleed duct which transports high temperature fluid from the turbine high stage compressor to the main fuselage where it's used to power various aircraft systems. The combination of both effects can again be very complex and proper understanding of the flow characteristics is vital to provide effective thermal management within the enclosure.

Significant research has been carried out in the field of differentially heated enclosures, with the effect of enclosure geometry [1-3], thermal boundary conditions [4,5] and aspect ratio [6-8] highly influential on the final enclosure thermal distribution. The introduction of a discrete source into such an enclosure has a marked effect on natural convection within. For a heated object within an isothermal or adiabatic enclosure, the flow regime is driven solely by the heat source and is primarily determined by position [9] and Rayleigh number. A much more complex system is present when the heat source is coupled with external boundary conditions (e.g. a differentially heated enclosure). In this case the interaction between the two systems produce a regime that is much more complex than for each contribution seen separately, which may be difficult to predict without some insight into the flow phenomenon present. To the best of the authors' knowledge, research in this area has not received considerable attention compared to the previous cases, especially in non-standard geometries.

Partitioning an enclosure can have a marked effect on natural convection [11] and can be detrimental to ventilation flow by inhibiting the transport of high temperature fluid from one region to another. Khalifa & Abdullah [12] investigated the effect of different partition configurations on the enclosure Nusselt No. Partitioning, regardless of configuration reduces the Nusselt No. due to the confining of high temperature fluid to a certain region of the enclosure. In extreme cases a large partition to enclosure height can reduce the enclosure Nusselt No by up to 75% [12].

This paper describes the effect of introducing a partitioning structure into the ventilated leading edge enclosure previously investigated in Part 1 [14]. The objectives of this research is to investigate the impact of enclosure partitioning on the ventilation performance and the enclosure thermal distribution. For the current enclosure configuration, the cylinder plume is the main driving force of the convective regime present within. As such the effect of cylinder placement is important with regards to the final enclosure conditions. An investigation into cylinder location within the partitioned ventilated enclosure is carried out in order to determine its impact on the ventilation efficiency and enclosure conditions.

DATA REDUCTION

The temperature, horizontal and vertical positioning were non-dimensionalised using the following transformations:

$$T^* = \frac{T - T_C}{T_H - T_C}, \quad X^* = \frac{x}{L}, \quad Y^* = \frac{y}{H}$$

where the subscripts C and H denote the coldest and hottest surface temperature respectively. The Rayleigh number is defined as:

$$Ra = \frac{g\beta(\Delta T)d^3}{\nu\alpha}$$

The fluid velocity normal to the vent boundaries are obtained from the expression

$$N = U_i Cos\theta + V_j Sin\theta$$

where θ is the angle of inclination of the vent. The mass flow rate is defined as

$$\dot{m} = \int \rho NA$$

where A is the unit area taken across the vent surface.

EXPERIMENTATION

Experimental temperature and velocity measurements were recorded within a ventilated leading edge enclosure. A detailed description of the experimental apparatus is outlined in Part 1 [14].

A number of different configurations within the leading edge enclosure are investigated. The enclosure geometrical configurations for Cases 1 – 4 are outlined in Table 1 in conjunction with Figure 1. Case 4 is the original unpartitioned enclosure subjected to displacement ventilation with two vent openings on the lower surface. Case 2 introduces a partition into the enclosure, with the effect of cylinder position determined from Cases 2-4. All cases are subjected to identical thermal boundary conditions, with the upper surface, lower surface and cylinder heated to 373K, 343K and 408K respectively. This results in a Rayleigh number based on the cylinder diameter of 6.5×10^5. All fluid properties are taken at the film temperature. A description of the methods used to obtain the temperature and velocity distributions are outlined in Part 1 [14].

RESULTS

In this section the effect of enclosure partitioning through the introduction of a leading edge sub-spar is investigated. The results are compared to the unpartitioned enclosure analysed in Part 1 [14]. In order to determine the sensitivity of natural convection regime to bleed duct placement within the partitioned enclosure, three cylinder positions are investigated and the subsequent effect on enclosure ventilation discussed.

Enclosure Partitioning

The impact of introducing a partitioning structure into the leading edge enclosure is examined in this section. From the literature, partitioning is seen to have a detrimental effect upon the natural convection regime present within an enclosure. This results in a restriction in the flow path which can

confine higher temperature fluid to a smaller region, reducing the overall Nusselt number within. A partition is placed in the enclosure as shown in Figure 1. To allow laser access into the front partitioned space, the partition is constructed from transparent glass, with conduction from the heated enclosure surface to the partition assumed negligible due to the low thermal conductivity of the material.

The partitioned and unpartitioned temperature distributions are presented in Figure 2. In the rear partitioned section of the enclosure, both temperature profiles show a constant T* along the horizontal centreline in Figure 2 (a), with T* = 0.54 for Case 1 and T* = 0.51 for Case 2. Upon reaching the partition, there is an increase in T* from 0.51 to 0.55 between the rear and front partitioned sections in Case 2, whilst Case 1 remains at 0.54. This illustrates that the front and rear sections are at significantly different temperatures in Case 2 and that higher temperature fluid will exit through the vent in the front partitioned region. Along the vertical centreline in Figure 2 (b), three distinct regions are present in the enclosure for Cases 1 & 2. Both profiles indicate an linear gradient in T* from 0.5 to 0.56 in the centre region of the enclosure between $0.34 < Y^* < 0.8$. Below Y* = 0.34, an increase in the thermal gradient is noted, primarily due to the cooler entrained air entering the enclosure and passing over the lower surface. A significant increase in the thermal gradient is also present above Y* = 0.8, which is also greater than that recorded below Y* = 0.34. This suggests that a higher temperature gradient and hence enhanced heat transfer is present in this region. This is contrary to the expected result, with the cooler ventilation flow passing over the lower enclosure surface, producing a sharper temperature gradient here compared to the upper surface. This further reduction in T* along the lower surface may be present in experimentation, with the spacing used between adjacent thermocouples not sufficiently small to capture such a temperature profile close to the surface.

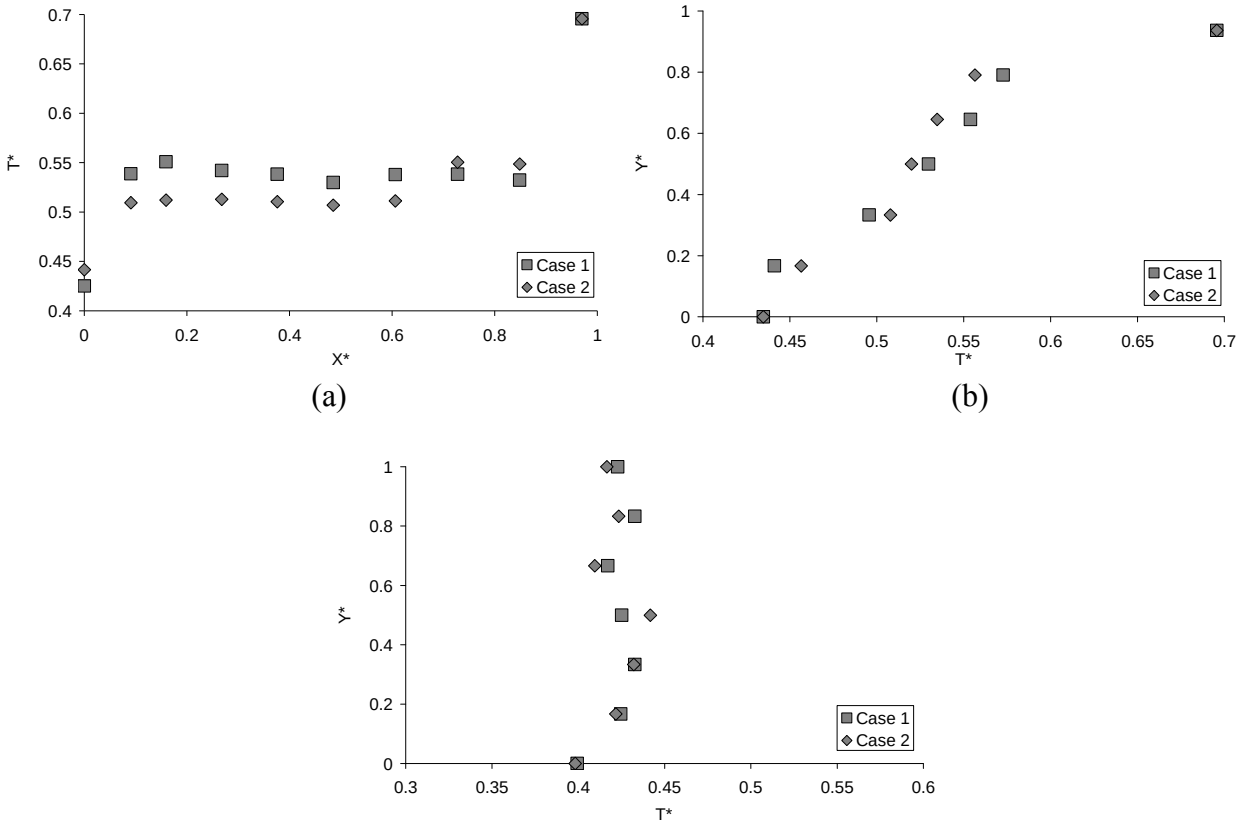

Figure 2 Partitioning effects upon the enclosure temperature distributions: (a) profile along horizontal centreline, (b) profile taken along vertical centreline, (c) profile taken along vertical centreline

Very little difference is seen in the rear wall temperatures of the enclosure after the introduction of the partition. T* along the wall height remains within the range of 0.42 – 0.44, highlighting the thermal isolation of the rear wall within the enclosure. A slight reduction in T* is seen in the region between Y* = 0.5 – 0.8 due an anticlockwise recirculation present in the upper left corner of the enclosure in both cases, enhancing mixing in this region and reducing T*. This recirculation is present even with the marked differences noted in the cylinder plume orientation for Case 1 & Case 2. In Case 1, the plume is deflected towards the centre of the enclosure, at an angle of approximately 75° to the horizontal. In Case 2, the plume is found to attach to the rear wall of the enclosure, but only for a maximum distance of 40mm. It then detaches and dissipates into the centre of the enclosure, minimising its influence on the rear wall temperatures. This is the opposite effect to that seen in Part 1 [14] where the plume orientation can have a large influence on the magnitude of rear wall temperatures, depending on ventilation configuration.

Cylinder positioning

Previous investigations into an unventilated leading edge [15] have shown the influence of cylinder position on the velocity and thermal distributions within the enclosure. In order to determine if cylinder positioning plays an important role in a ventilated and partitioned enclosure, a number of cylinder positions are investigated in Cases 2-4.

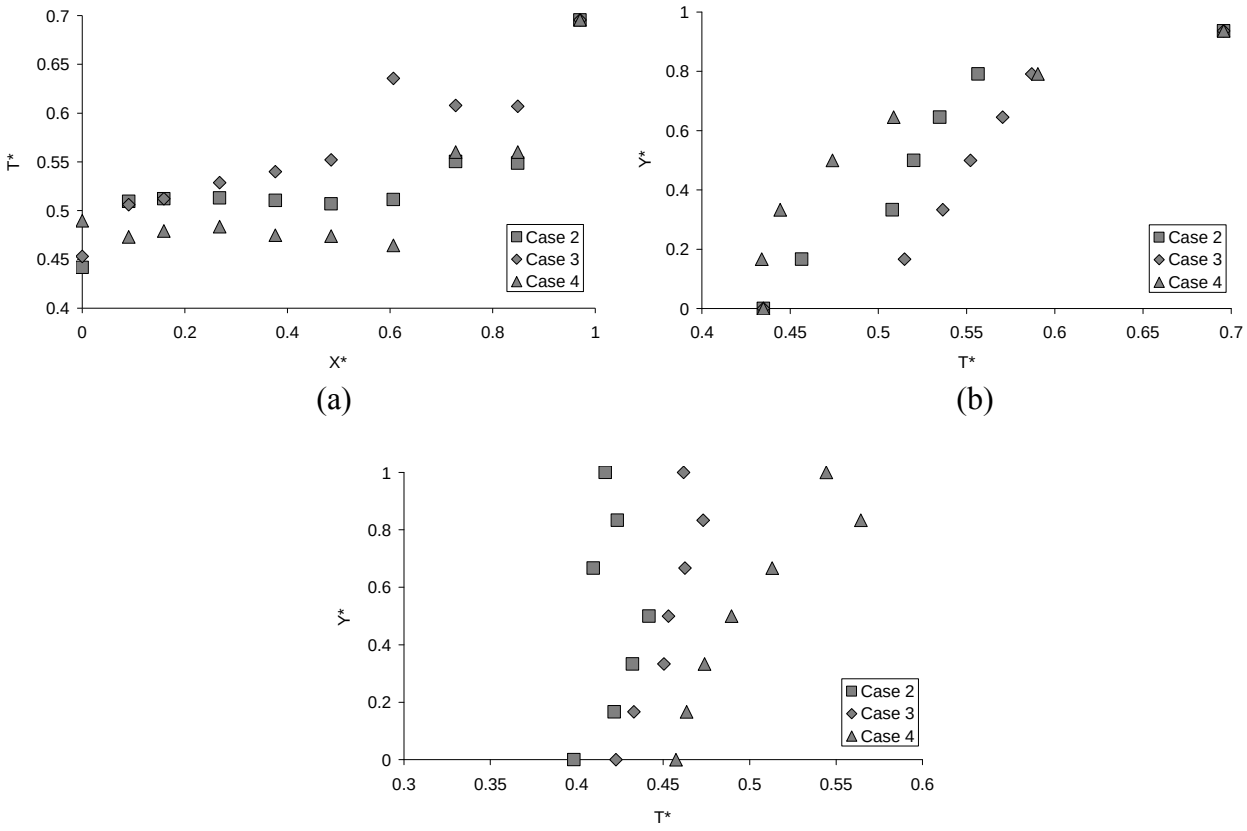

Figure 3 The effect of cylinder placement on the thermal distributions within the partitioned enclosure: (a) profile along horizontal centreline, (b) profile taken along vertical centreline, (c) profile taken along vertical centreline

Figure 3 (a) – (c) presents the enclosure temperature distributions for the various cylinder positions. Along the horizontal centreline, the lowest enclosure temperatures are found for the cylinder located in the upper left corner of the enclosure in Case 4. This is due to the confinement of the high temperature plume flow to the upper region of the enclosure, with minimal mixing below the cylinder and strong thermal stratification present in the rear partitioned space. A similar result was found for the

unventilated enclosure [15]. T* increases from 0.46 in the rear section to 0.55 beyond the partition, indication that the higher temperature plume flow travels along the upper surface of the enclosure before entering the front partitioned space. This is beneficial as it means the bulk of the high temperature fluid within the enclosure will enter the front section of the enclosure, when it can then be removed at the forward vent. This is also seen in Case 2 and Case 3, with a smaller difference recorded between front and rear temperatures in these cases compared to Case 4. Case 2 shows a constant T* of 0.51 along the centreline, increasing to 0.54 beyond the partition. Case 3 exhibits an increasing T* in the rear of the enclosure from 0.49 to 0.55, with a maximum of 0.65 due to the presence of the cylinder plume at this measurement location. A decrease in T* to 0.61 occurs in the front partitioned case.

Along the vertical centreline, three distinct temperature profiles are evident along the enclosure height for the varying cylinder positions. Case 2 consists of three separate fluid regions; adjacent to the lower surface, the core region of the enclosure and the upper surface as outlined in the previous section. Case 3 shows a region of increasing T* from 0.51 to 0.57 between $0.18<Y^*<0.8$, with large gradients present along the upper and lower enclosure surfaces, suggesting high heat transfer in these regions. Case 4 shows an increasing temperature gradient along the vertical height, due to the dominance of the cylinder plume in the upper region of the enclosure leading to the large increases in T* in Figure 3 (b).

The enclosure rear wall temperatures presented in Figure 3 (c) also show three different profiles present depending on cylinder positioning. Case 2 has two separate regions, an increasing temperature in the lower half of the enclosure $Y^* < 0.5$ with a reduction in T* seen above this region. This is attributed to the presence of the heated cylinder increasing the temperatures locally in the lower region, with an anticlockwise recirculation in the upper left corner of the enclosure. This recirculation zone enhances mixing and helps reduce T* in this region. With the cylinder positioned away from the rear wall in Case 3, a much shallower thermal gradient is present along the rear wall. T* increases slightly from 0.43 to 0.45 along the wall height. Case 4 shows a constantly increasing gradient along the rear wall surface reaching a maximum of 0.56 at $Y^* = 0.8$ due to the presence of the heated cylinder in the upper left corner of the enclosure. This then reduces to 0.54 at the uppermost point of the rear wall.

Comparing the effects of different ventilation configurations in Part 1 [14] to those seen in Cases 2 – 4 shows the large influence that cylinder positioning has on the resultant interior fluid and enclosure surface temperatures. In the different ventilation scenarios, the temperature profiles remained similar for all configurations, with only a change in magnitude noted between the different cases. Such a trend was not evident in the cylinder placement investigation, with the location of the cylinder having a marked effect on the final temperature distribution. This demonstrates that the natural convective regime within the leading edge enclosure is much more sensitive to partitioning and cylinder location than to the ventilation configuration alone and that these two geometrical effects are important parameter to be understood when dealing with natural convection ventilation in such an enclosure.

Enclosure flow comparisons

The cylinder plume velocity profiles recorded using PIV for Case 1 – 4 are presented in Figure 4. There is little difference between the plume magnitudes for Case 1 – 3, with a maximum of 0.2 m/s seen in Case 2 with Case 1 & 3 at 0.17 m/s. Different plume orientations however are noted, with Case 1 & 3 deflect slightly towards the centre of the enclosure. Case 2 veers towards the rear wall of the enclosure, where it will attach at approximately two-thirds of the enclosure height and Case 4 impinges on the upper enclosure surface. Due to the confinement effect of the upper enclosure surface on the plume, Case 4 exhibits a significantly lower velocity magnitude of 0.07 m/s, and is symmetrical about the cylinder centreline.

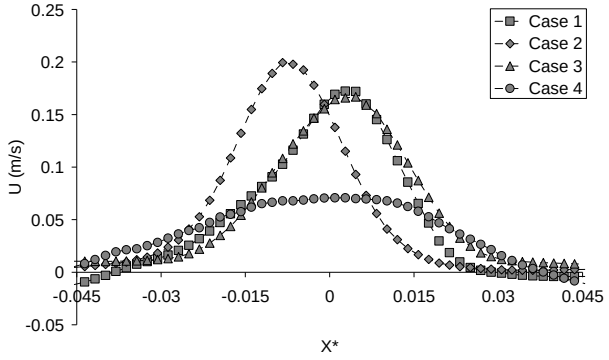

Figure 4 Horizontal cylinder plume velocity profiles, Case 1 – 4. Case 1 & 2 taken at location (i) in Figure 1, Case 3 taken at (ii), Case 4 taken at (iii)

The velocity profiles shown in Figure 5 are recorded above the partition and highlights shows the influence of cylinder positioning on the flow entering the front section of the leading edge. Depending on cylinder position there can be two opposing flows travelling in this region as in Case 2 and Case 4 or a single flow direction as in Case 3. This has a large impact of the overall mass flow entering the front section of the enclosure, which is then removed from the enclosure through the front vent. Case 2 & Case 3 have flow rates of 2.64×10^{-3} kg/s and 4.56×10^{-3} kg/s respectively. Case 4 has a mass flow of 3.59×10^{-4} kg/s entering the front of the enclosure, 92% lower that Case 3.

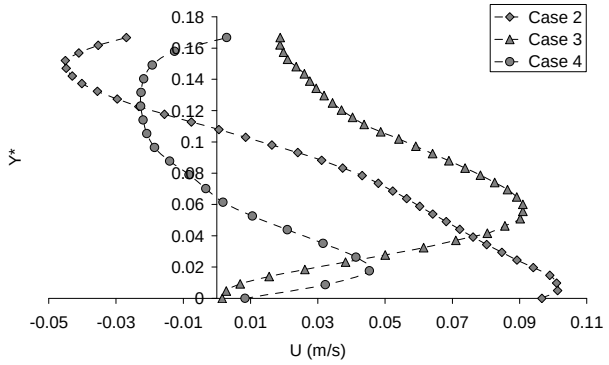

Figure 5 Velocity profile between the top of the partition and the upper enclosure surface taken along position (iv) in Figure 1

The velocity profiles normal to the exit vent boundaries in Figure 6 illustrate the effect partitioning and bleed duct positioning has on the ventilation flow in the enclosure. Partitioning the enclosure severely reduces the velocity and mass flow at the exit vent boundary for Case 2 – 4. A change from a pure displacement ventilation mechanism to a mixing/displacement combination is seen, with some back flow present along the vent boundary. This reaches a maximum of 33% of the vent opening in Case 4, which reduces the enclosure ventilation effectiveness as the overall mass flow out of the exit vent reduces to 8.9×10^{-4} kg/s in Case 4 from 5.59 $\times 10^{-3}$ kg/sin Case 1.

Partitioning the enclosure also severely reduces the amount of air exiting the enclosure compared to the unpartitioned enclosure in Case 1 as shown in Table 2. The introduction of the partition in Case 2 reduces the mass flow at the exit vent by 58% compared to Case 1. Case 2 and Case 3 show similar flow rates across the vent boundaries, even though the amount of air entering the front of the enclosure over the top of the partition is 73% higher in Case 3 A significant amount of recirculation occurs in the front partitioned section for this case, reducing the amount of air exiting the enclosure at the front vent. The temperature of the flow exiting the enclosure in Case 3 is higher compared to Case 2. This is beneficial from a ventilation perspective as the removal of higher temperature fluid at equal or lower magnitudes is seen to be more efficient than lower temperature fluid at higher velocities [16].

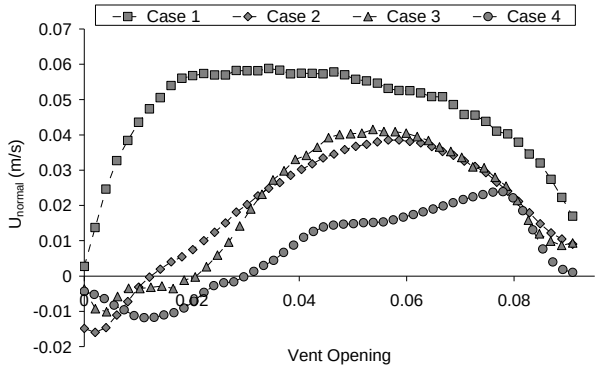

Figure 6 Velocity Profiles normal to the exit vent boundary

Table 2
Mass Flow Rates (kg/m) above the Enclosure Partition and along the Vent Boundary

	Case 1	Case 2	Case 3	Case 4
Top of Partition	-	2.64×10^{-3}	4.56×10^{-3}	3.59×10^{-4}
Exit Vent	5.59×10^{-3}	2.32×10^{-3}	2.26×10^{-3}	8.9×10^{-4}
T* in Front Partitioned Area	-	0.5495	0.6074	0.56

CONCLUSIONS

The introduction of a partition into the leading edge enclosure has a significant effect on the natural convection regime present. It forms a direct block in the ventilation path between the front and rear vent openings. This produces two distinct regions in the enclosure, the rear partitioned space, where the cylinder plume dominates and the front partitioned space, where the high temperature fluid is removed. Due to the partition gap located near the upper enclosure surface, only the higher temperature fluid from the rear partitioned space can travel towards the front exit vent. As a result the front partitioned space is at a noticeably higher temperature than the rear of the enclosure in Case 2.

In the partitioned enclosure, the dominance of the cylinder plume means that its flow path must be understood and optomised in order to ensure adequate ventilation. When the plume is orientated such that it travels towards the outlet vent of the enclosure as in Case 2 & 3, most of the high temperature fluid can be removed from the enclosure. When it does not travel directly towards the exit vent as in Case 4, the plume flow is recirculated within the enclosure, increasing the local wall and air temperaures. Its effect must be fully understood when considering the design of a leading edge enclosure.

