Both sensors are positioned centrally on the plate, and together with the jet and plate carriage arrangement, allow for heat transfer measurements beyond 20 diameters from the geometric centre of the jet. In this study, testing has only been concerned within the region of 1 to 6 diameters from the geometric centre of the jet.

The Senflex® hot film sensor operates in conjunction with a Constant Temperature Anemometer (CTA) to measure the fluctuating heat flux to the impinging jet. This sensor consists of a nickel sensor element that has been electron beam deposited onto a 0.051mm thick Upilex S polyimide film. The hot film element has a physical area of approximately 0.1mm x 1.44mm and is less than 0.2μm thick. The sensor has a typical cold resistance of between 6 and 8 Ohms. Two copper strips are also deposited on the film; these provide terminals for connection to the CTA. These strips have a resistance of approximately 0.002 Ω /mm. The hot film is maintained at a slight overheat (≈1°C) above that of the copper plate using a Dantec StreamLine CTA. The power required to maintain the film at this overheat is equal to the heat actively being dissipated from the film. The CTA essentially acts as a Wheatstone bridge where the hot film acts as one resistor in the bridge. The resistance of the film varies with temperature and therefore, this film temperature can be controlled by varying a decade resistance which forms one arm of the Wheatstone bridge. The square of the voltage required to maintain the film at a constant temperature is proportional to the heat transferred to the air as described in equation (2):

$$q_{dissipated} \propto \frac{V_{out}^2}{R} \tag{2}$$

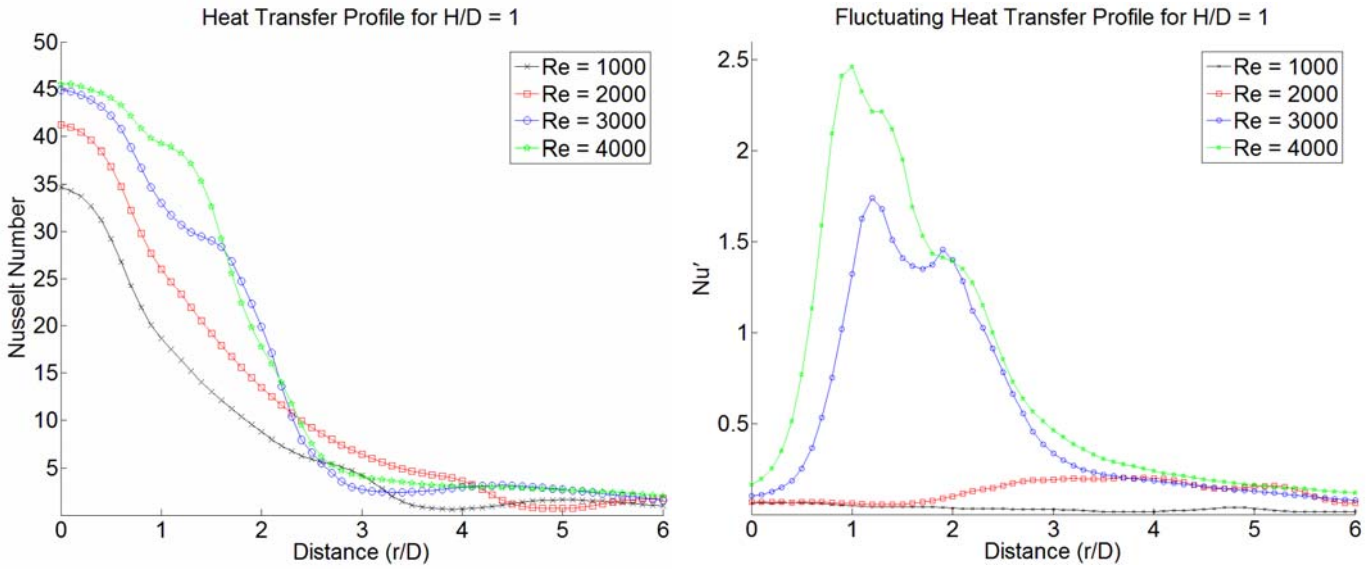
Time averaged velocity measurements have been performed using time resolved Particle image velocimetry (PIV). PIV has provided insight into both velocity and fluctuating nature of the jet flow at different Reynolds numbers.

The PIV system comprises of a Quantronix Darwin-Duo Nd:YLF twin cavity laser and a LaVision HighSpeedStar6 CCD camera.(1024x1024 pixels, 12 bit) with a 105mm lens. A glycol-water aerosol is used for seeding, with particle diameters between 0.2 and 0.3 µm. The velocity fields have been processed with LaVision's Davis 7 software using multi-pass cross-correlation with an interrogation window size decreasing from 64x64 to 16x16 pixels at 50% overlap.

RESULTS AND DISCUSSION

Results have been obtained for a jet that impinges perpendicularly to a flat plate. Four Reynolds numbers have been considered (1000, 2000, 3000, and 4000) and four surface to jet exit spacings (H/D = 1, 2, 4, and 6) were selected as this range provided a clear indication of the effects on impinging jets at low Reynolds numbers and low H/D values.

The results are presented as time averaged heat transfer distributions and fluctuating heat transfer distributions for each H/D from 1 to 6. A direct comparison between the time averaged and fluctuating heat transfer profiles of the jet will be made, with reference to corresponding PIV data where available.



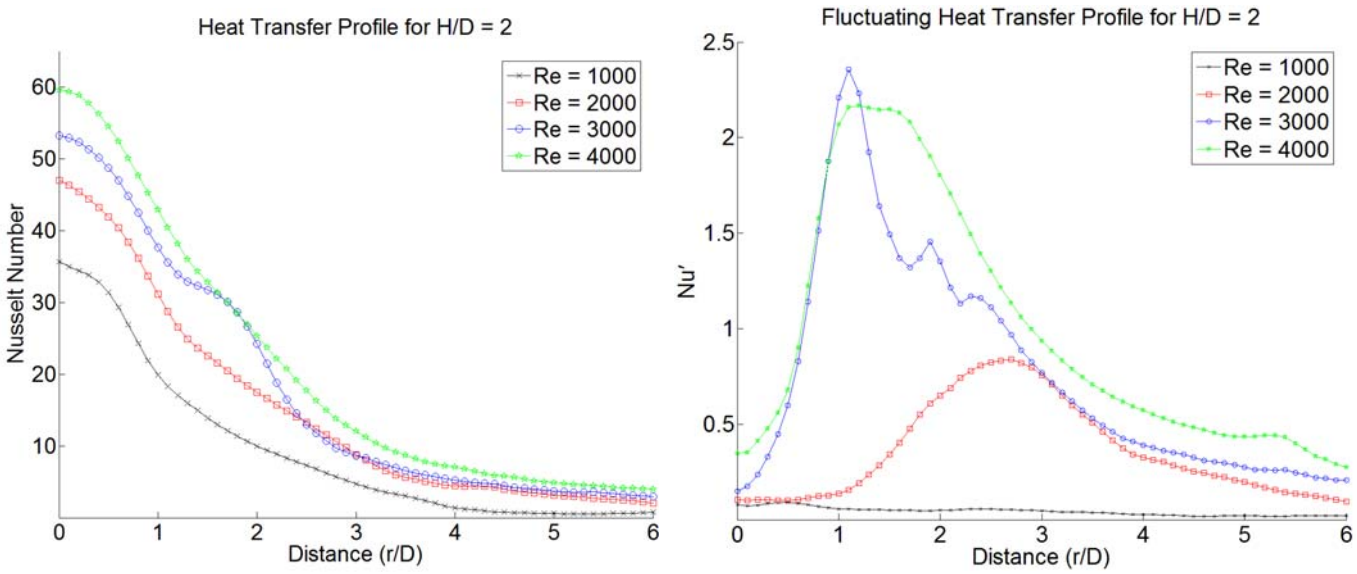
(a) Time averaged heat transfer distribution (b) Fluctuating heat transfer distribution

Figure 3. Time averaged and fluctuating heat transfer profiles H/D=1

Figures 3a and 3b illustrate the heat transfer profiles for the steady impinging jet at matching Reynolds numbers and jet exit to plate spacings (H/D). the presence of secondary peaks at a radial distance of approximately $1 < r/D < 2$ for the time averaged heat transfer distribution there appears

to be a transition to turbulence at Reynolds numbers 3000, 4000. This is clearly evident in the fluctuating heat transfer distribution (figure 3b) at Re = 3000 and 4000. There is quite a large fluctuation in heat transfer present between Re = 3000 and 4000 in figure 3b.

It is worth noting that at this H/D the orifice plate imposes a strong degree of confinement on the jet. As the height of the jet above the impingement surface is increased there is less likelihood of confinement occurring, therefore allowing the jet to fully propagate, and maximum heat transfer to take place.



(a) Time averaged heat transfer distribution (b) Fluctuating heat transfer distribution

Figure 4. Time averaged and fluctuating heat transfer profiles H/D=2

Figure 4 shows the heat transfer results for H/D = 2. From figure 4b, at a Reynolds number of 3000 there is what appears to be a laminar core which results in a transition to turbulence at r/D of approximately 1.5. This is reflected in a local increase in time averaged heat transfer, as shown in figure 4a.

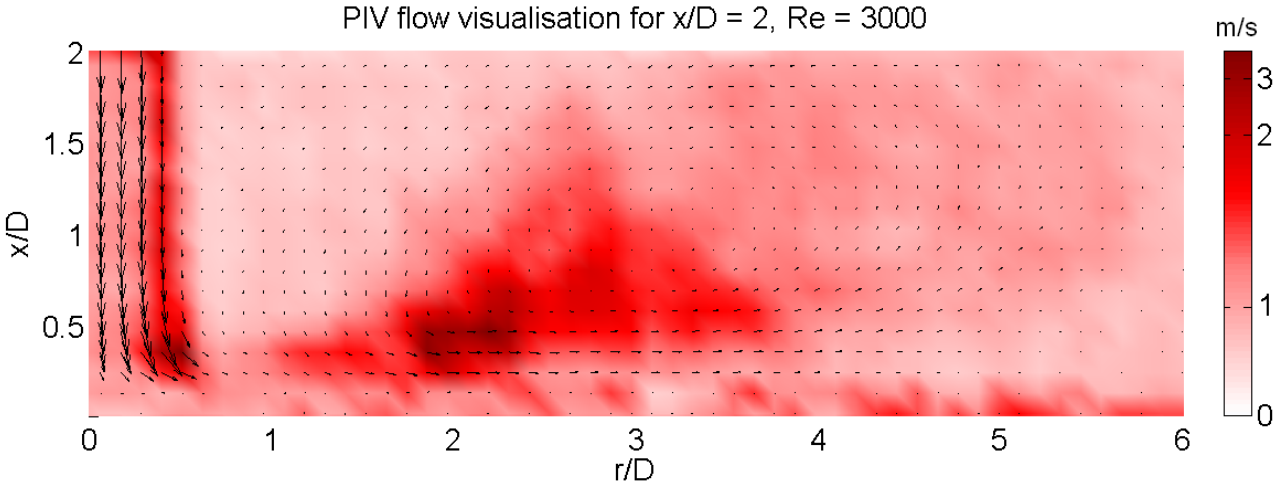


Figure 5. PIV fluctuating velocity plot x/D=2, Re=3000

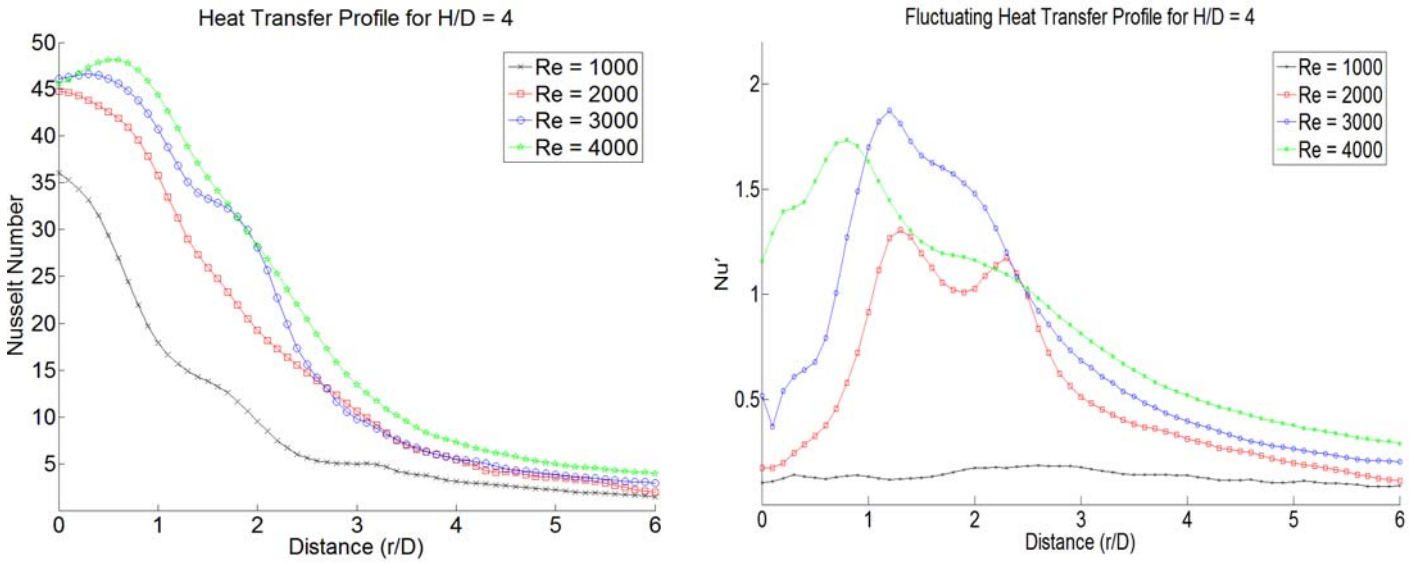
The PIV fluctuating velocity plot is a combination of the mean velocity vectors and the root mean square velocity colour map. The PIV fluctuating velocity scale is defined using a custom colour map where deep red signifies large fluctuations and white represents zero fluctuation. This scale was defined by using the mean and root mean square velocity maps that were outputted from DaVis 7. The R.M.S. velocity scale is defined using the colour bar on each PIV image. The mean velocity scale is from 0 – 17 m/s.

Figure 5 shows the PIV time average velocity plot for x/D = 2 and Re = 3000. It can be seen that there are very large fluctuations in the shear layer before impingement and subsequently a transition to turbulence. Since the jet is laminar at the parameters shown, transition to turbulence after impact and this can be seen in the fluctuating heat transfer and PIV data at $0.5 < x/D < 4$. The core is maintained right up until impingement; there are relatively low velocity fluctuations in the core, a coherent core which results in low fluctuating heat transfer. Where the jet impinges an area of high fluctuation are evident. Areas of recirculation can be clearly seen in the figure 5. The heat transfer fluctuations are caused by vortices in the shear layer impacting upon the plate, this can be seen at $0.5 < x/D < 2$ for both the PIV data and fluctuating heat transfer.



(a) Time averaged heat transfer distribution (b) Fluctuating heat transfer distribution

Figure 6. Time averaged and fluctuating heat transfer profiles

In figure 6 for H/D of 4, there is what appears to be a local minimum at a Reynolds number equal to 4000 on the time averaged heat transfer distribution which correlates with the fluctuating heat transfer distribution. Overall the fluctuations in heat transfer are higher in the stagnation zone, which could mean turbulence starts earlier in the jet due to the higher Reynolds number. There appears to be a loss of momentum in the jet at this H/D, which could be due to a diminished potential core.

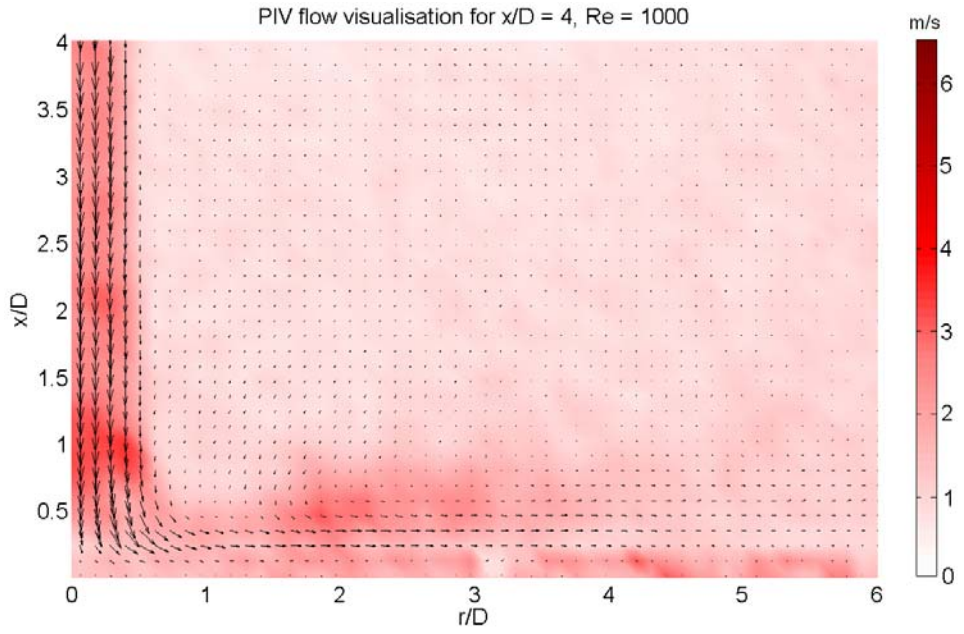


Figure 7. PIV fluctuating velocity plot x/D=4, Re=1000

Figure 7 shows very slight fluctuation in velocity in the core, this is due to a reduced potential core from a loss of momentum at H/D = 4 and low Reynolds number.

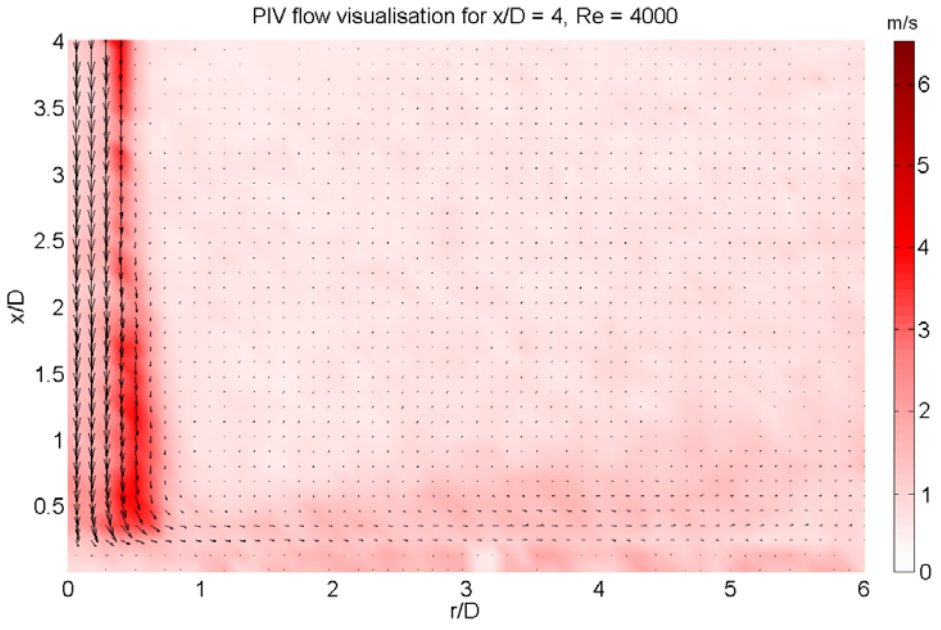

Figure 8. PIV fluctuating velocity plot x/D=4, Re=4000

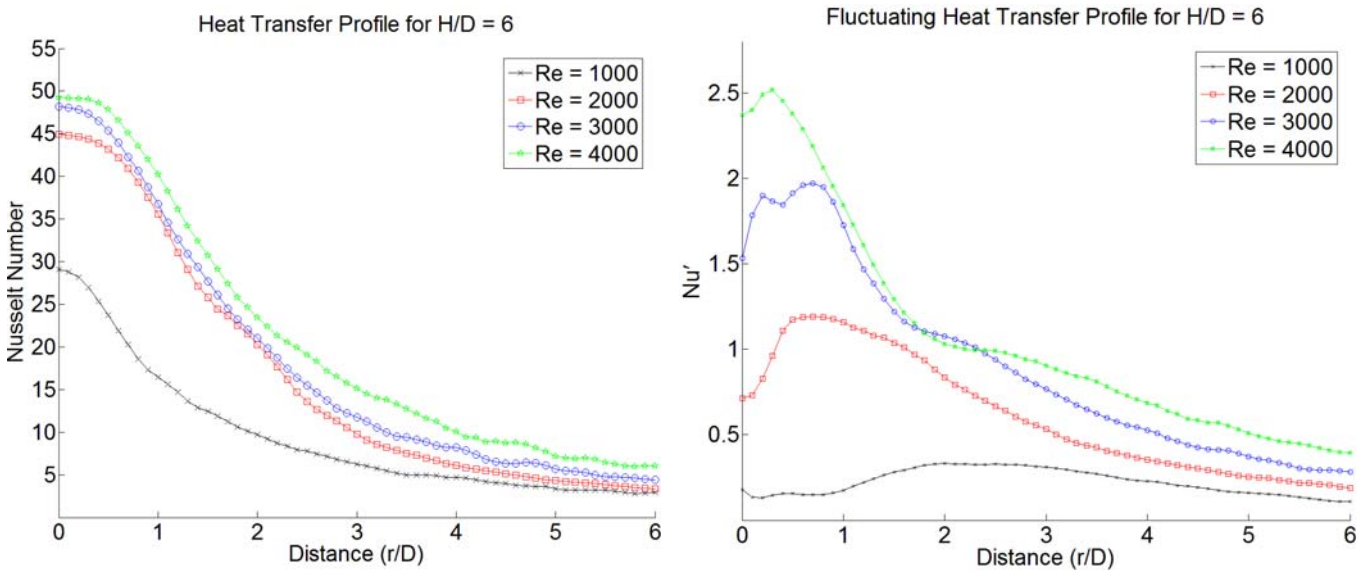
The potential core is maintained at a greater height above the surface due to increased flow momentum, the lower fluctuating velocity in the core corresponds with the low local fluctuating heat transfer (figure 6b) observed at this jet exit to plate spacing and Reynolds number. A turbulent shear layer is observed at this height



(a) Time averaged heat transfer distribution (b) Fluctuating heat transfer distribution

Figure 9. Time averaged and fluctuating heat transfer profiles

Comparison of figures 6a and 9a helps to illustrate the effects that jet exit to plate spacing have on the jet. A loss of momentum for Reynolds number of 1000 is apparent at H/D of 6, as the Nusselt numbers for this Reynolds number are lower than observed in figure 6a at the H/D = 4. The distributions in figure 9a show no evidence of secondary peaks and the Nusselt numbers reduce uniformly with increasing r/D, which indicates that the jet has been able to fully propagate; this is due to the higher jet to plate spacing allowing there to be a more fully developed flow. In figure 9b the Reynolds number of 2000 shows low levels of heat transfer fluctuation upon impingement. It is noted that Re = 1000 remains laminar throughout the H/D values tested (1, 2, 4 and 6)

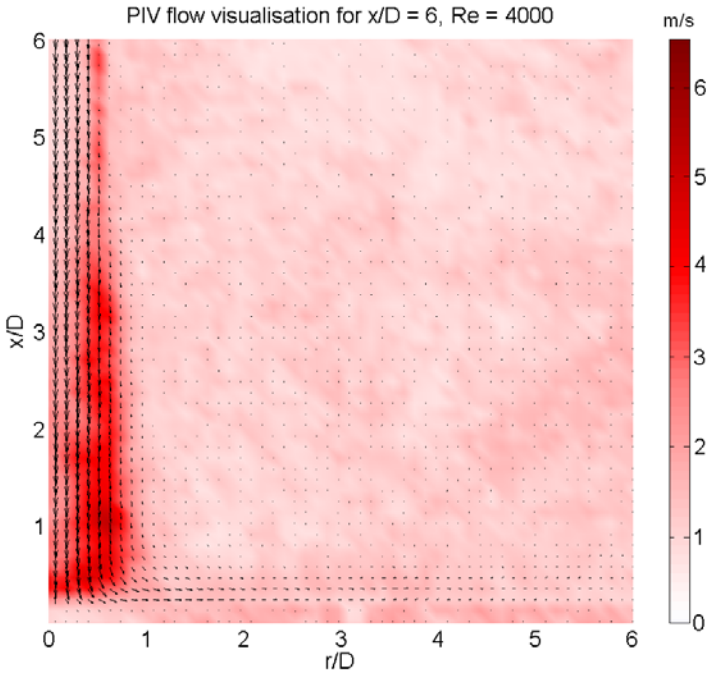


Figure 10. PIV fluctuating velocity plot H/D=6

Figure 10 shows a core that is almost diminished by the time it impinges on the surface and has greater fluctuating velocities. Less momentum in the potential core means that the core is less coherent and more turbulent before impingement, this is indicated by the intensity of the colours and this is also indicated in figure 9b for the fluctuating heat transfer profile. It is worth noting that there are lower fluctuations in the wall jet region for all PIV fluctuating velocity plots.

CONCLUSIONS

Results have been presented for time averaged heat transfer, fluctuating heat transfer and PIV fluctuating velocity plots relating to an axially symmetric impinging air jet. It has been shown that at low jet exit to plate spacing the time averaged heat transfer distribution in the radial direction shows evidence of secondary peaks. These peaks have been reported by several investigators including Farrelly et al [9] and have been attributed, in general, to an abrupt increase in turbulence in the wall jet boundary layer.