Partitioning severely reduces the velocity magnitude across the exit vent boundary and can introduce a region of backflow into the enclosure, which moves away from a pure displacement ventilation regime and reduces the ventilation efficiency.

Cylinder positioning is found to have a larger influence upon the temperature profiles within the leading edge compared to ventilation configuration. The different ventilation orientations analysed in Part 1 [14] produced similar profiles with varying magnitudes, whereas the different cylinder positions investigated here produced distinct profiles for each of the three cases investigated. This suggests that the convective regime within the leading edge is more sensitive to cylinder placement than ventilation configuration, and cylinder placement effects need to be understood.

THE EFFECT OF VELOCITY RATIO ON THE THERMAL-HYDRAULIC PERFORMANCE OF RECIPROCATING SCRAPED SURFACE HEAT EXCHANGERS AT LOW REYNOLDS NUMBER

J. P. Solano[1,*], A. García[1], P.G. Vicente[2], A. Viedma[1]

ABSTRACT. The thermal-hydraulic performance of a reciprocating scraper inserted in a round tube at low Reynolds number is studied. Pressure drop and heat transfer characteristics have been experimentally determined in static conditions in laminar regime (Re_h=30), and results are contrasted with dynamic performance at several velocity ratios (ω=0.1 - 1). Maximum increases of Fanning friction factor of the order of 1.2 have been found, together with increases in Nusselt number of the order of 2, using propylene-glycol as working fluid.

Keywords: *heat transfer enhancement, pressure drop, SSHE, fouling*

INTRODUCTION

Heat transfer processes in the food and chemical industries frequently deal with highly viscous liquids. The performance of heat exchangers working under these conditions is usually low, as a result of the characteristics of the encountered laminar regime [1]. Moreover, the heat transfer surfaces may become coated with a deposit of solid material after a period of operation. This phenomenon, known as fouling, causes a reduced overall heat transfer coefficient [2]. Heat exchangers are generally over-designed to compensate for the anticipated fouling [1]. Moreover, cleaning operations decrease equipment availability, which causes as well a considerable economic impact.

Among the several technical solutions for fouling cleaning and prevention [3], mechanically assisted heat exchangers, where a heat transfer surface is periodically scraped by a moving element, constitute a suitable solution for applications with severe tendency to fouling and low heat transfer rates. Dynamic heat exchangers with rotating scraping blades are found in commercial practice (SSHE): they prevent fouling and promote mixing and heat transfer. Many investigations have focused on these anti-fouling devices, studying flow pattern characteristics [4], their thermo-hydraulic performance [5] or scraping efficiency [6].

This work presents the study of a dynamic insert device moved alternatively along the axial direction by a hydraulic cylinder. The active insert device is made up of several semi-circular elements, which are mounted on a shaft with a pitch of 5D (Fig. 1). When inserted inside the tube,

E-mail address: juanp.solano@upct.es

the device produces a double effect: the induced flow generates macroscopic displacements from the boundary layer region to the axis of the tube, increasing heat transfer, and the elements with reciprocating movement scrape the inner tube-wall, avoiding fouling. The industrial version of this device is manufactured and market by the Spanish company HRS-Spiratube.

There is empirical evidence of the heat transfer enhancement and fouling prevention of this kind of active devices. However, the authors have not found in the open literature previous works related to this type of mechanically-assisted heat exchangers.

This work presents an experimental study on the pressure drop and heat transfer characteristics of the active insert device depicted in Fig. 1. Experimental results of Fanning friction factor *f* and Nusselt number *Nu* as functions of scraping frequency are provided for Re_{Dh}=30 (laminar flow).

EXPERIMENTAL SET-UP

A schematic diagram of the experimental setup is shown in Fig. 2. It consists of two independent circuits: the main circuit, where the dynamic insert device was installed, and the secondary circuit which was used for regulating the tank temperature to a desirable value. The reciprocating movement of the inserted scraper is achieved by means of a hydraulic unit. This unit moves a double-effect cylinder over which the shaft of the insert device is mounted. Mechanical arrangement of the end-stroke connections provides the system with a movement amplitude of 10D (180 mm). All the instrumentation was connected to a HP 34970A Data Acquisition Unit.

Pressure drop tests were carried out in the hydro-dynamically developed region under isothermal conditions. The hydraulic diameter $D_h = D - d$ was used as the reference diameter to calculate all friction factors. It takes account of the presence of the shaft inside the tube, but does not consider the effect of the plugs mounted on it. Fanning coefficients f_{Dh} were determined from fluid mass flow rate and mean pressure drop measurements by means of

$$f_{Dh} = \frac{D_h}{L_p} \frac{\overline{\Delta P}}{2 \rho \, \overline{u}_f^{\,2}} \tag{1}$$

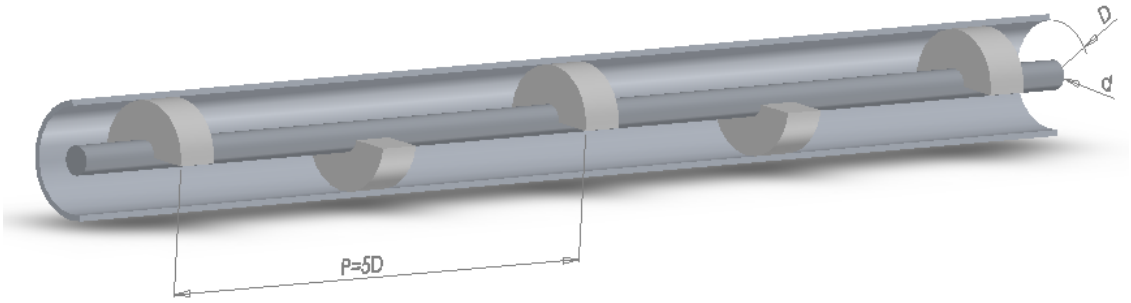

Figure 1. Sketch of the active device

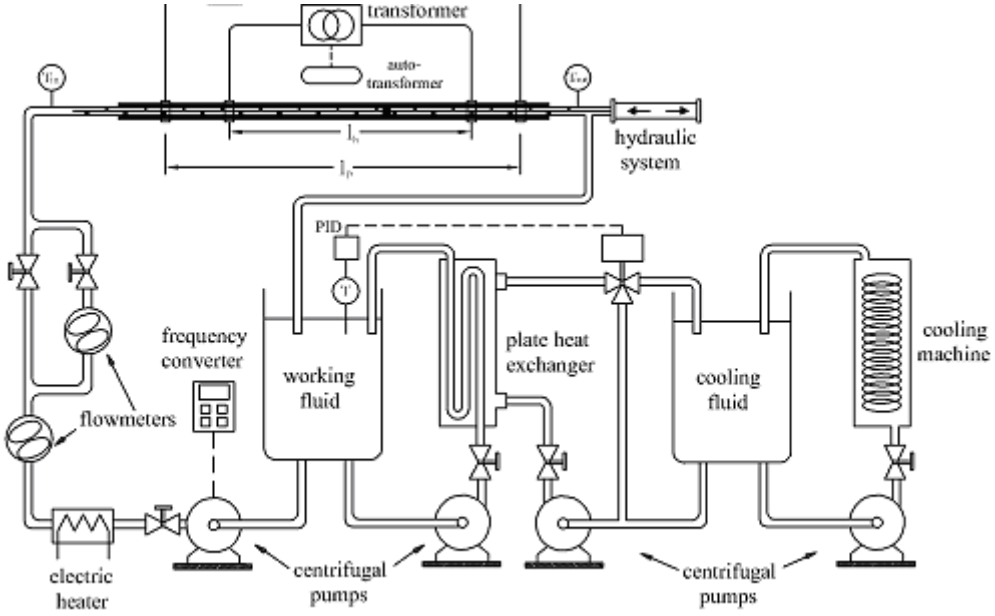

Figure 2. Experimental setup

Time-dependent pressure during the scraping process was measured in two sections of the tube separated by a distance L_p=1.8 m. Two piezorresistive pressure sensors (Kistler K-Line) were connected to each tube section with four pressure taps separated by 90º. Mean pressure drop in the tube over the scraping cycle, $\overline{\Delta P}$, was computed by integration of the instantaneous signal over 50 cycles.

Heat transfer experiments were carried out under uniform heat flux conditions, where energy was added to the working fluid by Joule effect heating. A 6 kVA transformer was connected to the smooth tube by copper electrodes and power supply was regulated by means of an auto-transformer. The length between electrodes defined the heat transfer test section (L_h = 1 m). To reduce heat losses, this section was coated with a thermal insulation of 20 mm thickness and thermal conductivity 0.04 W/mK. The overall electrical power added to the heating section, Q, was calculated by measuring the voltage between electrodes (0-15 V) and the electrical current (0-600A).

Fluid inlet and outlet temperatures, T_{in} and T_{out} were measured by submerged type resistance temperature detectors (RTDs). Since heat was added uniformly along the tube length, the bulk temperature of the fluid at the measuring section, $T_b(x_p)$, was calculated by considering a linear variation with the axial direction. Average outside surface temperature of the wall $\overline{T}_{wo}$ was measured at six different axial positions along a scraper pitch, located at 30 diameters from the upstream electrode, that ensure fully developed flow. The value of $\overline{T}_{wo}$ at each axial position was calculated by averaging the temperatures measured with eight surface type RTDs peripherally spaced by every 45º at each axial position.

The RTD naked sensors were wrapped with ultra-thin plastic films, which assured electrical isolation. The low thickness of the film makes its thermal resistance negligible. A highly thermal-

conductive paste was spread between the tube wall and the wrapped RTD sensor. Each temperature value used for data reduction was averaged over 30 data sampled every 9 seconds.

Two calibration tests with no electrical heating were done: the first test was performed to determine heat losses in the test section Q_1 by measuring $(T_{in} - T_{out})$ at low flow rates, and the second test at high flow rates to calculate the lay-out resistances of the surface type RTDs $(T_{in} \approx T_{out} \approx \overline{T}_{wo})$.

Heat flux added to the test fluid q'' is calculated by subtracting heat losses to the overall electrical power added in the test section. The power factor was 1.0, as the copper electrodes were directly connected to the metallic tube, which is a pure resistive load. The inner wall temperature $\overline{T}_{wi}$ for each experimental point, was determined by using a numerical model that solves the steady-state, one dimensional, radial, heat conduction equation in the tube wall and insulation from the following input data: $\overline{T}_{wo}$, Q, Q_1 and $T_b(x_p)$. The local Nusselt number was calculated by means of

$$Nu_x = \frac{D_h}{k} \frac{q''}{\overline{T}_{wi} - T_b(x_p)} \tag{2}$$

Visualization experiments [7] allow to state that the flow is fully developed at few pitches (2-3 p). Thus, local Nusselt number computed with Equation (2) is a periodic value. Nusselt number results at the six axial positions were corrected by the factor $(\mu_w / \mu_b)^{0.14}$ to obtain correlations free of variable properties effects [8]. Pitch-averaged Nusselt number was obtained by averaging the six local values computed with the presented methodology.

The experimental uncertainty was calculated by following the "*Guide to the expression of uncertainty in measurement*", published by ISO [9]. Details of the uncertainty assignation to the experimental data are given by the authors in [10]. Uncertainty calculations based on a 95% confidence level showed maximum values of 4% for Reynolds number, 3.5% for Prandtl number, 6% for Nusselt number and 8% for friction factor.

RESULTS

An experimental research was carried out to assess the effect of the scraping frequency on the thermal-hydraulic behaviour of the dynamic insert device sketched in Fig. 1. Experiments were carried out employing propylene-glycol at 15ºC, with a flow rate of 150 l/h, yielding to Reynolds number Re_{Dh}=30. The scraping frequencies ranged from 0.1 to 1 Hz. The velocity ratio ω, defined as $\omega = u_{scraping}/u_{fluid,}$ was found to be an excellent non-dimensional parameter to evaluate dynamic effects. The range of velocity ratios tested was ω=[0.1 0.3 0.5 0.75 1].

Pressure drop results

Pressure drop tests were carried out under isothermal conditions, covering the wide range of velocity ratios presented above, for constant Reynolds number Re_{Dh}=30. A test in static conditions (ω=0) was also performed. Time-averaged pressure drop results were employed for computing the mean Fanning friction factor as a function of ω.

Unsteady pressure signal. Figure 3 (left) shows a detail of the pressure signals over two scraping cycles, for working conditions Re_{Dh}=30 and ω=0.3. The scraper movement in the opposite direction of the flow is called "counter-current", and the scraper movement in the same direction of the flow

is called "co-current". The signals $p_1(t)$ and $p_2(t)$ can be substracted to obtain the unsteady pressure drop in the tube section (see Figure 4, right). Resulting mean pressure drop is also depicted in this graph.

The low, constant scraping velocity generates quasi-steady flow conditions in each semi-cycle, which can allow to assess the separate performance of the dynamic device in counter-current and co-current movement.

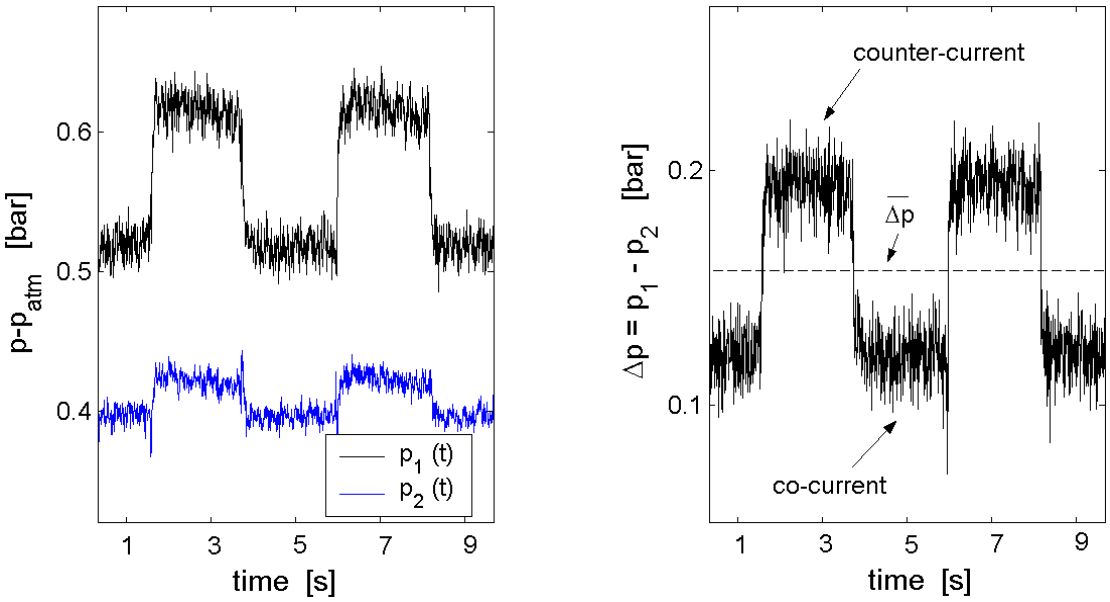

Figure 3. Unsteady pressure signal in the tube section, Re_h=30, ω=0.3

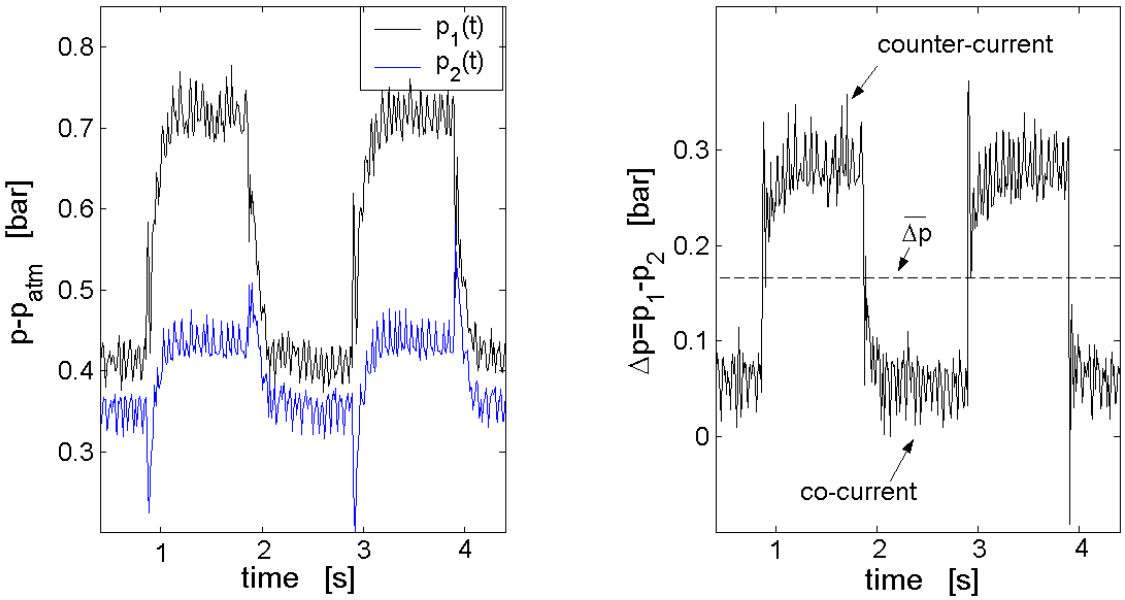

Figure 4. Unsteady pressure signal in the tube section, Re_h=30, ω=1

Counter-current performance yields to high pressure drops in the tube, as expected from the blockage effect generated by the scraper during its movement against the flow [7]. However, when the device

moves co-current, pressure drop decreases dramatically. This result reveals the lower blockage of the scraper when it moves within the flow direction.

Figure 4 shows the unsteady pressure evolution measured for the working condition Re_{Dh}=30 and ω=1. In this situation, the scraper velocity is 3.3 times higher than the velocity with ω=0.3, whereas flow rate in the tube is kept constant. Pressure drop across the tube shows transient evolutions at the commencement of each semi-cycle, as a result of the higher velocity of the scraper and the sudden movement reversal imposed by the hydraulic unit.

Pressure drop in the counter-current semi-cycle is 50% higher than for ω=0.3. Thus, scraper velocity can be stated as a remarkable factor in the increase of the blockage effect in counter-current performance. Conversely, pressure drop in the co-current semi-cycle is much lower than the equivalent result for ω=0.3. The velocity of the device in the flow direction generates a low pressure field downwards, yielding to lower pressure drops. Mean pressure drop for velocity ratio ω=1 is still higher than the corresponding value found for ω=0.3. Considering than, for higher scraping frequencies, counter-current pressure drop increases while co-current pressure drop decreases, the major influence of the counter-current characteristics in the global performance of the dynamic device can be assessed.

Fanning friction factor. The value of $\overline{\Delta P}$ for each velocity ratio can be employed to compute the mean Fanning friction factor, as explained in Equation 1. Experimental results for the range of interest are presented in Figure 5. Fanning friction factor results can be employed to estimate the pressure drop augmentation due to the insertion of the scraping device in a smooth tube with similar mass flow rate. This augmentation can be computed in laminar regime as follows:

$$\frac{\Delta P_{scraping}}{\Delta P_{smooth}} = f_{Dh} \times \frac{\mathrm{Re}_{Dh}}{16} \times \frac{D^4}{D_h{}^3 (D+d)} \tag{3}$$

According to this expression, pressure drop increases of 5.7 have been found in static conditions, referred to the smooth tube $(\Delta P_{\omega=0}/\Delta P_{smooth})$. In dynamic conditions, mean Fanning friction factor increases for higher velocity ratios. Pressure drop augmentation in the inserted tube due to the movement of the scraper with ω=0.1 is $\Delta P_{\omega=0.1}/\Delta P_{\omega=0}$ =1.06, while the increase due to the movement of the scraper at a velocity ten times higher (ω=1) is $\Delta P_{\omega=1}/\Delta P_{\omega=0}$ =1.21.

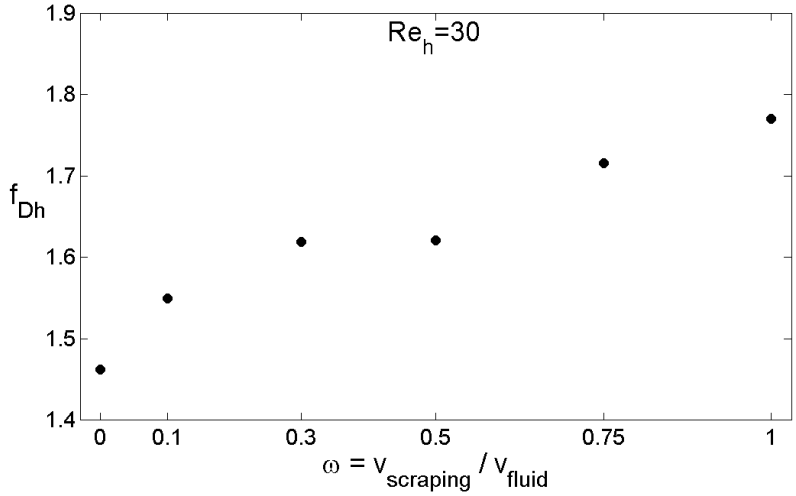

Figure 5. Mean Fanning friction factor as a function of velocity ratio (Re_{Dh}=30)

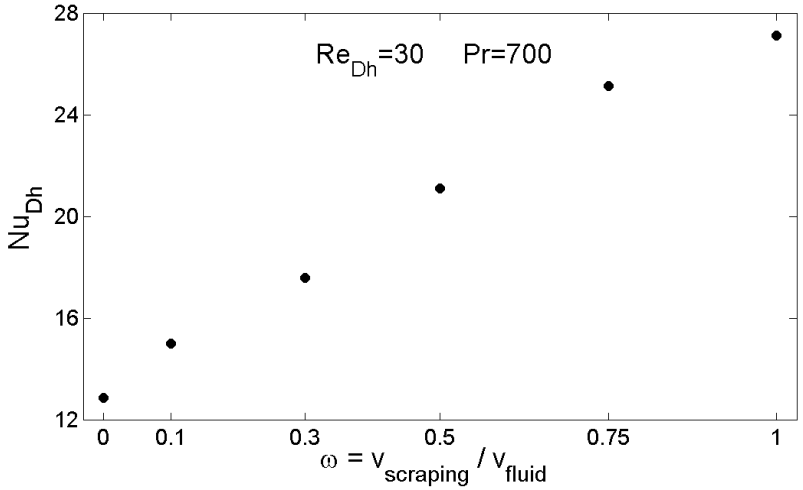

Figure 6. Mean Nusselt number as a function of velocity ratio (Re_{Dh}=30)

Heat transfer results

Heat transfer tests were performed under uniform heat flux conditions, for Re_{Dh}=30 and similar velocity ratios than in the previous section. Prandtl number was Pr=700, using propylene-glycol as working fluid at T=15ºC.

The insertion of the scraper in a smooth tube, working in static conditions, yields to heat transfer augmentations of 4.1 (referred to the asymptotic solution $Nu_{D,\infty}$=4.36). The mixing promoted by the insert device plays an essential role in this result. The effect of scraping movement increases heat transfer characteristics. For velocity ratio ω=0.1, heat transfer augments 1.35 times with respect to the static conditions. The continuous removal of the boundary layer, and the enhanced radial mixing between peripheral and core flows justify this result [11]. If scraping velocity increases ten times (ω=1), heat transfer augments only $Nu_{\omega=1}/Nu_{\omega=0.1}=1.55$. It reveals the fact that oscillatory flow mixing presents a saturation behaviour, owing to two opposite phenomena: during the counter-current semi-cycle, the flow structures that appear in the tube may promote intensive heat and mass transfer, and this effect should be as much important as the higher is the scraping velocity. However, during the co-current semi-cycle, the flow configuration may present low levels of enhanced heat transfer, according to the pressure drop signal (Figure 4) and the heat and momentum analogy [12]: the scraper movement in the flow direction generates low shear stress rates in the tube wall.

CONCLUSIONS

1. A comprehensive experimental research has been carried out to obtain the influence of scraping velocity on the thermal-hydraulic behaviour of a dynamic insert device, for low Reynolds number. The velocity ratio, ranging from 0.1 to 1, was found to be an excellent parameter to evaluate dynamic effects

2. The unsteady pressure evolution in the tube during the scraping cycle was assessed. Pressure drop in counter-current semi-cycle increases with scraping velocity, while it decreases during the co-current semi-cycle for higher scraping velocities.

3. Augmentations of pressure drop of 5.7 times were found for the device in static conditions, referred to a smooth tube with similar mass flow rate. Maximum increases of pressure drop of 1.2 times were found for ω=1, with respect to the static performance (ω=0).

4. Heat transfer increases of 4.1 times with respect to the smooth tube were found for the static device. The movement of the device promotes intensive heat and mass transfer, with augmentations of the order of 2 for ω=1, with respect to the static performance (ω=0).

I-16145 Genova, Italy

ABSTRACT. An experimental investigation of heat transfer in a rectangular channel with angled rib turbulators, inclined at 45 deg, is presented. The angled ribs were deployed with parallel orientations on one wall of the channel. The aim of the work was to study the effect of the rib spacing on the thermal performance of the ribbed channel. Experiments were based on the use of heating foils and the steady-state, liquid crystal thermography. From the processing of liquid crystal images, the maps of local heat transfer coefficient (and local Nusselt number) have been reconstructed. The thermal performance of each ribbed channel is identified by the average Nusselt number and by the friction factor obtained from the measured pressure drop across the ribbed test section. The optimal rib pitch-to-height ratio giving the best heat transfer performance was identified, for the explored range of Reynolds number, under the constraints of constant mass flow rate or pumping power.

Keywords: *heat transfer, forced convection, rectangular channel, angled ribs*

INTRODUCTION

Modern high-performance gas turbine engines operate at high entry gas temperature, well above the allowable metal temperature. Therefore, highly efficient cooling technologies (film cooling, impingement cooling, internal cooling) are required for vanes and blades of advanced gas turbines [1]. Internal cooling is achieved by passing the coolant through passages inside the blades. The specific technology has developed from simple smooth cooling passages to very complex geometries, involving a great number of different circuit designs and flow path surfaces. Rib turbulators, periodically deployed along the main direction of flow, were one of the first improvements of blade internal cooling.

The inclination of ribs can lead to superior heat transfer performance because of the secondary flow induced by the rib angle. This secondary flow has the form of two counter-rotating vortices, aligned with the inclined ribs, which carry cold fluid from the central core region towards the ribbed walls. These cells, interacting with the main flow, affect the flow reattachment and recirculation between ribs, and interrupt boundary layer growth downstream of the reattachment regions.

Since the 45 deg orientation of rib turbulators (relative to the main flow direction) appears to be the most common in practice today, the majority of recent research papers are focused (mainly or only) on this geometry. Despite the large mass of studies dealing with channels with 45 deg angled ribs, some issues still remain unresolved. For instance, whereas the ideal rib pitch-to-height ratio *p/e* for channels with transverse ribs is approximately equal to 10, irrespective of the value of the channel aspect ratio AR [2-4], angling the ribs (by 45 deg) gives the best thermal performance again at

E-mail address: giovanni.tanda@unige.it

p/e=10 for AR=1 ([5], only heat transfer from ribs considered, ribs in a staggered arrangement). As AR is reduced, the ideal *p/e* is still equal to 10 if the performance comparison with the smooth channel is based on the total heat transfer area; conversely, the optimum *p/e* is lowered to 3 and 2.5 (for AR = 0.5 and 0.25, respectively) when the comparison is based on the projected area ([6-7], heat transfer from ribs and inter-rib regions, ribs arranged in-line). These studies also indicated that the optimum rib spacing is very sensitive to other parameters, such as the rib height-to-hydraulic diameter ratio *e*/*D*, and the thermal conductivity of ribs (i.e., if the ribs exchange heat with convective fluid or not). Seemingly, no systematic studies on the effect of the rib spacing on heat transfer for AR values larger than one are available in the literature. A further, less investigated, aspect concerns the effect of the number of ribbed walls on heat transfer and friction characteristics in a channel. Most literature papers consider square or rectangular channels with ribs on two opposite walls, the other walls remaining smooth. In refs. [8-9] both the heat transfer coefficient and the friction factor were found to increase with an increasing number of ribbed walls, but the relative increase in heat transfer is lower that the relative increase in friction factor. This result seems to suggest that the heat transfer performance of one-ribbed wall channels (per unit pumping power) could be potentially similar or superior to the two-ribbed wall channels (with less manufacturing efforts).

In this paper, local and average heat transfer coefficients in a rib-roughened rectangular channel (aspect ratio AR=5, hydraulic diameter *D*=0.033 m) are presented. Configurations include sequences of continuous, 45 deg angled ribs, having square cross-sections (rib height *e* = 3 mm, *e/D* = 0.09). Ribs were regularly spaced over one side of the channel (the wider one), heated at uniform heat flux (the other sides remaining smooth and unheated). Four values of the rib pitch *p* were considered (*p*= 20,30,40, and 60 mm), so as to yield four values of the rib pitch-to-height (*p/e*= 6.66, 10, 13.33 and 20), the Reynolds number Re ranging from 9000 to 35500. Ribs, made of balsa wood, were considered to be nearly adiabatic for the thermal boundary condition; therefore attention was focused on local and average heat transfer coefficients on the inter-rib regions of the heated plate. The study was performed by using the steady-state liquid crystal technique.

EXPERIMENTAL APPARATUS AND PROCEDURE

Experimental setup

The description of the experimental apparatus is facilitated by reference to Figure 1. The main components are the wind tunnel, the test section, the heating arrangement, and the instrumentation.

An open-circuit suction-type wind tunnel was used for this study. Air, drawn at room temperature, passed through a filter and entered a rectangular channel (width *W*=0.1 m, height *H*=0.02 m, aspect ratio AR=5, hydraulic diameter *D*= 0.033 m) in which the test section was fitted.

The test section was a rectangular channel, as wide and high as the entry and exit sections and delimited by a thin heated plate (width *W*=0.1 m, length *L*=0.28 m) and lateral and frontal unheated Plexiglas walls. The plate was made of 0.5 mm thick stainless steel to which a plane heater had been attached to provide a controllable uniform heat flux. A thin liquid crystal (LC) sheet was applied on the side opposite to the heater to measure local wall temperature. Pressure taps, connected to a common alcohol manometer, were located at the inlet and outlet of the test section in the streamwise direction. A Venturi flowmeter was used for the measurement of mass flow rate.

Thermosensitive, cholesteric liquid crystals were used to measure temperature distributions on the heated surface. The pre-packaged LC sheet (0.15 mm thick) consisted of a thermochromic liquid crystal layer on a black background applied onto a mylar film and backed with a pressure-sensitive adhesive. The color distribution of the liquid crystals was observed by a CCD videocamera through the Plexiglas wall opposite to the heated surface and stored in a PC via an IEEE 1394 interface. The relationship between the color (hue) and the temperature of the thermosensitive liquid crystals was found by a calibration experiment. The calibration test was carried out by gradually heating a 5mm thick aluminum plate (calibration plate) covered by a LC film identical to that used in the experiments. LCs here employed had a red start temperature of 30°C with a bandwidth of 4°C. The

hue-temperature correlation was found to be fairly linear and repeatable in the range from 31.5 to 32.5 °C (hue in the 70-140 range): this field of hue was therefore selected for the quantitative analysis of each LC image. The corresponding calibration line has an uncertainty band (at the 95% confidence interval) of ±0.2 K.
Additional details of the experimental setup are available in refs. [10,11].

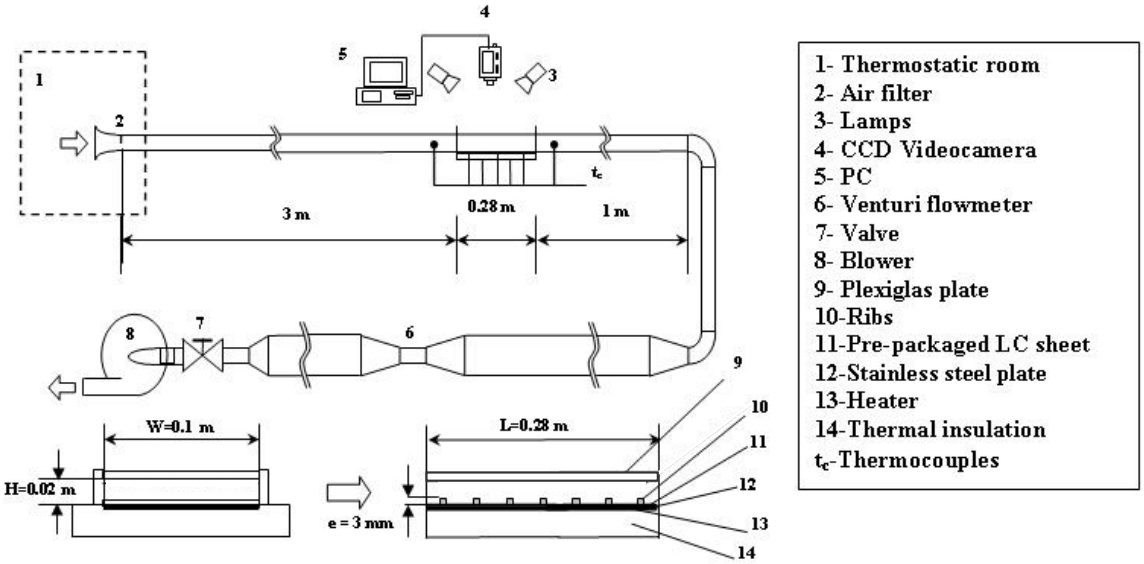

Figure 1. Schematic layout of experimental setup and test section

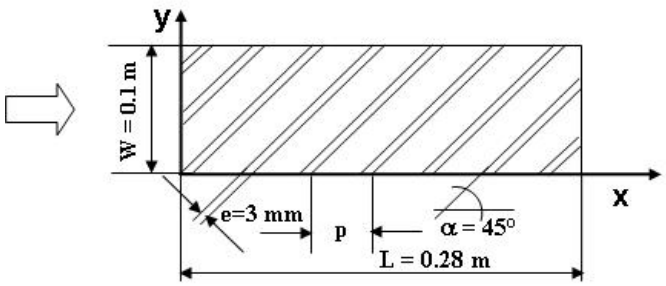

Figure 2. Geometry of the rib-roughened heated surface

Rib configurations
Ribs, made of balsa wood, had a square section (side *e* is equal to 3 mm) and a blockage ratio *e/H* = 0.15 (*e/D* =0.09). Owing to their low thermal conductivity, ribs were considered to be virtually adiabatic and their function was to generate turbulence in the airflow in order to increase the inter-rib heat transfer. They were glued at periodic streamwise stations (longitudinal rib pitch *p* from 20 to 60 mm, giving rib pitch-to-height values *p/e* from 6.66 to 20) as shown in Fig.2.

Operating procedure and data reduction
After the rib array had been set and the airflow had been adjusted to a prescribed velocity, the DC current was supplied to the heater. The surface temperature was maintained within the thermosensitivity region of the liquid crystals by controlling the input power delivered to the heater. Once steady-state conditions were reached, input power, thermocouple readings and the LC images were recorded. The image of the colored pattern of LCs, taken by the CCD were processed by using a custom-made software to convert the hue into the surface temperature in order to extract the local heat transfer coefficient according to the following relationship:

$$h = q_{conv}/(T_{LC}-T_{air,x}) \quad (1)$$

where q_{conv} is the convective heat flux, assumed to be uniformly distributed over the heated plate, T_{LC} is the surface temperature detected by the LCs, and $T_{air,x}$ is the bulk temperature of the air at the x position along the streamwise direction.
The convective heat flux was evaluated as follows:

$$q_{conv} = (Q_{el} - Q_{rad} - Q_{dis} - Q_{ribs})/A \quad (2)$$

where Q_{el} is the measured input power to the heater, Q_{rad} is the calculated radiative heat transfer rate to the surroundings, Q_{dis} is the calculated heat transfer rate dissipated through the insulation on the rear face of the heater, and A is the area of the plate surface exposed to the airflow. The term Q_{ribs} takes into account the heat dissipation from the ribs. Even though the ribs were deemed to be adiabatic owing to their low thermal conductance, the conventional one-dimensional fin model was applied to estimate (by an iterative procedure, assuming the heat transfer coefficient along the rib to be equal to the average heat transfer coefficient over the baseplate) the amount of heat transfer rate delivered to the airflow from their sides.
The bulk temperature of air at the x-position was calculated by the following equation:

$$T_{air,x} = T_{air,0} + (Q_{el} - Q_{dis} - Q_{rad})(x/L)/(m' c_p) \quad (3)$$

where $T_{air,0}$ is the air temperature measured at the entrance of the test section (where the flow is isothermal), c_p is the air specific heat, m' is the mass flow rate and L is the heated surface length.
As previously explained, only points with the hue within the 70-140 range were processed; outside the selected hue interval, no information is gained. Therefore, in those cases, tests were repeated at the same air flow rate and for 7-15 different values of the input power, so as to move the color pattern toward the regions not previously monitored and locally extract the values of the heat transfer coefficient.
Experimental data were recast in dimensionless form, introducing the Nusselt number Nu and the Reynolds number Re as follows:

$$\mathrm{Nu} = h D/k \quad (4)$$

$$\mathrm{Re} = G D/\mu \quad (5)$$

where $G = m'/(W H)$ is the air mass velocity in the channel (air mass flow rate per unit area) and $D = 2 W H/(W+H)$ is the channel hydraulic diameter.
To obtain a dimensionless representation of the pressure drop ΔP due to the ribs, the friction factor f, based on adiabatic conditions (i.e., test without heating), was introduced according to the Fanning definition:

$$f = (\Delta P/L') D \rho/(2 G^2) \quad (6)$$

where L' is the axial distance between the two pressure taps, approximately equal to the test section length L. Thermal conductivity k, dynamic viscosity μ and density ρ of air were evaluated at the film temperature.

RESULTS AND DISCUSSION

Local heat transfer coefficient

The flow pattern generated by the 45 deg angled ribs is typically three-dimensional owing to the interactions of the oblique secondary flows with the main flow over the ribbed wall. This can lead to significant spanwise variations of the local heat transfer coefficient, especially for channels having a low aspect ratio.
A typical liquid crystal image, recorded for the one-ribbed-wall channel, is presented in Fig.3: the main flow is from the left to the right. The color changes in each inter-rib region as one moves along the direction parallel to the ribs reflect the 3-D character of the flow and thermal fields. From

the processing of a set of LC images, the map of the heat transfer coefficient on the heated wall is recovered, as shown in Fig.4 for *p/e* = 13.33 and Re = 29000. Inspection of the figure shows a higher heat transfer performance in the upstream acute angle region, where the secondary flow brings core air to the wall and low heat transfer coefficients in the downstream, opposite, acute angle corner. This behaviour has been typically encountered for each rib configuration and Reynolds number explored.

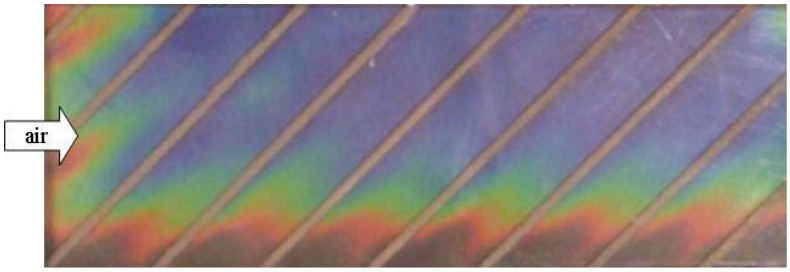

Figure 3. Typical liquid crystal image for the ribbed heated plate

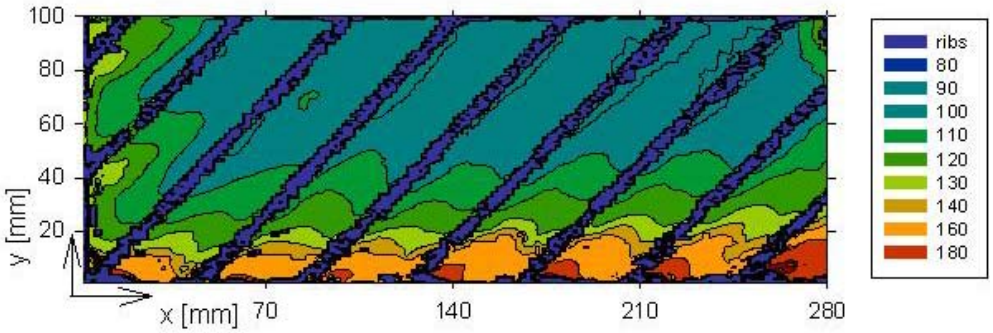

Figure 4. Local heat transfer coefficient *h* [W/m^{2}K] along the ribbed heated surface for *p/e*=13.33, Re=29000

Generally speaking, a development region is observed from the entrance up to about 3-4 diameters in the streamwise direction. Beyond the entrance region, the local, inter-rib h (and Nu) numbers exhibit a nearly periodic distribution whose features are strongly related to the rib pitch-to-height ratio and to the spanwise coordinate.

Local values of the heat transfer coefficient were spatially averaged over each wall region between two consecutive ribs (module) and presented, in dimensionless form, in Figure 5. The distributions of the per-module mean Nu value is reported as a function of the streamwise coordinate, identified by the module number N_x. Owing to the specific features of the rib installations, the geometry repeats itself identically from the 5th to the 13th module for *p/e*=6.66, from the 3rd to the 8th module for *p/e*=10, from the 3rd to the 6th module for *p/e* = 13.33 and from the 2nd to the 4th for *p/e*=20.0. Within these intervals, the per-module mean Nu appears to be only slightly affected by the streamwise coordinate for any experimental condition. The integration of local Nu values over the whole heat transfer area (the area of the heated wall not covered by the ribs) gives the full-surface Nusselt number that allows a direct comparison of heat transfer performance to be performed. To quantify the degree of heat transfer enhancement relative to the smooth channel, the full-surface Nusselt number was normalized by the Nusselt number Nu_0 given by the Dittus-Boelter correlation for fully developed turbulent flow in smooth circular tubes (Eq.7)

$$Nu_0 = 0.023\ Re^{0.8}\ Pr^{0.4} \qquad (7)$$

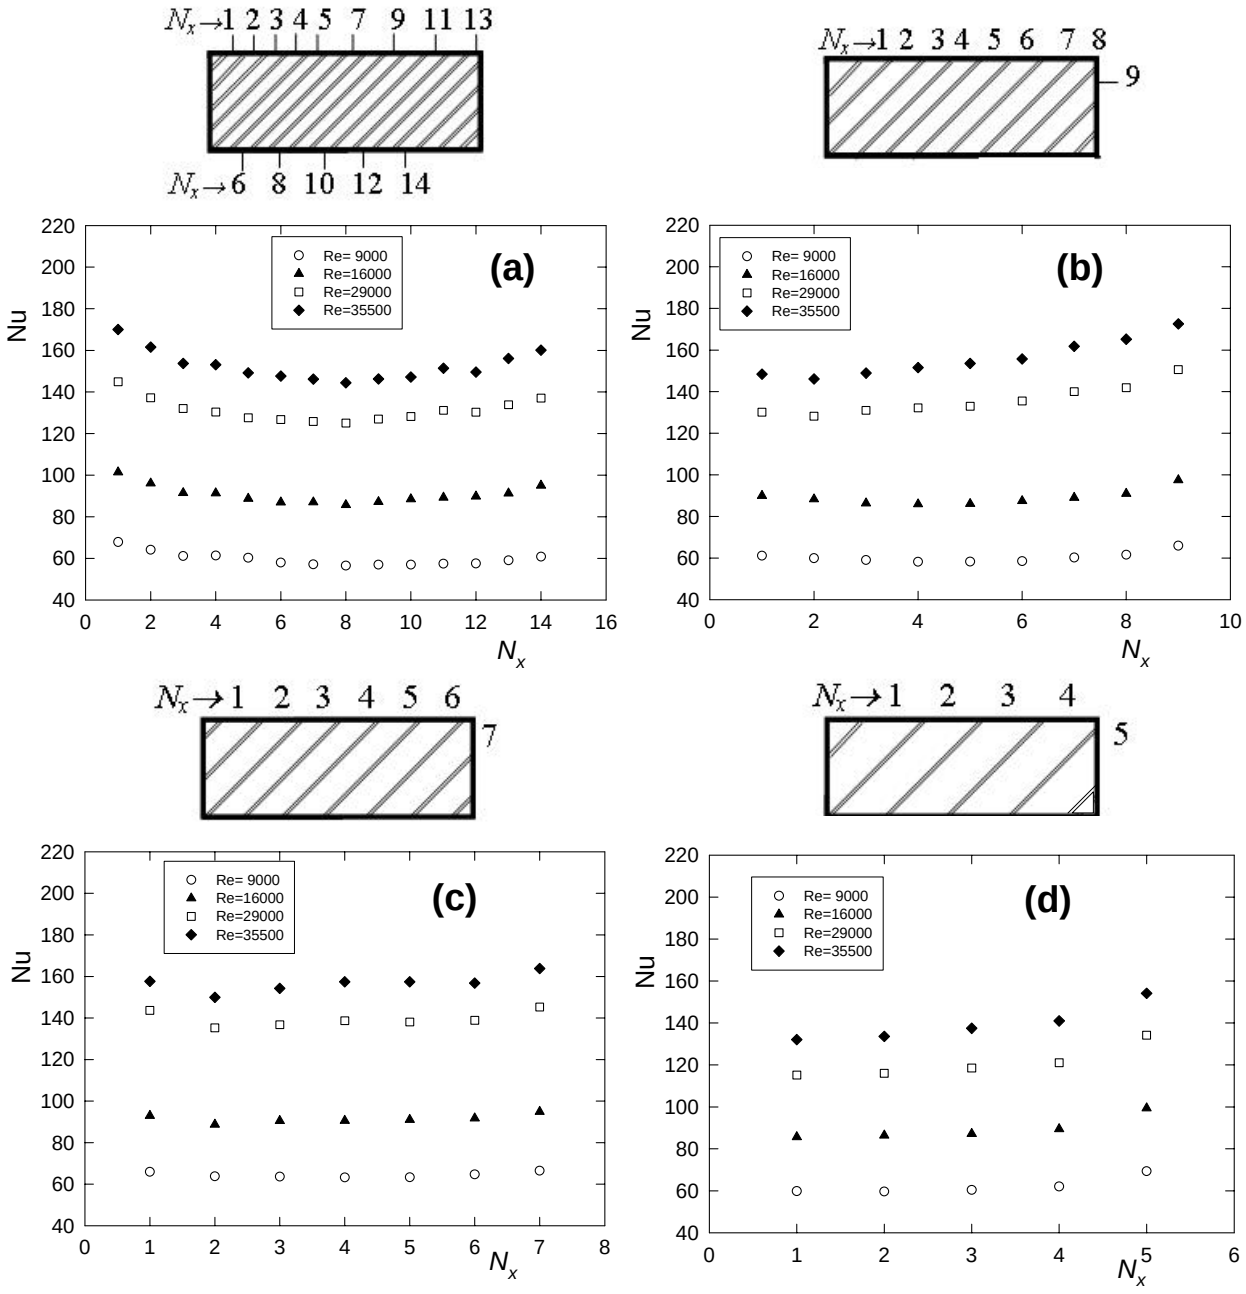

Figure 5. Per-module Nusselt number for *p/e* = 6.66 (a), 10.0 (b), 13.33 (c), 20.0 (d).