The fact that the peaks occur at approximately the same location for both Nu and Nu' distributions indicates a correlation between the heat transfer fluctuations and the mean heat transfer. Increasing Nusselt numbers for the time averaged heat transfer plots can be seen with increasing H/D at large r/D values, due to less confinement.

Peak Nusselt numbers recorded for the range of jet exit to plate spacings occur at an H/D = 2. An increase in H/D results in a loss of momentum and the onset of turbulent flow is reflected in the fluctuating heat transfer distributions at H/D = 4 and above. It is noted from the PIV data presented that there are lower fluctuations in the wall jet region.

A COMBINED EXPERIMENTAL-NUMERICAL APPROACH TO INVESTIGATE HEAT TRANSFER COEFFICIENT IN A TUBE-IN-TUBE HEAT EXCHANGER

F. M. Shemirani, M. A. Akhavan-Behabadi* , H.Aria
Faculty of Mechanical Engineering, University College of Engineering,
University of Tehran, Iran

ABSTRACT. In the present study, the flow boiling heat transfer coefficient of R-134a in a vertical and a horizontal helically coiled tube-in-tube heat exchanger have been investigated experimentally. The refrigerant flow inside the inner copper tube was heated by hot water flows in the annulus in opposite direction. The average vapor quality of R134a in the test section varies from 0.1 to 0.8. The refrigerant mass fluxes are 112, 132, and 152 kg/m^{2}s. A commercial Computational Fluid Dynamics package [FLUENT 6.0] was used to predict water-side heat transfer coefficient to find the best results for our special case. Furthermore, the variation of heat transfer coefficient with vapor quality and the mass flux is studied experimentally.

INTRODUCTION

The heat transfer equipments like evaporators and condensers have an important role to play in different industries such as refrigeration, air-conditioning, power plant, and chemical industries. To save the limited available energy resources, design and manufacturing of efficient heat transfer equipments is essential. Different methods have been used by numerous investigators to increase the heat transfer rates in these equipments.

One of the techniques to enhance the heat transfer coefficients in two phase flow is to use helical pipes instead of straight ones. The modification of the flow in the helically coiled tubes is due to the centrifugal forces[1]. The curvature of the tube produces a secondary flow field with a circulatory motion in the gas core, which pushes the liquid particles toward the center of curvature of the coil [2]. Thus the application of curved tubes in heat exchange process can be highly beneficial in comparison with the straight tube. These applications can arise in the food processing industry for heating and cooling of highly viscous liquid food, such as pastes, or for products that are sensitive to high shear stresses.

Garimella et al. [3] reported an experimental investigation on forced convection heat transfer in coiled annular ducts. They found that the heat transfer coefficients obtained from the coiled annular ducts were higher than those obtained from a straight annulus, especially in the laminar region.

Yang et al. [4] carried out a numerical-experimental study on flow boiling of R-141B in a horizontal coiled tube. They conducted their tests in two flow rates of 10 and 15 l/hr and three different heat fluxes, and observed that flow velocity predicted in the simulations showed a strongly dependence on the phase distribution. Moreover, they depicted the evolution of flow pattern inside the tube.

An investigation was done to study the boiling process in a horizontal coiled tube by Wu et al. [5]. They applied the Eulerian multiphase flow model and paid special interests in flow mode. They

* Corresponding Author: M.A. Akhavan-Behabadi
Email: akhavan@ut.ac.ir
Fax: +98 21 88337123

found that the phase distributions showed a continuous stratification in the horizontal tubes and were influenced by both buoyancy force and centrifugal force in the tube bends.
D. G. Prabhanjan et al. [6] reported comparison of heat transfer rates between a straight tube heat exchanger and a helically coiled heat exchanger during heating in single phase and with water bath. Their results show that helical pipes have greater heat transfer coefficients rather than straight pipes. Also, the increasing of water bath temperature increases the heat transfer coefficient, but changing of mass fluxes has no significant effect on heat transfer coefficient.
In the present study, a numerical-experimental investigation has been carried out on flow boiling heat transfer coefficient of R-134a inside horizontal and vertical helically coiled tube-in-tube heat exchangers. A numerical method is employed to calculate the water-side heat transfer coefficient. The refrigerant side heat transfer coefficient is obtained by applying an energy balance between the water and refrigerant (heat rejected by water = heat absorbed by refrigerant).
The effect of different parameters such as vapor quality and mass velocity on water site heat transfer coefficient and also refrigerant side heat transfer coefficient are discussed.

EXPERIMENTAL FACILITY

The experimental set-up which was used in this investigation is a well instrumented vapor compression refrigeration cycle. The schematic diagram of experimental apparatus has been shown in figure 1. It is consisted of: 1- compressor, 2-condenser, 3-rotameter, 4-accumulator, 5-filter-dryer, 6-expansion valve, 7-sight glass, 8-pre-evaporator, 9-pressure transmitter, 10-test section, 11-after-evaporator, and 12-accumulator.
The schematic diagram of test section is shown in figure 2. It is a helically coiled tube-in-tube counter flow heat exchanger. Refrigerant R-134a flow inside the inner tube is heated by the warm water flowing in the annulus. The outer diameter of the inner tube is 9.52 mm and its thickness is 0.62 mm. The inner diameter of the outer tube is 29 mm. The diameter and pitch of the coil are 305 mm and 45 mm, respectively.

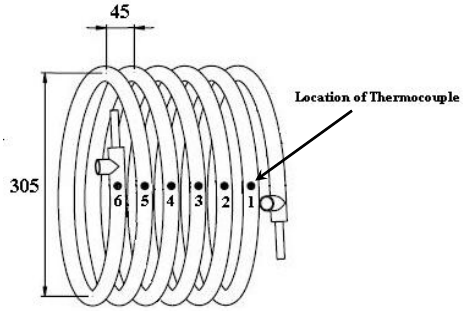

Figure 2. Schematic diagram of horizontal test section

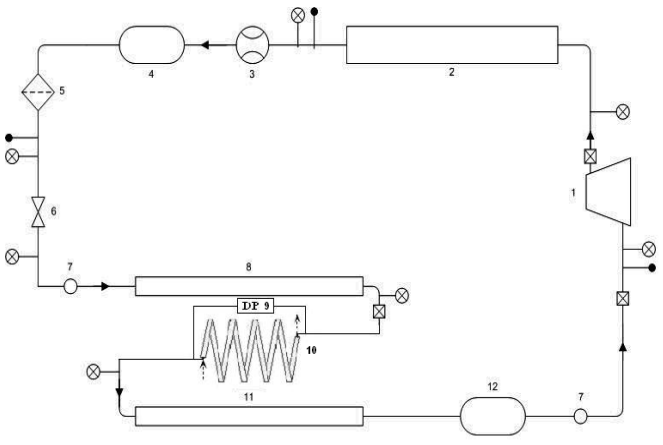

Figure 1. Schematic diagram of experimental apparatus (with horizontal test section)

In addition, there was a pre-evaporator used before the test-evaporator in order to achieve the required vapor qualities at the entrance of test-evaporator. Also, an after-evaporator was employed to ensure that the vapor will be superheated before entering the compressor. Refrigerant which flows inside the inner tube of pre-evaporator and after-evaporator is electrically heated by the coils wrapped around them. All the three evaporators were completely insulated.

NUMERICAL-EXPERIMENTAL APPROACH

Based on the definition of overall heat transfer coefficient, U_o, and using the energy balance equation, we have:

$$Q = U_o A_o . \Delta T_{lm} = \dot{m}_w C_{p_w} \left(T_{w,out} - T_{w,in} \right) \tag{1}$$

Then, the refrigerant-side heat transfer coefficient, H_f is obtained from equation (2).

$$H_f = \left(\frac{A_i}{U_o A_o} - \frac{A_i}{H_w A_o} - R_t A_i \right)^{-1} \tag{2}$$

where, R_t is the tube wall heat resistance. To calculate water-side heat transfer coefficient, H_w, there are some empirical correlations, however, using such correlations in the ranges of the operating parameters of the present study, is accompanied with a considerable error. Therefore, in the present work, we calculated H_w numerically using exact boundary conditions.

The critical Reynolds number for the transition from laminar flow to turbulent flow in a curved pipe or helical coiled tube is important for adoption of different formulas. Two criteria have been suggested. The first one is [7]:

$$Re_{cr} = 20000 \left(\frac{d}{D} \right)^{0.32} \tag{3}$$

and the second one is [8]:

$$Re_{cr} = 2100 \left[1 + 12 \left(\frac{d}{D} \right)^{0.5} \right] \tag{4}$$

Critical Reynolds numbers calculated by both of above mentioned equations are more than 8000, which is much higher than the Reynolds numbers of the present study, therefore, the flow regime is considered as laminar.

Using a commercial software, FLUENT, a finite volume method has been invoked to discretize and solve the governing equations of mass, momentum, and energy conservations.

A second-order upwind method has been employed throughout the domain to compute the heat and momentum fluxes. Also, SIMPLE method was used to calculate and correct the pressure and velocity fields.

As the convergence criteria, the residuals resulting from the integration of different equations were used. For this purpose, the computation was stopped when the residuals of all the governing equations were less than 10^{-6}.

RESULTS AND DISCUSSION

The numerical results for water-side heat transfer coefficient of the vertical and horizontal tube-in-tube heat exchanger versus water Reynolds number for different Prandtl numbers are depicted in figures 3 and 4, respectively.

It is obvious from these figures that water-side heat transfer coefficient increases by increment of water Reynolds number. The major cause of this phenomenon is that by increasing the Reynolds

number, the turbulence of the flow is promoted. Moreover, increasing the water Pr enhances water-side heat transfer coefficient.

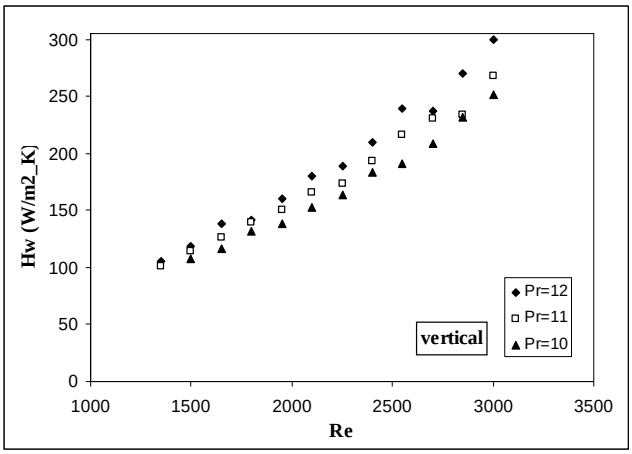

Figure 3. Water-side heat transfer coefficient versus water Reynolds number for vertical helically coiled tube

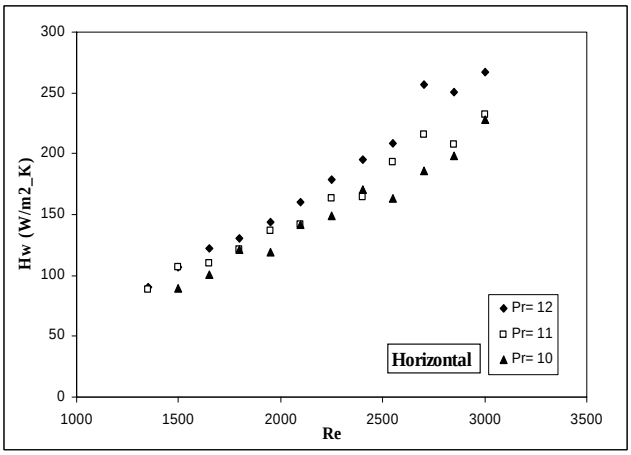

Figure 4. Water-side heat transfer coefficient versus water Reynolds number for horizontal helically coiled tube

The variation of refrigerant-side heat transfer coefficient h_f for vertical and horizontal heat exchangers versus average vapor quality at different mass fluxes are shown in figures 5 and 6.
It is seen from these figures that refrigerant-side heat transfer coefficient reduces with the decrease of vapor quality, continuously. This reduction is due to the lower specific volume of gas which based on the continuity causes the velocity of fluid decreases, which in turn leads to lower heat transfer coefficients. It is also because of the increment of the liquid film thickness and therefore more thermal resistance.
It can be seen that the mass flux has a strong effect on the heat transfer performance, especially at high average vapor qualities. This effect may be explained by the previous studies by Berthoud and Jayanti [1] in that the interfacial vapor liquid shear stress and the intensity of the secondary flow was augmented with increasing mass flux, which resulted in the enhancement of droplet entrainment and redeposition. This enhancement induced the increased numbers and larger sizes of waves on the liquid film surface, which increased the heat transfer area. In addition, at higher velocities, which were due to the raised mass flux, the degree of turbulence of the fluid was intensified, and hence, the heat transfer coefficients were augmented [9].

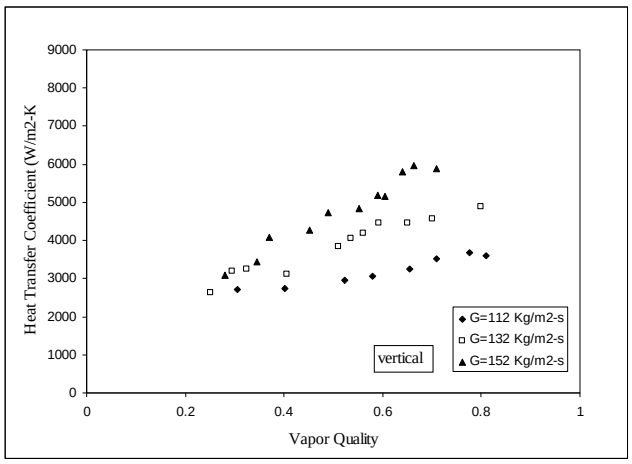

Figure 5. Refrigerant-side heat transfer coefficient versus average vapor quality for vertical helically coiled tube

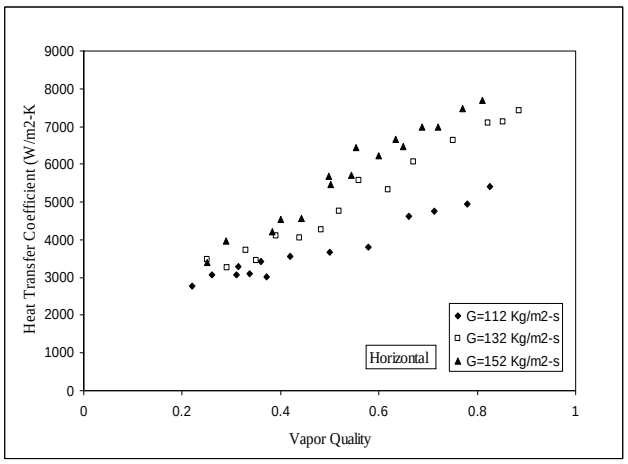

Figure 6. Refrigerant-side heat transfer coefficient versus average vapor quality for horizontal helically coiled tube

In figures7-9, the comparison of h_f for different mass velocities at different vapor qualities is illustrated. It can be seen from these figures that horizontal helically coiled tubes always have greater refrigerant-side heat transfer coefficients. It may be because of greater mixings in horizontally orientated heat exchangers.

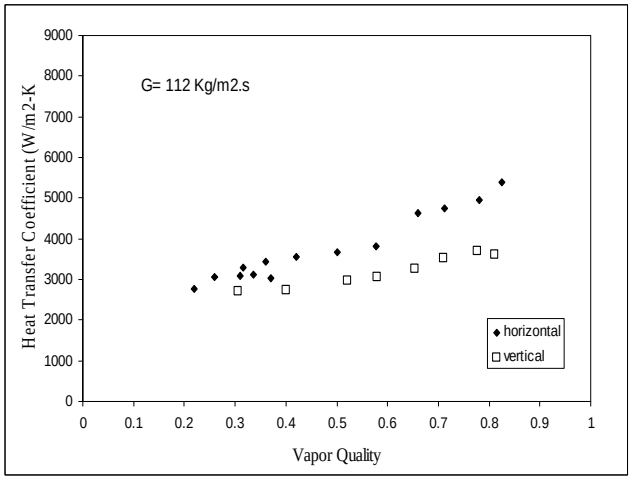

Figure 7. Comparison of horizontal and vertical helically coiled tube refrigerant-side heat transfer coefficients at G=112 kg/m^{2}s

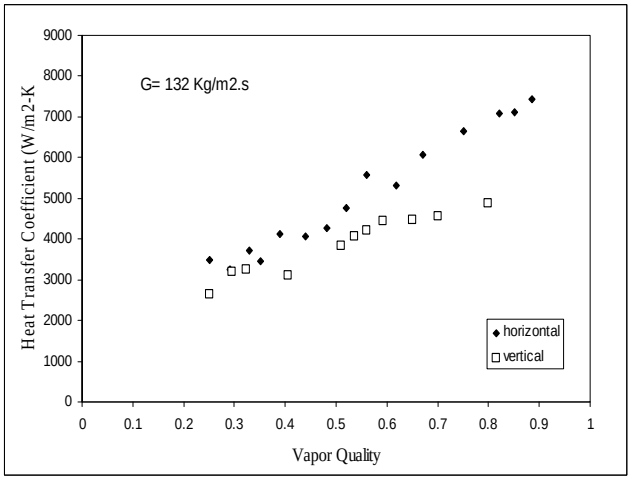

Figure 8. Comparison of horizontal and vertical helically coiled tube refrigerant-side heat transfer coefficients at G=132 kg/m^{2}s

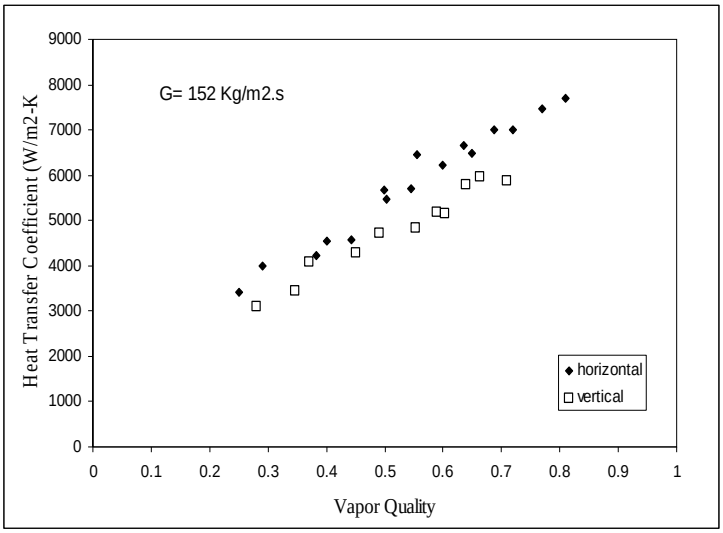

Figure 9. Comparison of horizontal and vertical helically coiled tube refrigerant-side heat transfer coefficients at G=152 kg/m^{2}s

CONCLUSIONS

1. Water-side heat transfer coefficient increases by increasing the water-side Reynolds number.
2. Increment of the water Prandtl number increases water-side heat transfer coefficient.
3. Refrigerant-side heat transfer coefficient reduces with the decrease of vapor quality, continuously.
4. Increase in mass velocity enhances the refrigerant-side heat transfer coefficient.
5. Horizontal helically coiled tubes have greater refrigerant-side heat transfer coefficients than vertical helically coiled tubes.

ABSTRACT. In this work the experimental results of heat exchange and hydrodynamics researches of flat-oval tubes with plate rectangular fins are presented. Results of comparative tests of the heat exchangers fabricated from flat-oval tubes with plate rectangular fins, from round steel tubes with welding spiral fins, from oval tubes with oval fins and from round bimetallic tubes with spiral aluminium fins are resulted also. It is shown that flat-oval tubes have advantages on heat exchange and hydraulic resistance in comparison with existing types of fining tubes.

Keywords: *flat-oval tube, plate rectangular fins, thermo-aerodynamic efficiency*

The considerable increase in the price of materials and power resources stimulates the research in areas of power and material saving. Important decisions in these areas relate to the design of new type developed convective heat exchange surfaces and the equipment on their base, which is characterized by high heat power efficiency, adaptability to manufacture and by a low manufacture cost. Convective heat exchange surfaces with cross-section-fining tubes are widely used in the power industry as elements of boiler-recuperators for gas turbines, in dry-type cooling towers and in air condensers, in waste heat recuperators of industrial installations, at gas cooling in gas compression stations etc. However, the type of fining tubes actually applied in such devices possesses a number of essential flaws. Those are weak thermal contacts between the fins and tube surfaces, high cost of materials for bimetallic tubes, rather low degree of developed surfaces, the big complexity and process cost for fabrication of steel tubes with spiral fins. These disadvantages limit the wide application of fining tubes. Taking into account the large necessity in heat transfer equipments for the different industries the design of fining tubes with the smaller material consumption and low production cost leads to essential material and power saving.

The complex investigation of heat and mass flows for fining surfaces has been done [1] and the new kind of fining tubs with flat-oval cross-sections and with plate rectangular fins [2] has been designed (Figure 1). The flat-oval tubes have plate rectangular fins on flat lateral sites only. This design allows increasing the thermal-aerodynamic efficiency of fins due to the withdrawal of its sites which are in an aerodynamic shade. At the same time the cheap and high-efficiency technology of contact welding of fines can be applied, providing almost ideal thermal contacts to tube surfaces. Moreover, other advantages deal with high parameters of fin factors and the value of specific surface H_1, which are close to the characteristics of best surfaces with completely fining tubes (ψ = 22, H_1 = 1.8 m^2/m), and with the low fining tube aerodynamic resistance.

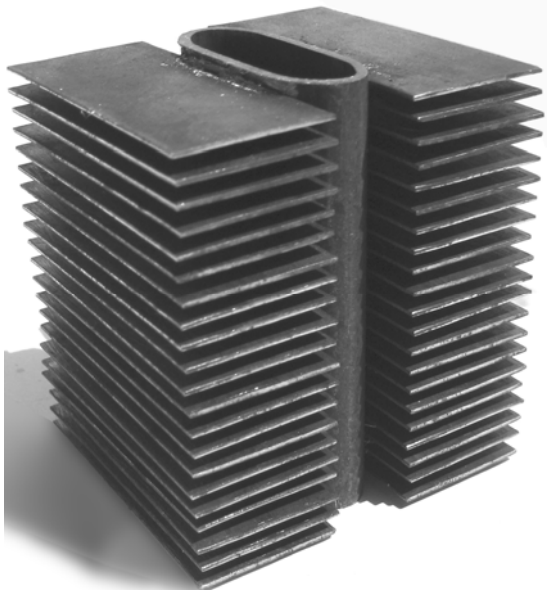

Fig.1. Flat-oval tube with plate rectangular fins.

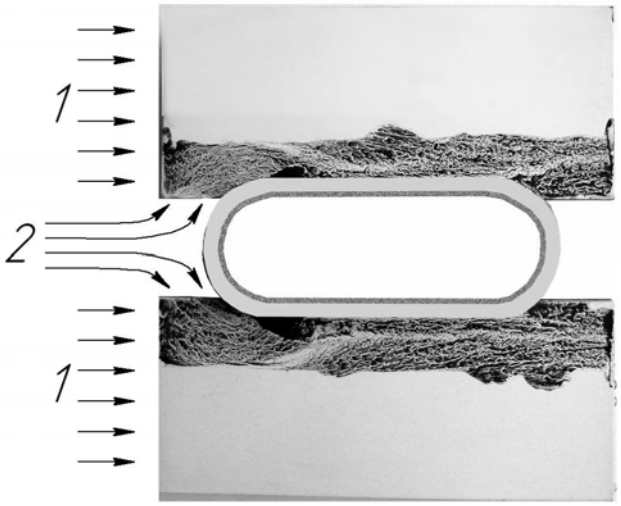

Fig.2. Flow visualization on a surface of fins of a flat-oval tube with plate rectangular fins: 1- a frontal part of stream: 2 - a part of stream getting in inter-fin cavities from the space not occupied by fins at a front part of flat-oval tube.

It is important to notice that due to the design features of flat-oval tubes with plate rectangular fins the turbulisation of stream of external fluid takes place owing to interaction of its components getting in inter costal space from a first line of an fin (Figure 2, a position 1) and from the space not occupied by fins at a front part of a tube (Figure 2, a position 2). Some increase of intensity has been reached in such configuration due to the heat exchange, comparable to effect related to the action of a whirlwind in a front part of completely fining tubes.

The investigation of heat transfer and aerodynamic resistances of tube banks with flat-oval tubes and plate rectangular fins has been carried out with a variation of parameters: i) relative lengths of tube cross-section, $d_2/d_1 = 2.0, \ldots, 2.8$, ii) fin factors, $\psi = 15.2, \ldots, 21.5$ and iii) relations of transversal (S_1) and longitudinal (S_2) steps of tubes in the bank, $S_1/S_2 = 0.99, \ldots, 2.55$ (Figure 3). The comparison of mentioned characteristics for new type of fining tubes has been done with the characteristics of most widespread tube types, such as: steel oval tubes with oval fins coated by zinc, steel round tubes with welding spiral fins and bimetallic tubes (aluminum spiral fins on a steel tube).

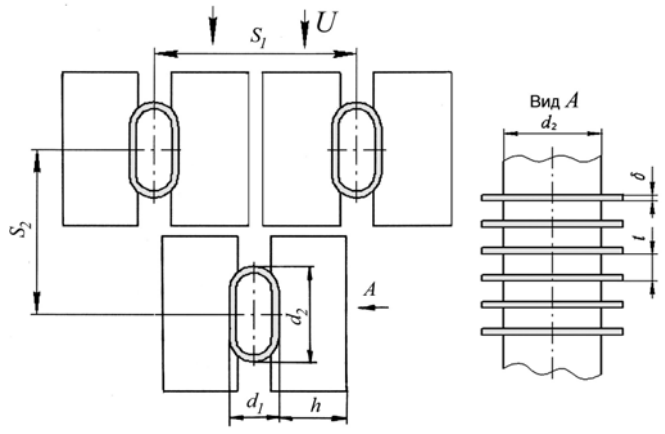

Fig.3. Geometrical characteristics of flat-oval tubes with plate rectangular fins.

The analysis has shown that offered tubes are characterized by the high intensity of convective heat exchange (the same as a round completely fined bimetallic tubes) and by lower aerodynamic resistance than oval tubes with oval fins (Figure 4). These factors allow expecting their high thermo-aerodynamic efficiency, despite the rather low heat conductivity of steel fins in comparison with the aluminum one.

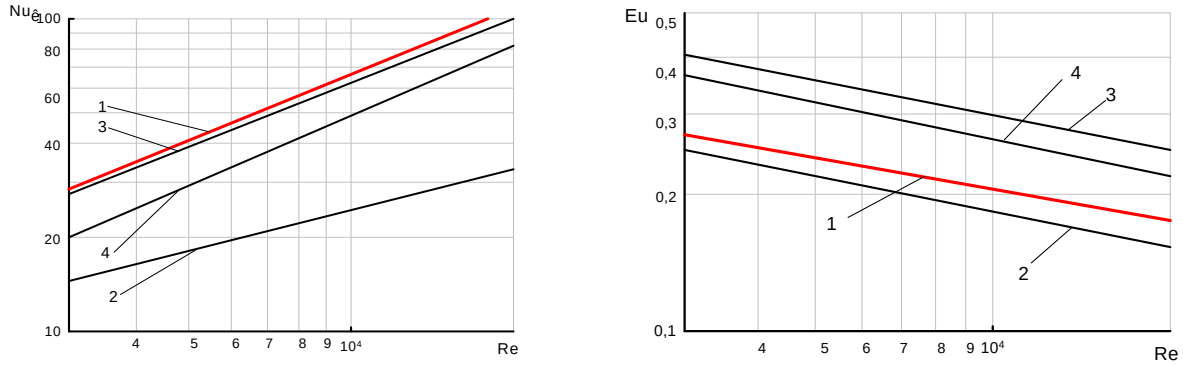

Fig.4. Comparison of the heat transfer intensity (a) and aerodynamic resistance (b) of fining tube banks with flat-oval tubes with plate rectangular fins (1), oval tubes with oval fins coated by zinc (2), round tubes with welding spiral fins (3) and bimetallic tubes with spiral aluminium fins (4).

The comparison of parameters of different air condensers with a capacity of 1280 kW designed on the base of offered tubes and on the tubes specified in Table 1 has been presented as well.

Table1. The comparison of parameters of different air condensers

Variant number		1	2	3	4
Heat surface tube type		Flat-oval tube with plate rectangular fins	Oval tubes with oval fins coated by zinc	Round tubes with welding spiral fins	Bimetallic round tubes with spiral aluminum fins
Transversal tube step, S_1, mm		65	62	65	65
Longitudinal tube step, S_2, mm		60	42	53	60
1	Total length of tubes , L, m	373	865	540	411
2	Thermal capacity removed from 1m of tube, q_1, kW/m	3,43	1,48	2,36	3,11
3	Tube bank aerodynamic resistance, ΔP, Pa	142	138	329	229
4	Compactness factor of heat transfer surface, C, m^2/m^3	393	323	253	421

Results of comparison are presented in Table 1 and in Figure 5. From the analysis follows those former two parameters (L and q_1), almost defining labor input of manufacturing and the cost of heat transfer equipment. Two designs are the best: flat-oval tubes with plate rectangular fins and bimetallic tubes with close to highest possible for pipes of a round profile the degree of surface heat transfer. Taking into account that the high-quality aluminium, (which cost now more than in six-fold exceeds the cost of carbonaceous steel) is necessary for manufacturing of bimetallic tubes, the design from steel flat-oval tubes with plate rectangular fins looks more attractive now concerning the high-efficiency, low-energy-expense and simple technology of their manufacturing. The manufacturing techniques of flat-oval tubes with plate rectangular fins, based on using of simple

contact welding, are integrally connected with an idea of offered design of ridge pipes and completely corresponds to requirements mentioned above.

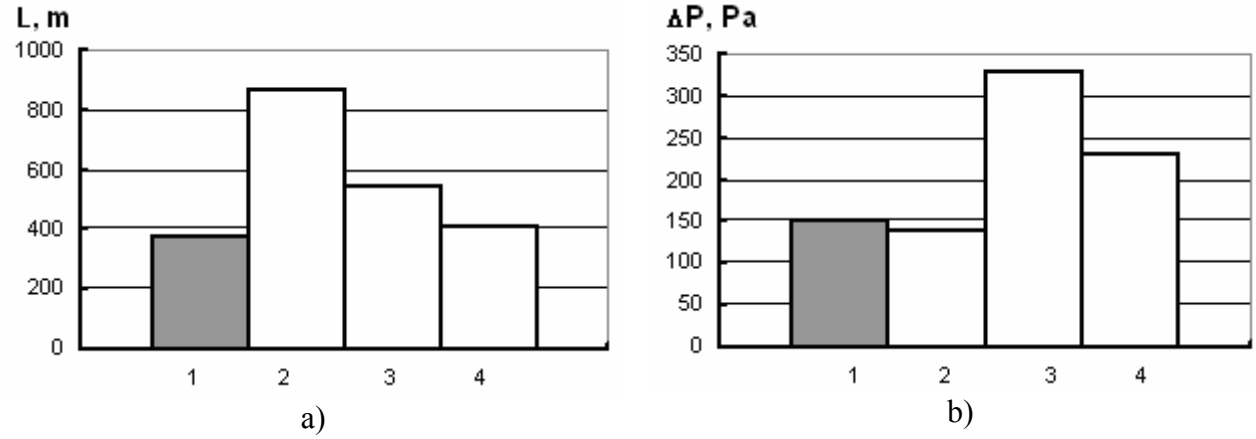

Fig.5. Comparison of total lengths of tubes *L* (a) and aerodynamic resistance *ΔP* (b) for different variants of the air condenser: 1- flat-oval tubes with plate rectangular fins; 2- oval tubes with oval fins; 3 - round steel tubes with welding spiral fins; 4 - bimetallic tubes.

The length of pipes in the cases of # 2 and # 3 in 2.3 and 1.5 times, respectively, exceeds a length of pipes of heat exchanger from flat-oval tubes with plate rectangular fins that considerably reduces competitiveness of corresponding cases of fining tubes in many almost important applications.

The comparison of aerodynamic resistances, actually defining operational expenses, connected with power consumption on a fan drive, and also in the appreciable degree installation expenses caused by necessary capacity of a drive has shown in Figure 5. It is clear that a design of condenser with flat-oval tubes with plate rectangular fins has the same aerodynamic resistance, as a variant of most aerodynamically perfect oval tubes with oval fins. The condensers from bimetallic tubes and from steel pipes with welding spiral fins have in 1.6 and 2.3 times, respectively, higher aerodynamic resistances. It allows to assume that flat-oval tubes with plate rectangular fins will be more preferable: i) in devices for air cooling, and ii) in the design of boiler recuperators of heat of gas turbines, which profitability in a great extent depends on pressure losses in a gas path, and iii) in the design of dry towers with natural draught.

The important characteristic of extended surface (*C*) is its compactness which is estimated as the area of heat transfer surface holding in 1 cubic meter of volume of heat transfer devices. The comparison of these characteristics for different designs has shown that heat transfer surfaces from flat-oval tubes with plate rectangular fins practically do not concede the surfaces from bimetallic pipes, which is characterized by the greatest value of C among developed tubular surfaces. Thus the flat-oval tubes with plate rectangular fins have higher heat power efficiency of surface unit, than in completely fining pipes which surfaces include "badly working" parts located in an aerodynamic shade.

CONCLUSIONS

Thus the offered new type of fining tubes possesses a number of essential advantages in comparison with the pipes used now in the industry. There are:

– an adaptability to manufacture and rather low cost of the manufactures caused by application of technology of contact welding, not demanding the difficult equipment, special materials and the big consumption of energy;

– the higher relative area of heat transfer surfaces, reaching the characteristic for best samples of bimetallic tubes, the use of carbonaceous steels as constructional materials is much cheaper, in comparison with aluminum;

– the high intensity convective heat exchange owing i) to absence of fin parts, working in an aerodynamic shade with low values of local velocities of a stream, and ii) due to turbulization of stream in an inter-fin cavities at the interaction of its components getting there from front and from space not occupied by edges at a front part of the flat-oval tube,

– the ideal thermal contact between fins and flat-oval tubes, caused by the technology of contact welding;

– the low aerodynamic resistance connected with using of flat-oval profile tubes, which provides, in comparison with round tubes of equal cross sections for internal fluids, the considerably smaller area of the block up section;

– the lower thermal resistance in comparison with round tubes at the condensation in tubes of the vapor of technological liquids due to the reduction of condensate film thickness which is localized mainly in the narrow area adjoining to the bottom part of a flat-oval profile.

Presented experimental results have shown the essential advantages of flat-oval tubes with plate rectangular fins. It allows asserting that the heat transfer equipments designed on the base of such tubes will have considerably smaller cost than samples actually used, and will find a wide distribution in various industrial areas.

OPPOSING MIXED CONVECTION HEAT TRANSFER IN AN INCLINED FLAT CHANNEL IN A LAMINAR-TURBULENT TRANSITION REGION

R. Poskas*, P. Poskas, G. Drumstas
Lithuanian Energy Institute, Kaunas, Lithuania

ABSTRACT. In this paper we present the results on experimental investigation of the local opposing mixed convection heat transfer in an inclined flat channel (inclination angle $\varphi = 60^o$ from horizontal position) with symmetrical heating in the laminar-turbulent transition region. The experiments were performed in airflow (p = 0.4 MPa) in the range of Re from $1.5 \cdot 10^3$ to $5.3 \cdot 10^4$ and Gr_q up to $1.5 \cdot 10^{10}$ and at the limiting condition $q_{w1} \approx q_{w2} \approx$ const. The experimental data show similar tendencies in the heat transfer as it was revealed in vertical channel, i.e. heat transfer at large x/d_e in vortex flow region ($Re \leq 6 \cdot 10^3$) is more intensive than in case of turbulent flow. But at small x/d_e ($x/d_e \leq 10$) heat transfer variation with Re is different then in case of vertical channel. Analysis revealed also that for the inclination angle $\varphi = 60^o$ there are only minor differences in the local heat transfer for upper (stable density stratification) and bottom (unstable density stratification) walls.

Keywords: *Local heat transfer, opposing mixed convection, inclined flat channel, transition region, experiments*

INTRODUCTION

For modern nuclear and thermal energy technologies, computer, chemistry and other technologies reliability requirements are very important. So, designers of such technologies must have the detailed information about the processes including thermal ones that very often are defining the reliability and operation lifetime of the equipment.

Heat and momentum transfer in single-phase flows in case of complex processes under effect of buoyancy, are still not investigated in details. Due to the importance of the problem for engineering applications a lot of researchers concentrated their attention to the turbulent mixed convection heat transfer investigations in vertical circular tubes. Wide investigations on this problem for turbulent flow in the vertical and horizontal channels were performed at the High Temperature Institute in Moscow [1], at the Manchester University [2, 3] and at the Lithuanian Energy Institute [4 - 6]. At the Lithuanian energy institute also investigations of the turbulent mixed convection in the inclined flat channels with one side heating (under effect of stable and unstable air density stratification) have been performed [7 - 9]. It was revealed that heat transfer is closely related to the channel inclination angle in case of the stable density stratification but heat transfer practically does not depend on the channel inclination angle in case of the unstable air density stratification.

Investigations of heat transfer in the laminar-turbulent transition region under the effect of buoyancy are rather limited. The flow character in pipes in a laminar-turbulent transition region was investigated in [1, 10 - 12]. In paper [13] the results on numerical investigation of the local

opposing mixed convection heat transfer in a vertical flat channel with symmetrical heating for laminar and vortex airflow (at p = 0.1; 0.2 and 0.4 MPa and Re numbers from 1500 up to 4310, with Gr_q number variation from $1.65 \cdot 10^5$ to $3.1 \cdot 10^9$) were presented. The new correlations were suggested for determination of the non-dimensional distance at which the flow stability is lost in the flat channel with opposing flows. In other paper [14] the detailed results on experimental and numerical investigation of the local opposing mixed convection heat transfer in a vertical flat channel with symmetrical heating ($q_{w1} \approx q_{w2} \approx$ const) in the laminar-turbulent transition region were presented. It was shown that as the influence of the buoyancy becomes stronger the circulating flows appear along the channel. These flows cause asymmetry of velocity profiles and increase in heat transfer up to $Re \approx 8 \cdot 10^3$, when p = 0.4 MPa. The experiments were performed in airflow of different pressures (0.1, 0.2 and 0.4 MPa) in the range of Re from $2 \cdot 10^3$ to $5 \cdot 10^4$ and Gr_q up to $1.5 \cdot 10^{10}$. In the newest paper [15] originated from Lithuanian Energy Institute the results on experimental investigations of the local opposing mixed convection heat transfer in the same vertical flat channel with symmetrical heating in the laminar-turbulent transition region at higher air pressures (0.7, 0.8 and 1.0 MPa) when buoyancy effect is prevailing in the range of Re from $2 \cdot 10^3$ to $4 \cdot 10^4$, and Gr_q up to $1.0 \cdot 10^{11}$ was presented. The experimental data show similar tendencies in the heat transfer at higher air pressures (0.7 – 1.0 MPa) as it was revealed at smaller air pressures (0.2 – 0.4 MPa). But at higher air pressures the transition from the vortical flow regime to the turbulent one does not causes such drastic decrease in heat transfer as it was noticed at smaller air pressures (for p = 0.2 MPa at Re ≈ 4000, for p = 0.4 MPa at Re ≈ 8000). The recent review of the mixed convection in the channels including transition region was presented in [16].

In this paper the results on experimental investigations of the local opposing mixed convection heat transfer in the laminar-turbulent transition region in the same flat channel but with inclination angle $\varphi = 60^o$ from horizontal position is presented. Experiments were performed at air pressure p = 0.4 MPa with symmetrical heating in the range of Re from $1.5 \cdot 10^3$ to $5.3 \cdot 10^4$, and Gr_q up to $1.5 \cdot 10^{10}$.

METHODOLOGY

The same aerodynamic setup was used for the experiments in the transition region in an inclined position as it was used for the experiments in the turbulent region in a vertical or inclined positions [6, 9] and in the transition region in a vertical position [14]. As it was already indicated the experiments are performed at air pressure p = 0.4 MPa. So, the air under a pressure of 0.4 MPa comes from compressors to the group of receivers. Here it loses some moisture. Then it passes one of the three parallel lines with paired flow metering orifices having different flow cross sections and flows into test section. Then the air is released into the atmosphere via bypass valves. The air pressure and flow rates are controlled by bypass valves. A direct electric current generator was used for heating the elements of the experimental section. The current strength was regulated by varying the voltage, applied to an excitation winding of the generator, and determined from the voltage drop on shunts of accuracy class 0.5. The high stability of the generated voltage, which also means the stability of the supplied heating power, was attained by a special electronic control device with feedback of the voltage drop at the test section.

The thermocouples were used for measuring the wall temperature and the voltage drop along the channel. All electric signals from thermocouples and voltage drops along the calorimetric surface and shunt were recorded automatically by a computer-based data acquisition system and processed on line.

A special test section (Fig. 1) for the studies of heat transfer for mixed convection in a flat channel was constructed at the Lithuanian Energy Institute. The flat channel has a height-to-width ratio of about 1 : 10 (40.8 : 400 mm) and it is 6260 mm long. The channel consists of a fluid-dynamic

stabilizer and a calorimeter. The stabilizer is 2370 mm long. Its height and width are the same as that of the calorimeter. The entrance to the channel is fitted with a well-designed smooth intake with an array of laminarizing grids. The calorimeter is 3890 mm ($x/d_e \approx 50$) long. The test section contains two central and two lateral duraluminium plates. The internal side of this duraluminium rig is insulated by 120 mm thick asbestos strips on the central plates and by 60 mm thick asbestos-cement strips on the lateral plates. The calorimetric heated surfaces of the two central plates are made of stainless steel foil 0.38 mm thick and 370 mm wide, fixed at the inlet to the brass contacts.

In order to achieve higher values of Gr_q and higher effects of buoyancy pressurized air up to 1.0 MPa was used. For this purpose the whole test section had to be placed in a pressure vessel of an 870 mm diameter and 7200 mm long. The vessel consists of two halves fixed together by flanges.

The temperature of the calorimeter test-surface (heated foil) was measured by 25 chromel-alumel thermocouples of a 0.3 mm diameter wire, which are fixed to the outer surface of the test foil. Longitudinal voltage drop on this heated foil was measured by the same thermocouples. Thermocouples also measured the temperatures in the insulation layers, which were used to define the losses.

The above construction enables experiments on heat transfer in a flat channel for different pressures of the heat carrier (air). The air was supplied through the top of the channel, so the experiments were accomplished on downward flow with two-side heating of the channel. All experiments were performed at the limiting condition $q_{w1} \approx q_{w2} \approx$ const. The maximum surface temperature was at the rage of 540 K, and the minimum temperature difference between surface temperature and flow bulk temperature was at least 47 K. The air pressure was measured using manometers. Well-type differential manometers filled with distilled water measured the pressure drops across the orifices. Electric signals from thermocouples and pressure probes as well as voltage drops on the calorimetrically measured surface and shunt were all recorded automatically by a computer-based data acquisition system, and processed on line. More detailed description of the test section and methodology of investigations is presented in [7].

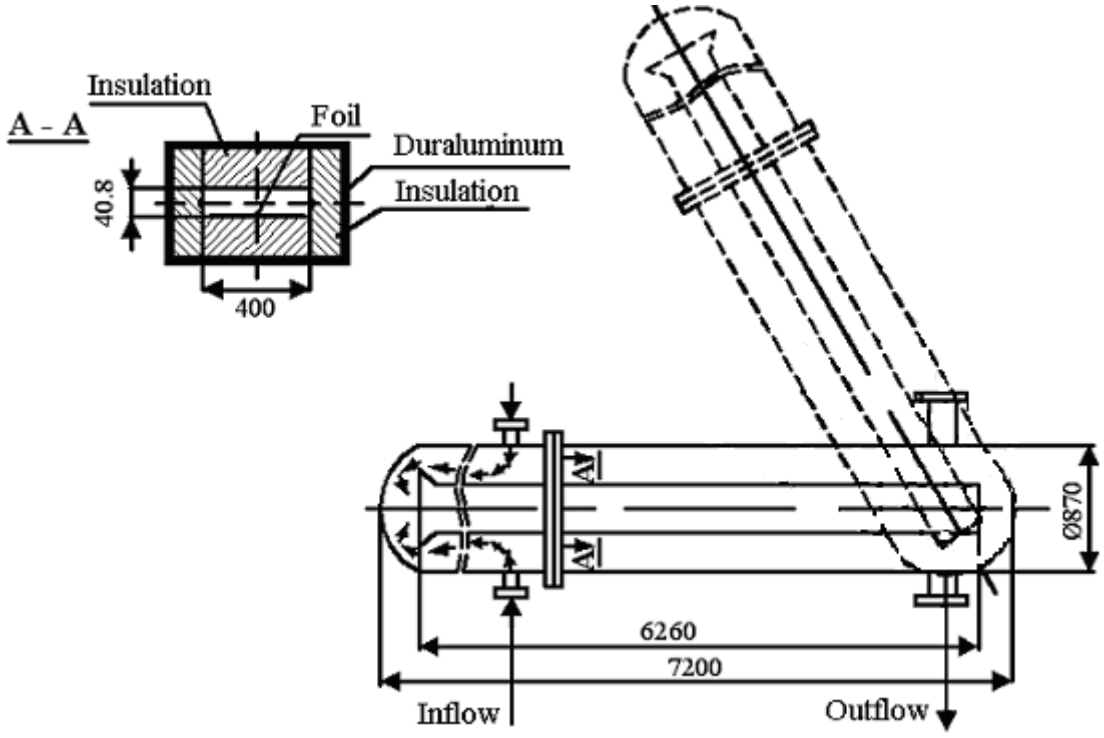

Figure 1. Test section geometry (not to scale)

In the primary interpretation of the data, the values of Nu, Re, Gr_q and Pr were evaluated. Local bulk flow velocity, temperature and equivalent diameter of the channel were used as reference values. Experimental uncertainties were as follows: Re – 3.2-3.4 %, Nu – 3.9-4.1 %, Gr_q – 5.6-5.8 %. The methodology presented in [17] was applied for the evaluation of uncertainties.

RESULTS AND THEIR ANALYSIS

Variation of heat transfer with Re number in stabilized region (x/d_e = 42) of the calorimeter is presented in Fig. 2. From the data obtained for the air pressure p = 0.4 MPa, it is clear that Nu for small Re numbers are higher than the forced turbulent convection heat transfer, but when the Re reaches Re ≈ $6 \cdot 10^3$, a sharp decrease of heat transfer is observed. This phenomenon indicates that in the narrow region of Re = $(6 - 8) \cdot 10^3$, the character of the flow inside the channel changes drastically from the vortex to non-vortex flow. For Re numbers higher then Re = $8 \cdot 10^3$ forced convection heat transfer is prevailing. This is different from the one side heating cases where even for the turbulent region for the same channel geometry (the same channel) and heating loads well expressed mixed convection was identified [7, 8]. It is necessary to notice also that in the region of Re = $8 \cdot 10^3 – 1.5 \cdot 10^4$ heat transfer is les intensive then forced convection one. It is possible that this decrease in heat transfer is caused by the deformation of the velocity profile due to the buoyancy effect, i.e. decrease of the velocity gradient at the wall like in case of the laminar mixed convection with opposing flows.

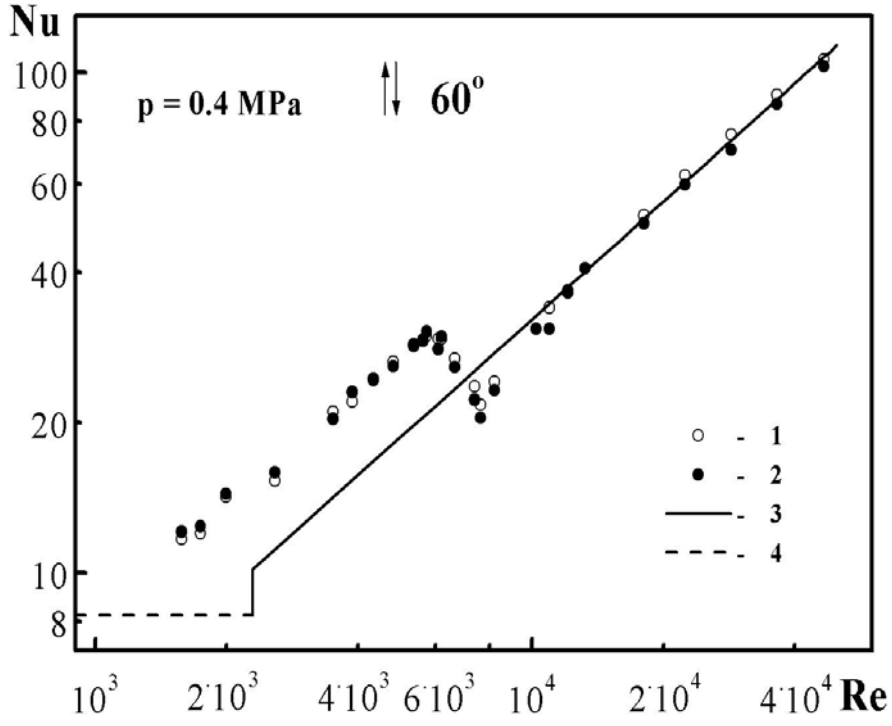

Figure 2. Heat transfer variation with Re (x/d_e = 42). 1 – upper wall, 2 – bottom wall, 3 – turbulent forced convection [1], 4 – laminar forced convection [18]

Heat transfer variation with Re number at p = 0.4 MPa and different x/d_e is presented in Fig. 3. We can notice sharp changes in heat transfer intensity at Re = 5000 – 8000 for larger x/d_e (x/d_e = 22.3 – 42) as we discussed above. It is interesting to notice that in the region close to Re = 4000 heat transfer rate practically does not depend on x/d_e (Fig. 3a). But with small increase in Re, changes in

heat transfer intensity for smaller x/d_e (x/d_e = 3.9 – 10.1) are not in line with the tendency defined for higher x/d_e. There is rather sharp increase in heat transfer at Re ≈ 5000 so different flow structure can be expected at the beginning of the heating section at Re = 5000 – 8000. For the smallest investigated Re numbers it is clear dependence of heat transfer rate on x/d_e. For x/d_e = 42 we have vortex flow regime at Re = 2000 – 6000 and it survives till Re = 6000 – 8000. The length of the vortex region is decreasing with decreasing of x/d_e, and for small x/d_e (x/d_e = 3.9 – 10.1) there is a region where Nu is not dependent on Re (Re = 2000 – 4000). But at Re = 4000 intensity of heat transfer is increasing rather sharply. In the vertical channel in this Re region (Re = 2000 – 4000) heat transfer is dependent on Re for all x/d_e as it is indicated in Fig. 3 by short dashed line.