Figure 6 shows the normalized Nusselt number versus the Reynolds number, for all the investigated geometries. This figure serves as a comparison of the thermal performance among the different configurations for the constraint of constant mass flow rate. The heat transfer augmentation is in the 1.6-2.4 range and decreases with Re, as typically occurs in rib-roughened channels. It is conjectured that the secondary flow features are affected the rib pitch; in particular, the rib pitch-to-height ratio which accommodates the maximum heat transfer is *p/e*=13.33 at the lowest mass flow rates and *p/e*=10.0-13.33 at the highest mass flow rates. For the optimum value *p/e*=13.33, the ribbed wall with transverse ribs (data from [10]) performs slightly better than that with angled ribs, as found also in [12] for ribbed channels with high aspect ratio. This is ascribed to the fact that, for high channel aspect ratios, the secondary flows induced by angled ribs have a reduced impact on heat transfer levels.

Fanning friction factor of the ribbed channels, calculated according to Eq.(6), was normalized by the friction factor f_0 for fully developed turbulent flow in smooth circular tubes proposed by Blasius:

$$f_0 = 0.046\ \mathrm{Re}^{-0.2} \quad (8)$$

As expected, the normalized friction factor, shown in Fig.7, increases with increasing Reynolds number. Relative to the smooth channel, the degree of enhancement of the friction factor is between 2.6 and 4.3. A criterion to evaluate the performance of the rib-roughened channels is to estimate the quantity Nu/Nu_0 according to the same power required to pump the convective fluid inside the ribbed (enhanced) and the smooth (reference) channels. In order to comply with this constraint, the mass flow rates passing through the enhanced and reference channels cannot be the same; the assumption of constant pumping power leads to

$$f_0\,\mathrm{Re}_0^3 = f\,\mathrm{Re}^3 \quad (9)$$

where Re_0 is the value of the Reynolds number for the reference channel. If Eq.(8) is used to correlate f_0 and Re_0, it follows that:

$$\mathrm{Re}_0 = (21.74\, f\mathrm{Re}^3)^{0.357} \quad (10)$$

with Re_0 representing the value to be used in Eq.(7) to evaluate Nu_0.
The value of Nu/Nu_0 reported in Figure 8 (where the abscissa Re_0 was chosen as a convenient reference for all the ribbed channels) can determine whether or not a given geometry is potentially advantageous under the requirement that the pumping power must be the same. Again, the surface with angled ribs having *p/e*=13.33 performs better than the other surfaces, including that having transverse ribs of same dimensions and pitch (data from [10]).

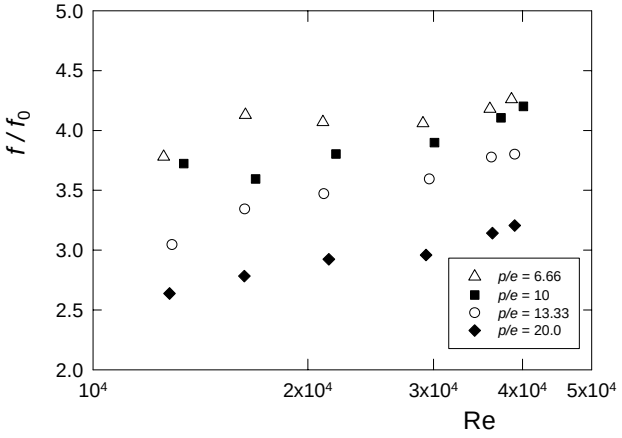

Figure 7. Normalized friction factor f vs. Re

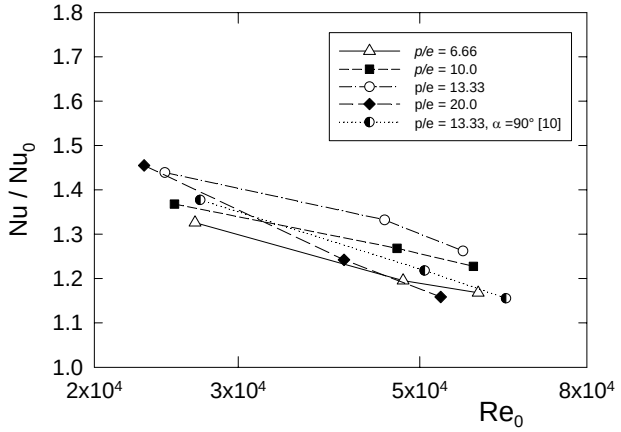

Figure 8. Normalized full-surface Nu vs. the smooth-channel Reynolds number Re_0 for angled (α=45°) and transverse (α=90°,[10]) ribs and the constraint of constant pumping power.

CONCLUSIONS

Heat transfer characteristics of rectangular channels (AR=5) with 45 deg angled, parallel ribs with different values of the rib pitch, have been experimentally investigated by means of the steady-state liquid crystal thermography. The parallel ribs have been installed either onto one wall of the channel. Based on the results, the following conclusions are drawn.

After a relatively short entrance region, local Nusselt number attains a nearly periodic distribution along the streamwise direction, with features markedly affected by the rib pitch and the spanwise coordinate; in particular, spanwise Nusselt number values decrease along the rib direction, from the acute upstream angle to the acute downstream angle.

The per-module mean Nu values appear to be only slightly affected by the streamwise coordinate for any experimental condition.

The full-surface averaged Nu values have been compared to those for a reference condition (a smooth channel with the same hydraulic diameter). Heat transfer augmentations relative to the smooth channel, for the constant mass flow rate criterion, are in the 1.6-2.4 range and decrease with Re, as typically occurs in rib-roughened channels. Heat transfer performance, relative to a smooth channel under the constraint of constant pumping power, is generally better for the higher rib pitch-to-height ratio (p/e=13.33), regardless of the value of the Reynolds number.

THERMAL ANALYSIS OF CAR AIR COOLER UNIT

D. Trzebinski*, I. Szczygiel*
*Institute of Thermal Technology, Gliwice, Poland

ABSTRACT. In the paper thermodynamic analysis of car air cooler is presented. Typical refrigerator cycles are studied. One with uncontrolled orifice and non controlled compressor, second with thermostatic controlled expansion valve and externally controlled compressor. The influence of refrigerant charge and the inlet air temperature on the coefficient of performance, exergy efficiency, heat flux and temperature in evaporator and compressor net power was investigated. The impact of improper refrigerant charge on the performance of A/C systems was also checked. The simplified CFD model of car interior is also provided.

Keywords: *thermal comfort, air conditioning, COP, cooling systems*

THERMAL COMFORT IN CAR CABIN

The problem of proper thermal comfort inside the compartments is seriously treated nowadays. The techniques of achieving quite good effects of thermal comfort are well recognized in the habitats, but in mobile spaces, like cars, trains and buses are still under development. Temperature in an vehicle cabin is closely related with the occurrence of traffic accidents [1]. Zlatoper has created the ranking list of the factors which affect the traffic accidents in United States and placed the temperature on the third position [2]. In hot summer days internal temperature often exceeds +40°C. So it is obvious, that the thermal conditions in the vehicles' cabins directly influences on the driver's and passengers safety.

Both too high and too low ambient temperature influences human physical and mental state. Driver`s efficiency researches indicate that it can be even 35% higher at +20°C than at +35°C. Decrease of efficiency at +5°C can be the same as that at +35°C [3, 4].
There are also additional parameters, which influences on the thermal comfort: air flow speed, air humidity, outer wall temperature and, what is important in vehicles cabins, sun radiation. In many cases thermal parameters are controlled only by regulating air temperature and mass flow rate. Due to that, air flow speed can locally exceeds its reasonable value.
It is hard to strictly define the thermal comfort. Usually thermal comfort means that temperature is between 20°C and 22°C, humidity is about 50% and air velocity is under 0,5 m/s. This can be called independent factors.

There is also second group of factors affecting thermal comfort – individual human feelings which are much harder to define, because each person has their own preferences for thermal comfort. One can say there is thermal comfort when amount of people saying “I fell bad here” is the lowest. [5].
The symptoms of thermal discomfort are intensive sweat production, increment of heart beat frequency, and as a result , the decrease of driver concentration and efficiency.

The investigations presented in this paper are the part of larger project, which assumes complex modelling of thermal state of car interior. First part assumes creation of CFD model of car interior.

This part should should answer the question how the air mass flow rate distribution at the inflow to the cabin influences the temperature and air flow inside the cabin, especially in the passengers surroundings. The full numerical model of cabin and the numerical simulations will be helpful in optimization of air inlets, air mass flow rate, humidity conditions etc. with the respect to the thermal comfort. In the paper the very first results of the simplified model are presented. Second part is thermodynamic modelling of air cooling unit in order to estimate the influence of basic cabin parameters on the A/C unit COP, power consumption of the unit and fuel consumption of the vehicle. Different types of working fluid will be checked. In the paper the initial results of this part are shown. The A/C unit model and CFD model are assumed to be coupled. In the third part of the project the experimental verification of both models will be performed.

NUMERICAL MODEL OF CAR INTERIOR

The numerical model was built within the Gambit/Fluent environment. In the paper simplified (rough grid with 800000 cells), 3D model is presented. At this stage of investigations the flow is isothermal: only the air flow in the cabin is investigated and presented. Contours of velocity in the model are shown in figures 2 and 3. Full 3D CFD model including sun radiation and internal heat generation with more detailed geometry is under construction now.

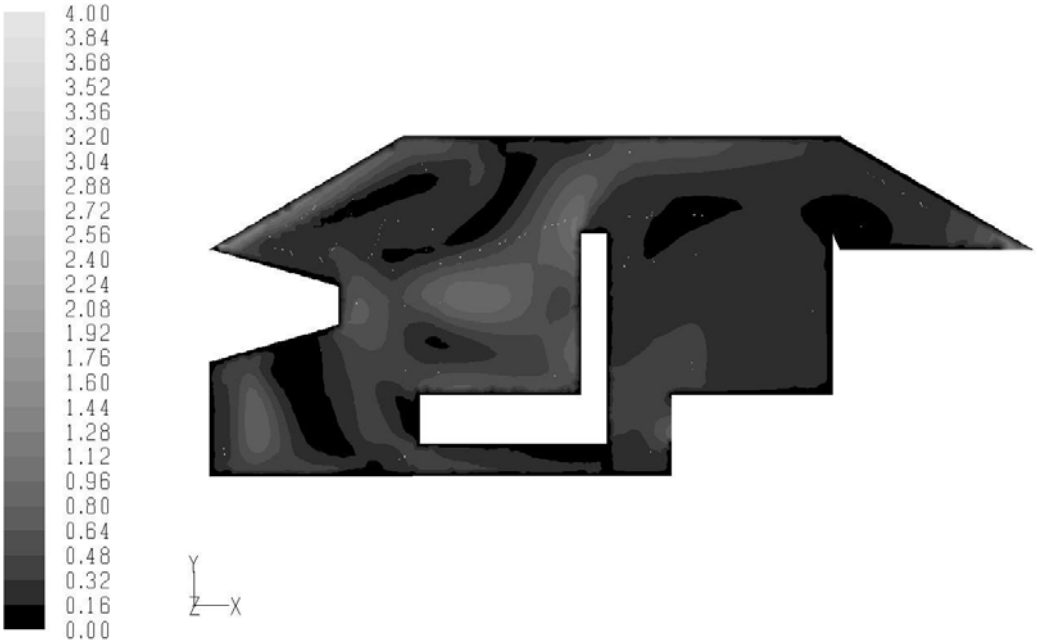

Figure 1. Contours of velocity [m/s]

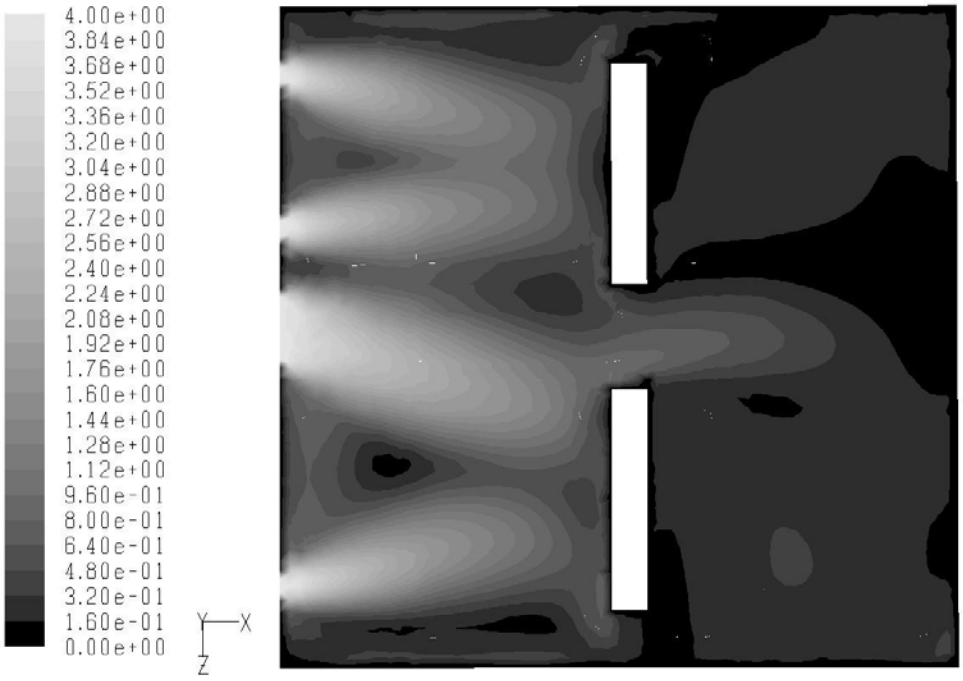

Figure 2. Contours of velocity [m/s]

THERMAL ANALYSIS OF REFRIGERATOR CYCLE

The heat flux which should be transfered out of the car cabin is about 2 kW [6, 7]. Heat balance of car cabin is shown in figure 1.

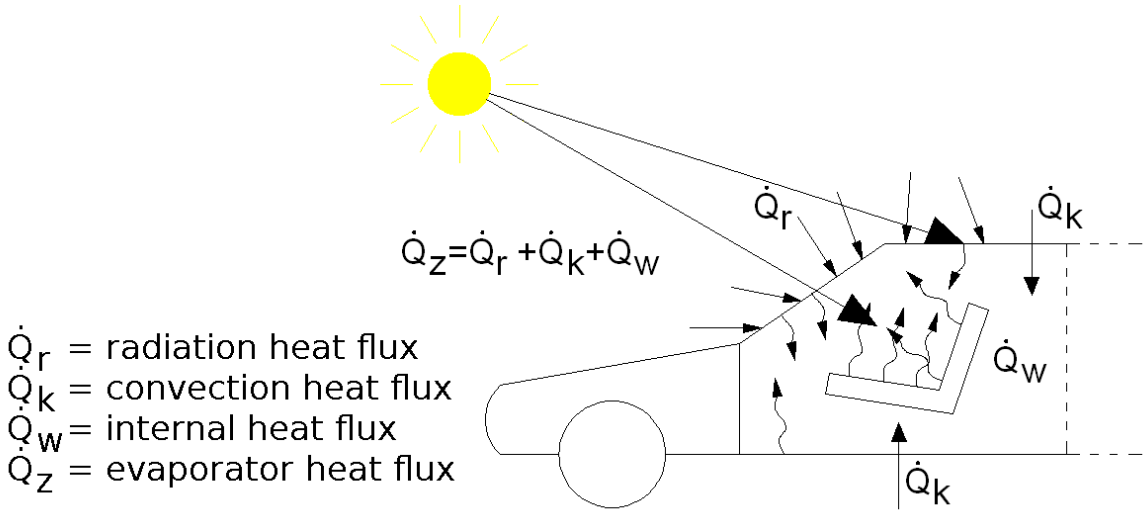

Figure 3. Car cabin heat balance.

An optimum A/C unit should assure thermal comfort under time varying thermal loads with minimal energy consumption. Compressor in the unit is driven by the vehicle engine and therefore considerably increases the fuel consumption. In the paper two types of unit are considered. First with uncontrolled orifice and non controlled compressor (fixed piston displacement), second with thermostatic controlled expansion valve assuring 1K superheating of refrigerant at compressor inlet

and externally controlled compressor (piston displacement from 60 to 120 cm^3). Both cases work with compressor speed 1000 and 3000 rev/min. Nominally refrigerant charge (medium – R134a) is 0,44 kg. The charges 0,22 kg (50% nominal) and 0,055 kg (12% nominal) were also considered. Air temperature changes from 20°C to 45°C. The refrigerator scheme is shown in figure 4. For the simulations commercial Kuli software was used [8].

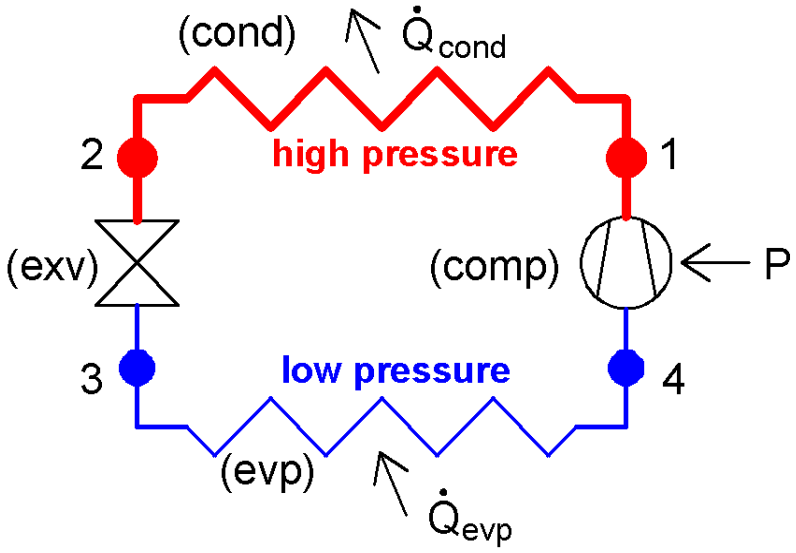

Figure 4. Scheme of refrigerator cycle.

As it was mentioned, the aim of the investigations was the influence of refrigerant charge and inlet air temperature on the air A/C unit parameters: COP, exergy efficiency (η_{carnot}), heat transfer in evaporator (Q_{evap}), refrigerant temperature inside evaporator and compressor driving power. The parameters are defined in the following way:

$$COP = \frac{\dot{Q}_{evap}}{\dot{Q}_{comp}} \tag{1}$$

$$\eta_{carnot} = COP \frac{T_{cond} - T_{evap}}{T_{evap}} \tag{2}$$

$$\dot{Q}_{evap} = \dot{M}(h_4 - h_3) \tag{3}$$

where:
T_{cond} – condenser temperature
T_{evap} – evaporator temperature
h_4 – refrigerant enthalpy after evaporator
h_3 – refrigerant enthalpy before evaporator
$\dot{M}$ – refrigerant factor mass flow rate

Non controlled cycle

In this case as expansion valve is orifice and everything depends on orifice effective throttle area.
If the area is too high the compressor works properly (without fluid droplets) only in some range. If effective throttle area is too low the refrigerant at evaporator outlet is always superheated but the temperature at compressor outlet can be very high. That high temperature involves two another problems. First is higher compressor material durability, second is a problem with liquid phase at condenser outlet, especially with higher ambient air temperature. When the refrigerant is not liquid, or what is better, subcooled, efficiency of all system decreases significantly.

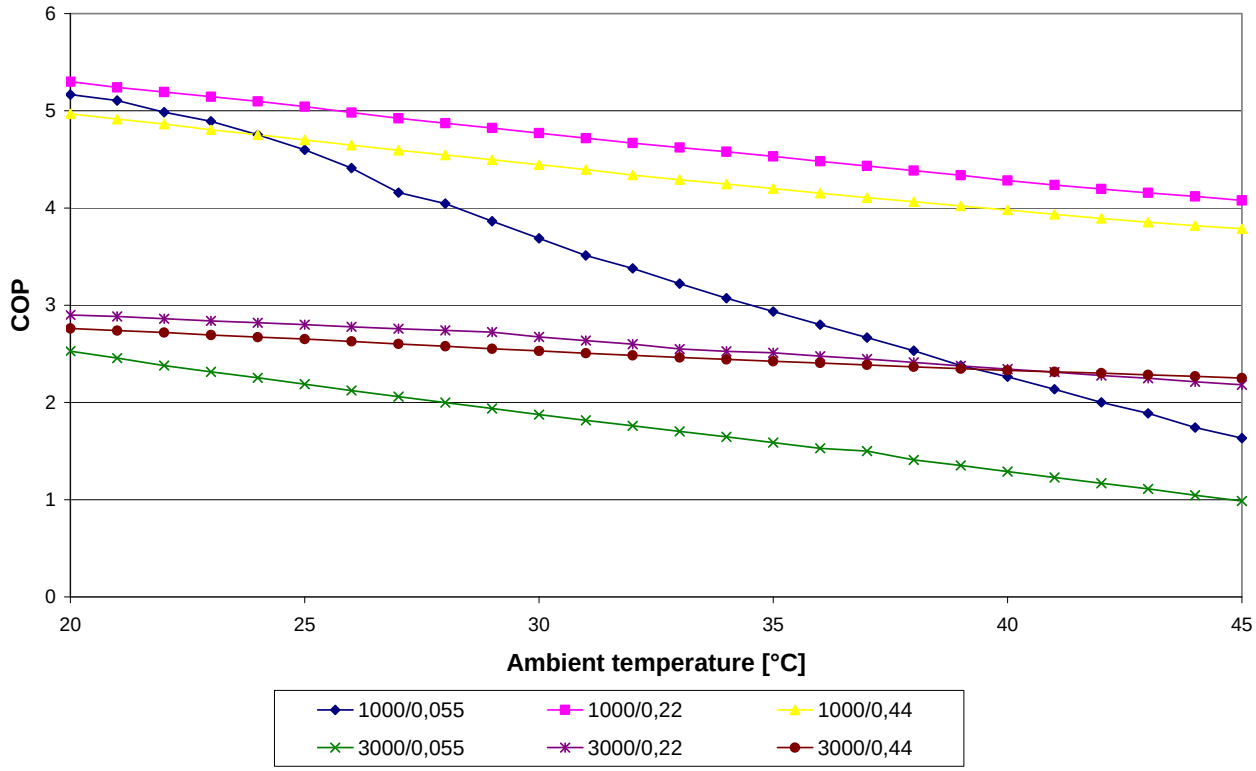

Figure 5. COP as a function of ambient temperature.

In this case, at 20°C irrespectively of refrigerant charge, COP is about 5 for 3000 rev/min and 3 for 1000 rev/min and decreases of 1 at 45°C air temperature. For 0,055 kg charge the drop is about 3 for 1000 rev/min and 2 for 3000 rev/min (figure 5).

Similarly behaves heat transferred in the evaporator. For the charge 0,44 kg and 0,22 kg, the heat flux increases with air temperature. It is shown in figure 6. For 45°C the heat flux is two times higher than for 20°C. For the charge 0,055 kg the situation is opposite – heat flux decreases with air temperature.

There is one advantage of 0,055 kg charge case: compressor power is low: at 3000 rev/min is below 1 kW while for 0,44 kg is twice higher. But here is almost impossible to achieve required temperature inside car cabin in this case. Heat transferred in the evaporator is just too low.