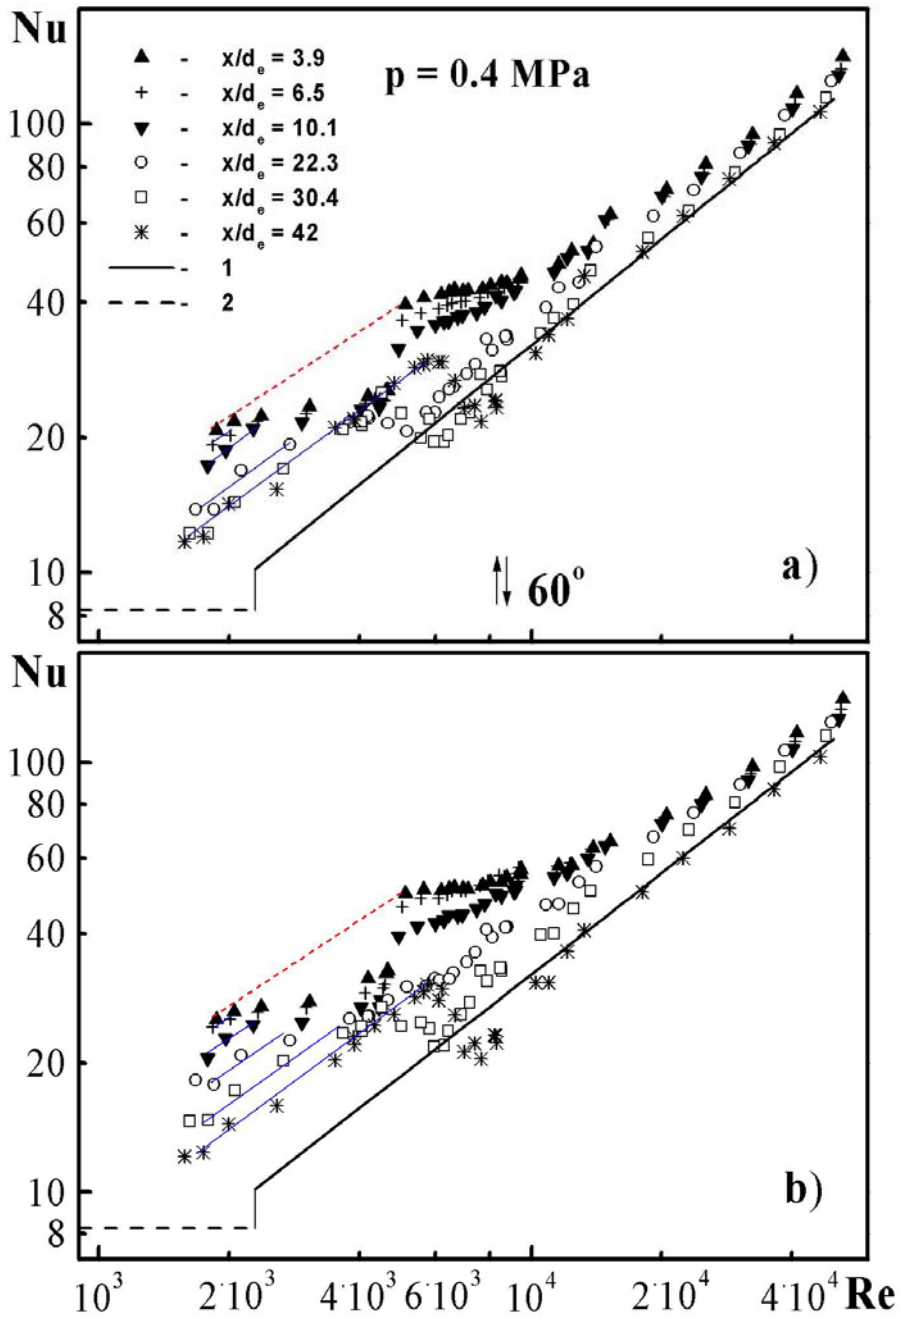

Figure 3. The dependence of the mixed convection heat transfer on Re for different x/d_e. a) – upper wall, b) – bottom wall, 1 – turbulent forced convection [1], 2 – laminar forced convection [18]

Analyzing the heat transfer from the bottom wall (unstable density stratification) (Fig. 3b) we can notice similar tendencies in heat transfer variation but intensity of heat transfer at smaller x/d_e is a little bit higher then for upper wall (stable density stratification). Also, for $x/d_e = 22.3$ at Re = 4000 there is no more heat decrease as it can be noticed for upper wall (Fig. 3a). At small Re (Re = 2000 – 4000) there is also decrease of heat transfer in comparison with vertical channel (short dashed line) as it was indicated for upper wall.

Analysis of the wall temperature variation along the channel for different regimes can provide some additional information to explain heat transfer processes. Fig. 4 presents the results on upper (Fig. 4a) and bottom wall (Fig. 4b) temperature variation along the channel for different regimes at air pressure p = 0.4 MPa. As it is seen from Fig. 4a, for high Re number (Re = 9548–8218) we have forced convection heat transfer and here there is a regime with monotonous variation of the wall temperature along the channel. At smaller Re numbers (Re = 7860–6654 – 5241–4334) we have local temperature maxima at certain x/d_e (for Re = 7860–6654 at $x/d_e \approx 35$, for Re = 6789–5745 at $x/d_e \approx 30$, for Re = 5241–4334 at $x/d_e \approx 25$), and after this maxima there is significant decrease of the wall temperature due to flow separation from the wall and intensification of the heat transfer. But the temperature distributions do not show any drastic temperature changes at the beginning of the channel (at small x/d_e).

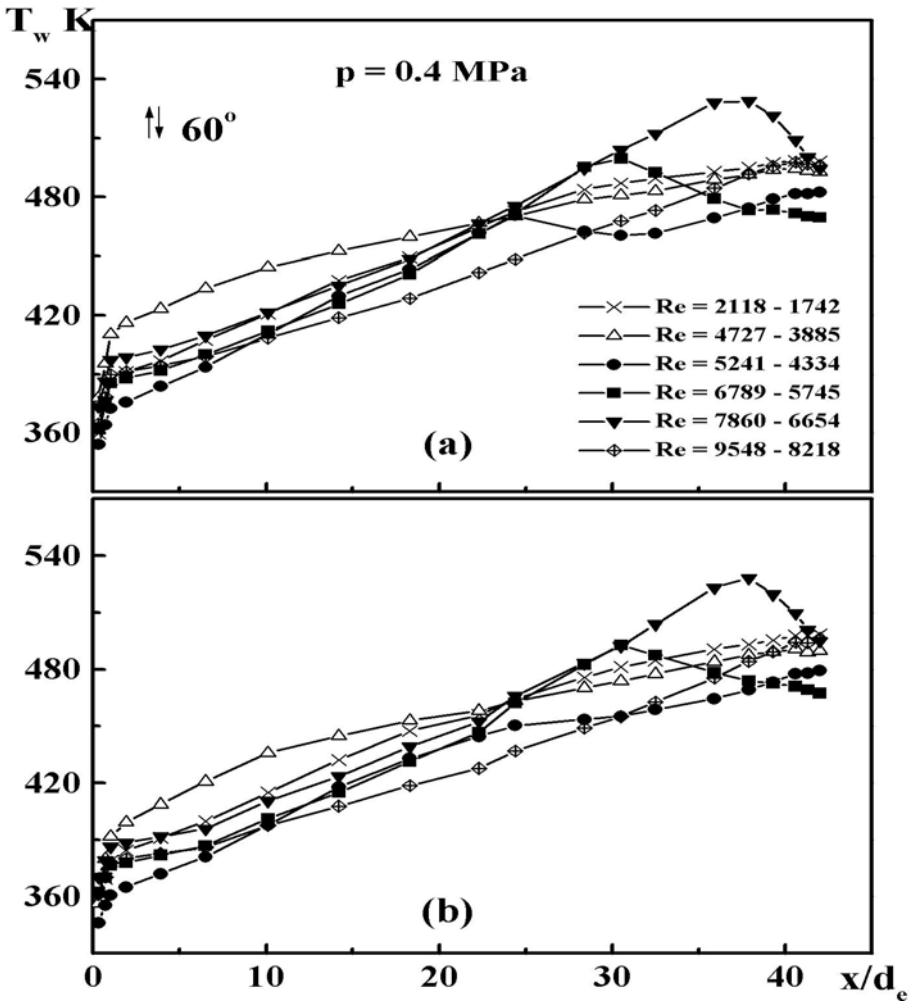

Figure 4. Longitudinal variations of wall temperature for different Re. a) – upper wall, b) – bottom wall. The higher value of Re is at the beginning of the heating and the smaller one is at the end ($x/d_e = 42$) of the channel

There are similar tendencies in temperature variation along the channel for the bottom wall (Fig. 4b). Most significant difference is for the regime with Re = 5241–4334. For the upper wall there is well expressed maximum of the temperature at $x/d_e = 25$, but for the bottom wall a change in temperature variation at $x/d_e = 25$ is observed, but not local temperature maximum.

NOMENCLATURE

d_e	equivalent diameter of the channel (m)	Re	Reynolds number, $Re = ud_e/\nu$
Gr_q	Grashof number defined by the heat flux specified on the surface, $Gr_q = g\cdot\beta\cdot d_e^4\cdot q_w/\nu^2\cdot\lambda$	x	axial coordinate measured from start of heating (m)
		w	at the wall
Nu	Nusselt number ($Nu = \alpha d_e/\lambda$)	in	at the inlet
q	heat flux density (W/m^2)	1,2	first and second wall

CONCLUSIONS

After analysis of the experimental results on local heat transfer for opposing mixed convection flows in an inclined flat channel ($\varphi = 60^o$) with symmetrical heating in the laminar-turbulent transition region the following conclusions can be made:

1. The analysis of the results revealed that depending on the effect of buoyancy different flow modes could be noticed along the channel. For the air pressure of 0.4 MPa at large x/d_e vortex flow regime with intensive heat transfer exists for $Re < 6000$.
2. Heat transfer at small x/d_e practically is not dependent on Re in the region 2000 – 4000 but it is increasing sharply at Re = 4000 – 5000. Such heat transfer variation is characteristic for upper (stable density stratification) and bottom (unstable density stratification) walls, and is different from heat transfer in vertical channels.
3. Analysis revealed that for the inclination angle $\varphi = 60^o$ there are only minor differences in the local heat transfer for upper (stable density stratification) and bottom (unstable density stratification) walls.
4. Further investigations are necessary at smaller inclination angles of the channel to reveal the effect of stable and unstable density stratification on the mixed convection in the transition region.

EXPERIMENTAL INVESTIGATION OF PULSATING HEAT PIPES AND A PROPOSED CORRELATION

Sajad Arabnejad[1], Hamed Jamshidi, M. B. Shafii*, Y. Saboohi
[1]Mechanical Engineering Department, Sharif University of Technology, Tehran, Iran

ABSTRACT. Pulsating heat pipes (PHPs) are complex heat transfer devices, and their optimum thermal performance is largely dependent on different parameters. In this paper, in order to investigate these parameters, first a Closed Loop Pulsating Heat Pipe (CLPHP) was designed and manufactured. The CLPHP was made of copper tubes with internal diameters of 1.8 mm. The length of the evaporator, adiabatic, and condenser sections were 60, 150, and 60 mm, respectively. Afterwards, the effect of various parameters, including the working fluid (water and ethanol), the volumetric filling ratio (30%, 40%, 50%, 70%, 80%), and the input heat power (5 to 70 watts), on the thermal performance of the CLPHP were investigated experimentally. The results showed that the manufactured CLPHP has the best thermal performance for water and ethanol as working fluids when the corresponding filling ratios are 40% and 50%, respectively. Finally, with the available experimental data set of CLPHPs, a power-law correlation based on dimensionless groups was established to predict their input heat flux. Compared with the experimental data, the root-mean-square deviation of the correlation prediction was 19.7% and in addition, 88.6% of the deviations were within ±30%.

Keywords: *Closed Loop Pulsating Heat Pipe, Experimental, Correlation, Modeling*

INTRODUCTION

With the advances in packaging technology, thermal management of electronic components gained new impetus. Novel cooling strategies are required for successful thermal management. Pulsating heat pipes (PHPs) are relatively new innovations in this direction, which have been recently investigated by many engineers and scientists around the world. PHP was introduced by Akachi in the 1990s [1]. Pulsating heat pipes are different from conventional heat pipes in design and working principle. It is made from a long continuous capillary tube bent into many turns, with the evaporator and condenser sections located at these turns. Moreover, an optional adiabatic zone in between may exist (Figure 1). There is no wick structure used in PHPs, so its simple and cheap structure has made PHPs very attractive compared with conventional heat pipes. The diameter of a PHP should be small enough (0.1–5mm) so that vapor plugs can be formed by capillary action. Since the surface tension force is dominant over the gravitation force, the working fluid will be put in slug-plug order in the PHP (Figure 1). These slugs and plugs are randomly distributed in the PHP after it is partially filled with working fluid (Xu et al [2]). The input heat flux, which is the driving force, increases the pressure of vapor plugs in the evaporator, and the heat output decreases the pressure of vapor plugs in the condenser. This pressure difference between the evaporator and condenser results in the oscillation of vapor plugs and liquid slugs in the PHP. Therefore, heat is transported from the evaporator to the condenser region by means of local axial movements of the working fluid (sensible heat) and phase changes (latent heat). Due to the continuous heating of bubbles formed by

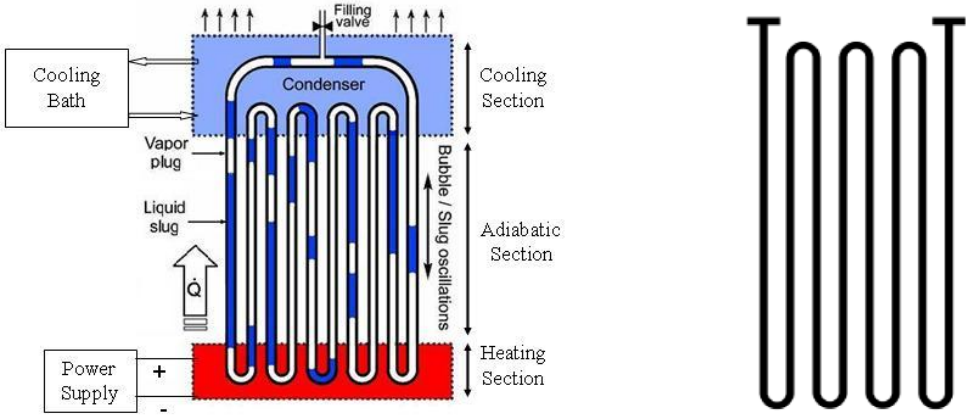
E-mail address: Behshad@sharif.edu

nucleate boiling, there will not be steady-state vapor pressure equilibrium for an operating PHP. Therefore, this type of heat pipe is essentially a non-equilibrium heat transfer device.

There are two types of PHPs: (i) open loop PHP (OLPHP), (ii) closed loop PHP (CLPHP). In the CLPHP the two ends of the tube are connected to one another and the working fluid is able to circulate, which enhances the capability of the working fluid in transporting heat from the evaporator region to the condenser region. Unlike the CLPHP, the two ends are sealed in the OLPHP. Compared with the CLPHP, the only advantage of the OLPHP is its cheaper and simpler structure.



a) CLPHP b) OLPHP

Figure 1. Schematic of Pulsating Heat Pipes.

There are many parameters which affect the PHP operation. These can be summarized as the tube diameter, input heat flux, number of turns, filling ratio (γ), inclination angle, and thermo-physical properties of the working fluid. The filling ratio is defined as the net liquid volume charged into the PHP divided by the total internal volume of the PHP.

Many researchers have investigated these parameters experimentally and analytically [2-11]. Among these researchers, Khandekar et al [3-5,7-8] have done the most comprehensive research on the thermal performance of PHPs. Khandekar et al [3] experimentally investigated the effects of different working fluids (water, ethanol, R-123), input heat flux, and filling ratio (range of 0%-100%) on the thermal performance of a CLPHP. Their experimental set-up was formed from a copper tube (ID 2.0 mm, OD 3.0 mm) with 5 turns in the evaporator section. In their experimental studies, valuable information related to the fundamental characteristics and operational regimes of CLPHPs were obtained. They concluded that for the given input heat flux range, a better performing and self-sustained thermally driven pulsating action of the device is only observed in the filling ratio range of 25–65% depending on the working fluid. Above this range of filling ratio, due to the lack of vapor plugs, the overall degree of freedom and the pumping action of bubbles is insufficient for generating pulsations inside the tubes. Therefore, the thermal performance of CLPHPs would not be suitable. Below a certain range of filling ratio, the probability of partial dry-out of the evaporator and reaching the critical state exists, which causes the evaporator temperature to increase and the thermal performance of CLPHPs to decrease.

Khandekar [4, 5] performed an experimental study on two CLPHPs having 20 turns of copper tubes with inner diameters of 2.0 and 1.0 mm, respectively. The working fluids were water, ethanol, and R-123 with filling ratios of 30%, 50% and 70%. The effect of the inclination angle was also investigated. The results showed that a combination of a large number of turns and a high input heat flux ensures continuous CLPHP operation in any inclination angle. Furthermore, they found that the CLPHPs with 50% filling ratio showed a better thermal performance and a higher performance

limit, while the CLPHPs with 30% and 70% filling ratios experienced a dry-out of the evaporator and reached the critical state at lower thermal performances.

Katpradit et al [6] experimentally studied the heat transfer characteristics of some OLPHPs at the critical state. A set of 27 copper-tube OLPHPs with internal diameters of 2.03, 1.06 and 0.66 mm, consisting of 5, 10 and 15 meandering turns and section lengths of 50, 100 and 150 mm was used in their study. Each OLPHP had a condenser, adiabatic and evaporator section of equal length. The working fluids used were R123, ethanol, and water with a filling ratio of 50% of the total volume of the tube. The results showed that the critical heat flux increases with an increase in the latent heat of vaporization of the working fluid. They also presented two correlations based on dimensionless groups to predict the critical heat flux of the OLPHPs. The correlations were only valid with a filling ratio of 50%. Compared with the experimental data, the standard deviation of the correlation prediction was 29%.

Due to the complicated behavior of PHPs, the published analytical models are very limited in scope and applicability. Therefore, semi-empirical correlations based on dimensionless groups, and an artificial neural network technique could be offered for the modeling of PHPs as a complex system [7, 8]. Therefore, in this study, first a CLPHP was designed and manufactured. Then, the effect of the most important parameters, including the working fluid (water and ethanol), volumetric filling ratio (30%, 40%, 50%, 70%, 80%), and input heat power (5 to 70 watts), on the thermal performance of the CLPHP were investigated experimentally. Finally, with available experimental data sets of the CLPHPs, a correlation based on dimensionless groups was established to predict the input heat flux of CLPHPs.

EXPERIMENTAL SETUP

A schematic diagram of the device used during the experimental tests is shown in Figure 1. A pulsating heat pipe configured as a CLPHP was built using a capillary copper tube with a 3.0 mm OD, 1.8 mm ID, and approximately 4m length to form 10 parallel channels with 9 curves (Figure 2). Therefore, the experimental set-up is a CLPHP with 5 meandering turns. The CLPHP consisted of three regions: a heating section (evaporator), adiabatic section, and cooling section (condenser) with a height of 60 mm, 150 mm, and 60 mm respectively; the whole width of the system was about 250mm. During the tests, the evaporator section was always below the cooling section. The cooling section contains a water-filled tank with an inlet and an outlet for circulating the constant temperature water of cooling bath. The cooling water was always maintained at about 20°C and it flows through the inlet of the water tank, around U-shape bends in the condenser zone. The mass flow rate of the cooling water always ensured that isothermal conditions existed in the condenser.
The evaporator section was in thermal contact with an electrical element, a Ni-Cr heating wire, twisted around U-shape bends on the outer surface and attached to a power supply to deliver a desired heat load (Figure 2). The total electrical resistance of the heater was 45.5Ω at 25°C. The heating power was provided by a precisely designed power supply unit. The input power and consequently the input heat flux were controlled with a rheostat by controlling the heater voltage. Both the evaporator and adiabatic sections were thermally insulated in order to make sure that there is no heat loss in these sections.

Ten Chromel–Alumel (Omaga, K type, accuracy ±0.5^{o}C) thermocouples were applied to measure the system's temperature during the tests. Five thermocouples were placed in each turn of the evaporator section to measure the average evaporator temperature. Three thermocouples were placed at adiabatic zone, and the other two thermocouples measured the inlet and outlet flow temperatures of the cooling section. All these thermocouples were connected to a PC via the data logger, so that the temperatures could be recorded and saved in a spreadsheet on the PC.

Before introducing the CLPHP with any working fluid, the fluid was heated and the CLPHP was placed under vacuum in order to empty the non-condensable gases from the fluid and the CLPHP. The reason for this is that these gases decrease the thermal performance of PHPs [2]. In addition, the minimum purity of all working fluids was about 99.5%.

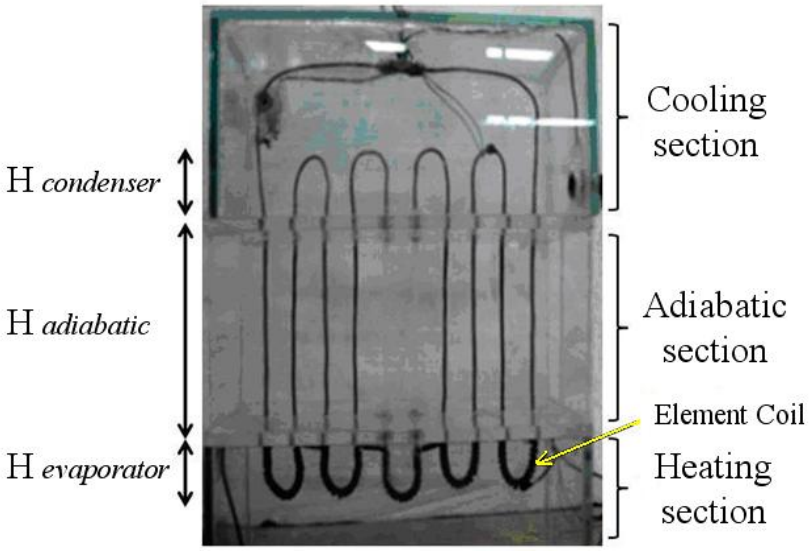


Figure 2. The Manufactured CLPHP

A vacuum and charging system, particularly designed and manufactured in our laboratory, was used to vacuum the CLPHP and to introduce a controlled amount of liquid into the CLPHP tube. This system was also used to empty the undesirable gases from the working fluid.

PROCEDURES AND RESULTS

In the present experiment, two working fluids were employed, which were water and ethanol. Tests were conducted for filling ratios of 30%, 40%, 50%, 70%, 80% for water and 30%, 40%, 50%, 70% for ethanol. The input heat power was in the range of 0 to 70 watts. This input heat power was increased by 5 watts in each step.

In the beginning of the experiment, the CLPHP was partially filled by working fluid. Then, the input heat power was stepwise increased. As a result, the heat flux raises the temperature and pressure in the evaporator region. Therefore, the slugs and plugs moved within the pipe and transferred heat from the evaporator to the condenser. For different input heat fluxes, working fluids, and filling ratios, the average temperature difference between the evaporator and condenser were recorded when the evaporator temperature reached a steady state condition. The experimental results are graphically depicted for ethanol and water in Figures 3 and 4.

It can be seen from Figures 3 and 4 that that the average evaporator temperature increases with increasing input heat flux. Furthermore, it can be concluded from these figures that the CLPHP has different thermal performance at different filling ratios. Figure 3 shows that the manufactured CLPHP has the best thermal performance for water as the working fluid when the filling ratio is 40%. The reason is that in this filling ratio, the CLPHP has the capability to transfer the maximum heat flux with a minimum temperature difference between the evaporator and condenser. When filled with ethanol, the CLPHP has the best thermal performance at a filling ratio of 50% (Figure 4).

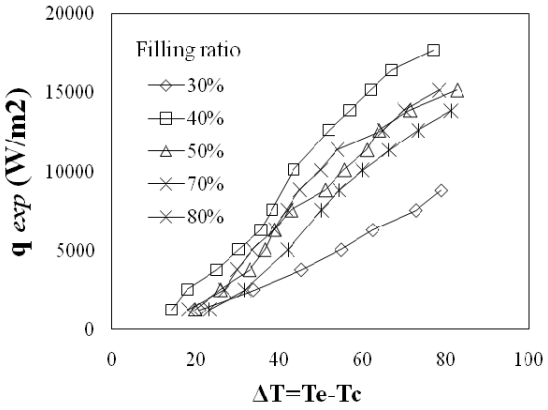

Figure 3: Experimental results for water as the working fluid

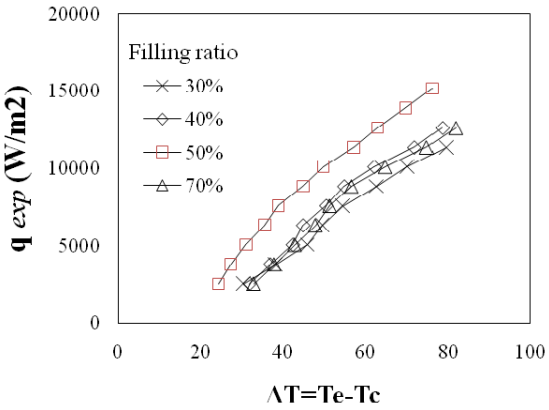

Figure 4: Experimental results for ethanol as the working fluid

Fig. 5 shows the maximum achievable heat flux of the CLPHP when the average evaporator temperature reaches approximately 100°C (for water and ethanol). Figure 5 also shows the comparison between the thermal performance of the CLPHP when it is partially filled with water and ethanol in different filling ratios. It can be concluded from Figure 5 that the CLPHP has better thermal performance when it is partially filled with water because the thermal properties of water, including thermal conductivity, latent heat of vaporization, and constant pressure specific heat, are more suitable than those of ethanol. This result is in complete agreement with previous researches about the effect of working fluid on PHPs performance [3, 6].

It is also expected from Figure 5 that if the filling ratio is below 30% or above 70%, the thermal performance of the CLPHP would decrease. This result is in complete agreement with Khandekar et al's results [3].