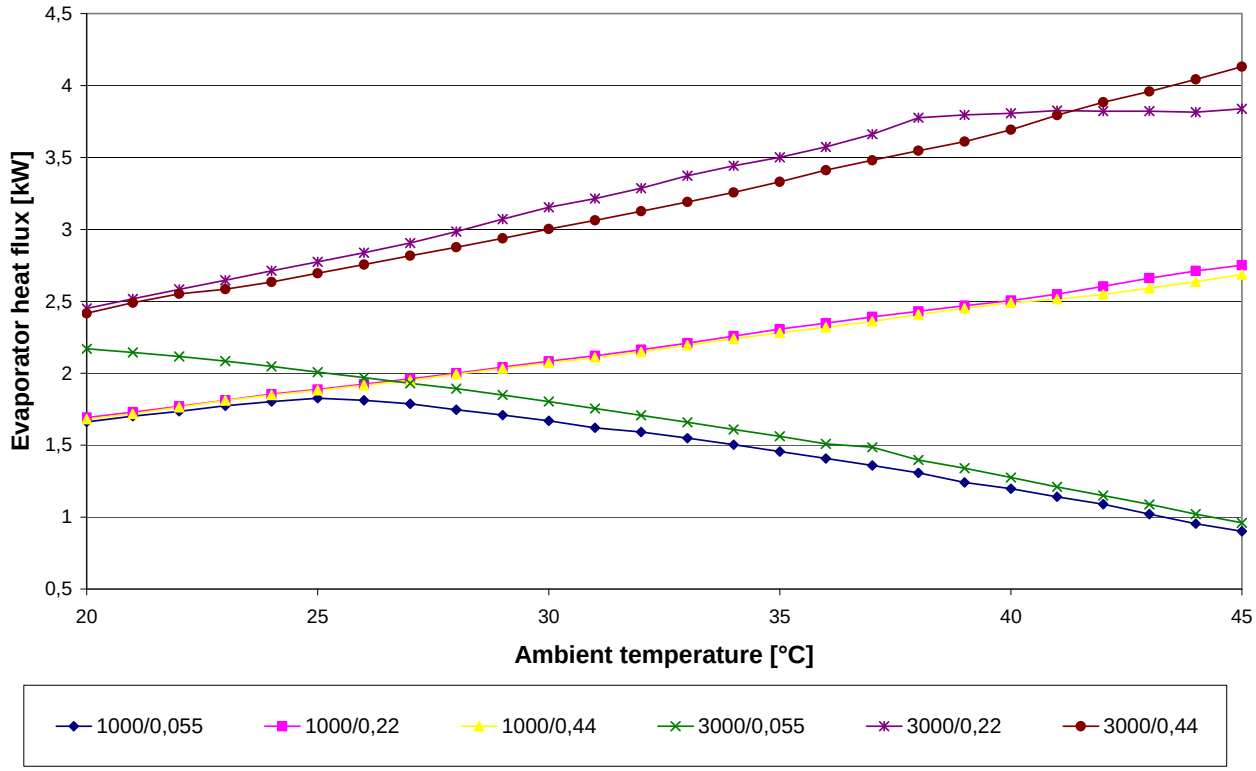

Figure 6. Evaporator heat flux as a function of ambient temperature.

Controlled cycle

In this case there is no problem with too high temperature, because expansion valve always assures 1K of superheating. So there is no problem with high temperature material durability, because temperature at compressor outlet is lower too. If the temperature at compressor outlet is lower it is also easier to obtain liquid phase at condenser outlet.

One can say the controlled cycle is more "flexible". In this case heat flux in evaporator can be about 1,5 kW higher than in non controlled one, which means that we can reject 1,5 kW of heat flux more from car compartment. For 0,055 kg charge, compressor inlet (evaporator outlet) temperature is about 40°C at 45°C air temperature. It means that temperature at compressor outlet can be about 100°C.

For other charges inlet temperatures are similar and always below 15°C.

COP tendency is similar to non controlled cycle but the values are a little bit lower (figure 7). The compressor power is always higher than in non controlled cycle. There is also higher heat flux in evaporator for both 1000 and 3000 rev/min cases (figure 8). For the charge 0,055 kg COP is equal to 0,25 at 45°C air temperature.

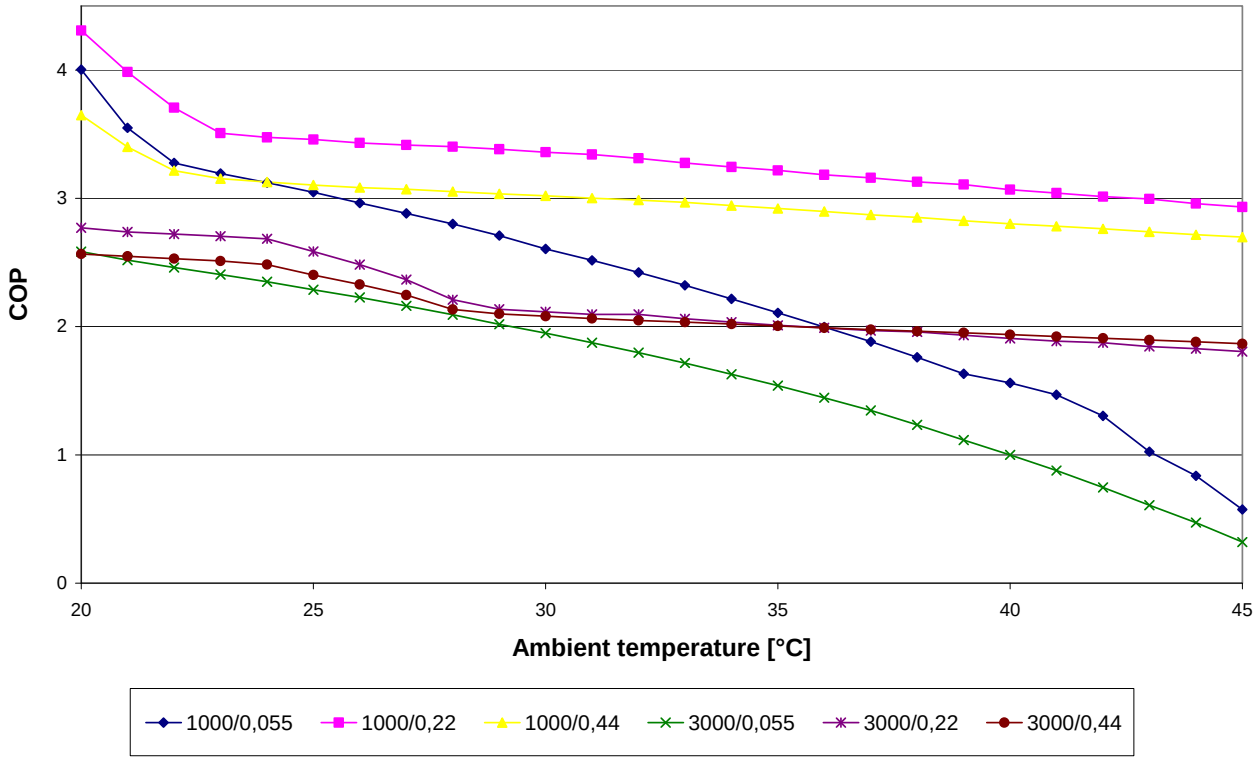

Figure 7. COP as a function of ambient temperature.

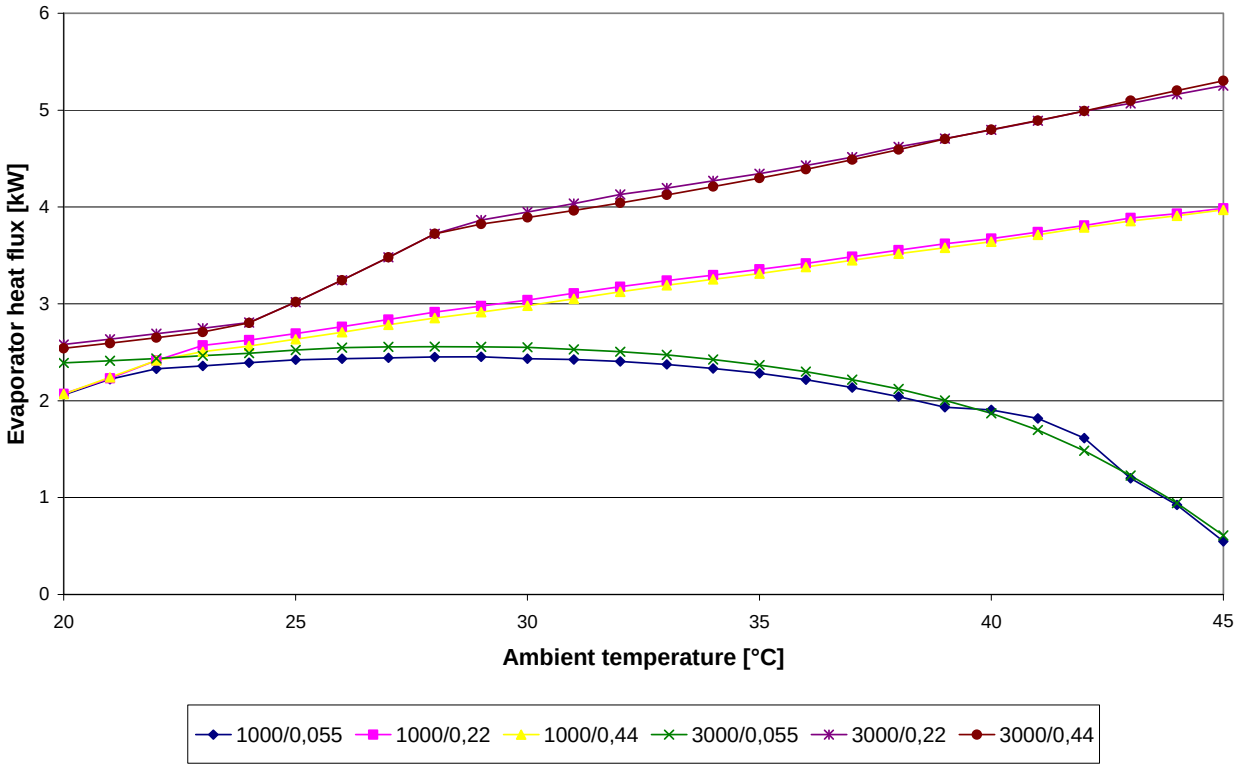

Figure 8. Evaporator heat flux as a function of ambient temperature.

Comparing the cases one can say that non controlled case is better than controlled. COP values are higher for non controlled, compressor power is lower (lower fuel consumption) but from the other side heat flux in evaporator is lower and refrigerant temperature is higher.

Additionally it should be stressed out, that for the charge 0,055 kg compressor works only with vapour phase refrigerant. For the charge 0,11 kg it works with vapour phase above 35°C air temperature. For the charge 0,44 kg liquid always appears in compressor.

All the simulations show how important is proper refrigerant charge in A/C systems. It is impossible to estimate the amount of refrigerant in the cycle without special measuring instruments. There is only one symptom to say that refrigerant charge is too low – the outlet air temperature from A/C is too high.

CONCLUSIONS

In the paper, the initial, simplified numerical model of the car interior as well as the thermal analysis of A/C unit cycle are presented. The plans for future investigations assume the full 3D, temperature dependent numerical model coupled with thermal model of A/C unit. Experimental verification of the model is also planned.
Basing on the simulations to date, it can be noticed that the decrease of the refrigerant charge decreases COP. Decrease is higher in controlled cycle because the temperature in evaporator is higher which causes lower heat flux in evaporator and higher compressor power. Beneficial is that compressor works always with refrigerant in gas phase. For non controlled cycle efficiency is higher but the hazard of compressor work with liquid appears.
In both cases COP is lower when refrigerant charge is below its nominal value. This is the reason why refrigerant charge control is so important, especially in car air conditioning units, which are not so hermetic like home air conditioning units.

HEAT TRANSFER ENHANCEMENT IN DUCTS DUE TO ACOUSTIC EXCITATION

G. Bennett*, J. Mahon, D. Murray, T. Persoons, I. Davis
University of Dublin, Trinity College, Dublin 2, Ireland

ABSTRACT. The thermoacoustic effect that results from the interaction of a sound wave in a compressible fluid in contact with solid boundaries is known to be capable of removing heat from power dissipating systems. In this paper the standing wave acoustic field that is generated in an open ended duct, a section of which is heated, and how it interacts with the aerodynamic flow field is examined by an experimental study. Specifically, the effect the fluctuating acoustic pressure and associated particle velocity have on the internal fluid dynamics is investigated. The ultimate goal is to fully understand and optimize the interaction mechanisms in order to enhance the overall convective heat transfer from a heated duct to internal flow. An experimental rig which has been designed and built allows the fundamental fluid dynamic, acoustic and heat transfer mechanisms to be studied. The rig consists of a circular duct with a central copper isothermally heated section which is instrumented with thermocouples, a heat flux sensor, microphones and a cross-wire probe. The cross wire is used to measure both time varying temperature and velocity at a high frequency and spatial resolution and a calibration procedure which allows the sensor to measure fluctuating velocity at elevated temperatures is reported. Results from the current investigation demonstrate how convective heat transfer from the heated duct section to the internal flow is enhanced due to acoustic excitation. In this preliminary, investigative study, it is suggested that two different heat transfer mechanisms are identified: one associated with the increased turbulent mixing due to the added particle velocity; the second associated with acoustic streaming. The results show significant increases in flow temperature and heat transfer coefficients for free and forced convection regimes.

INTRODUCTION

Thermal management remains today one of the most important bottlenecks in the further development of electronic devices. Whilst new approaches, such as heat pipes and thermoelectric cooling technologies, are being developed, forced convection is still a necessary technique. As acoustic power is approximately proportional to (flow velocity)^6 to (flow velocity)^8 it is crucial that fan performance be optimised. The acoustic penalty for an increase in flow velocity is addressed in this paper, as an effective means to reduce the noise created by the fan would facilitate increased heat transfer. The long term goal of this exploratory work aims to address the following question ***"To what extent can the existing noise from fans in electronics' thermal management systems be optimized to enhance convective cooling?"***

The 2006 market report by the European Electronic Component Manufacturers Association (EECA) shows [1, 2] that the European market for electronic components is worth in excess of €45 billion. The global semiconductor market grew by over 11.5% in the first half of 2006, covering the areas of power transmission, telecommunications, computers and peripherals, automotive and

aerospace [3]. The industry supports over 207,000 direct jobs in the EU [1], and many more indirect jobs.

Current fan-based forced convection techniques[4] with high performance heat sinks are capable of cooling up to 13 W/cm^2. For microprocessors, the heat dissipation is still increasing exponentially, while current processor designs are around the limit of 15 W/cm^2 corresponding to the forced air cooling bottleneck[5]. Since the current integrated circuits are pushing the power boundary, new cooling technologies are being examined. In telecommunications, the maximum power density is currently around 24 W/cm^2, requiring heat pipes to spread the heat to a larger surface area[6]. Present thermoelectric cooling technology[7] is limited to a power density of about 10 W/cm^2, although more advanced materials are being developed to increase the power density to beyond 500 W/cm^2. However, this is an expensive solution with a limited relevance for broad range applications.

The substantial research effort going into removing the heat generated by the electronic circuitry, using advanced methods such as heat pipes or liquid cooling provides an effective way of transporting the heat away from the confined chip geometry to a larger heat-sink with fan, where the heat is more easily transferred to the surrounding air. Crucially, the use of advanced high heat flux cooling methods does not eliminate the need for fan-based air cooling. This is the framework for the proposed research, which aims to use fan noise in a constructive way, to enhance convective heat transfer in thermal systems.

The thermoacoustic streaming theory initiated by Lord Rayleigh[8] has excited researchers and engineers for over one hundred years. The thermoacoustic instability observation of Rijke's Tube that Rayleigh's theory was able to explain, is found today in pulse combustor engines and low NOx aero-engine multi-stage annular combustors, and attempts to computationally model the phenomenon continue[9, 10]. Since Rayleigh, more recent fundamental theoretical studies have been carried out by Karimi et al.[11], and Swift[12, 13] and Garrett[14] in the area of thermoacoustics applied to refrigeration. The theoretical acoustic enhancement of heat transfer to particles and droplets such as pulverized coal particles and coal-water slurry fuel droplets[15, 16] has been examined as have experimental studies for configurations such as enclosures[17], parallel plates[18], flow over cylinders[19], heated wires[20] and impinging jet flows[21, 22]. Recently, the phenomenon has been applied to cooling of products within the electronics industry by Komarov and Hirasawa[20], and Lee and Loh[23] and to plasma screens by Kim at al.[24].

A fundamental experimental study on the heat transfer enhancement in ducts due to the acoustic excitation of axial fans is proposed in this project. The results of the work will find application in thermoacoustic refrigeration, heat transfer in ducts and in the electronics sector.

EXPERIMENTAL SETUP

General rig layout

The principal element of the experimental rig is a vertically oriented circular duct of an overall length equal to 2.944m and an internal diameter of approximately 0.1m. The duct, as shown in figure 1, consists of three parts: lower and upper sections of PMMA (Polymethyl Methacrylate) and a central section of copper. The transparent PMMA was chosen for its low thermal conductivity and for its suitability for future PIV measurements. The wall thickness is 10mm with an internal diameter of 100mm. The central copper section of 0.520m length and 1.5mm wall thickness was chosen for its high thermal conductivity and is mounted to a support frame via an Ertalon 6 PLA flange of 10mm thickness clamped at each end. The copper section thus butts against the PMMA at both ends and is in contact with just the two low conductivity 10mm thick Ertalon flanges. This mounting arrangement was designed to reduce conductive heat loss from the copper section which is heated on its external

surface by a Holroyd 1.5 kW H/SR-PA silicon heater mat over the length between the flanges of 0.5m. The mat is powered by a RegaVolt Variac, and the current to the mat is monitored via a multi-meter which allows the power input to be measured. The schematic also shows the copper pipe to be instrumented with two T-type thermocouples, which are mounted, at either end, flush with the inside of the pipe surface. Three 6mm holes were cut through the heater mat and copper piping along its length to allow for access of the cross-wire anemometer and for microphone pressure measurements, with any unused holes blocked during testing. A type 27036 RdF Micro-foil heat-flux sensor with integral T-type thermocouple is placed mid-point of the total length of the pipe which is 9.1mm below the top cross-wire hole. As a right-angled cross wire was employed to ensure no disturbance to the flow field by the hot wire support, the 9.1mm length corresponds to the extension of the cross-wire normal to the probe. This set up allows for temperature and velocity profiles to be measured at the same mid-point axial location as the heat flux sensor.

A D.C. tube-axial fan is mounted at the top of the duct and is used to control the fluid velocity through the pipe. In addition to the cross-wire velocity measurements, a pitot-static tube was used to monitor average flow velocities. A 600W JBL 2206 H speaker is located at the lower end of the duct and is used to introduce pressure fluctuations at set frequencies. A gap between the speaker and the duct allows air to be drawn up through the duct for forced convection tests.

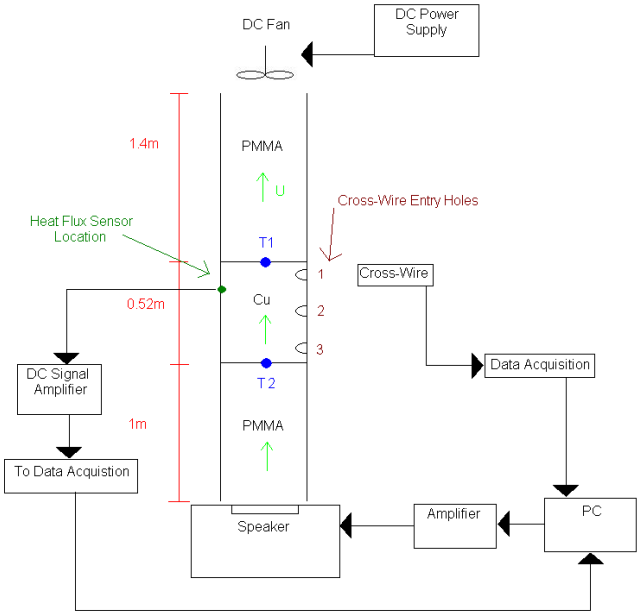

Figure 1. Experimental test rig

Instrumentation

A Dantec X-probe type 55P63, with a right angle between the sensor and the probe holder, is used to obtain velocity and temperature measurements. One of the wires of the cross-probe is used to measure fluctuating velocity obtained using a Dantec StreamLine Constant Temperature Anemometer (CTA). The other 'cold-wire' is configured to act as a resistance thermometer using constant-current anemometry (CCA) the temperature of which is determined by an accurate measure of its resistance.
The radial position of the cross-wire is accurately controlled by a linear actuator attached to a stepper motor which was calibrated to ensure spatial precision. The micro-foil sensor signal, of the order of μV, is amplified x1000 using an Omega Omni-Amp III DC Signal Amplifier. The thermocouples are connected to an Omega Toggler device which displays the temperature on-screen. The DC fan used is powered by a Thurlby 30V-1A DC power source. The speaker used to introduce the standing wave receives a signal from a QSC Power amplifier, which in turn receives a signal from .wav files

generated in Matlab and output via LabView through a National Instruments D/A converter. All data from the heat-flux sensor, the cross-wire and the microphones are acquired by a National Instruments data acquisition system, using N.I.'s LabView and and Dantec's StreamWare software on a Dell Precision T3400 PC. A LabView programme was written to automate control of the speaker frequency, the cross-wire location via the stepper motor and data acquisition of the heat flux sensor and cross-wire measurements.

Cross-Wire Calibration

Hotwire anemometry is based on convective heat transfer from a heated wire. However, in this test setup the temperature of the fluid may vary with time and/or is at a different temperature to nominal ambient temperature at which the hotwire was calibrated. As the principle underlying the measurement of flow velocity is based on heat transfer it is necessary to measure the actual temperature of the flow and hence correct for the temperature difference.

There are a number of approaches to correct the velocity for elevated temperature. The simplest method is based on the assumption that heat transfer from the probe is proportional to the temperature difference (between the wire and ambient temperature) and the relationship is shown in equation 1

$$E_{corr} = \left(\frac{T_w - T_0}{T_w - T_a} \right)^{\frac{1 \pm m}{2}} E_a \tag{1}$$

where E_a = acquired voltage, E_{corr}= temperature corrected voltage, T_w=hotwire measurement, T_0= ambient reference temperature, T_a= fluid temperature during calibration and m = temperature loading factor, which is a dimensionless physical material property (for air, m = 0.16).

A more accurate approach for calibrating the hotwire is direct calibration of the hotwire at the ambient temperature of the fluid under test. In the current study both the fluid velocity and temperature vary significantly, hence direct calibration was the most accurate and appropriate method. A discussion of this approach can be found in Bearman[2].

The accuracy of the results from the hotwire anemometry system is dependent on both the acquired voltage (velocity) and temperature of the fluid. Hence, it is important to measure both simultaneously. Both quantities were measured using a cross wire probe, type 55P63. The method of temperature measurement used in this paper is based on a resistance thermometer. The temperature measurements were obtained from the resistance measurement of wire 1. Wire 2 was used to measure flow velocity using a standard constant temperature anemometer.

The resistance wire was calibrated by exposing the wire with flow at a known temperature and fitting a curve between temperature and measured resistance. A linear relationship was measured between the two quantities. Equation 2 shows the relationship between wire resistance and temperature. This was the basis for the temperature measurement.

$$R = R_0 \left[1 + \alpha \left(T - T_0 \right) \right] \tag{2}$$

where R is the wire resistance at temperature T, R_0 is the wire resistance at the reference temperature T_0 and α is the temperature coefficient of resistance.

The velocity and temperature sensitivity of the hotwire were obtained by operating the hotwire at a fixed overheat ratio of 1 and hence a fixed wire resistance. The hotwire system was balanced at an ambient temperature of *20.1°C*. The output voltage was recorded as a function of velocity and fluid

temperature by using a specially designed calibration rig as shown in figure 2. The calibration was performed at a range of flow velocities ranging from 1m/s to 7m/s at four ambient temperatures of 20, 30.1, 39.8 and 50.1°*C*. The set of calibration data are shown in figure 3. A fourth order polynomial was used to fit the data as per equation 3.

$$U = C_0 + C_2 E + C_2 E^2 + C_3 E^3 + C_4 E^4 \tag{3}$$

where C_0 to C_4 are the calibration constants and E is the anemometer voltage.