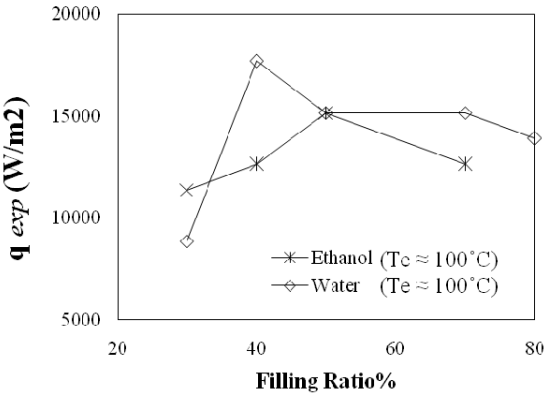

Figure 5. Maximum performance of the CLPHP obtained in different filling ratios.

CORRELATION

In order to find a heat transfer correlation, it is generally convenient to extract effective thermo-physical properties for heat transfer as non-dimensional quantities. In a fixed filling ratio, it was found from the experimental results and physical phenomena analysis of the CLPHPs that the thermo-physical properties of working fluids, the temperature difference between the evaporator and condenser, the internal diameter, and the evaporator section length can affect the thermal performance of the CLPHPs:

$$\dot{q} = \frac{\dot{Q}}{2\pi.D_i.N.L_e} = f\{h_{fg}, K, \mu, Cp, \rho_v, g\Delta\rho, \sigma, \Delta T_{e-c}, D_i, H_{eva}\} \quad (1)$$

By considering M, L, t, T, and J as independent fundamental physical quantities (Incropera and DeWitt [12]), the variables in equation (1) can be grouped into an important set of dimensionless groups including Ku, Ja, Pr, Bo, $\frac{\mu(g\Delta\rho)^{0.25}}{\rho_v^{0.5}\sigma^{0.75}}$ ($Mo^{0.25}$,Morton Number), and aspect ratio ($\frac{D_i}{H_{eva}}$).
These dimensionless groups can be arranged into the following equation:

$$Ku = f\{Ja, \Pr, Bo, Mo, D_i / H_{eva}\} \quad (2)$$

The meaning of each dimensionless parameter in equation (3) can be explained as follows:
Ku is the ratio of the input heat flux of a CLPHP to the critical heat flux in the pool boiling:

$$Ku = \left(\frac{q}{h_{fg}\rho_{vap}^{0.5}[\sigma g(\rho_{liq} - \rho_{vap})]^{0.25}}\right) \quad (3)$$

This dimensionless group represents the pool boiling phenomenon of the working liquid in the evaporator section.
The next numbers of interest are the Jakob number and the liquid Prandtl number, defined respectively as,

$$Ja = \left(\frac{C_{p,liq}.\Delta T_{e-c}}{h_{fg}}\right) \quad (4)$$

$$\Pr_{liq} = \left(\frac{C_{p,liq}.\mu_{liq}}{k_{liq}}\right) \quad (5)$$

The Jakob number indicates the ratio of sensible heat to the latent heat of vaporization in a CLPHP, and the liquid Prandtl number shows the single phase convective effect on heat transfer.
The Bond number is the ratio of the buoyancy force to that of the surface tension of the working fluid and is defined as follows:

$$Bo = D_i\sqrt{g(\rho_{liq} - \rho_{vap})/\sigma} \quad (6)$$

The Morton number shows the interaction between the viscous, buoyancy, inertia, and surface tension forces acting on a bubble formed by nucleate boiling in the evaporator section. In fluid dynamics, the Morton number is used together with the Bond number to characterize the shape of bubbles or drops moving in a surrounding fluid. For more information about the Morton number and its applications, Haberman and Morton [13] or Clift et al. [14] can be investigated.
Using the experimental data of the present and previous research ([3, 4, 5]), it was found that Ku could be described by the following correlation:

$$Ku = a\left(\frac{C_{p,liq}.\Delta T_{e-c}}{h_{fg}}\right)^b\left(\frac{C_{p,liq}.\mu_{liq}}{k_{liq}}\right)^{-0.7}\left(D_i\sqrt{\frac{g(\rho_{liq} - \rho_{vap})}{\sigma}}\right)^{0.85}\left(\frac{\mu(g\Delta\rho)^{0.25}}{\rho_v^{0.5}\sigma^{0.75}}\right)^{0.8}\left(\frac{D_i}{H_{eva}}\right)^{0.7} \quad (7)$$

By considering the effect of the filling ratio on the thermal performance of the CLPHPs, coefficients a and b can be computed from the following equations:

$$a = -2222\gamma^4 + 4704\gamma^3 - 3584\gamma^2 + 1157\gamma - 125.8 \quad (8)$$

$$b = -142.5\gamma^4 + 301.5\gamma^3 - 227.6\gamma^2 + 72.21\gamma - 6.87 \quad (9)$$

For a specific filling ratio, a and b are calculated using equations (8) and (9), and then the input heat flux is obtained by equation (7). In using equation (7), the thermo-physical properties of working fluids are calculated at the evaporator temperature (T_{eva}). Figure 6 shows the comparison between the results obtained from the experiments and those obtained from equation (7).

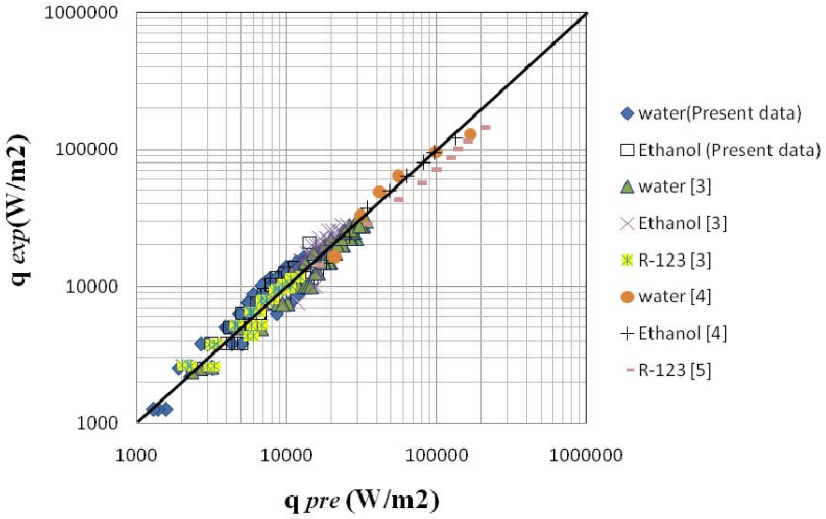

Figure 6: Comparison between the power-law correlation results and those of the experiments

Compared with the experimental data, the root-mean-square deviation of the correlation prediction was 19.7% and approximately 88.6% of the deviations were within ±30%. Therefore, it seems that the correlation can reasonably predict the input heat flux of CLPHPs.

CONCLUSIONS

In this paper, first a CLPHP was designed and manufactured. Then, the effect of various parameters, including working fluid (water and ethanol), volumetric filling ratio (30%, 40%, 50%, 70%, 80%), and input heat power (5 to 70 watts), on the thermal performance of the CLPHP were investigated experimentally. Then, the dimensionless parameters including Ku, Ja, Pr, Bo, Mo, and Di/H_{eva} that affect thermal performance of CLPHPs were obtained. Afterward, a power-law correlation based on dimensionless groups was established to predict the input heat flux of the CLPHPs using available experimental data sets of the CLPHPs. Compared with the experimental data, the root-mean-square deviation of the correlation prediction was 19.7% and approximately 88.6% of the deviations were within ±30%. It seems that the correlation can reasonably predict the input heat flux of CLPHPs.

HIGH SPEED BOILING VISUALIZATION FOR FINS WITH SUBSURFACE TUNNELS

R. Pastuszko
Kielce University of Technology, Kielce, Poland

ABSTRACT. The paper presents experimental investigations of boiling heat transfer from a system of connected horizontal and vertical subsurface tunnels. The experiments were carried out for water at atmospheric pressure. The tunnel external covers were manufactured out of perforated copper foil of 0.05 mm in thickness (holes diameter 0.5 and 0.3 mm), sintered with the mini-fins, formed on the vertical side of the 10 mm high rectangular fins and horizontal inter-fin surface. Visualization studies were conducted with a real sample and with a transparent structured model of joined tunnels having a cover of perforated foil. The investigations aimed both at identifying differences between pool boiling mechanism for horizontal and vertical tunnels and at determining the diameter and frequency of departing bubbles. The calculated and measured departure bubble frequency for a vertical tunnel showed good agreement at low and medium superheating. The holes in the foil acted as elements feeding the surface tunnel structure. The vapor escaped through the tunnel outlets in vertical tunnels and holes in foil (pores) in horizontal tunnels. Observations of internal and external visualizations confirmed most of the assumptions made for the semi-analytical model for boiling from enhanced structures composed of connected vertical and horizontal tunnels.

Keywords: *pool boiling, visualization, subsurface structure*

INTRODUCTION

Developing an analytical or semi-analytical model for boiling in enhanced subsurface structures requires conducting visualization experiments both for the actual surface and for a selected segment of this structure. The segment, with transparent walls, enables observations of boiling inside the subsurface tunnels. The first method of observation, called external visualization, makes it possible to identify the sites of vapor bubble nucleation and departure, to calculate the diameter and frequency of the departing bubbles and nucleation site density. Internal visualization enables observation of boiling structures, active and inactive pores localization, and the extent to which vertical and horizontal tunnels are filled with vapor.

Nakayama et al. [1] was one of the first to conduct boiling visualization in horizontal structural surfaces (subsurface tunnel covered with foil having triangular holes), using a section of the structure, surrounded by transparent walls. Their visualization study of boiling R-11, water and nitrogen suggested the important role of evaporation inside the tunnel in heat transfer enhancement.
Chien and Webb's [2] visualization experiments conducted for an enhanced tubular surface, having subsurface tunnels and surface pores (micro-fins 0.8 mm in height and pores 0.23 mm in diameter), showed that all the tunnels were vapor filled, except for liquid menisci, just as in the horizontal tube at high heat fluxes. Also Chien and Webb [3] reported bubble dynamics data (diameter, frequency and nucleation site density) for this type of enhanced surface using R-123. In their conclusion they

E-mail address: tmprp@tu.kielce.pl

presented the dependence of nucleation site density on the latent heat generated inside the tunnel, and stated that the latent heat constitutes half of the total heat flux.

Chen et al. [4] also observed the boiling process for structures with subsurface tunnels, on the external surface of tubes, where propane, isobutene and their mixtures were working fluids. The authors focused on the identification of the bubble shapes in different liquids, the generation of small bubbles (of diameters less than 0.5 mm), their arrangement and distribution, and the analysis of their behaviour on different enhanced surfaces. Ramaswamy et al. [5], using a fast camera (1500 frames/sec), determined the data concerning the bubble growth for a silicone structure composed of interconnected mini-channels, and placed in the boiling FC-72. The data included the diameter of departing bubbles (0.61 – 0.66 mm), frequency (150 – 250 Hz), and the density of nucleation sites. It was concluded that the pore diameter had a significant effect on the diameter of the departing bubbles. Visualization for a similar structure, though made from copper and quartz and placed in PF 5060, was also performed by Ghiu and Joshi [6]. They showed different boiling regimes for the investigated materials and confirmed the dynamic nature of the boiling process.

Yu and Lu [7] presented boiling structure visualization results for copper mini-fins (the height: 0.5 – 4.0 mm, the width of the inter-fin space: 0.5 – 2.0 mm), placed in the boiling FC-72 fluid at four different heat fluxes. The departing bubble diameters were estimated to be 0.2 – 0.3 mm. For small and medium heat fluxes (measurements covered the range from 20 to about 1000 kW/m^2) the number of active nucleation sites and frequency of the departing bubbles increased for a small increase in the heat flux. At the highest heat fluxes, emerging „vapor mushrooms" caused the vaporization in the central part of the fin system, which resulted in the sudden superheating.

Pastuszko and Mroczek [8] describe water boiling visualization for subsurface structures in the form of a connected system of horizontal and vertical tunnels. For low values of the heat flux ($q \approx 100$ kW/m^2) the generation of vapor bubbles could be seen in horizontal tunnels and bottom sections of vertical tunnels. The bubbles, which remained separate, were getting out into the inter-fins space via pores of the horizontal tunnel. The increase in the heat flux and superheating ($q \approx 145$ kW/m^2) caused the increase in frequency and diameter of the forming bubbles. At substantial heat flux ($q \approx 185 – 260$ kW/m^2), large vapor structures formed, and through intensive convection, disturbed the steady motion of bubbles visible for low values of q. Pastuszko [9] presented experimental investigations of boiling heat transfer for system of connected narrow tunnels. The experiments were carried out with water at atmospheric pressure. The tunnel external covers were manufactured out of perforated copper foil of 0.05 mm in thickness (hole diameters 0.4 and 0.5 mm), sintered with the mini-fins, formed on the vertical side of the 10 mm high rectangular fins and horizontal inter-fin surface. Visualization studies were conducted with a real sample as well as with a transparent structured model of joined narrow tunnels limited with perforated foil. Diameter and frequency of departing bubbles were determined. The holes in the foil acted as elements feeding the surface tunnel structure and the vapor bubbles generated in menisci in the tunnel corners departed through tunnel outlets in vertical tunnels and holes in foil (pores) in horizontal tunnels.

The objective of the present study is to understand the boiling phenomena for a system of connected horizontal and vertical subsurface tunnels and to verify assumptions for a theoretical model.

EXPERIMENTAL SET-UP AND SAMPLES

External and internal visualization set-up

The diagram of the measurement stand for external visualization is presented in Figure 1. It is modified set-up described in [10]. The main stand module consisted of a cylindrical vessel (7), filled with working fluid, and placed over the investigated sample (9). The sample was soldered to a 170 mm long cylindrical copper bar (10) of 45 mm in diameter.

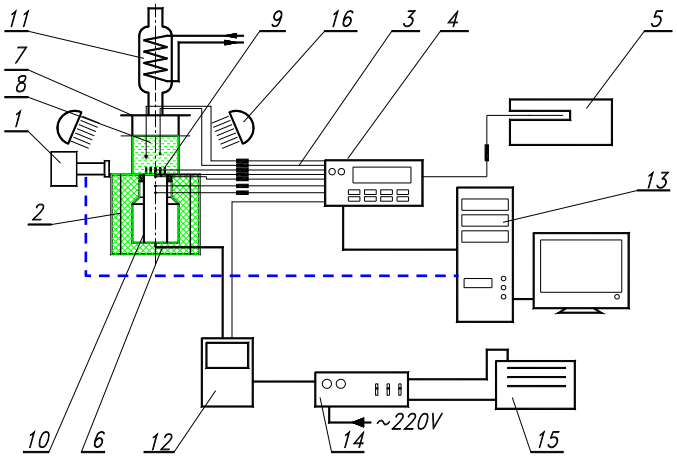

Figure 1. Schematic diagram of the external visualization system: 1 – digital camera; 2 – Teflon casing; 3 – compensating cables; 4 – data logger; 5 – dry-well calibrator; 6 – insulation; 7 – glass vessel; 8 – boiling liquid; 9 – investigated sample; 10 – copper bar with cartridge heater; 11 - condenser; 12 - wattmeter; 13 – PC; 14 – power supply and fuses; 15 – autotransformer; 16 – lights.

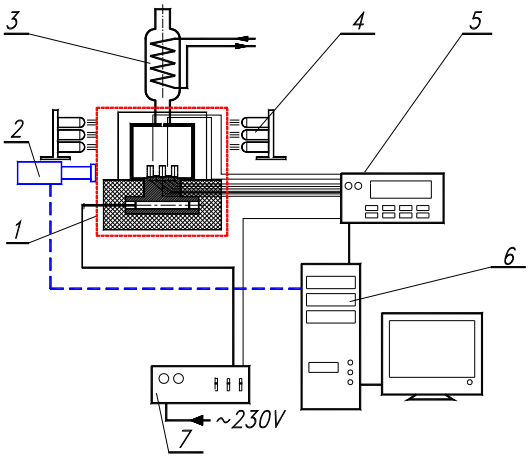

Figure 2. Schematic diagram of the internal visualization system: 1 – main module; 2 – digital camera; 3 – condenser; 4 – lights; 5 – data logger; 6 – PC; 7 – power regulator

The cylinder diameter corresponded to the diagonal of the sample base. A 1000 W electric cartridge heater of 19 mm in diameter and 130 mm in length was installed into the bar.

The estimated uncertainties were as follows:

- low heat flux (20 kW/m^2): heat flux ±15%, wall superheat at the main fin base ±0.2 K, heat transfer coefficient ±18.5%,
- high heat flux (550 kW/m^2): heat flux ±1.2%, wall superheat at the main fin base ±0.42 K, heat transfer coefficient ±2.4%.

The principal part of the internal visualization system is the main module (Figure 2, item 1), which combines a sample segment with a heating system. The visualization images were obtained using a high speed digital monochrome camera PHOT MV-D1024-160-CL (*Photonfocus*) of resolution 1024x1024 pixels as well as high speed camera EX-FH20 (*Casio*) of resolution 480x360 at 210 fps.

Samples

The enhanced structure, which was the focus of the investigations, is shown in Figure 3. A sample with tunnel structure formed a square of 27 mm-long side (w_f). It had three main fins with additional surface modification (mini-fins covered with perforated foil). The visualization studies were conducted with a real sample (external visualization – Figure 3) and with a transparent structured model of joined tunnels limited with perforated foil (internal visualization – Figure 4). Table 1 shows the parameters of the tested samples.

The main stand module for internal visualization (Figure 4) consisted of the base block with the cartridge heater inside, connected with the segment of the sample. Two U-shape copper foils (item 4, Figure 4) having two rows of holes with 0.5 mm in diameter were connected with mini-fins with thermal adhesive. Two transparent plexiglas plates were attached to the edges of the segment and foil by means of epoxy adhesive. The whole module was sealed by high temperature silicone.

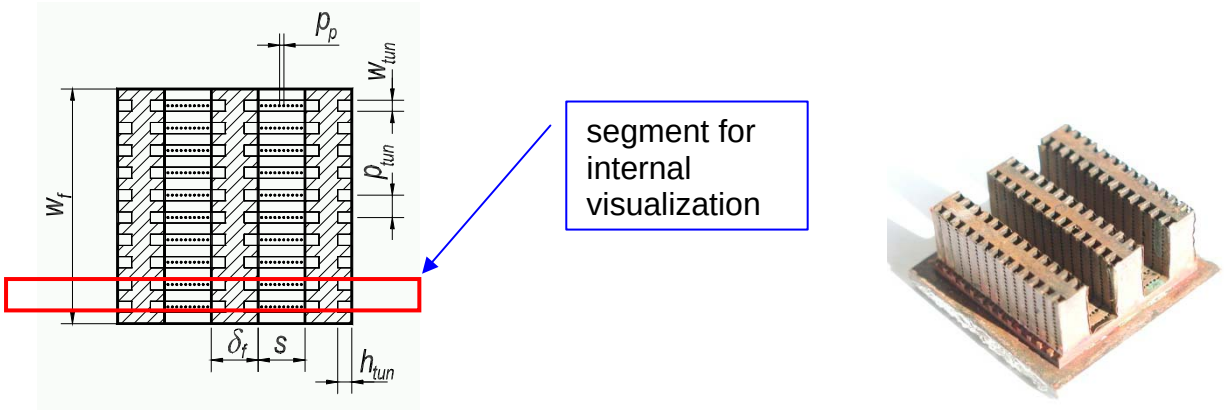

Figure 3. Horizontal section of the tunnel structure and photograph of the sample.

Table 1
Sample code and specifications

sample code	visualization type	pore dia. d_p	pore pitch p_p	tunnel height h_{tun}	tunnel width w_{tun}	tunnel pitch p_{tun}

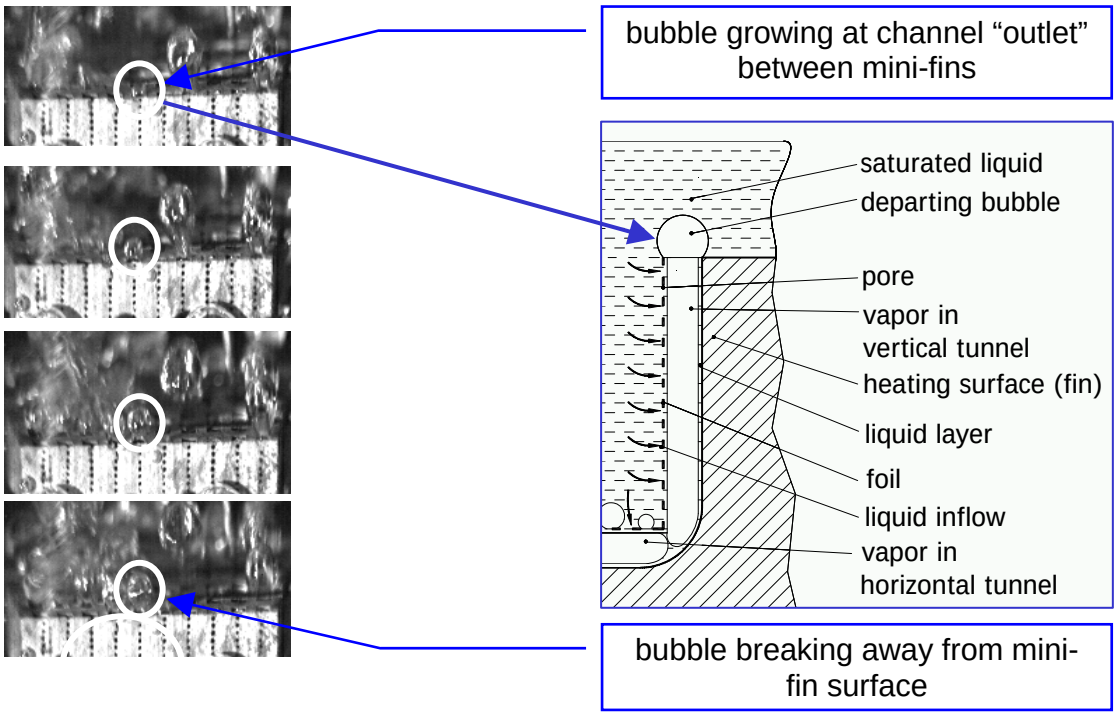

Figure 5. Bubble growing and departing for vertical tunnel outlet, TS-10-2.50-0.3, boiling water $q \approx 40$ kW/m^2, 193 fps.

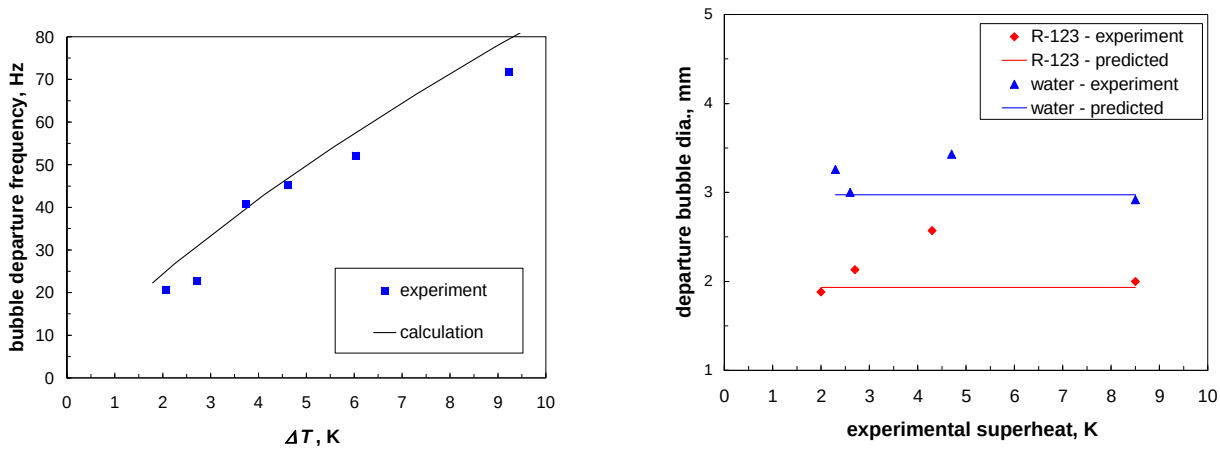
into pores in the perforated foil, vapor bubble inside tunnels and bubble growth preceding departure are all marked in the figure. Despite small heat flux, one can observe that the majority of vertical tunnels are active.

Bubble departure frequency and diameter

A comparison of the experimentally observed values and the calculated values for bubble departure frequency at boiling water and R-123 in vertical tunnel is shown in Figure 6.



(a) (b)

Figure 6. Comparison of the calculated and measured departure bubble frequency (a) and diameter (b) for the vertical tunnel at the boiling of water and R-123 (data for TS-10-2.50-0.3), according [11].

The experimental data for the vertical tunnel were obtained by means of high-speed photography (193 fps): for each superheat 5 frequency measurements referred to three randomly chosen tunnel outlets were taken and averaged. The measurements show satisfactory agreement with the theoretical calculations.

The maximum error of computed frequencies, compared to the experimental data, do not exceed 30% and occur for small superheats, 2 – 3 K [11]. The discrepancy between the measurement and calculation of bubble diameter reached 15%. The measurements were based on the photographs from a digital camera. The estimated error in defining the diameter was up to 10% (including the error resulting from the non-sphericity of bubbles). The calculations of these parameters were based on semi–analytical approach proposed in [11] for this kind of enhanced structures.

Internal visualization

The internal visualization method allows observation of differences in pool boiling mechanism for the subsurface horizontal and vertical tunnels. At low values of heat flux ($q \approx 130$ kW/m^2) the generation of vapor bubbles can be seen in horizontal tunnels and the bottom regions of vertical tunnels (Fig. 7). In horizontal tunnels, cyclical changes in vapor volume result from cyclical processes of liquid suction by inactive pores, vaporization in menisci and generation of vapor bubbles by active pores [1]. Changes in activity of particular pores take place: an active pore becomes inactive after generating a few bubbles. These findings agree with those of Chien and Webb [2]. In vertical tunnels, all pores in foil remain inactive; vapor escapes through the outlets at the main fin tips. The vapor is generated in the bottom regions of the tunnels, at the contact with vertical tunnels. One may suppose that some of the liquid from horizontal tunnels supplies vertical tunnels. In some vertical tunnels single bubbles can be observed, in other tunnels larger areas are filled with vapor, which results in the increase in the departing bubble diameter.

At medium heat fluxes ($q \approx 180$ kW/m^2) the frequency of bubbles departing through active pores of horizontal tunnels and the number of active pores increase (Figure 8). Increased bubble average diameter is a characteristic feature of bubbles departing from vertical tunnel pores. Most regions of vertical tunnels are filled with vapor, but separate bubbles can also be observed.

At heat flux $q \approx 230$ kW/m^2 (Figure 9) more and more bubbles depart from the horizontal tunnel pores, and the departure frequencies and nucleation site density increase. Bubble coalescence in the space between vertical tunnels intensifies and may affect the whole system of tunnels. The vapor fills nearly the whole space of the horizontal and vertical tunnel, and at the main fin tips the coalescence of bubbles generated by the two analyzed tunnels can be observed.

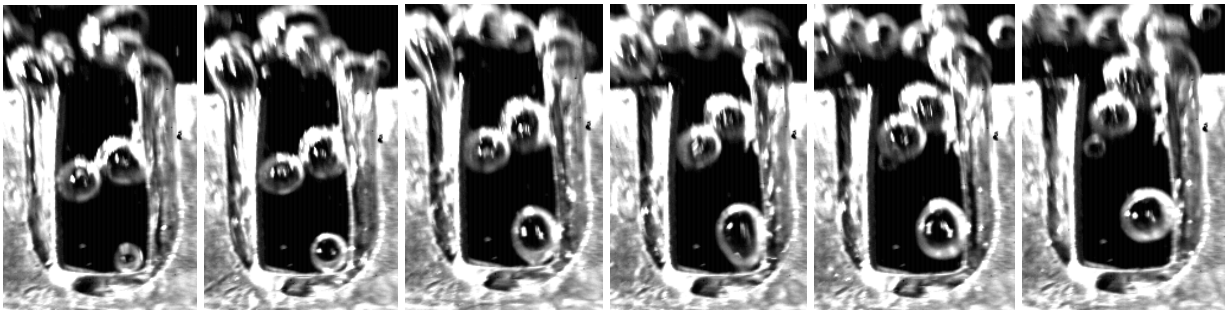


Figure 7. Water boiling internal visualization at small heat flux ($q \approx 130$ kW/m^2), frames every 0.005 s.

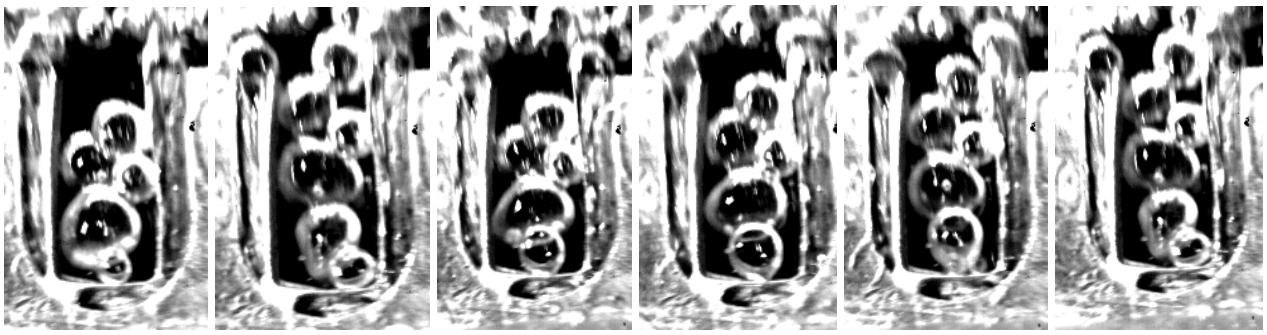

Figure 8. Water boiling internal visualization at medium heat flux ($q \approx 180$ kW/m^2), frames every 0.005 s.

Figure 9. Water boiling internal visualization at high heat flux ($q \approx 230$ kW/m^2), frames every 0.005 s.

CONCLUSIONS

The visualization experiments allow drawing the following conclusions concerning the mechanism of boiling in the system of connected tunnels:

- Passive and active pores were observed for horizontal tunnel. Passive pores make it possible to provide subsurface tunnels with liquid, whereas the active pores act as the vapor outlets.
- Increased heat flux generates a larger number of active pores in the horizontal tunnel, which contributes to higher nucleation site density. Diameters of departing bubbles increase.
- Pores in the perforated foil of vertical tunnel are inactive – their task it to only feed the subsurface space. Liquid layer evaporation takes place inside the tunnel and the vapor bubbles depart through tunnel outlets at the main fin tips.
- Vertical tunnel outlets are active within the whole range of investigated heat fluxes, and the bubbles departing from them have similar diameters at different heat fluxes.
- The tunnels "work" independently, only some fraction of liquid evaporated from the contact area of the horizontal and vertical tunnels.
- The observations based on internal and external visualization confirm most of the assumptions made before developing the semi-analytical model for boiling from enhanced structures composed of connected vertical and horizontal tunnels [11].

AN INVESTIGATION OF A CONDENSATION PROCESS EFFICIENCY IN AIR-COOLED CONDENSER COILS

T. Bohdal, H. Charun, M. Czapp

Chair of Thermal Engineering and Refrigerating Engineering
Koszalin University of Technology, Koszalin, Poland

ABSTRACT. The authors designed an experimental investigation of the R404A refrigerant condensation process in a long air-cooled coil of length L. The experiments were performed for the following range of the basic parameters: $\dot{m}$ = 100 ÷ 400 kg/(m^2·s), $\dot{q}$ = 4000 ÷ 23000 W/m^2, T_s = 20 ÷ 40°C, L = 10 ÷ 25 m. The experimental setup as well as some of the experimental results are shown in the paper. Heat transfer coefficients on the tube inner surface of the coil within the condensation zone and the influence of the coil length on the efficiency of the condenser are discussed. Based on the experimental results, a correlation describing a R404a condensation process in long coils was worked out. A comparison between results calculated from various formulas and the experimental ones is also given.

Keywords: *heat transfer, condensation, refrigeration, air-cooled condenser, R404A*

INTRODUCTION

Air-cooled condensers have a wide range of applications in refrigerating and air-conditioning units. Heat transfer from the refrigerating medium being condensed by air is a relatively complicated process. It relates to the process of heat transfer from the medium to the tube inner surface as well as the transfer from the outer (finned) surface of a condenser unit to air. Heat transfer occurring during the refrigerating media condensation has been discussed in many papers. Mostly, however, determination of local and average heat transfer coefficients of refrigerating media being condensed in horizontal and straight tubes is discussed. There are not so many research activities concerned with a condensation process inside a cooling coil itself. Such problems as for instance the influence of a cooling coil length on the heat transfer process are considered rather seldom. The designer, however, while working out a air-cooled condenser, should have a lot of that kind of data at his disposal. To analyse the heat transfer process during condensation of a refrigerating media in air-cooled condensers, one has to take into account the specific conditions of their work, i.e. [1, 2, 3]:

1. a small temperature difference between the condensation point and the cooling air temperature (ΔT = 10 ÷ 25 K),
2. small values of the heat flux density ($\dot{q}$ = 500 ÷ 12000 W/m^2),
3. small values of the mass flux density (an order of a few hundred kg/(m^2·s)),
4. condensation of the refrigerating media occurs inside of the coils. Such coils consist of horizontal tube elements joined with elbow connections,
5. condenser coils are supplied with superheated vapour and leave them as supercooled liquid, under real work conditions.

There are three characteristic heat transfer zones:

- superheating zone,
- condensation zone,
- subcooling zone.

It is relatively simple to calculate heat transfer coefficient h in a single-phase flow (superheating zone or subcooling zone), and this problem is widely discussed in literature. The calculation of the h coefficient in a condensation zone is far more complicated. It is necessary, for instance, to take into consideration the properties of a condensation mechanism itself and a larger amount of data such as properties of vapour and condensate are required. It is not uncommon that differences in the estimation of heat transfer coefficient h for refrigerating media condensation process in straight tubes reach the level of 300 % using formulas from different literature sources. The situation may be even much worse in the case of refrigerating media condensation taking place in tube coils. The further discussion will focus on this problem [5, 6, 7].

EXPERIMENT APPARATUS

The aim of the experimental investigation performed was to determine whether the length of a tube coil influenced the values of heat transfer coefficient α within a condensation zone of an air-cooled condenser. The investigation was performed on a single-coil condenser, finned from the outer (cooling air) surface. It was possible to change the coil length of a condenser in the experiments. The coil was made out of a copper tube (OD = 16 mm) and it consisted of several straight connection tubes (with a unit length equal to 1800 mm), joined together with the elbow type connections. By reducing the number of straight connection tubes, various length coils were obtained: L = 10, 12, 15, 20, 25 m. They had fins of 0.18 mm in thickness, distributed in a pitch of 2.5 mm. The coil under consideration, working as the air-cooled condenser, was put into an isolated cold room. The installation allowed to maintain the assumed inlet air flow as well as refrigerating medium R404A parameters. For different coil lengths, the refrigerant and air parameters were measured. The temperature distribution of R404A lengthwise the coil was measured using thermocouples and a medium flow rate with the use of calibrated tanks. All the measurements were performed as the steady state conditions were achieved. The schematic diagram of the experimental setup is shown in Figure. 1 [8, 9].

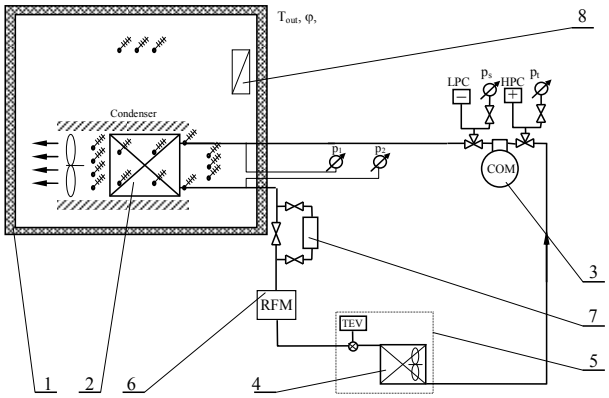

Figure. 1. Schematic diagram of experimetal setup: 1- insulated testing chamber, 2- lamellar condenser subjected to test, 3- compressor unit, 4- fan cooler, 5- cold room, 6- refrigerant flow meter, 7- dewatering filter, 8- stabilising system for air parameters, *T*- temperature measurement, *P*- pressure measurement, *HPC*- high-pressure control valve, *LPC*- low-pressure control valve

RESULTS

The condenser coil was supplied with a superheated vapour of R404A medium and discharged in supbcooled liquid condition. Three zones with an entirely different heat transfer intensity were observed in each condenser, regardless of its coil length. Measuring the medium temperature distribution lengthwise the coil, it was possible to determine the exact position as well as the length of the condensation zone. An example of the temperature distribution is shown in Figure 2 and

Figure 3 and Figure 4 presents an example of the dependence of the pressure drop of the R404A refrigerant in the condenser's coil pipe of length L = 12 m versus the mass flux density $\dot{m}$

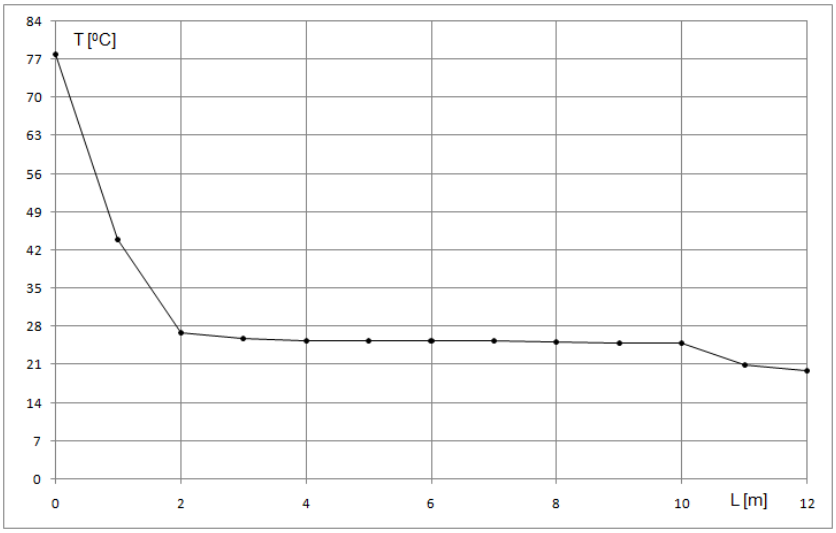

Figure. 2. Distribution of refrigerant temperature while condensing in a coil pipe; $\dot{m}$ = 156 kg/(m^2·s)

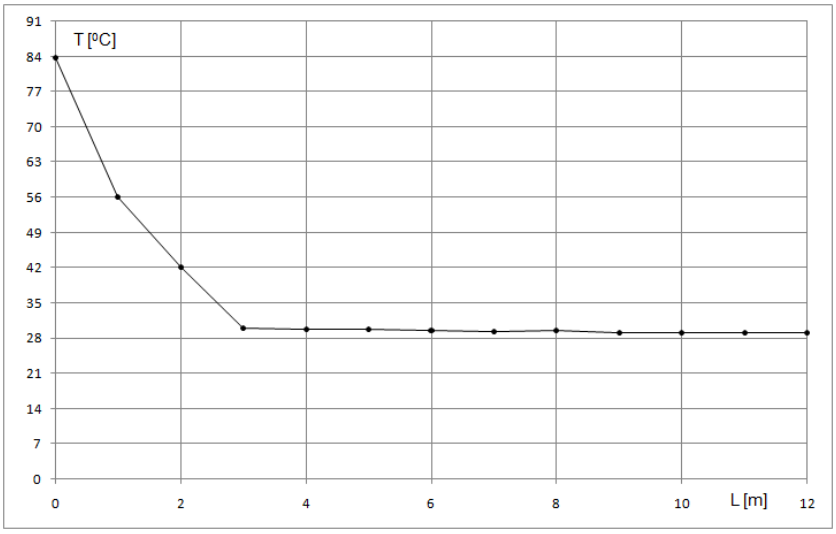

Figure. 3. Distribution of refrigerant temperature while condensing in a coil pipe; $\dot{m}$ = 366 kg/(m^2·s)

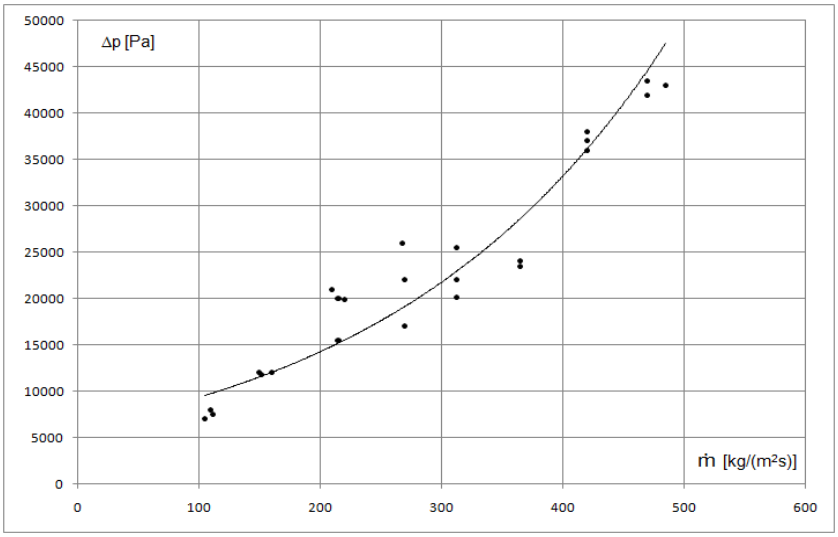

Figure. 4. Results of investigations of flow resistances of R404A refrigerant in condenser's coil pipe depending of mass flux density $\dot{m}$; L = 12 m

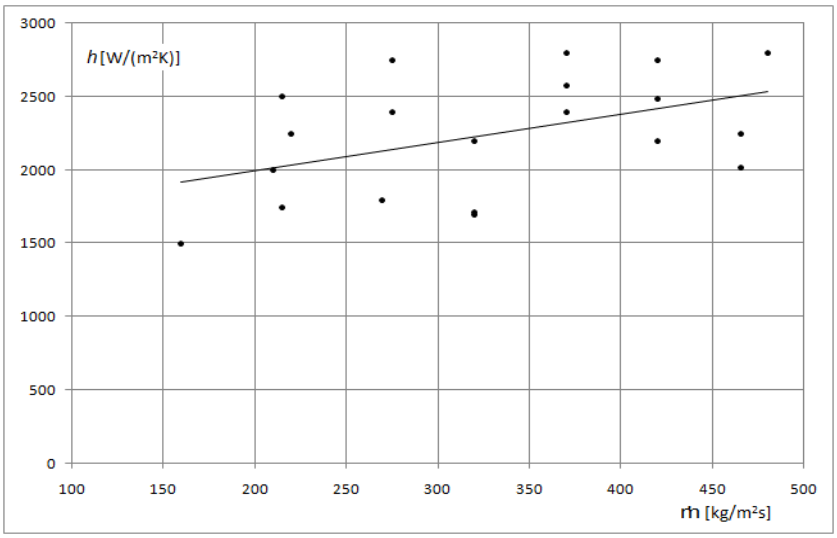
Heat transfer coefficients h typical for the condensation zone were determined for the refrigerating media in the experiments. They are shown in Figure 5 and 6 as a function of mass flux density $\dot{m}$, as well as heat transfer flux density $\dot{q}$ for the selected coil investigated. During the experiments, the characteristic parameters were maintained within the scope as given below:

- heat transfer flux density $\dot{q} = 4000 \div 23000$ W/m^2,
- mass flux density $\dot{m} = 100 \div 400$ kg/(m^2·s),
- temperature of condensation $T_s = 20 \div 40$ °C,
- coil length $L = 10 \div 25$ m.

a)



b)

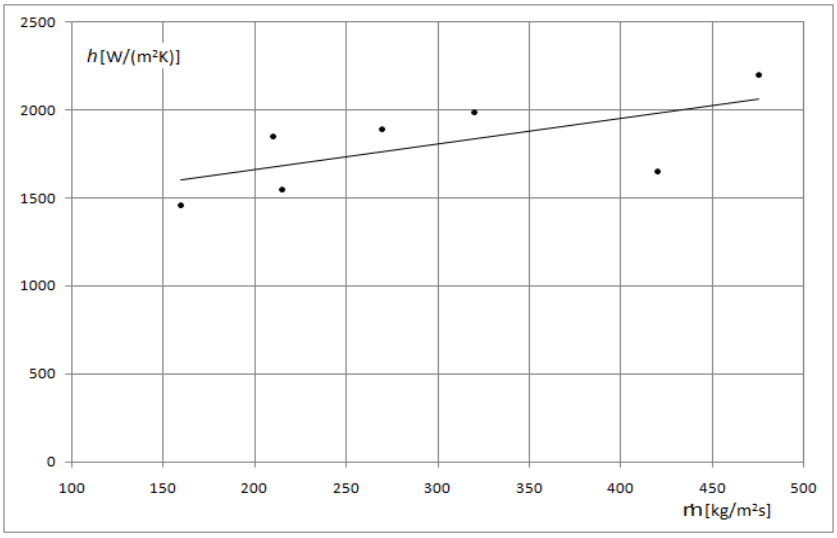


Figure. 5. Experimental mean heat transfer coefficient h versus mass flux density $\dot{m}$: a) $L = 12$ m, b) $L = 20$ m

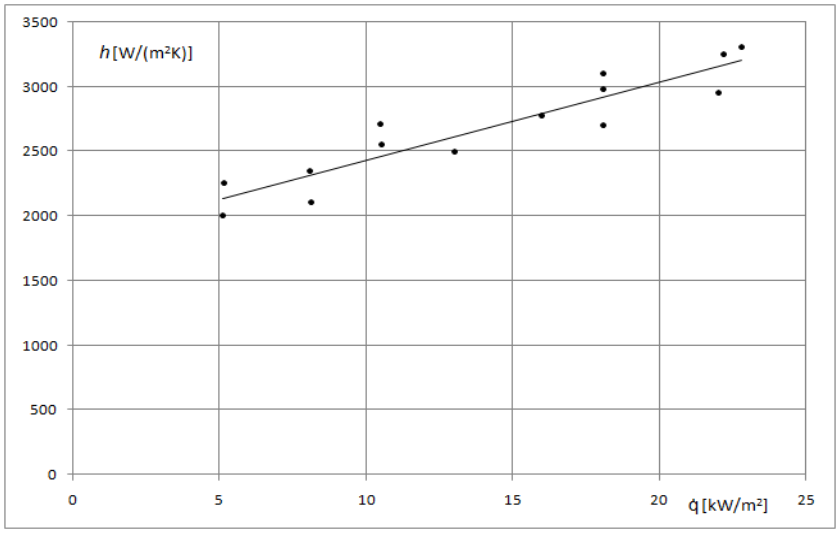
a)



b)

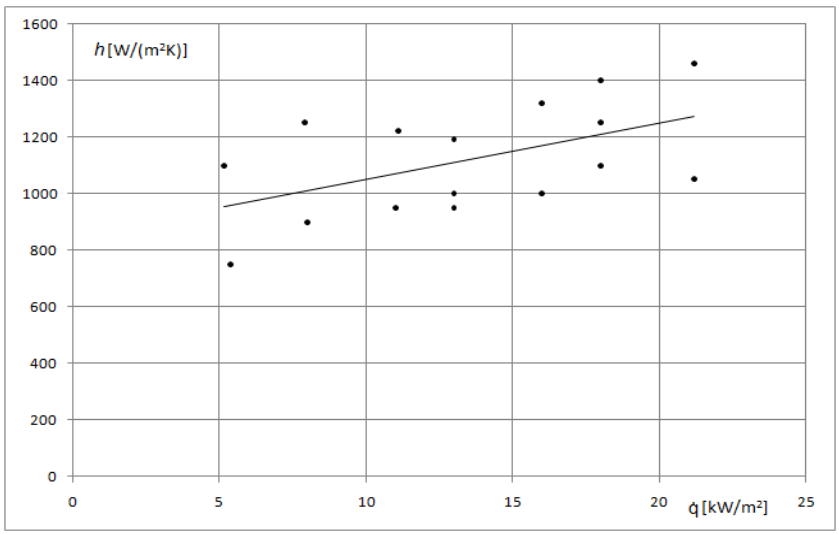


Figure. 6. Experimental mean heat transfer coefficient h versus heat flux density $\dot{q}$: a) L = 10 m, b) L = 25 m

The results presented demonstrate that heat transfer coefficient h increases as the mass flux density $\dot{m}$ and heat transfer flux density $\dot{q}$ rise. Moreover, the h coefficient clearly depends of the coil length. Based on the experimental investigation, the correlation describing a refrigerating media condensation process in long coils is worked out.
The new formula is as below:

$$Nu = 279 \cdot M \cdot \dot{q}_w^{0,21} \cdot L^{-0,61} \cdot D^{0,75} \quad , \tag{1}$$

where:

$$M = \frac{(\rho_l)^{0,1}}{(r \cdot \nu_l)^{0,5} \cdot (\rho_g \cdot \sigma)^{0,3}} \quad , \tag{2}$$

Nu - Nusselt's number,
$\dot{q}_w$ - heat flux density in reference to the internal surface of coil tubes, [W/m^2],
L - length of a coil pipe in a condensation zone, [m],
D - internal diameter of a pipe, [m],
ν_l - coefficient of kinematic viscosity of a saturated liquid , [m^2/s],
ρ_l - saturated fluid density, [kg/m^3],
ρ_g - dry saturated vapour density, [kg/m^3],
r - heat of evaporation, [J/kg],
σ - surface tension, [N/m].

The formula gives the best results in refrigerating media condenser calculations within the scope of parameters investigated by the authors and given previously. A comparison between the calculated results as the formula (1) was applied and the experimental ones, is shown in Figure 7. It can be deduced that 90% of the experimental results are within ±15% scope compared to the values calculated on the basis of correlation (1). The correlation (1) was also verified against the formulas given by the other authors. However, because of the authors' lack of formulas describing the heat transfer coefficient as a function of the coil length, the formulas describing the condensation process in straight tubes were used. The comparison between various formulas is shown in Figures 7 and 8. Within the scope of the $\dot{m}$ and $\dot{q}$ values, being of a real interest in refrigerating engineering, a satisfactory compliance was achieved. The influence of the coil length on the heat transfer coefficient is evident.