The cross-wire as a sensor was chosen as an attractive solution for temperature and velocity measurement as high spatial and frequency resolutions could be achieved at almost coincident positions. In addition, as both wires were contained within the one holder, a good aerodynamic seal could be obtained at the sensor/copper duct interface. However, due to these proximate locations, tests had to be conducted to ensure that the "cold-wire" was not influenced by the presence of the hot wire, i.e. the "cold-wire" measured the fluid temperature independently of the hot-wire temperature. Tests were conducted to determine the influence of operating the hot-wire (*286°C*) on the resistance wire for a range of ambient temperatures (*20*, *40* and *60°C)* and for two flow velocities of 2m/s and 3m/s. The values chosen are comparable to the parameters under test. It was found that the temperature fluctuated about a mean value and that the variation in measurement with and without the hot-wire operating was consistent with random experimental error.

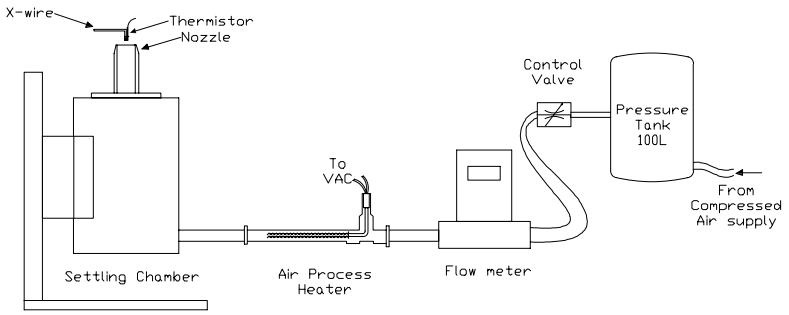

Figure 2. Rig to calibrate "cold-wire" for temperature measurement and the hot-wire for temperature corrected velocity measurement.

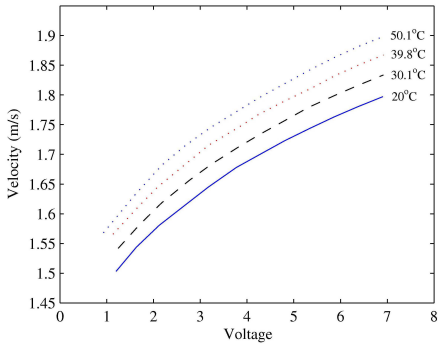

Figure 3. The dependence of hot-wire voltage on flow velocity at a number of ambient temperatures

Hydrodynamic, Thermal and Acoustic Considerations

For the forced convection tests discussed in this paper the mean velocity was measured to be 1.93m/s which for air in a duct of diameter 0.1m results in a Reynolds number of 12,841. Being greater than 10,000, the flow is considered to be fully turbulent. The axial measurement position of the heatflux

sensor and cross-wire was located at the downstream end of the heated section. This results in x/D≈15 from the entrance of the duct and x/D≈5 from the beginning of the heated section.

The upper section of the duct was thus increased in length so that the heatflux sensor was located at exactly the midpoint of the total duct length. Fixing the measurement plane at the centre of the pipe allowed acoustic pressure or particle velocity nodes and anti-nodes to be easily aligned at this plane. By exciting the duct with random noise, and measuring its response with a microphone located flush with the inside of the duct wall, the duct resonant modes could be measured. These frequencies agreed closely with the theoretical resonant modes for an open ended duct according to the equation

$$f_n = n\left(\frac{c}{2(L+\Delta)}\right) \tag{4}$$

where Δ is an end correction to account for the radiation impedance at the end of an open duct. Δ =(D/2)*z, where z is a function of the flange size at the termination. For our rig z is approximately equal to 0.61. Figure 4 shows an illustration of the first four resonant frequencies examined in our duct and how the normalised pressure distribution, in blue and normalised particle velocity distribution, in red, vary along its length. The heat flux sensor is indicated by a small black square towards the end of the heated section at the midway point. Frequencies 63Hz and 167Hz result in particle velocity nodes at the measurement plane, whereas 113Hz and 223Hz result in particle velocity antinodes.

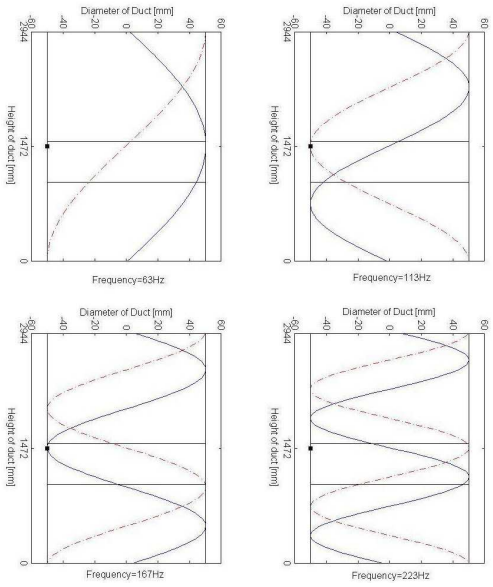

Figure 4. Acoustic pressure (blue) and particle velocity (red) distributions along the length of the duct for the first four resonant modes of the duct.

RESULTS AND DISCUSSION

Temperature, velocity and heat flux measurements were taken at the mid point of the duct (the measurement plane) for a series of experimental configurations. The main variables were: wall temperature [ambient, hot]; flow [free convection, forced convection]; frequency [0Hz, 63Hz, 113Hz, 167Hz, 223Hz]. For free convection the wall temperature was 78.8°*C* whereas for forced convection the temperature was 60.4°*C*. As both 63Hz and 167Hz result in particle velocity nodes at the

measurement plane, these shall be referred to as N1 and N2 where as frequencies 113Hz and 223Hz will be referred to as A1 and A2, due to the fact that particle velocity is a maximum at this location. Figure 4 shows the effect that the standing wave has on the time averaged temperature profile for both free and forced convection configurations. For the free convection situation, the added sound serves to reduce the temperature near the duct wall (8-4mm from the wall) whereas the temperature in the main body of the flow increases significantly. A2 differs in a band centred at 10mm from the wall where the temperature is particularly elevated - an increase of 50-80%. For the forced convection case, an increase in mean temperature is again to be seen but this time the effect is localised to bands near the wall, the centre distance of which changes with frequency. Again, the temperatures decreases very close to the wall for all frequencies.

Figure 5 plots temperature corrected mean and fluctuating velocity readings for hot and cold wall temperatures for forced convection. These results show that N1 and N2 behave similarly to each other as do A1 and A2 and, at least qualitatively, for most positions there is little difference between the cold and hot wall conditions. From observation of the fluctuating velocity of frequencies A1 and A2, the particle velocity can be quantified as approximately 0.4m/s at the measurement plane. As the plane wave cut-off frequency for this diameter duct is approximately 2kHz, all four frequencies considered generate plane wave standing waves and thus the particle velocity should increase uniformly across the diameter. This is clearly seen for frequencies A1 and A2, as expected with a slight difference close to the wall for the heated wall condition. In contrast for frequencies N1 and N2 the fluctuating velocity should be expected to remain unchanged as the location is at a velocity node. This is the case except, surprisingly, at banded distances from the wall where large increases in fluctuating velocity are measured. In the same bands for the same two N1 and N2 frequencies, the mean velocity is also seen to increase significantly. For all frequencies, the mean velocity also increases, to a varying extent, outside of these bands.

Qualitatively, the unusual banded behaviour is suggested to be caused by acoustic streaming where two different types of circulatory flow structures may be generated: “Rayleigh” structures generated outside viscous boundary layers and a second streaming “Schlichting” structure generated in the immediate vicinity of the viscous boundaries. In the results presented in this paper, the Rayleigh structure is thought to be identifiable for the N1 and N2 frequencies. Some qualitative differences between the hot and cold wall conditions close to the wall might be attributed to Schlichting structures but further testing needs to be done to verify this. If this is the case, these circulatory structures serve to remove heat from the wall surface and to circulate this heat into the flow where it is exhausted with the mean flow. Whereas acoustic streaming is normally restricted in the literature to closed ended ducts, the experimental setup described here benefits from the fact that standing waves can be generated in open ended ducts at low frequencies.

Figure 6 summarises these results for the hot wall case from the point of view of heat transfer. For the no flow case the mean temperature is plotted as a function of frequency whereas for the forced convection case both the mean temperature and a mass-flow rate averaged temperature (bulk temperature) is presented. The bulk temperature is calculated according to equation (5)

$$T_b = \frac{\sum_{j=1}^{N}\left(T_j \times U_j\right)}{\sum_{j=1}^{N} U_j} \tag{5}$$

where j is a measurement location. For the free convection case, the average temperature increases due to acoustic excitation, markedly at A1, whereas for forced convection only N1 and N2 result in a temperature increase.

Availing of the heat flux measurement, the convective heat transfer coefficient can be calculated according to equation 6.

$$h = \frac{q^{"}}{(T_s - T_m)} \tag{6}$$

where Ts is a surface temperature and Tm is mean fluid temperature. In figure 6, results using both the mean temperature and the bulk temperature are used for comparison. However, unfortunately, due to an instrumentation error, the heat flux thermocouple failed. This means that an accurate measure of the surface temperature at the heat flux sensor as a function of frequency was not available. To overcome this, the "cold-wire" temperature closest to the heat flux sensor, which was approximately 1mm away was used. Using this approach, the heat transfer coefficients are presented relative to the 0Hz benchmark. Despite the erroneous surface temperature, qualitative similarities are apparent with the other data which give credence to the results. For the free convection case, remarkable increases in heat transfer coefficient are measured for all frequencies. For higher velocities again the N1 and N2 frequencies pair off as do the A1 and A2 frequencies, with the velocity node frequencies giving the greatest increase in heat transfer coefficient.

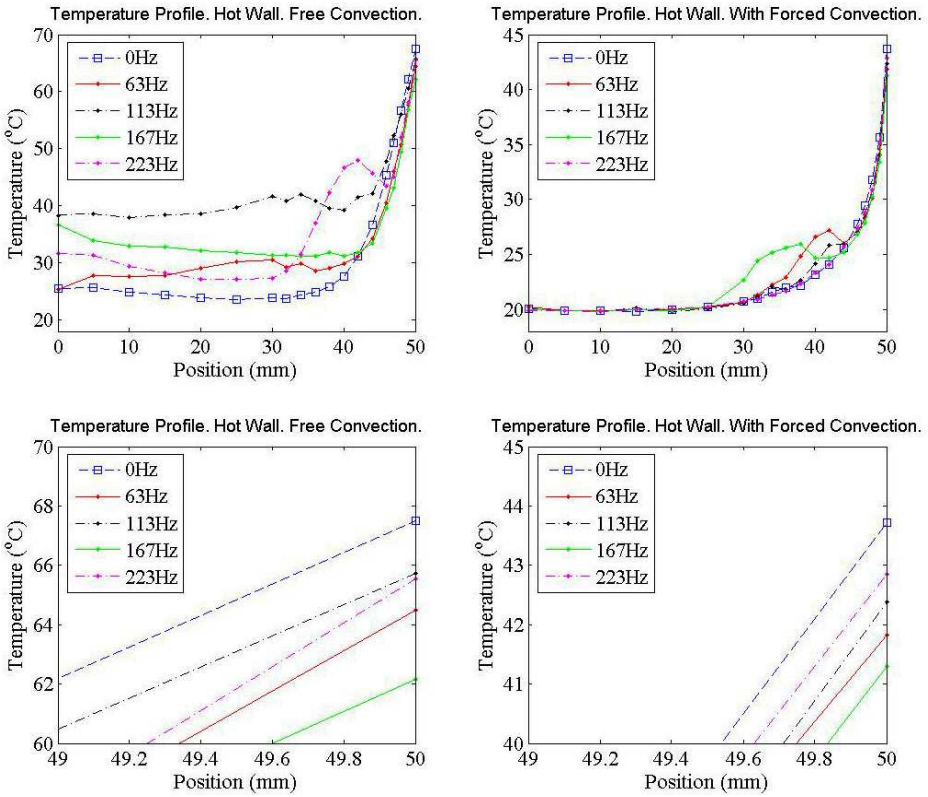

Figure 4. Time averaged temperature profiles over a radius of the duct at the measurement plane as a function of resonant mode frequency. The first figure is for a free convection condition with a wall temperature of *78.8°C.* The second plot is for forced convection with mean velocity of 1.94m/s and a wall temperature of *60.4°C.* The bottom two figures are close ups at the wall surface. The centre line of the duct corresponds to 0mm.

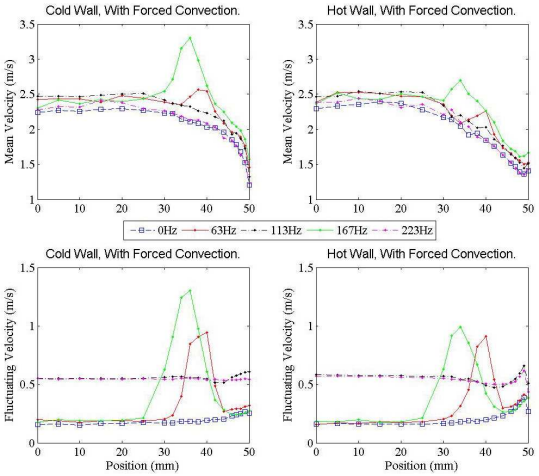

Figure 5. Mean and fluctuating velocity profiles as a function of frequency and wall temperature in the direction of flow.

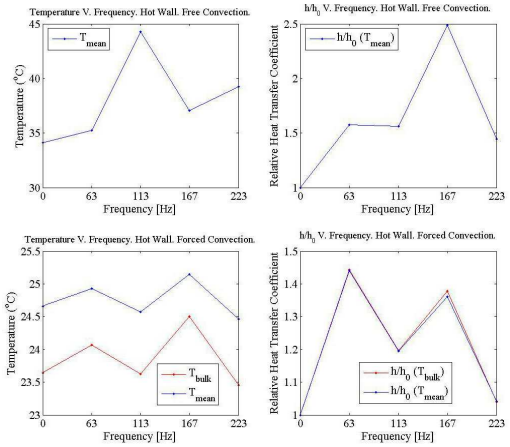

Figure 6. Averaged temperature and relative heat transfer coefficient as a function of standing wave frequency.

CONCLUSIONS

Temperature, mean velocity and fluctuating velocity distributions across the radius of a vertical heated open ended duct subject to acoustic excitation have been presented for forced and free convection cases. By exciting the duct at different standing wave resonant modes, the influence a particle velocity anti-node (pressure node) versus a particle velocity node (pressure anti-node) has on measurements at the same plane could be isolated. From the velocity results two principal heat transfer mechanisms are suggested. The first is due to an increase in particle velocity associated with the anti-node. This increase in fluctuation is aligned with an increase in turbulence and the resultant increase in turbulent mixing is seen to increase the heat transfer. The second mechanism is suggested, in this investigative work, to be attributed to acoustic streaming where two different types of circulatory flow structures may be generated. These sound induced heat transfer mechanisms coupled with free convection are seen to combine efficiently, serving to transport heat into the flow to be exhausted from the duct.

PLATE HEAT EXCHANGER - INERTIA FLYWHEEL PERFORMANCE IN LOSS OF FLOW ACCIDENT

A. Talal*, A. Amr
Reactors Department, Atomic Energy Authority, Egypt

ABSTRACT**.** One of the most wide used heat exchangers in process plants is the plate heat exchanger (PHE) for its wide advantages. Its plates are assembled or disassembled easily; hence, it has a high availability for altering its heat transfer characteristics. Egypt second research reactor uses the PHE on its primary core cooling circuit (11MWatt/PHE). So, modeling and simulation for PHE is acquired a great attention where the changing in its mass flow rate or its number of plates are worthy to be studied due to their effects on reactor core performance. An inertia flywheel is mounted on the core cooling system pump to feed the core and hence the PHE with a coolant flow during the loss of electrical power supply transients to protect the core against overheating. Accordingly, the PHE is played a strong role in the case of Loss of Flow (LOF) transients; it continues in transferring the core decay power to the cooling tower until the forced core cooling mode is valueless hence the natural convection core cooling is a matter of must. The PHE performance during the LOF transient is one of the parameters that determine the time of transition from forced to natural mode. The developed model is validated in two ways, first by a set of Alfa Laval available data for M30-FG PHE and secondly by comparing the developed model results with that obtained by A. D. WRIGHT model. The validation showed that the developed model can be used for simulating the PHE with a good accuracy. From the simulation of M30-FG PHE, it is concluded that, the heat exchanger primary flow can be increased by 20% over its nominal value without exceeding the permissible pressure limit (100KPa) and hence its power is increased to 12.4 MWatt. This type of PHE can withstand a decrease in its nominal number of plates up to 15%, with nominal flow fixed, without exceeding the pressure limit and give a performance near the designed performance. Increasing the number of plates over its nominal value, with nominal flow fixed, could not produce a noticeable enhancement as could be expected. After a 62 sec from the initiation of loss of flow transient, the primary side outlet temperature is equaled to the secondary side inlet temperature (30 ^{o}C), this time is adequate to change the core cooling mode from forced to natural by opening a passive device (flapper valve) to establish it. During this time the PHE with the aid of inertia flywheel are dissipated energy of 207.917 MJ through the cooling tower and protected the core from over heating.

Figure 1. Plate type Heat exchanger

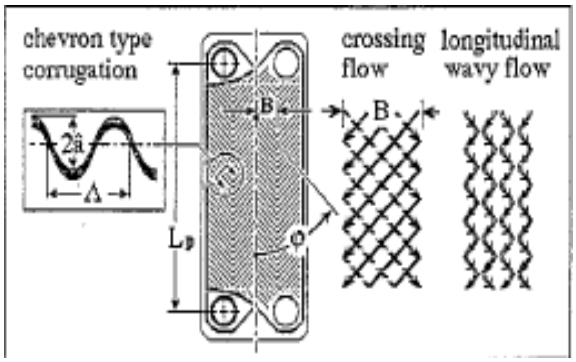

Figure 2. Two flow types at gap

behavior of heat exchangers accurately and at the same time using simpler modeling concepts has been taken up in different ways by different investigators. Plate and frame heat exchangers are offered by a large number of manufactures as standard series production equipment over a wide range of sizes. They consist of a number of gasket metal plates clamped between a stationary head and a follower plate by tie bolts as shown in Figure 1. A number of detailed experiments studies have been focused on that type of heat exchangers. Theses studies incorporated in addition to the fundamental nature of the corrugation patterns some important parameters like the corrugation amplitude, corrugation wave length, corrugation inclination angle and flow rate [1, 2, 3, 4]. The inclination angle of the crests and furrows of the sinusoidal corrugation heat exchanger pattern relative to the main flow direction has been shown to be the most important design parameter with respect to fluid friction and heat transfer. Two kinds of flow may exist in the gap between two plates [5]: The crossing flow of small sub-streams following the furrows of the first and the second plate, respectively, over the whole width of the corrugation pattern, dominating at lower inclination angles (lower pressure drop); and the wavy longitudinal flow between two vertical rows of contact points, prevailing at high inclination angles (high pressure drop), as shown in Figure 2. A better method has been developed for calculating the effectiveness and the pressure drop of two streams PHE after plate's rearrangement, based on its existing performance [6], this therefore means that, complete Knowledge of the friction factor and heat transfer correlations is not needed and a full rating calculation is unnecessary. The methodology in its present form, however only works for systems in which true counter-currency can be assumed and the number of channels per pass is the same on both sides; this methodology is adopted in the present work to determine the worth from increasing or decreasing the number of plates for M30-FG PHE used in Egypt Second Reactor (ETRR 2) cooling system. A mathematical model is developed in algorithmic form for the steady state simulation of gasket heat exchangers with generalized configurations [7]; the configuration is defined by the number of channels, the number of passes at each side, fluid locations, feed connection locations and type of channel flow. The main purposes of this model are to study the configuration influence on the exchanger performance and to further develop a method for configuration optimization. A thermal modeling of a PHE on steady state assuming constant fluid physical properties and uniform flow distribution inside the PHE was presented [8], leading to two approaches for obtaining the log-mean temperature difference correction factor: approach 1, that assumes pure counter current flow conditions and approach 2, that accounts for different configurations and requires the solution of the differential thermal model of the PHE. An optimal design of PHE has been carried out [9]; this design consists of two catalogues: the design with fixed allowable pressure drops and the complete optimal design without pressure drop specifications. Compared the traditional design methods, the current approach does not contain many trials [9]. In the design with fixed allowable pressure drops, full utilization of allowable pressure drops is taken

as the design objective. In the complete optimal design without pressure drop specifications, pressure drops are economically optimized during the design [9].

EFFECTIVNESS AND HEAT TRANSFER CALCULATIONS

The following model has been developed to study the PHE performance during the change in primary side flow rate, the change in the number of plates and also it is used for the evaluation of PHE performance in loss of flow (LOF) transient. The NTU method is the one adopted in PHE calculations, and it's therefore explained as follows; the effectiveness of the heat exchanger is the ratio of the actual heat transfer rate to the maximum possible heat transfer rate.

Effectiveness calculations

$Q = E\, C_{min}\, (T_{hi}-T_{ci})$ (1)

$C_h = W_h\, c_{p,h}$ (2)

$C_c = W_c\, c_{p,c}$ (3)

$C_{max} = C_h$ and $C_{min} = C_c$ if $C_h > C_c$ (4)

$C_{max} = C_c$ and $C_{min} = C_h$ if $C_c > C_h$ (5)

For counter currency flow:-

$E1 = 1-\exp(-NTU\,(1-C_{min}/C_{max}))$

$E2 = 1-(C_{min}/C_{max})\exp(-NTU\,(1-C_{min}/C_{max}))$

$E = E1 / E2$ (6)

$NTU = UA/C_{min}$ (7)

$U = 1/(1/h_h + x_p/k_p + 1/h_c)$ (8)

Heat transfer calculations

Turbulent flow mode. Dittus Boelter's correlation is used for calculating the heat transfer coefficient in turbulent flow regime.

$$Nu = 0.023\ \mathrm{Re}^{0.8}\ pr^{0.4} \times Fac \qquad \mathrm{Re} \succ 10000 \qquad (9)$$

Where; $\mathrm{Re} = G \times D_e / \mu$, $D_e = 4\hat{a}$ and $d = 2\hat{a}$

The dimensions D_e, $\hat{\mathbf{a}}$ and d are as shown in Figure 2. The coolant mass flux, G, has the following definitions in both sides of PHE.

$G = \dot{M} / N \times d \times W$, (primary side) and $G = \dot{M} / (N+1) \times d \times W$ (secondary side)

Laminar flow mode. With the aim of calculating the heat transfer coefficient for forced laminar regime, the H. Martin [5] recommended correlation for obtaining the heat transfer coefficient as a

function of the corrugation inclination angle φ, the Reynolds number Re, and the friction factor is used.

$$Nu = Nu^* \,\mathrm{Pr}^{1/3}\left(\frac{\mu}{\mu_w}\right)^{1/6} \qquad \mathrm{Re} \le 2000 \tag{10-a}$$

$$Nu^* = c_q\left[\zeta.\mathrm{Re}^2\,\sin(2\varphi)\right]^q \tag{10-b}$$

The parameters c_q, q and ζ are functions in the corrugation inclination angle φ [5] and the value of ζ is equal 4 times the Fanning friction factor (f)

$$\frac{1}{\sqrt{f}} = \frac{\cos\varphi}{\sqrt{a_1\,\tan\varphi + a_2\sin\varphi + f_o/\cos\varphi}} + \frac{1-\cos\varphi}{\sqrt{a_3\,f_1}} \tag{10-c}$$

Where; $f_o = 16/\mathrm{Re}$ and $f_1 = (149/\mathrm{Re}) + 0.9625$

The value of the constants a_1, a_2 and a_3 are calculated as defined in the H. Martin [5]

Transition flow mode. To evaluate the heat transfer coefficient in the transition regime the interpolation between Laminar and turbulent is used.