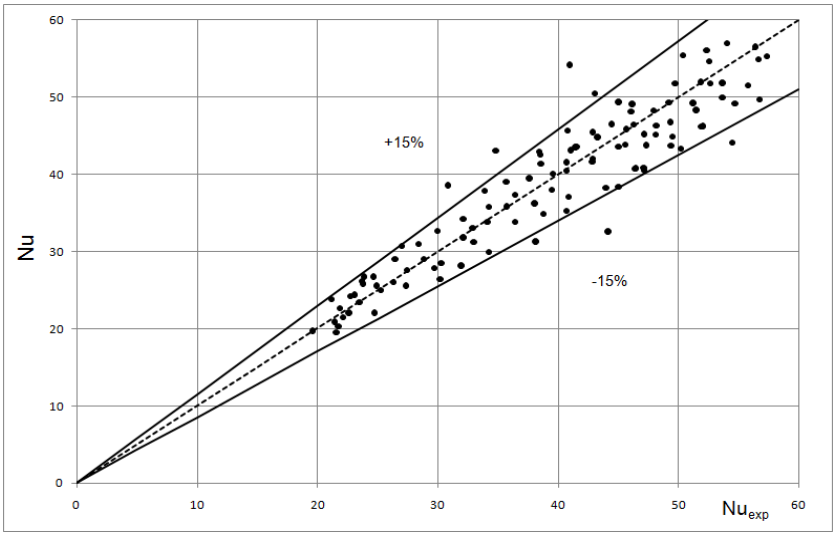

Figure. 7. Comparison of the experimental results Nu_{exp} with the calculations according to correlation Nu_{th}

A comparative listing of the authors' own investigations with the results of the calculations according to the correlations as given by other authors is presented in Figures 8 and 9. Those comparative correlations given by other authors were taken into consideration in which a dependence is noted of the Nusselt's number *Nu* from the coil pipe length. Figure 8 presents a comparison of the dependence of Nusselt's number *Nu* from the density of heat flux $\dot{q}$, while Figure 9 presents a comparison of the authors' own research results and calculations from the correlations given by other authors in the range of characteristics $Nu = f(\dot{m})$, where $(\dot{m})$ is the mass flux density.

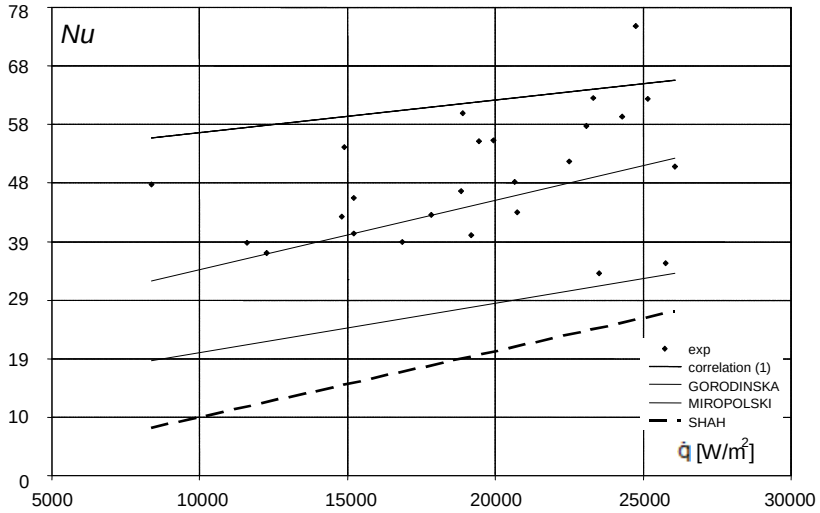

Figure. 8. Comparison of the results of investigations of Nusselt's number $Nu = f(\dot{q})$ with the results of calculations according to correlations provided by other authors [10, 11, 12]

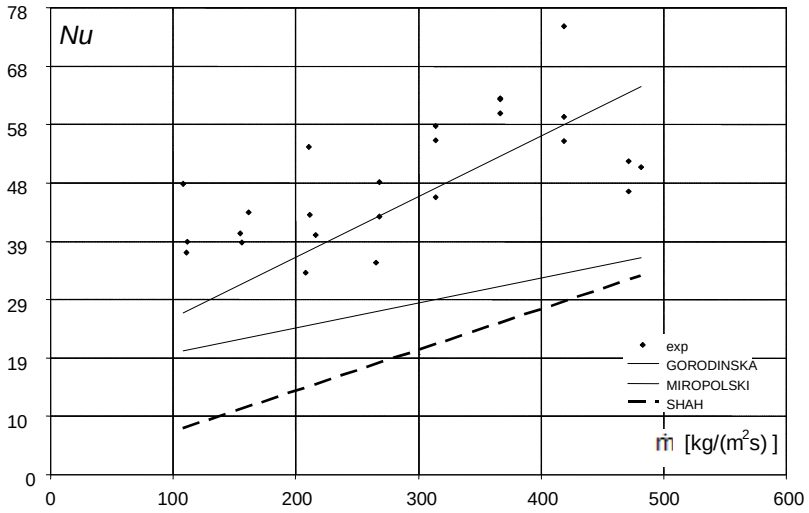

Figure. 9. Comparison of the results of investigations of Nusselt's number $Nu = f(\dot{m})$ with the results of calculations according to correlations provided by other authors [10, 11, 12]

CONCLUSIONS

1. During the condensation of a refrigerant in a flow through a vertical pipe, channel length L has practically no influence on the quantity of heat transfer coefficient h. If this process occurs in a flow through a coil pipe with large length L/D = 1500 (where D – internal diameter), then an influence of the channel length on the value of the coefficient is to be noted. This is so because the mechanism of the refrigerant's condensation changes in a pipe channel of a large length, with a substantial influence of the impeding of the flow through the condensate which leaves subsequent cross-sections of a long channel.
2. The authors conducted their own experimental investigations concerning the condensation of the R404A refrigerant in coil pipes with internal diameter D = 13 mm and length L = 10 ÷ 25 m. For design calculations, formula (1) is recommended, which allows one to calculate the mean h coefficient for coil pipes. The authors had previously checked the usability of formula (1) for engineering calculations with the following refrigerants: R12, R22, R134a and R404A.

ABSTRACT. In this work, the boiling flow heat transfer in horizontal metal-foam partially filled tubes is experimentally studied using HFC134a with water heating. The interface wall temperature distributions are tested. The effect of mass flow rate, vapour quality, and operation pressure on flow resistance, and two phase heat transfer coefficient are investigated. The two phase flow and heat transfer performance are compared with conventional smooth tube. It is revealed that the boiling heat transfer will be enhanced by increasing vapour quality for high mass flow rates more significantly than in the case of low mass flow rates. The facts are due to different flow patterns occurred inside the metal-foam tubes. The flow pattern can be predicted by monitoring the cross-sectional wall surface temperatures.

Key words: *metal foams, horizontal tube, flow resistance, boiling heat transfer, flow pattern*

INTRODUCTION

High porosity metal foams as a porous media for thermal transport has been a hotspot in the past several decades[1-10]. In order to ignore the effect of thermal radiation ,Calmidi and Mahajan [1] measured the effective thermal conductivity in the condition of low temperatures. As a result, an two-dimensional structure analytical model for predicting the effective thermal conductivity of metal foams was established. Later, a three-dimensional idealized cellular structure model was developped by Boomsma and Poulikakos [2]. The effects of thermal dispersion of metal foams is investigated by Hunt and Tien [3] and Lee et al. [4]. It is noted that high heat fluxes even up to 100 W/cm2 can be dissipated easily by metal foams in the convective condition. Recently, Lu et al. [5] developped an inter-connected cylinders model for analysing the thermal transport characteristics in metal foams, which is approved to be appropriate for most situation. Flow resistance and heat transfer characteristics of metal foams are numerously studyed[6-10]. Calmidi and Mahajan [6] and Kim et al. [7,8] both investigated flow resistance and heat transfer in metal-foam filled pipes through experimental test. It is found that the heat transfer coefficient enhances quickly while the pressure drop increases heavily at the same time. Bastarows et al. [9] found that the heat transfer coefficient in metal foams is as three times as that in conventional microfin. Hwang et al. [10]experimentally investigated the effect of foam porosity on flow resistance and heat transfer coefficient in luminum foams filled pipe.

Forced convection in metal foams without phase change has been studied in recent years[11-16]. Kim etal.[11]carried out experimental studies on single phase convective heat transfer performance in channels. Zhao etal. [12,13] analytically investigated performance of heat transfer and pressure drop and the influencing factors including porosity and pore size of the metal foam and the flow conditions.In contrast, Zhao et al. [14] also conducted experimental test and numerical simulation for

convective flow and thermal transport in foams filled channnels. Mahjoob and Vafai [15] reviewed correlation of flow resistance drop and heat transfer in open cell metal-foam filled channel which will provide help information for heat exchanger design.

Qu and Mudawar[16] investigated the boiling mechanisms in micro channels. It is noted that the nucleation boiling and growth of vapour bubbles are sustained by the difference of temperature of channel wall and fluid by nucleate boiling, while the heat is transferred mainly by single-phase convection through the thin annular liquid film in the convective dominant region. Sondergeld and Turcotte[17] and Zhao et al[18] experimentally investigated boiling heat transfer in closed cavity in porous media. Rahli [19],Topin[20] studyed boiling performance for forced convection in porous media filled channels. The effects of heat flux and mass flux on the distribution of boiling region were discussed. Majumdar[21] and Chung[22] developped a flow model for each phase fluid based on Darcy law. Although research on single phase for metal foams and boiling performance for porous media attract more and more attention, little work was referred to the flow and heat transfer in metal foams with phase change due to complicated boiling mechanism in metal foams.

In this work, the boiling flow heat transfer in horizontal metal-foam partially filled tubes is experimentally studied using HFC134a with water heating. The flow and heat transfer performance are compared with conventional smoothe tube and fully filled foam tube. The effects of mass flow rate and operating pressure on boiling heat transfer and pressure drop are presented in the paper. The flow pattern predicted by monitoring the cross-sectional wall surface temperatures are also referred.

EXPERIMENTAL APPARATUS AND METHOD

Experimental system

Experimental system is comprised of a R134a receiving tank, a R134a pump for refrigerant circulation, a mass flow meter, a pre-heater, a test section, and two chillers. Water-heated method is adopted in the test section, seen in Figure 1(a). Before the refrigerant enters into the mass flow meters, it is firstly sub-cooled in a chiller in case of possible evaporation in pipe. The measurement range of flow meter is between 0.1 and 3 kg/min. A well-insulated pre-heater is used to control the inlet quality of refrigerant to the test section. The enthalpy of the sub-cooled refrigerant before the pre-heater can be determined from its pressure and temperature, thus the refrigerant quality and enthalpy at the inlet of test section can be determined by an energy balance on the pre-heater section. The temperature and pressure of the refrigerant at the inlet and outlet of the test section will be measured. The exit quality is calculated by an energy balance between the imposed heat flux by hot water and enthalpy change of the refrigerant across the test section. The pressure drop in the test section is measured using a differential pressure transducer. A glass tube after the test section will facilitate visualisation of the flow. After the test tube, the refrigerant will enter a separator with the liquid flowing from the bottom of the separator to the refrigerant reservoir and the vapour passing through a condensing heat exchanger where it will condense to liquid before returning to the reservoir.

Test section

The 18mm inner-diameter copper tube is initially used for the tests. The copper foam tube is sintered in the inner pipe with a thickness of 5mm. In addition, 32 T-type thermocouples are attached on 8 outer wall-surface locations along the flow direction. At each location, 4 thermocouples are placed on the circumference of the tube with angles of 0^o , 45^o , 90^o , 180^o, respectively, shown in Figure 1(b). The test tube will be heated by hot water in a double-pipe heat exchanger.

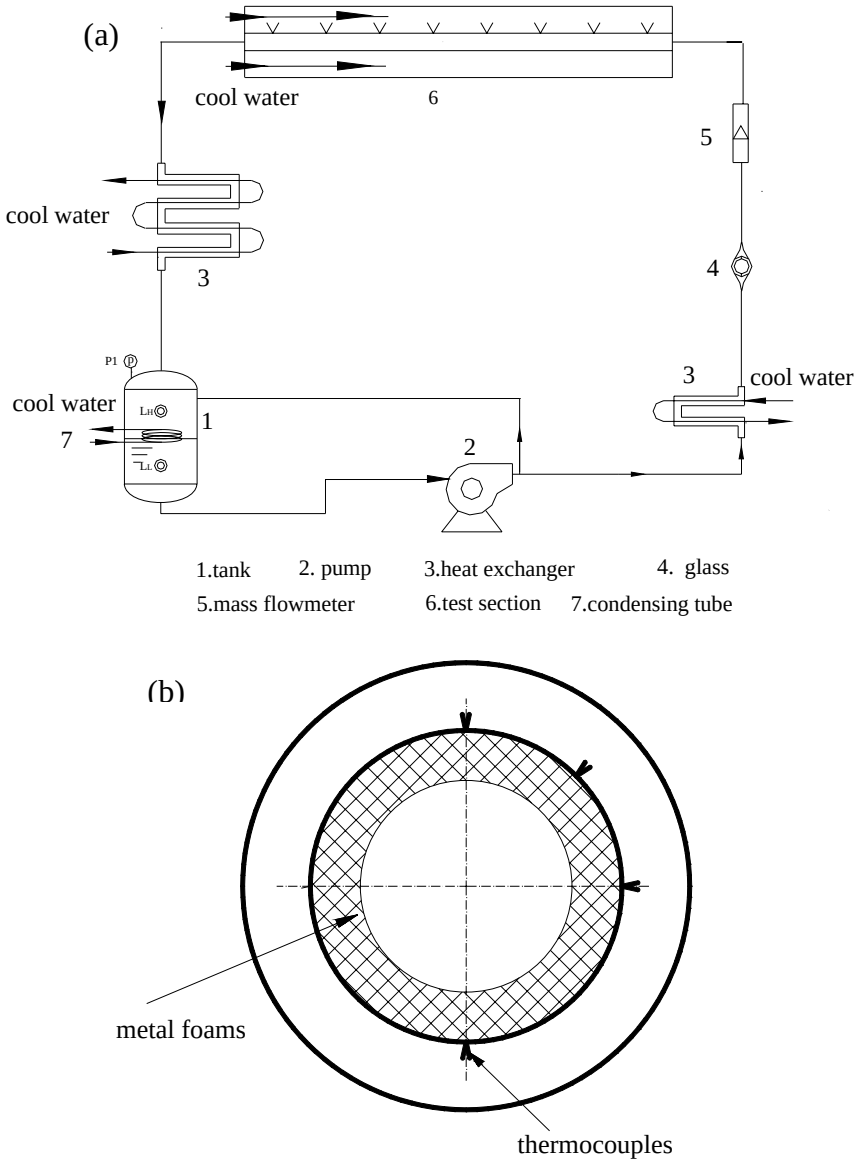

Figure 1. (a) Schematic diagram of test rig. (b) Location of thermocouples at cross section.

RESULT AND DISCUSSION

Experimental results for convective boiling flow resistance

Comparison with smoothe tube. Flow resistance characteristic for convective boiling is compared with that in smoothe tubes, shown in Figure 2(a). As is shown in Figure 2(a), it is noted that flow resistance and friction factor in partially filled tube is one to three magnitudes higher and much more sensitive to the value of vapor quality than that in smoothe tube. It is mostly related to the channel surface drag resistance, which is affected by flow velocity, vapor-liquid composition and the generating and movement of the boiling bubbles.

Effect of mass flux. The effect of mass flux of refrigerant R134a is described in Figure 2(b). Figure 2(b) indicates that pressure drop per unit length is affected obviously by the mass flow rates of R134a

except for vapor quality in the section. The results show that the pressure drop enhances with the increase of mass flux, accorded with Darcy law. Furthermore, it is seen that the difference of pressure drop becomes larger with the increase of vapor quality. It can be attributed to the higher quantity of vapor due to the increase of mass flux. The resistance characteristic is dramatically different from that in smoothe tube.

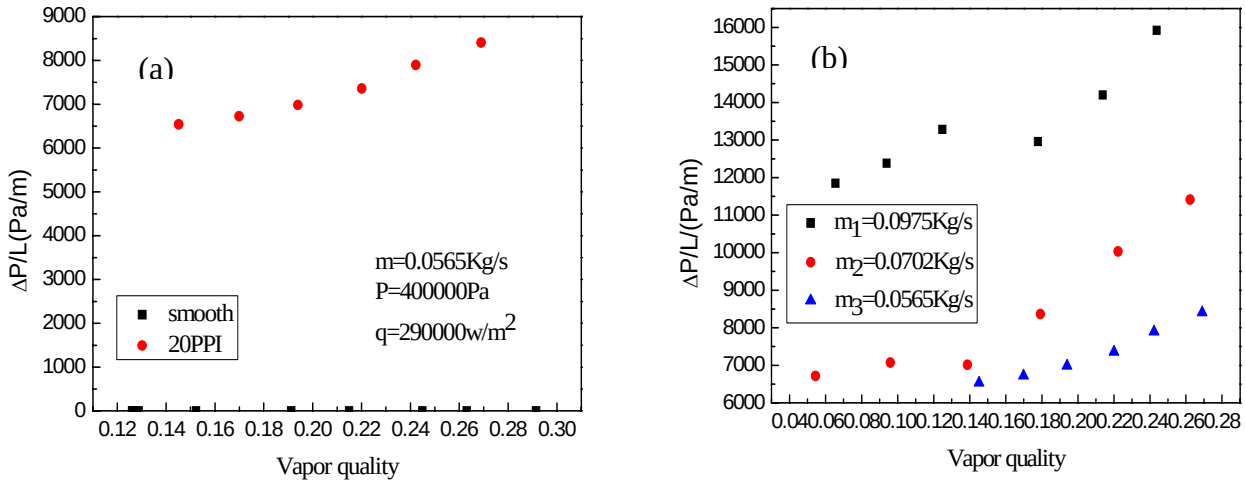

Figure 2. (a) Comparison of pressure drop for convective boiling. (b) Relation of pressure drop and vapor quality.

Effect of operating pressure. Figure 3 is the effect of operating pressure of refrigerant R134a on flow resistance in metal-foam partially filled tube. It indicates that oprerating pressure affects significantly on pressure drop and friction factor due to its influence on vapor density and vapor velocity. With the increase of operating pressure, the pressure drop for convective boiling decreases obviously by reason of the compressed vapor and reduced flow velocity of the vapor-phase, shown in Figure 3(a). It can be concluded that surface drag resistance for vapor- liquid convective boiling is essentially dominated by flow character of vapor-phase in metal foams. However, Figure 3(b) shows that friction factor becomes bigger with the increase of operating pressure, opposite to the pressure character. It can be explained by the definition of friction factor, which indicates that quadric vapor-phase velocity changes much more evidently than the influence of vapor velocity on the pressure drop.

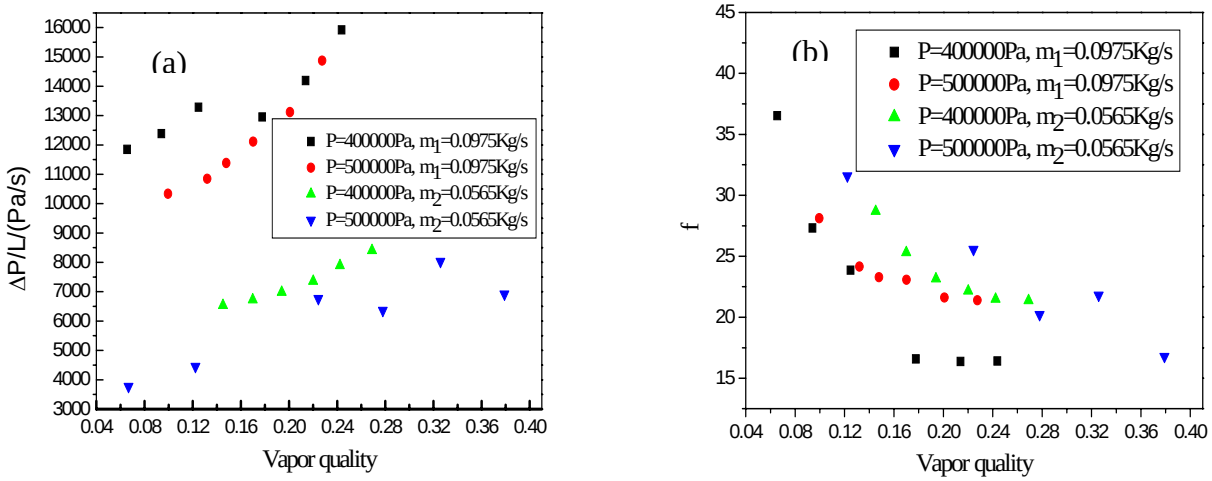

Figure 3. (a)The effect of operating pressure on pressure drop, (b)The effect of operating pressure on friction factor.

Experimental results for boiling heat transfer characteristic

Effect of mass flux of R134a. The boiling heat transfer coefficient is defined in equation (1). Δt represents the difference of refrigerant R134a and the average temperature of inner wall, while q means the uniform heat flux supplied by hot water. Mass flow rate of refrigerant R134a and vapor quality of the test section both influence the performance of boiling thermal transport in metal-foam partially filled tube, as shown in Figure 4. From Figure 4 it is seen that heat transfer coefficient and average Nusselt number along the test section increase with the increase of mass flow rate before the mass flux of 0.0702 *kg/s*, while heat transfer coefficient becomes smaller from mass flow rate 0.0702 *kg/s* to 0.975 *kg/s*. It may be concluded the flow pattern in the metal-foam partially filled tube changed during these two different range of mass flux. It indicates that convective boiling which is affected dramatically by mass flux is mainly processed in metal-foam partially filled tube before mass flux of 0.0702 *kg/s*. For the metal foams filled channel, microstructure of metal foams prevents the growth of bubbles and reduces the diameter of leaving bubbles resulting in uniformity flow and distribution of fluid temperature in metal foams. With the farther increase of mass flux, nucleate boiling whose thermal transport relies on liquid layer nearby the heated wall may become dominant due to the excessive liquid-phase.

$$h = \frac{q}{\Delta t} \tag{1}$$

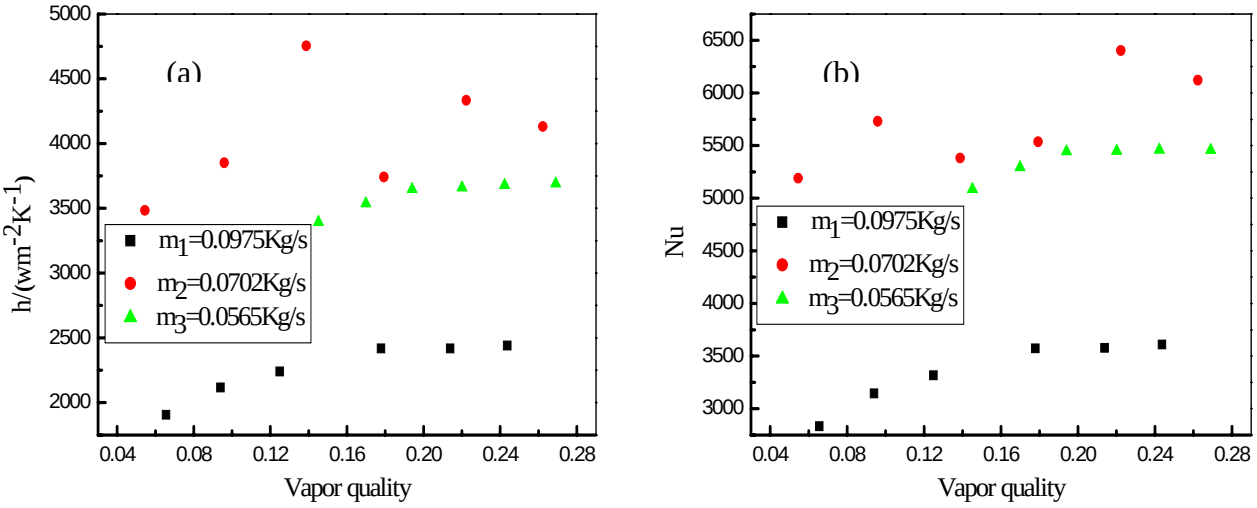

Figure 4. (a) The effect of mass flow rate on heat transfer coefficient, (b) The effect of mass flow rate on nusselt number.

Effect of operating pressure. The effect of operating pressure on convective boiling in metal-foam partially filled tube is shown in Figure 5. It is clear that boiling heat transfer coefficient enhances with the increase of operating pressure of refrigerant R134a. Vapor-phase is compressed and vapor velocity is reduced, attributed to the increase of operating pressure. In the thermal conductivity dominant situation, contact-time of the two phase flow and metal foams extends, resulting in enhanced heat transfer coefficient.

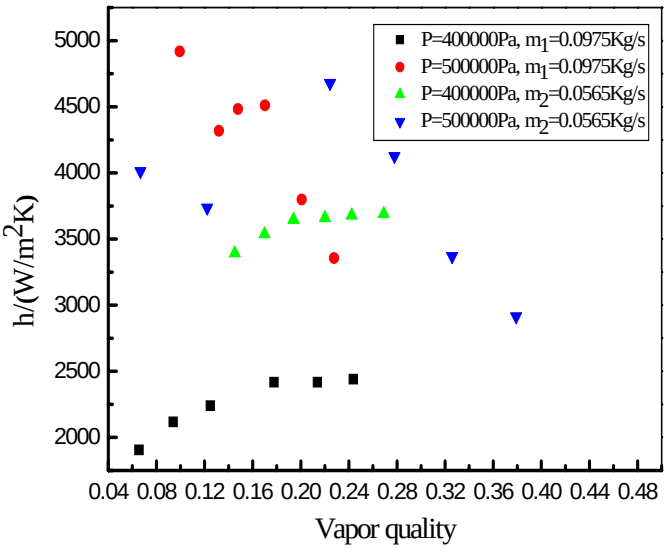

Figure 5. The effect of operating pressure on heat transfer coefficient.

Flow patterns in metal-foam partially filled tube

The flow patterns in metal-foam partially filled tube can not be directly viewed and studied , known from that in smoothe tube. However, it can be partially analysed by the distribution of wall temperature at the cross section. The fluctuations of wall temperature with time for different vapor quality is presented in Figure 6, in which the tempretures of 0 degree , 90 degree and 180 degree are noted down with top, middle and down, respectively.