PRESSURE DROP CALCULATIONS

A similar procedure to that used in A. D. Wright [6] work is adopted here for calculating the pressure drop in both the primary and secondary side of the PHE. The fanning friction factor used in [6] is corrected in this study according to H. Martin work [5] because the constants K (φ) and n (φ) depend on the corrugation inclination angle φ .

$$\mathbf{f = K(\varphi) / Re^{n(\varphi)}} \tag{11}$$

Channel pressure drop:-

$$\Delta P_{ch} = \frac{2\,L\,K(\varphi)(G)^2}{\rho\,D_e}(\mathrm{Re})^{-n(\varphi)} \tag{12}$$

Port pressure drop:-

$$\Delta P_{po} = 1.3\left(G_{po}\right)^2\frac{1}{2\rho_{po}} \tag{13}$$

Where; $G_{po} = 4\dot{M}\ /\pi D_p^2$

$$\Delta P_{tot} = \Delta P_{ch} + \Delta P_{po} \tag{14}$$

A. D. Wright [6] has developed a method for calculating the effectiveness and pressure drop of PHE based on its existing performance. This method therefore, means that complete Knowledge of the friction factor and heat transfer correlations is not needed and a full rating calculation unnecessary.

$$\Omega = \left(\frac{1 - E_{old}}{1 - E_{old}\, C_{\min}} \right) \tag{15}$$

$$\psi = \frac{q_1 \left(2N_{new} - 1\right) N_{old}^{b1}}{n_1 \left(2N_{old} - 1\right) N_{new}^{b1}} \tag{16}$$

$$E_{new} = \frac{1 - \Omega^{\psi}}{1 - C_{\min}\, \Omega^{\psi}} \tag{17}$$

$$\Delta P_{new} = \Delta P_{old} \left(\frac{N_{new}}{N_{old}} \right)^{n(\varphi)-2} \tag{18}$$

LOSS OF FLOW SIMULATION

The transient behavior of ETRR-2 core in case of loss of flow (LOF) transient is simulated by a PARET code [10]. The code was validated by the actual experimental measured transient response in various SPERT cores [11]. A one core cooling channel (average channel) is represented the reactor core in this simulation. It is required to calculate the core average exit temperature variation with the flow cost down caused by the inertia flywheel after the reactor is scrammed. Both the decay power generated after scram, that is neutronically calculated [12], and the flywheel flow coast down, that is measured experimentally, were feed to PARET code as a function of time to calculate the average core exit temperature with time. Hence, the average core exit temperature and the flywheel flow coast down were introduced to the PHE developed program to calculate the PHE performance during the LOF transient.

HEX. MODEL VALIDATION

A set of Alfa Laval data [13], for the PHE M30-FG, were used for the developed model validation. Different PHE primary side flow rates ranging from 10^6 Kg/h to 5×10^4 Kg/h, with a fixed secondary side flow rate of 1.35×10^6 Kg/h were used in the validation. Both the PHE primary side inlet temperature and the secondary side inlet temperatures were fixed to 49.5 ^{o}C and 30 ^{o}C respectively during the validation. With these conditions, the model were used to calculate the primary side outlet temperature, the secondary side outlet temperature, the PHE transferred power, the effectiveness and primary side pressure drop. The model results were compared with the available data as shown through Figure 3 to Figure 5. A reasonable consistence was existed between the developed model results and the Alfa Laval data. Based on these comparisons, the developed model is reliable to simulate the PHE.

RESULTS AND DISCUSSION

Variation of the primary side mass flow:-

The PHE performance were studied during the variation of the primary side flow rate around its designed value (10^6 Kg/h) , by steps equaled ± 5 % each. The PHE inlet temperatures for both the primary and the secondary sides were fixed to 49.5 ^{o}C and 30 ^{o}C respectively in all

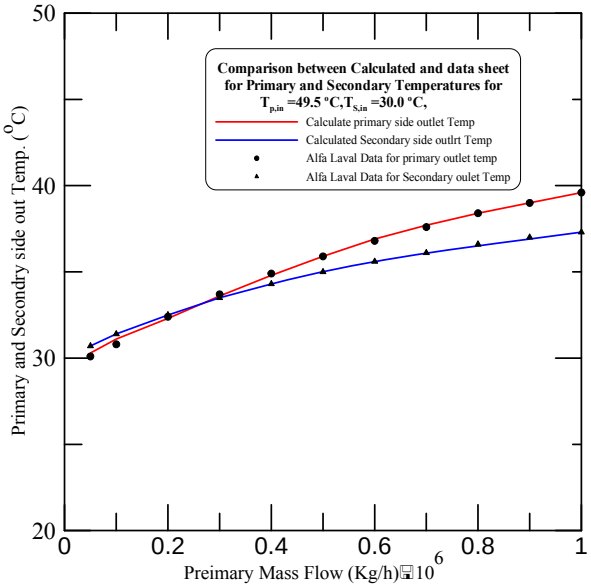

Figure 3. PHE primary and secondary outlet temperatures variation with flow rate

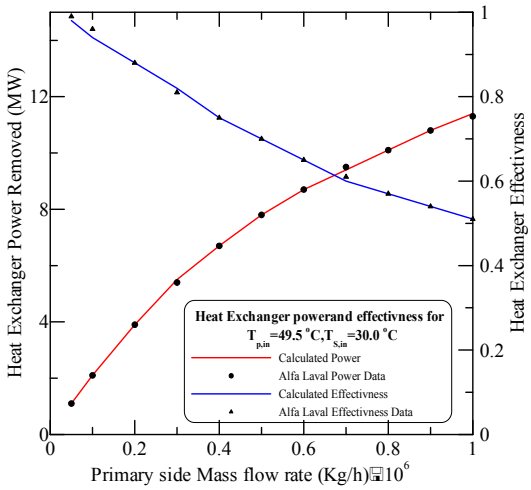

Figure 4. PHE power and effectiveness variation with flow rate

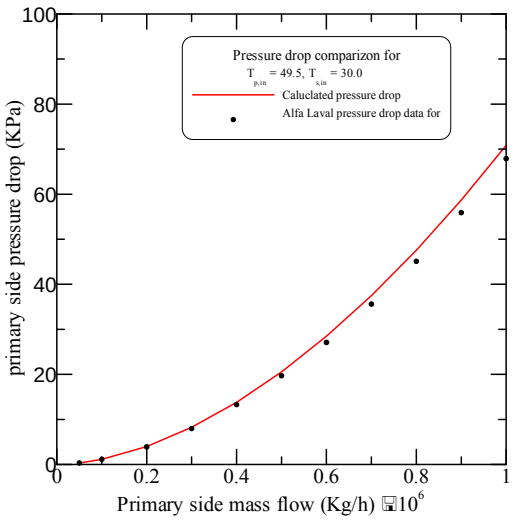

Figure 5. PHE primary side channel pressure drop variation with flow rate

the simulated steps. This study has a complete illustration in both Table 1 and Figure 6, where the following parameters were recorded, the PHE power, the primary side pressure drop, the primary side outlet temperature and the effectiveness. A gradual increase in the PHE power was recorded as the primary side mass flow rate was increased. The increase in the primary side pressure drop was limited the increase in mass flow at +20% from the designed value. The calculated pressure drop at +20% increments in primary flow was 98.1 KPa and the maximum permissible value for this type of PHE is 100 Kpa, so, the maximum permissible power for this PHE was limited to 12.4 MW. The primary side outlet temperature at this limit condition was increased from 39.6 ^{o}C (nominal design value) to 40.5 ^{o}C while the effectiveness was reduced from 0.51 to 0.46. Decreasing the primary side flow rate enhanced the PHE effectiveness and reduced the pressure drop but the transferred power was reduced as a result.

Variation in PHE plates:-

The PHE performance studied here was incorporated the variation in its nominal plates with fixed nominal flow rates (10^6 Kg/h in primary, 1.35×10^6 Kg/h in secondary), fixed inlet temperatures in both the primary and secondary sides. The simulation was carried out at steps each of ± 5 % of the nominal value (161/159 Pl). The results of this study was represented in both Table 2 and Figure 7, where the following parameters were calculated, the PHE power, the primary side pressure drop, the secondary side pressure drop, the primary side outlet temperature and the effectiveness. The results were showed that, slight changes from the nominal values were occurred during the reduction steps except for those occurred in the pressure drop values in both the PHE sides. The primary side pressure drop was increased from 70 KPa at nominal condition to 105.63 KPa at -20% reductions in the nominal plates. While, the secondary side pressure drop was increased from 123.5 KPa to 183.1 KPa for the same condition. So, the maximum permissible reduction in plates without a great change in PHE performance was limited to –15% of the nominal value, where the primary side pressure drop was less than 100 Kpa. Form this simulation; one can be expected that a reasonable PHE performance is attained if a number of its plates are lost in maintenance. Increasing the number of PHE plates could not cause a great performance enhancement as could be expected, where most of the thermal parameters still around its designed values, while the pressure drops in both sides were recorded a high decrease due to the increase in the number of channels with fixed flow rates. For more conservative, this study was performed again by A. D. WRIGHT [6] model that described through equations (15) to (18).

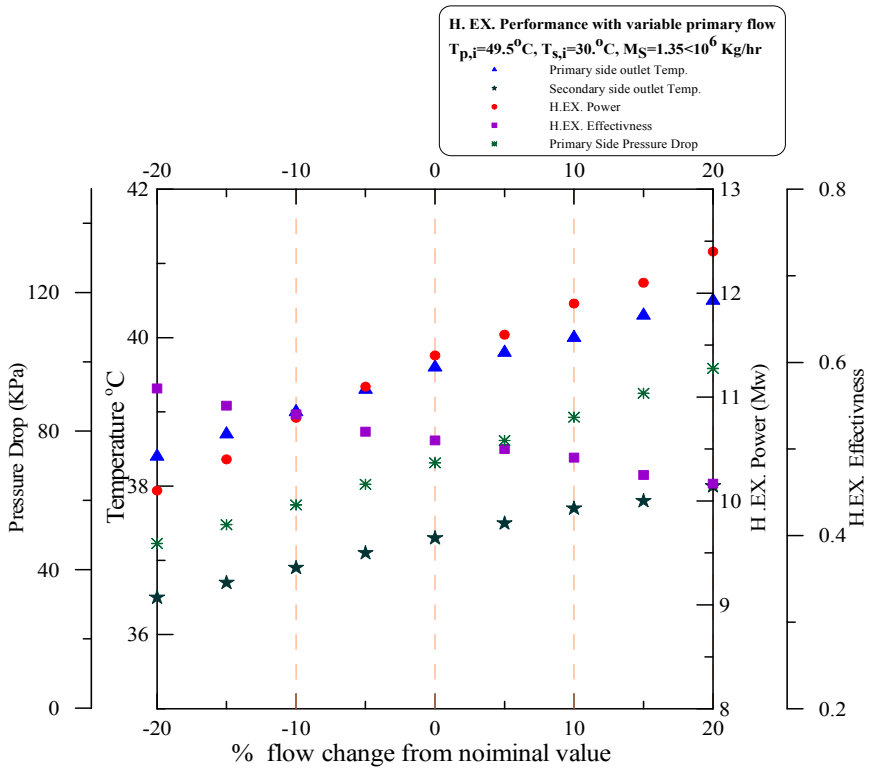

Figure 6. Heat exchanger performance for varying the primary mass flow

The results obtained by A. D. WRIGHT model were represented between brackets in Table 2, to compare them with the developed model results. The comparisons were indicated a good degree of consistency, but A. D. Wright model has a limited using for the cases with fixed flow and only the variations in the HEX plates. Also, it is required the known of the previous PHE performance to make a new study by A. D. Wright model.

PHE performance for loss of flow transient:-

A trip in the primary core cooling system pump, while the reactor was operated at full power (22MW), is one of the probable events that cause loss of flow transient. Figure 8 shows the experimental values of the total core flow cost down (two primary pumps) and the neutronic core decay power [12] that were feed to the PARET code to calculate the average core outlet temperature variation with time; hence this temperature was feed to the PHE developed model, as an inlet temperature to the PHE primary side, to calculate both the PHE power and the removed energy variation with time as shown in Figure 9. The calculated thermal power through the PHE was followed the flow cost down trend and did not follow the core power trend, where the core power is related to neutronic calculations that are based on fission fragments decay. After a 62 sec from the initiation of loss of flow transient, the PHE primary side outlet temperature was equaled to the secondary side inlet temperature (30 ^{o}C), this time is adequate to change the core cooling mode from forced to natural by opening a passive device (flapper valve) to establish it. During this time the PHE with the aid of inertia flywheel were dissipated energy of 207.917 MJ through the cooling tower and protected the reactor core over heating.

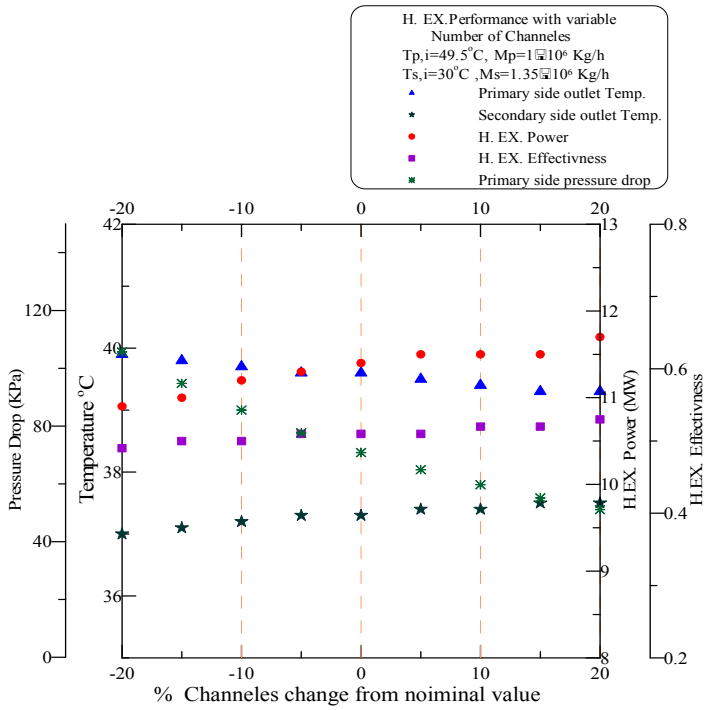

Figure 7. Heat exchanger performances for varying the number of plates

The power at which the PHE flow was cut of is 1.781 MW, it a reasonable value where the reactor main pool has the capability to remove up to 2 MW through the natural convection cooling. If there was no flywheel the PHE flow is cut of at the moment of scram, hence energy of 207.917 MJ will be dissipated in the core zone before the establishment of the natural convection cooling mode, the matter that will cause core over heating, local boiling and voids. The PHE temperature responses, effectiveness and pressure drops during the LOF transients were illustrated in Figure 10 and Figure 11. The primary side outlet temperature and the secondary side outlet temperature approximately

reached each other after 62.0 sec; hence the effectiveness was reached its maximum value at this time (0.9). By this time a nearly stable HEX. Performance was obtained where the PHE primary flow and hence primary side pressure drop were reached their lower values.

CONCLUSION

A M30-FG PHE with 161 plates, a total heat transfer area of 292 m^2, nominal primary side flow of 10^6 Kg/h and nominal secondary side flow of 1.35×10^6 Kg/h, can withstand the increase in flow through its primary side by a 20% of its nominal value without exceeding the pressure drop limit (100 Kpa) and can transfer a thermal power up to 12.4 MW to the cooling tower, where both the PHE primary side inlet temperature and the secondary side inlet temperature are fixed to 49.5 ^oC and 30 ^oC respectively. This type of PHE can withstand a reduction in its nominal number plates by -15% without affecting its thermal performance. While increasing the number of its plates with the same nominal flow does not produce a significant effect. The inertia flywheel with the PHE plays a strong turn during the first few

seconds after (62 sec) SCRAM trip, where they protect the core from over heating and hence from local boiling. During this time a dissipated energy of 207.917 MJ through the cooling tower is achieved. The power at which the PHE flow is cut of is 1.781 MW, hence the flapper valve open to change the cooling mode from forced to natural. This transition ensures the reactor safety criteria; the maximum removed power by natural convection is 2 MW.

ENHANCEMENT, SUPPRESSION AND INVERSION OF THE CONVECTIVE MODES OF A PARAMAGNETIC FLUID IN A DIFFERENTIALLY HEATED CUBICAL CAVITY PLACED UNDER A STRONG MAGNETIC FIELD

T.P. Bednarz[1,*], E. Fornalik[2], J.S. Szmyd[2], C. Lei[1], J.C. Patterson[1], F. Xu[1], H. Ozoe[3]

ABSTRACT. This report is concerned with the influence of a strong magnetic field generated by a 5-Tesla and 10-Tesla super-conducting magnet respectively on natural convection of a paramagnetic fluid in a differentially heated cubic enclosure. The working fluid is prepared to be a mixture of an aqueous solution of glycerol (80% in mass) and gadolinium nitrate hexahydrate of 0.8 mol/kg. A small quantity of thermo-chromic liquid crystals is added to the working fluid for visualisation purpose. The cube of side 0.032 m is heated and cooled from two opposing vertical walls and placed under different configurations of the magnetic field. Flow visualization and heat transfer measurements are carried out to show a full picture of the flow phenomena. Three different cases are described here in order to show how to enhance, suppress or invert the convective motion and heat transfer.
It should be emphasized that knowing how to control the magnetic force makes it possible, for instance, to suppress the influence of the gravity and to study particular low gravity convection phenomena under terrestrial conditions. It is far more economical to conduct preliminary experiments on earth before sending a space-craft to the outer space to do the experiments. Moreover, magnetic convection finds applications in crystal growth, mixing, material processing, etc, where the effects of convection may be undesirable.

INTRODUCTION

The phenomenon of natural convection is present everywhere in nature and is ubiquitous in our daily experience. In many scientific and industrial applications, it is often necessary to control convective flows induced by natural convection in order to achieve specific outcomes. This work presents a novel method for controlling convective flows in terrestrial conditions, i.e., enhancing, suppressing, or inverting convection with the application of a magnetic field acting on a common paramagnetic fluid. More specifically, the focus here is on understanding the relation between an applied magnetic field and the resulting flow and the corresponding heat transfer rate for a particular thermal system configuration. The present work is also a step forward in understanding the complex processes that may occur in microgravity environments in space where natural convection has no place. Moreover, conducting experiments in terrestrial conditions as though they were occurring in the Cosmos provides an economical way to investigate processes relevant to microgravity environments. Acting along with

the gravitational force, the magnetic force has great potential for applications ranging from quasi-non-gravitational or enhanced gravitational acceleration at a scale comparable with the bore of a super-conducting magnet to micro-scale magnetic effects in atomic level processes.
It is well known that a magnetic field acts not only on ferrous materials but also on ordinary substances such as water, air, wood, etc. The atomic configuration of materials with a very small value of magnetic susceptibility determines whether a specific material is paramagnetic or diamagnetic, that is, whether it is attracted to or repelled by the magnetic field. Paramagnetic materials have positive magnetic susceptibility which is a function of the absolute temperature. In contrast, the magnetic susceptibility of diamagnetic materials is negative and independent of the temperature.
The present experiments are pertinent to the thermal magnetic convection in a cubic cavity filled with a paramagnetic fluid. Magnetic convection is driven by the magnetic buoyancy force, which is proportional to the gradient of the square of the magnetic induction and also depends on the temperature field [1-3].
A number of examples of application of a magnetic force on the convection of paramagnetic or diamagnetic fluids have been reported in the past, after the discovery in 1986 of high-temperature super-conducting materials for producing super-conducting magnets for laboratory use. In 1991, Braithwaite et al. [4] described the enhancement or cancellation of gravitational convection due to a magnetic field for a solution of gadolinium nitrate in a shallow layer heated from below and cooled from above. Subsequently many research works have been conducted in this area. Ikezoe et al. [5] has succeeded in droplet levitation for diamagnetic and paramagnetic fluids. The group of Wakayama investigated the behaviour of air in a strong magnetic field, and a new magneto-aerodynamic airflow generation [6] and the promotion of combustion [7] were reported. Also, Kitazawa and co-workers [8, 9] have reported many new findings and applications of the magnetic force. Most of the early works on magnetic convection are summarized in a recent book by Ozoe [2].
The present work shows that, by applying a magnetic field, the convective motion can be suppressed, enhanced or inverted, and the heat transfer rate can be controlled accordingly.

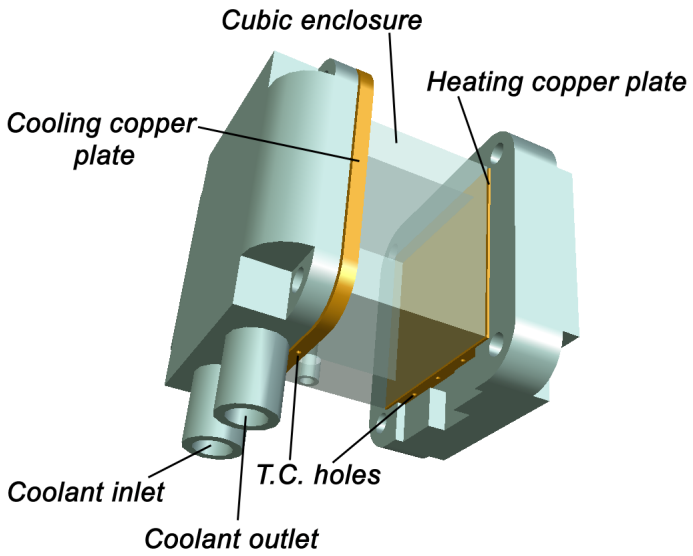

Figure 1. Experimental apparatus. Internal dimensions of the cube are 0.032m × 0.032m × 0.032m.

EXPERIMENTAL APPARATUS

The experimental apparatus is comprised of five separate elements and is shown in Figure 1. These include two copper plates (one for the cooling side, the other for the heating side), a cubical cavity of internal dimensions of l = 32 mm on each side made of transparent Plexiglas, and the cooling and heating chambers, also made of Plexiglas. The experimental system was set up in a way so that both copper plates were vertical. One copper plate was heated with rubber-coated nichrome wire located in

the heating chamber and connected to a DC power supply Kikusui PAK 60-12A, and the other copper plate was cooled by running cold water from a constant temperature circulator LAUDA RK20 KS. The electric voltage and current of the nichrome wire were measured with two multi-meters Keithley 2000 respectively. The temperatures of the two copper plates were measured with six T-type thermocouples inserted into small and deep T.C. holes, three in each plate for averaging purpose.

WORKING FLUID AND EXPERIMENTAL PARAMETERS

The enclosure was filled with an 80% mass aqueous solution of glycerol in which gadolinium nitrate hexahydrate $Gd(NO_3)_3{\cdot}6H_2O$ was dissolved to a concentration of 0.8 mol/kg in order to make the working fluid paramagnetic. The magnetic susceptibility of the working fluid was measured with a magnetic susceptibility balance by Evan's method (MSB Mk1) [12], the density ρ with a pycnometer (Brand 25 ml), the viscosity μ with an Ostwald's viscometer and the thermal expansion coefficient was estimated using $\beta = -\rho^{-1}\left(\partial\rho/\partial T\right)$. The other properties were estimated for the 80% mass aqueous solution of glycerol [13]. The major properties of the working fluid are listed in Table 1.
The present experiments may be characterized by dimensionless parameters such as the Rayleigh number *Ra* which is based on the temperature difference obtained in convection experiments and is defined as follows:

$$Ra = \frac{g\beta l^3\left(\theta_{hot} - \theta_{cold}\right)}{\alpha\nu} \tag{1}$$

and the Prandl number computed at the reference temperature:

$$Pr = \frac{\nu}{\alpha} \tag{2}$$

where θ_{hot} and θ_{cold} are the hot and cold wall temperatures respectively measured as the average of the three thermistor readings from each plate, α is the thermal diffusivity. The dimensional values of magnetic induction measured in the centre of the solenoid system are used to characterize the strength of the magnetic field.

Table 1
Important properties of the working fluid

Property	α [13]	β	λ [13]	μ	ν	ρ	χ	Pr
Value	1.01×10^{-7}	0.52×10^{-3}	0.397	86.9×10^{-3}	5.9×10^{-5}	1463	23.1×10^{-8}	584
Unit	m^2/s	1/K	W/(m·K)	Pa·s	m^2/s	kg/m^3	m^3/kg	–

FLOW VISUALISATION

In order to visualize and measure the temperature field, a very small amount of thermo-chromic liquid crystal slurry (KWN-20/25, Japan Capsular Products) was added to the working fluid. The colour response of the liquid crystal slurry is presented in Figure 2. The concentration of the slurry was adjusted for each experiment, and was in general less than 0.1 ml per litre of the working fluid. Quantitative temperature information was extracted non-invasively from the experimental photographs using the Particle Image Thermometry (PIT) technique [14]. This was done using a calibrated hue versus temperature curve. With the calibration data, every pixel of the colour photograph was transformed to a temperature value, and thus accurate experimental temperature maps were obtained. More details about this method can be found in [14-17].

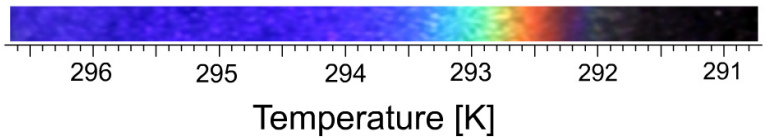

Figure 2. Relation between temperature and color indicated by the TLCs used in the experiment.

For visualization purpose, the 10-Tesla super-conducting magnet was used. The cube was placed outside of the bore for clear view of the flow field. The centre of the cube was always placed at a distance of 0.233 m from the centre of the solenoids and depending on the case investigated the magnet could be oriented vertically or horizontally. A light sheet coming from a projector lamp located at a distance of 3 m was used to illuminate a middle cross-section of the cube giving a colour map of the temperature field. All experimental images were taken by a Canon EOS 10D digital camera with a Canon EF 70-200mm f2.8 IS lens after a steady state was attained for each case.

HEAT TRANSFER MEASUREMENTS

For the purpose of heat transfer measurements, the method developed by Ozoe and Churchill [18] was used. At first, a conduction experiment was carried out. The cubic enclosure was placed in a position to be heated from above and cooled from below. Then, the temperature difference was measured between the hot and cold walls at various heating rates with the cold plate held at a fixed temperature and controlled by the thermostatic water bath and the opposite plate heated by the nichrome wire. The net conduction heat flux through the working fluid layer was then estimated theoretically using Fourier's law:

$$Q_{cond\_net} = \frac{\lambda A(\theta_{hot} - \theta_{cold})}{l} \tag{3}$$

where A is the area of the cross section.
The power input $Q_{cond} = UI$ [W] to the heated cooper plate, where U is the measured voltage and I is the measured current, allowed an estimate of the heat loss which is given by:

$$Q_{loss} = Q_{cond} - Q_{cond\_net} = Q_{cond} - \frac{\lambda A(\theta_{hot} - \theta_{cold})}{l} \tag{4}$$

The net convection heat flux could be then calculated from a specific convection experiment carried out with the same experimental apparatus. The measured value of the heat supply from the heated plate ($Q_{conv} = UI$) can be directly used to calculate Q_{conv_net} as follows:

$$Q_{conv\_net} = Q_{conv} - Q_{loss} \tag{5}$$

with the assumption that the heat loss (Q_{loss}) for a specified temperature difference ΔT depends only on the temperature difference and does not depend on the heat transfer mode inside the enclosure (whether it is in conduction or convection mode) [18]. Therefore, the estimated values of Q_{loss} from the conduction experiment are also used in the convection experiments.
After the two quantities Q_{cond_net} and Q_{conv_net} are determined, the average Nusselt number can be easily obtained for A= ℓ^2 as follows:

$$Nu = \frac{Q_{conv\_net}}{Q_{cond\_net}} = \frac{Q_{conv} - Q_{loss}}{l\,\lambda(\theta_{hot} - \theta_{cold})} \tag{5}$$

It should be pointed out that all heat transfer measurements were carried out using the 5-Tesla super-conducting magnet instead of the 10-Tesla super-conducting magnet. For these measurements the experimental apparatus was placed inside the bore of the magnet and thermally insulated to minimise the heat loss. Readers can refer to [2-3, 10-11, 14] for further details.

RESULTS

The results presented in this paper are for the cases of natural convection resulted in a differentially heated cube subject to a strong magnetic field, and three different configurations are considered. The purpose here is to demonstrate how to enhance, suppress or invert the convective motion using a strong magnetic field. Also heat transfer measurement results are described here for each of the case.

Enhancement of the convection

Enhancement of the convection using a strong magnetic field is presented for the case in which the super-conducting magnet was oriented horizontally and the hot wall was close to the solenoid. The gravitational and magnetic buoyancy forces acting on the fluid for this case are depicted in Figure 3a. Figure 3a also plots the average Nusselt numbers versus the magnetic induction measured at the centre of the solenoid. As seen in this figure, the average Nusselt number at the magnetic induction of 0 T was around 5 as the convective flow was present in the enclosure without the magnetic field. As the strength of the magnetic field was increased, the heat transfer rate also increased. Therefore, the results clearly indicate the enhancement of the convection with the increasing strength of the magnetic field in this case.
Figures 3b and 3c show vertical cross-sections of the temperature fields at 0 T and 10 T respectively. In these figures, the experimental images along with the isotherms obtained using the PIT method are shown. At the magnetic induction of 0 T, the usual natural convection temperature structures can be observed. The cold fluid close to the cooled wall moves down the wall and then along the bottom toward the right-hand side hot wall. Being heated up there, the fluid climbs up the heated wall and then moves along the top ceiling toward the left-hand side cooled wall. A convective circulation was established. An increase in the strength of the magnetic field causes stronger convection in this case as indicated by the increase of the heat transfer rate. It is seen in Figure 3b that the thicknesses of the thermal layers above the floor and under the ceiling are reduced at 10 T, suggesting a stronger circulation. At the magnetic induction of 10 T, clear thermal tongues are observed close to the cold and hot walls. They are caused by strong attraction of the relatively colder fluid towards the solenoid and repulsion of the warmer fluid. In fact, paramagnetic fluids are always attracted toward the magnet, however to obey Curie and continuity laws in the enclosed cavity, the warmer fluid appears to be repelled, i.e., is pushed or squizzed by the colder fluid which is always attracted more than the warmer fluid.

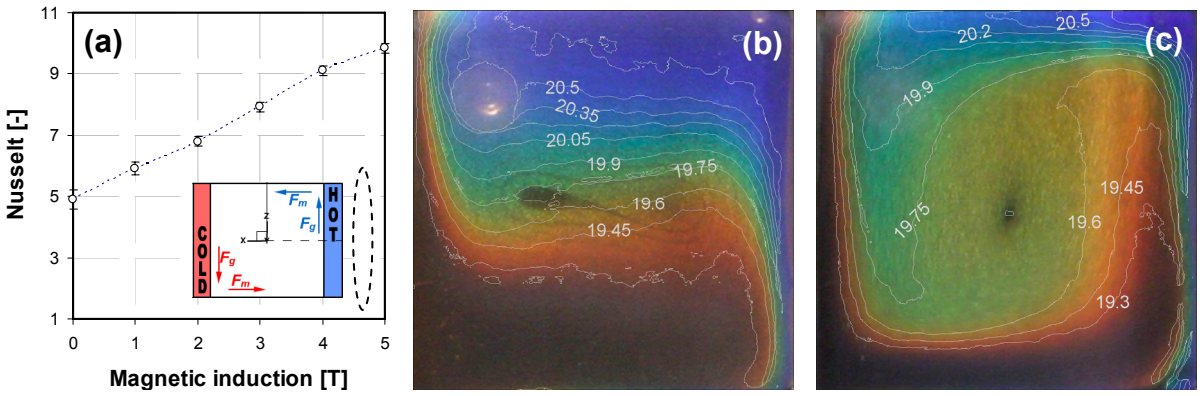

Figure 3 Enhancement of the convection. (a) Nusselt numbers at various magnetic inductions (obtained with *Ra* ranging from 1.49×10^5 to 9.93×10^4); (b) and (c) TLC color images and temperature profiles at (b) 0 T; (c) 10 T.

Suppression of the convection

Suppression of the convection using a strong magnetic field is presented for the case in which the super-conducting magnet was oriented horizontally and the cold wall was close to the solenoid. The gravitational and magnetic buoyancy forces acting on the fluid for this case are depicted in Figure 4a. Figure 4a also plots the average Nusselt numbers versus the magnetic induction measured at the centre of the solenoid. As seen in this figure, the average Nusselt number at the magnetic induction of 0 T was around 3.7 as the convective flow was present in the enclosure without the magnetic field. It is worth noting that reported average Nusselt numbers at the 0-T magnetic induction are not the same for different experiments (refer to Figures 3a and 4a). This is due to some adjustment of the experimental conditions from one experiment to another. The adjustment is necessary to ensure the observed temperature field is always within the visible range of the TLCs over the full range of the magnetic induction. It is seen in Figure 4a that, as the strength of the magnetic field was increased, the heat transfer rate decreased. Therefore, the results clearly indicate the suppression of the convection with the increasing strength of the magnetic field in this case.
Figure 4b shows the isotherms at a mid-vertical plane of the enclosure at the magnetic induction of 0 T. The left side wall is heated and the right side wall is cooled. Since the walls are made of copper plate, the isothermal condition is well satisfied. These isotherms are typical for pure natural convection with a clockwise circulation and a thermal stratification in the core region. Figure 4c shows the results obtained at the magnetic induction of 10 T. The isotherms become approximately vertical, indicating a conduction-like temperature structure. In this case, the cold fluid is trapped close to the cooled vertical wall by the strong magnetic field, and as seen the convection in the enclosure is suppressed.

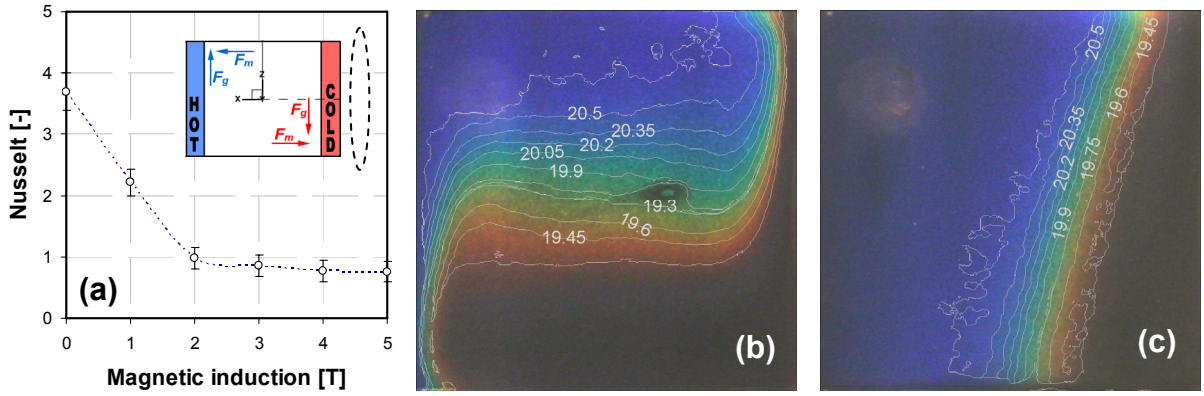

Figure 4 Suppression of the convection. (a) Nusselt numbers at various magnetic inductions (obtained with *Ra* ranging from 1.49×10^5 to 9.93×10^4); (b) and (c) TLC color images and temperature profiles at (b) 0 T; (c) 10 T.

Inversion of the convection

Inversion of the convective motion using a strong magnetic field is presented for the case in which the super-conducting magnet is placed vertically with the cube located below the solenoid. The Nusselt numbers were estimated from equation (5) and are presented in Figure 5a. The Nusselt numbers are plotted versus the maximum magnetic induction. Also, as shown in Figure 5a, the magnetic and gravitational buoyancy forces act in the opposite direction and when the strength of the magnetic field is relatively weak, they compensate each other. The Nusselt number reaches its minimum at around 1 T. For higher strengths of the magnetic induction, the Nusselt number increases with the increasing magnetic induction. Therefore, it can be said, that when the magnetic field strength increases, the magnetic buoyancy force becomes dominant and the convection is inverted.
At 0 T (Figure 5b) the usual gravitational convection occurred. However, when the magnetic field is imposed, the magnetic buoyancy force is expected to cancel or overcome the gravity effect. At 8 T, the

magnetic force is already dominant and the convection is reversed in comparison with that at 0 T. As seen in Figure 5c, relatively colder fluid is attracted to the solenoid's location. The cold fluid moves up along the left-hand side cooled wall, and then along the top ceiling toward the heated wall. After being heated by the hot wall, the relatively warmer fluid falls down along the heated wall.

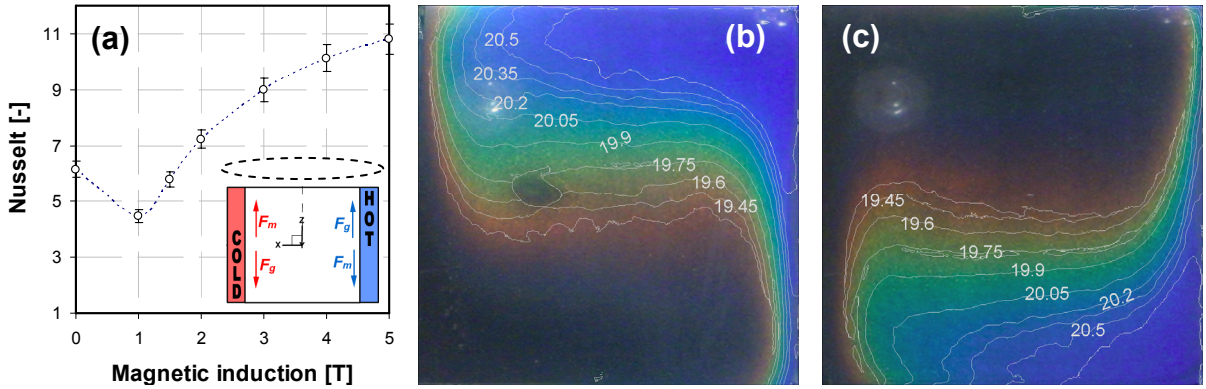

Figure 5 Inversion of the convection. (a) Nusselt numbers at various magnetic inductions (obtained with *Ra* ranging from 1.62×10^5 to 9.51×10^4); (b) and (c) TLC color images and temperature profiles at (b) 0 T; (c) 8 T.

CONCLUSIONS

In this paper, convection of a paramagnetic fluid in a differentially heated cubical enclosure subject to a magnetic field has been investigated experimentally. The enclosure was placed in different configurations relative to the magnetic field. As demonstrated above, using a strong magnetic field we can either enhance, suppress or invert the usual gravitational convection with different combinations of the two forms of body forces (gravitational and magnetic buoyancy forces) that act together to drive thermo-magnetic convection of a paramagnetic fluid. For instance, a suppression of the convection to an almost conduction-like state was presented. The cold fluid was trapped by the magnetic buoyancy force acting in a horizontal direction along the cold vertical wall situated close to the solenoid system. Another example presents an inversion of the usual gravitational convection when the magnet is located above the enclosure. The purpose of this study is to demonstrate that gravitational convection can be controlled in terrestrial conditions with the application of a sufficiently strong magnetic field. This finds applications in many industrial processes such as crystal growth procedures, in which gravitational convection is undesirable.

FLUCTUATING AND TIME AVERAGED HEAT TRANSFER CHARACTERISTICS OF A STEADY JET AT LOW REYNOLDS NUMBERS.

R. Farrelly *, A. McGuinn, T. Persoons, D. B. Murray

Trinity College Dublin, Dublin, Ireland

ABSTRACT**.** A study has been carried out to compare fluctuating and time averaged heat transfer measurements of a steady impinging air jet at low Reynolds numbers. The steady jet issued from a 5mm diameter orifice plate with air being supplied by a compressor via a plenum chamber, and being controlled by a mass flow controller. Tests were conducted for Reynolds numbers ranging from 1000 to 4000, and for non-dimensional surface to jet exit spacings (H/D) from 1 to 6. Initial studies have shown a distinct difference between trends in time-averaged and fluctuating Nusselt number profiles. Whereas the time-averaged profiles show a uniform/linear increase with Re from 1000 to 4000, the fluctuating Nu profiles seem to indicate a transition from a nearly laminar jet at Re=1000 to turbulent jets at Re = 3000, 4000.'

Keywords: *Steady Jet, Fluctuating, Nusselt Number, Reynolds number, Impinging, Velocity, PIV*

INTRODUCTION

Steady impinging jet heat transfer has received considerable attention over the last few decades particularly in many industrial and engineering applications (e.g. manufacturing, material processing and electronics cooling). This is largely due to the fact that an impinging air jet is known to yield relatively high local and area averaged convective heat transfer coefficients, O'Donovan et al. [1]. Hollworth and Durbin [2] investigated the impingement cooling of electronics and Babic et al. [3] used jet impingement for the cooling of a grinding process. In these, and in other cases research has been conducted with a specific application as the focus but there has also been many investigations into the fluid flow and heat transfer characteristics. These have led to the identification of several parameters which influence heat transfer on the impingement surface.

The flow and heat transfer characteristics of an impinging jet are affected by numerous parameters like confinement and impingement angle but the two parameters with greatest influence are the jet Reynolds number, and the surface to jet exit spacing (H/D). Impinging jets are commonly divided into three regions on the basis of the flow structure (i) the free jet region, (ii) the stagnation region and (iii) the wall-jet region, as illustrated in figure 1. Numerical modelling and theoretical studies have also formed part of the extensive research into jet impingement heat transfer; a theoretical study by Shadlesky [4] developed a solution for heat transfer at the stagnation point. More fundamental research has been conducted into the effects of turbulence on heat transfer. Jet turbulence intensity has been augmented by Gardon and Akfirat [5] by the use of turbulence grids at the jet exit. The flow along the plate from the geometric centre through the stagnation zone and the eventual formation of the wall jet are investigated by Lytle and Webb [6]. Although jet impingement heat transfer has been studied extensively by many researchers including O'Donovan

et al [7], the amount of information available for low Reynolds number jet flows, in the laminar to turbulent transition range, is more limited. In particular the approach of examining both the fluctuating and time averaged heat transfer characteristics at low Reynolds numbers has yet to be explored fully.

The purpose of this study is to acquire an understanding of how steady impinging air jets behave at low H/D values and low Reynolds numbers, by comparing time averaged and fluctuating heat transfer data, with the use of Particle Image Velocimetry (PIV) to elucidate the heat transfer results.

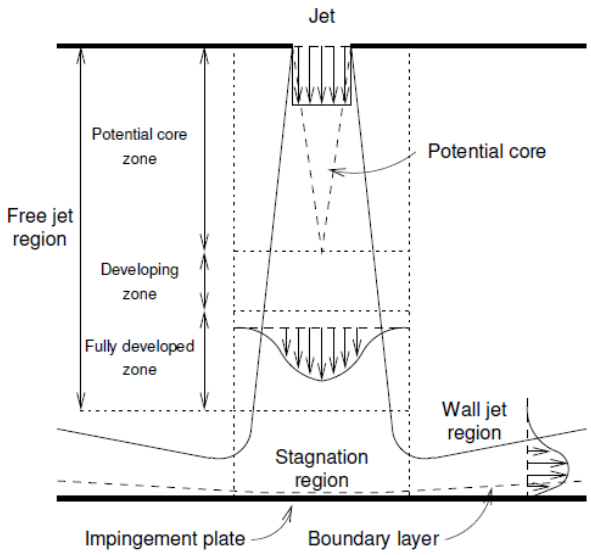

Figure 1. impinging jet flow regimes [8]

EXPERIMENTAL SETUP

There are three main elements that make up the experimental rig, these being the steady jet, heated, instrumented impingement surface and the particle image velocimetry (PIV) system. The impingement surface and the jet are mounted on independent carriages that travel on orthogonal tracks; the carriage for the impingement surface is moved using a computer controlled traverse, whereas the carriage for the jets is moved using a manually operated lead screw actuator. The instruments associated with the heated impingement surface are two single point heat flux sensors and two thermocouples. The rig design is presented in figure 2.

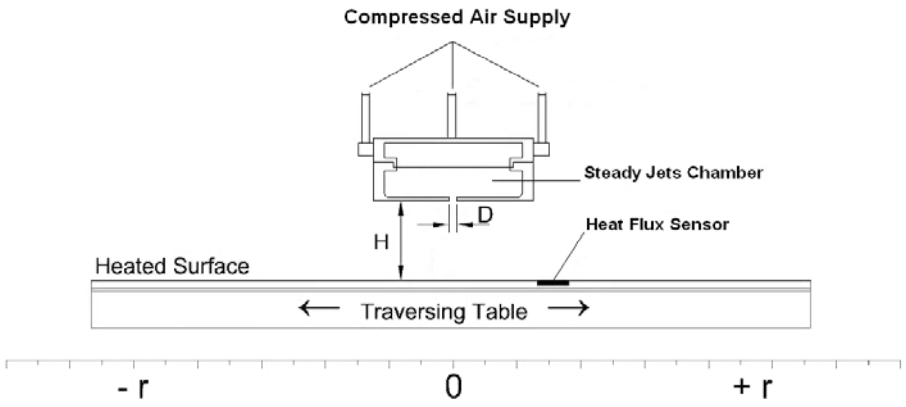

Figure 2. Schematic of the steady jet apparatus

The cavity body and orifice plate are constructed from a thermoplastic and were fabricated using a method of rapid prototyping called fused deposition modelling. The cavity has an approximate volume of 100cm^3 with an orifice diameter of 5mm. Care was taken to ensure a well defined outlet velocity profile with the use of a flow straightener. The steady jet is clamped onto a carriage, which allows for height adjustment from 1 to 6 diameters above the impingement surface. The jet is fixed at a normal angle of impingement (90°).

The steady jet was formed from a constant compressed air source that was maintained at flow rates corresponding to jet Reynolds numbers ranging from 1000 to 4000 by an MKS® Instruments 1579A Digital Mass Flow Controller, which has an accuracy of 1% of full scale and a repeatability of ± 0.2% of full scale (300 slm). The jet impinges onto a surface that consists of a 5mm thick flat copper plate measuring 425mm x 550mm. To the underside of the plate a silicon rubber heater mat is glued with a thin layer of adhesive. The mat is approximately 1.1mm thick. The underside of the plate and mat assembly is insulated from the surroundings. The entire assembly is such that it approximates a uniform wall temperature boundary condition. The system is typically operated at a surface temperature of 40°C.

Two sensors were utilised in this study (i) an RdF Micro-Foil® heat flux sensor, and (ii) a Senflex® hot film sensor. The first sensor measures the temperature differential across a known thermal barrier using a differential thermopile. The heat flux through the sensor is based on the following equation:

$$\ddot{q} = k_s \frac{\Delta T}{\delta} \tag{1}$$

where ΔT is the temperature difference across the thickness (δ) of the barrier and k_s is the thermal conductivity of the barrier (kapton). A single pole T-type thermocouple is also embedded in this sensor to measure the local temperature.