As well known, refrigerant R134a is accumulated at the bottom of the horizontal tube due to gravity effect. It is proved in Figure 6(a) and Figure 6(b) by the lowest temperature at the bottom. It is also indicated that upper part of the tube is more possibly occupied by vapor-phase while middle part is potentially filled with mixture of vapor-liquid two-phase fluid. The top wall temperature is the highest while the bottom temperature is the lowest due to the component of the vapor-liquid phases, as is shown in Figure 6(a). However, the middle wall temperature is mostly close to the top wall temperature at the vapor quality of *x=0.301*, shown in Figure 6(b), compared to the quality of *x=0.066*, shown in Figure 6(a). It can be noted that proportion of vapor-phase increases heavily at the 90 degree of the cross section. Therefore, stratified flow can be predicted at the vapour quality of *x=0.301*.

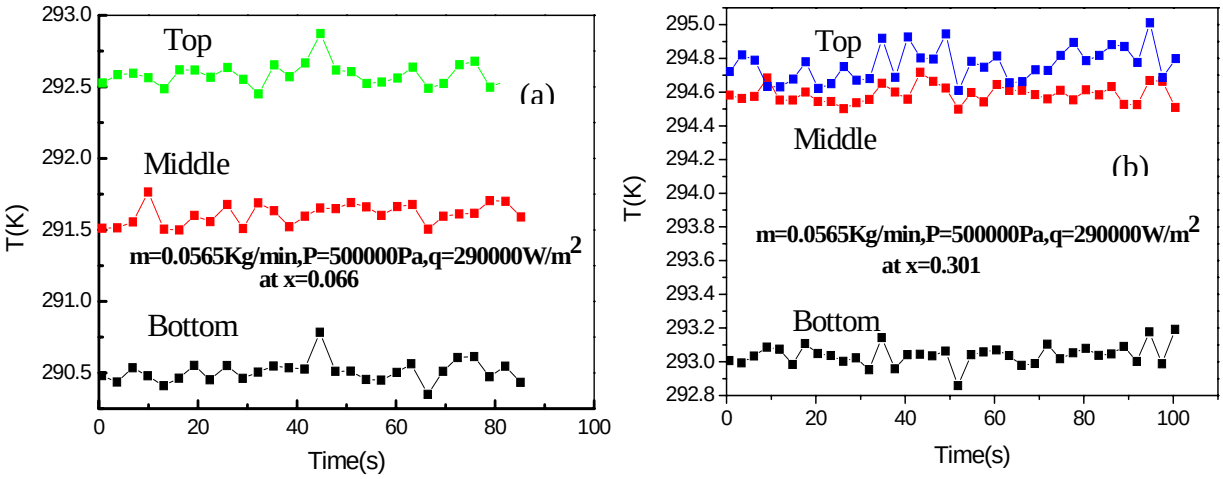

Figure 6. (a)Fluctuations of wall temperature at low vapor quality. (b) Fluctuations of wall temperature at higher vapor quality.

CONCLUSIONS

Flow boiling heat transfer in horizontal metal-foam partially filled tube is experimentally investigated in this paper. It can be concluded as follows:

For convective boiling, flow resistance and friction factor in partially filled tube is one to three magnitudes higher and much more sensitive to the value of vapor quality than that in smoothe tube. However, boiling heat transfer coefficient in metal foams partially filled tube is approximately as three times as that in smoothe tube.

For convective boiling, the pressure drop is increased with the increase of mass flux, or the decrease of operating pressure. However, the characteristic of friction factor for convective boiling is opposite to that of pressure drop.

Boiling heat transfer coefficient is increased with the increase of operating pressure of refrigerant R134a. It is indicated that vaper-phase is compressed and vapor velocity is reduced, attributed to the increase of operating pressure.

The relation of boiling heat transfer coefficient and mass flow rate depends on the flow pattern of the fluid in metal-foam partially filled tube.It can be noted that proportion of vapor-phase enhanced heavily at the 90 degree of the cross section at the vapour quality of $x=0.301$. Therefore, stratified flow can be predicted.

EXPERIMENTAL ANALYSIS OF THERMOMAGNETIC CONVECTION IN VERTICAL ANNULAR ENCLOSURE

W. Wrobel*, E. Fornalik, J. S. Szmyd
AGH - University of Science and Technology, Krakow, Poland

ABSTRACT. In the present paper an experimental analysis of a thermomagnetic convective flow of paramagnetic fluid in an annular enclosure with a round rod core and a cylindrical outer wall is presented. The convection in the annulus between two vertical coaxial cylinders resulting from gravitational and magnetic environments has been investigated for the first time. In this configuration, natural convection heat transfer is due to the gravity and gravitational buoyancy force. However, it is not always possible to influence this convection at will as physical, technological or economic limitations may arise. A strong magnetic field can be an alternative to heat transfer enhancement. The experimental enclosure was placed in a bore space of a super-conducting magnet of 10 T in three selected positions: 0.09 m above, 0.09 m below and at the centre of solenoid. The axis of bore space was maintained vertically and an aqueous glycerol solution with dissolved gadolinium nitrate hexahydrate (paramagnetic) was employed as the working fluid. The effect of the magnetic field on convection in the annular vessel in selected positions was compared.

Keywords: *thermomagnetic convection, strong magnetic field, paramagnetic fluid, vertical annulus, average heat transfer rate*

INTRODUCTION

The control of fluid convection by a strong magnetic field is an interesting concept that has possible applications for industrial processes. Engineering processes under the influence of magnetic field such as crystal growth using Czochralski method or continuous steel casting are described by Ozoe [1]. The natural convection driving force comes from the density difference between the hot and cold regions of the fluid. If the fluid's magnetic susceptibility varies with temperature, magnetic force can also induce the convective motion.
The magnetic force per unit volume in magnetic field gradient can be defined as [2]:

$$F_{mz} = \mu_0 M \frac{\partial H}{\partial z}, \tag{1}$$

where: M is the magnetization, H is the magnetic field and z is distance.
For paramagnetic fluid, magnetization M is proportional to the applied magnetic field:

$$M = \chi_v H, \tag{2}$$

where χ is the volume magnetic susceptibility which depends on density ρ: $\chi_m = \chi_v / \rho$ and temperature following Curie's law $\chi_m \sim 1/T$. It is important that the magnetic force works only in the non-uniform field. The final expression for the magnetic force, which is based on the mentioned laws, is presented in Table 1. In this expression the most important quantities are the gradient of the square magnetic induction and the magnetization. For the paramagnetics, the gradient of square magnetic induction is equivalent to the gravitational acceleration $\vec{g}$ in the case of natural

E-mail address: witold@agh.edu.pl

convection and the magnetization is equivalent to the thermal expansion coefficient β [2]. A comparison of the natural and thermomagnetic convections is listed in Table 1.

Table 1. Comparison of natural and thermomagnetic convection

Gravitational convection	Thermomagnetic convection
$F_{gz} = -\vec{g}\rho_0\beta(T-T_0)$	$F_{mz} = -\left(1+\frac{1}{\beta T_0}\right)\frac{\rho_0\chi_m\beta}{2\mu_0}(T-T_0)\frac{\partial B^2}{\partial z}$
$\vec{g}$	$\frac{\partial B^2}{\partial z}$
β	$\left(1+\frac{1}{\beta T_0}\right)\frac{\chi_m\beta}{2\mu_0}$

where: μ_0 is the magnetic permeability, B is the magnetic induction, T_0 is the average temperature of fluid, and T is the temperature of fluid.

EXPERIMENTAL SYSTEM

Experimental apparatus

The experimental vessel is presented in Fig. 1.

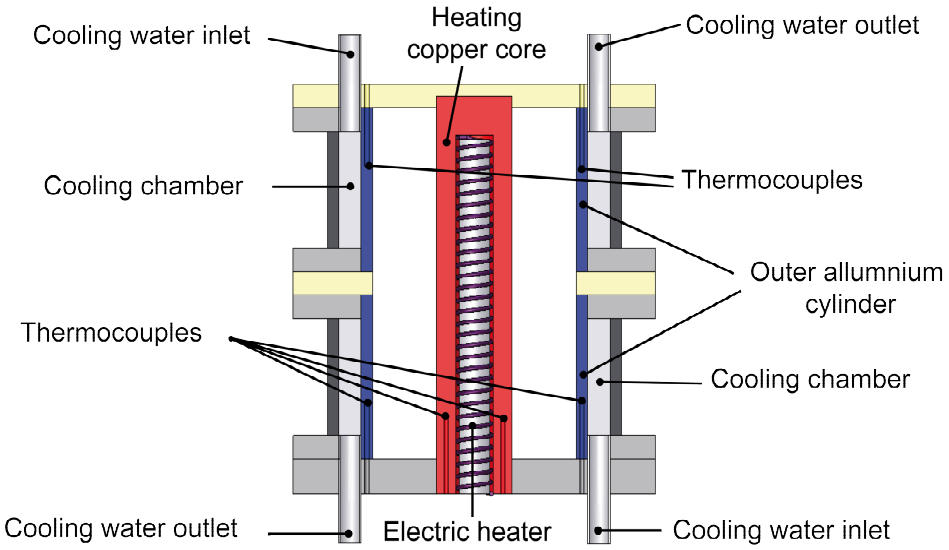

Figure 1. Cross-section of the experimental vessel

The experimental vessel is an annular enclosure with a round rod core and a cylindrical outer wall. The core diameter was 0.02 m and the diameter of the outer cylinder was 0.054 m. The outer cylinder was made of aluminum of 0.003 m thickness, while the core was a copper rod that could be electrically heated. A resistance wire was wound around a ceramic element and placed in a drilled hole inside the copper bar. The electric heater was charged with DC power and the voltage and electrical current were constantly controlled. The outer cylinder was cooled with the water kept at constant temperature inside a thermostating bath. In the middle height a Plexiglas plate of 0.006 m thickness was inserted. The core temperature was measured with two T-type thermocouples and the temperature of the aluminum side wall with three T-type thermocouples. The enclosure was closed by a Plexiglas plate of 0.006 m thickness from one side and an ebonite plate of 0.009 m thickness

from the other. There was a small hole in the closing Plexiglas plate through which the experimental fluid was injected. The total height of the enclosure was 0.092 m. The assembled experimental system is shown in Fig. 2 and the aspect ratio is defined

$$A = \frac{h}{r_o - r_i}, \tag{3}$$

where: h is the height of the enclosure, r_i is the radius of the core, r_o is the radius of the aluminum cylinder. The aspect ratio for the studied geometry was equal to A = 5.41.

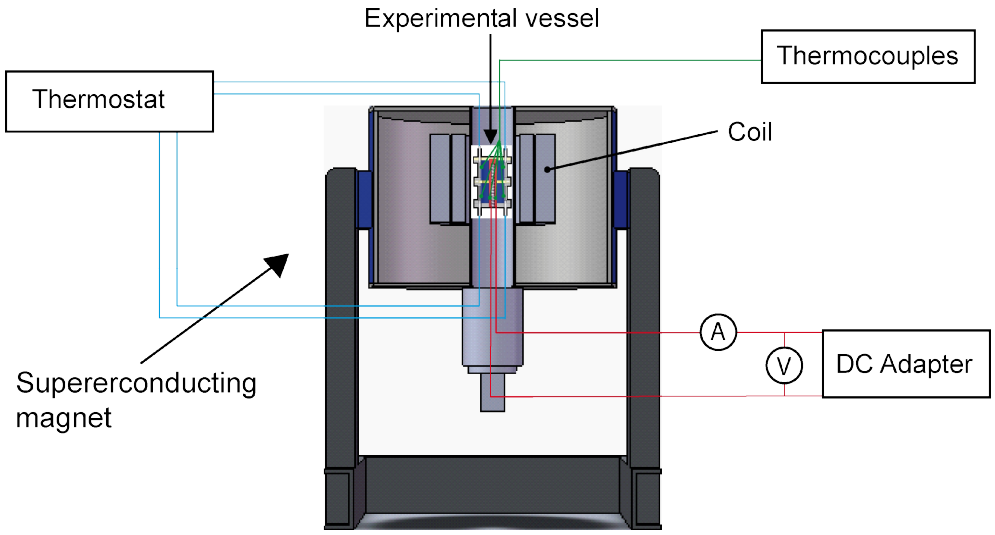

Figure 2. Pictorial drawing of the experimental setup

Fluid

A 50% volume aqueous solution of glycerol with 0.3 mol/(kg of solution) concentration of gadolinium nitrate hexahydradte ($Gd(NO_3)_3 \times 6H_2O$) was used as the working fluid. 150 ml of water and 150 ml of glycerin were mixed to yield 0.320629 kg of solution. To obtain a 0.3 mol/(kg of solution) concentration of gadolinium nitrate hexahydradte of molar mass (0.45136 kg/mol), 0.05030 kg, was added. The thermal expansion coefficient, thermal conductivity, electrical conductivity, density and dynamic viscosity were all found experimentally. The mass magnetic susceptibility of the fluid was measured with the magnetic susceptibility balance. Dynamic viscosity is a function of temperature and the expression describing it was obtained from the experimental data; this equation was subsequently formulated

$$\mu_{(T)} = 0.816 - 5.05 \cdot 10^{-3} T + 7.854 \cdot 10^{-6} T^2 . \tag{4}$$

The properties of 50% volume aqueous solution of glycerol are listed in Table 2.

Table 2. Properties of the fluid at T_0 = 298 K

Properties	Symbol	Value	Unit

EXPERIMENTAL PROCEDURE

The enclosure was filled with the working fluid with a syringe and needle. The water temperature in the constant temperature bath was set at 18 ^{0}C and the supplied power of electrical heater placed in the core set up at a certain level. The level of supplied power was a variable parameter. Three values of the power were studied in particular detail: 4.45 W, 13.11 W and 27.21 W. The experimental studies were divided into a few steps, the first of which was to examine the natural convection in the presented annular vessel. When the power was set, the apparatus was left to reach steady state. This lasted about 30 to 40 minutes, after which the measured values were recorded and the supplied power set to the next level. The recorded temperature data was averaged and then analysed. The data taken during the last 10 minutes before changing the parameters was included in the average.

When the measurements for various supplied power were done, the next stage was started. The enclosure was placed in a bore of a 10-Tesla superconducting magnet. Three positions were chosen to be studied and are presented in Fig. 3a: (A) the upper maximum value of gradB^2 at the level of 0.101 m from the upper edge of the magnet which corresponds to the 0.090 m above the solenoid centre; (B) the lower maximum value of gradB^2 at the level of 0.281 m from the upper edge of the magnet which corresponds to 0.090 m below the solenoid centre; (C) the centre of the magnetic field – the centre of the enclosure was at the centre of the coils, which means 0.191 m from the upper edge of the magnet, which related to the maximum of magnetic induction.

The distribution of magnetic field inside the bore at 1 T of magnetic induction obtained numerically is shown in Fig. 3b. An example of the gradient square magnetic induction distribution is presented in Fig. 3c. The magnified distributions of the magnetic field induction square gradient inside the experimental vessel for three studied positions A, B and C are presented in Fig. 4. As in Fig. 4a, the vectors in the position above the coil are directed downward, those below the coil (Fig. 4b) are directed upward and in the centre (Fig. 4c) they are directed both upward and downward. The distribution presented in Fig. 4 is important because the magnetic force is proportional to the gradient of square magnetic induction, as listed in Table 1.

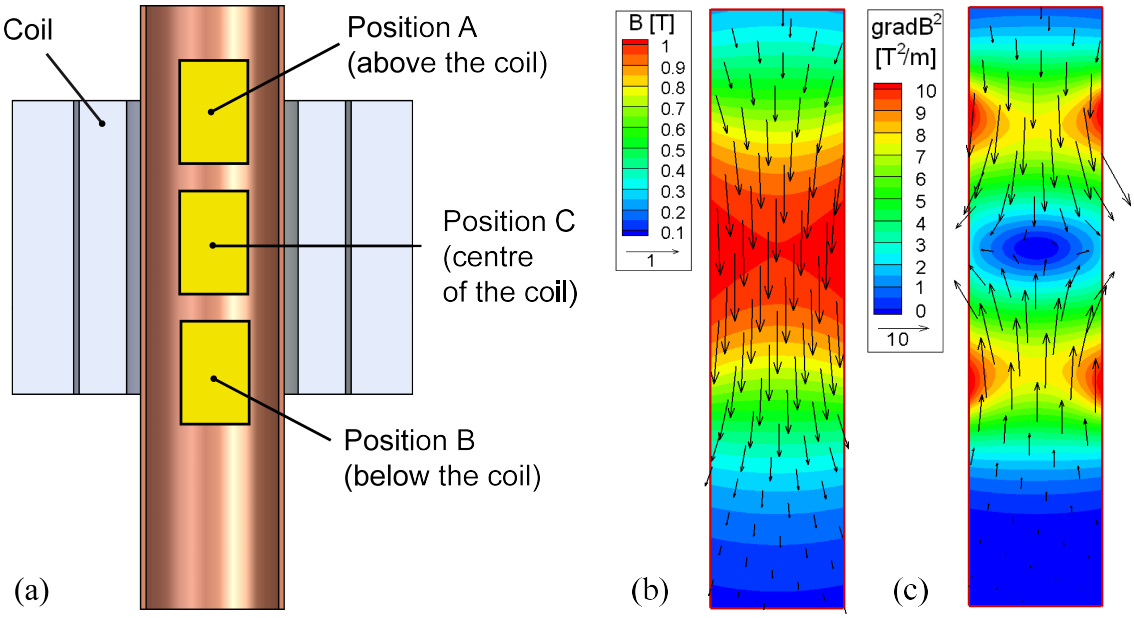

Figure 3. (a) Position of experimental vessel in the bore, (b) distribution of magnetic induction inside the bore from numerical calculation at 1 T of magnetic induction at the centre, (c) distribution of gradient of square of magnetic induction inside the bore at 1 T of magnetic induction

The enclosure was first placed in position A (above the solenoid centre). The temperature of cooling water and certain value of the heater's electric power were set. The system was left to reach a steady state, which took 30-40 minutes. The magnetic field was then applied to the system. At first the magnetic induction of 1 T was set and the apparatus was left to reach the steady state. Then all controlled parameters (temperature, electrical current, voltage) were recorded and the magnetic induction was changed to 2 T. The procedure of setting the controlled parameters, reaching the steady state and recording the data was repeated up to 10 T of magnetic induction. In some cases the magnetic induction was changed from 10 T to 0 T, but the direction change of the magnetic induction (increasing or decreasing) did not have a visible influence on the results. All steps were repeated for three selected power supplies and for the other positions in the magnet bore.
The last stage of the experiment was related to the estimation of heat loss from the enclosure to the environment. The enclosure was emptied and placed inside the magnet bore. It was assumed that the convection and conduction of air was negligible and that the heat loss depended only on the temperature of the heated core. The heat loss measurements were conducted for various powers of the electrical heater.

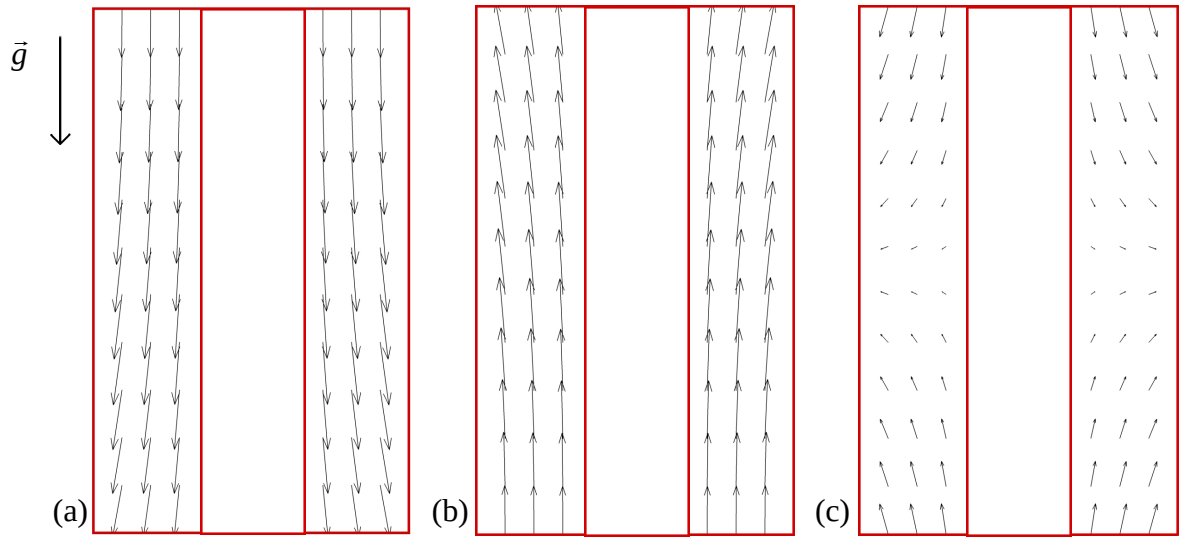

Figure 4. Schematic view of magnetic induction square gradient distribution, (a) above the coil, (b) below the coil, (c) in the centre of the coil

ESTIMATING THE NUSSELT AND RAYLEIGH NUMBERS

To describe the rate of net convection heat transfer, it is easy to use the quantified value known as the Nusselt number. The Nusselt number was calculated as

$$\mathrm{Nu} = \frac{Q_{conv\_net}}{Q_{cond\_theor}}, \tag{5}$$

where Q_{conv_net} indicates the convection heat flux and Q_{cond_theor} is the theoretical heat flux due to the conduction:

$$Q_{conv\_net} = Q_{conv} - Q_{loss}, \tag{6}$$

and:

$$Q_{conv} = U \cdot I, \tag{7}$$

where: U is voltage, and I is electrical current.
The theoretical conduction heat flux Q_{cond_theor} was calculated numerically from the energy equation:

$$\nabla^2 T = 0, \tag{8}$$

and the final form of its definition can be written

$$Q_{cond\_theor} = F_{CFD}\lambda\left(T_h - T_c\right), \tag{9}$$

where F_{CFD} - configurational parameter was calculated for the geometry of the experimental vessel, λ is the thermal conductivity, T_c is the temperature of the cooled wall and T_h is the temperature of the heated wall. The heat loss was calculated from the equation

$$Q_{loss} = 0,082 \cdot (T_h - T)_c, \tag{10}$$

which is a linear approximation of experimental data presented in Fig. 5. It should be emphasized that, due to the configuration of the experimental enclosure, the heat loss was quite small relative to the power supplied.

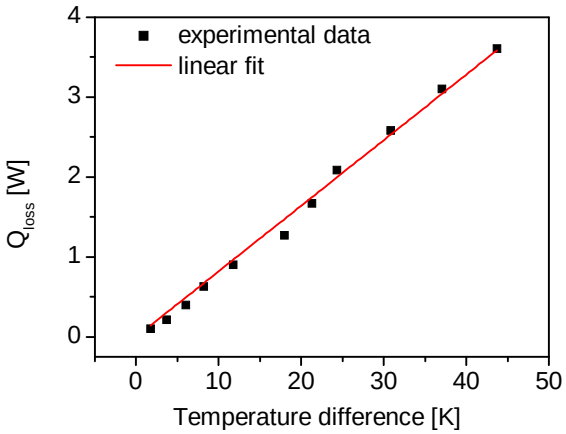

Figure 5. The experimental relation between the heat loss and the temperature difference

The Rayleigh number combines the buoyancy, viscosity, momentum diffusivity and the thermal diffusivity of the fluid in one dimensionless parameter. In the absence of magnetic field, for the annulus in a vertical position [3], the number can be expressed

$$\mathrm{Ra} = \frac{g\beta}{\alpha\nu}(T_h - T_c)(r_o - r_i)^3, \tag{11}$$

where: g is the gravitational acceleration, β the thermal expansion coefficient, α the thermal diffusivity, ν kinematic viscosity, r_i the inner radius of cylinder and r_o the outer radius of the cylinder. For the paramagnetic fluid in the non-uniform magnetic field, following Table 1, the magnetic Rayleigh number can be defined as:

$$\mathrm{Ra_m} = \mathrm{Ra}\left[1 + \frac{\partial B^2}{\partial z}\left(1 + \frac{1}{\beta T_0}\right)\frac{\chi_m}{2\mu_0 g}\right]. \tag{12}$$

RESULTS

Figure 6 presents the Nusselt number values versus the magnetic induction in the centre of solenoid for all studied configurations. In Fig. 6a the data were obtained for the vessel in A configuration (above the solenoid centre). It presents continuous growth from the magnetic induction 1 T. The Nusselt number increased with the magnetic induction. This tendency is observed for the three examined values of power supply. At 10 T of magnetic induction the Nusselt number was two times higher than without the magnetic field. Even the highest studied Rayleigh number did not cause such a high heat transfer rate, which suggests strongly intensified convection. This enhanced heat transfer was obtained due to both forces (gravitational and magnetizing) acting in the same direction. As seen in Fig. 4a, the vectors of gradB^2 are directed downward, similarly to gravity.

In Fig. 6b the Nusselt number values were obtained for the enclosure placed in configuration B (below the coil). At magnetic induction of 0 T to 2 T a decrease in the Nusselt number was observed. A Further increase in magnetic induction up to 10 T caused an increase in the heat transfer rate. The minimum Nusselt number is observed. The same tendency was obtained for three studied power supplies. This data at first suggested the suppression of convection but enhancement of it later.

In configuration C (Fig. 6c), when the magnetic induction was 0 T, 1 T and 2 T, there was no visible influence on the heat transfer rate. At the magnetic induction of 3 T the Nusselt number decreased, which suggests suppression of the natural convection. Increasing the magnetic induction from 4 T to 10 T caused the Nusselt number to increase.

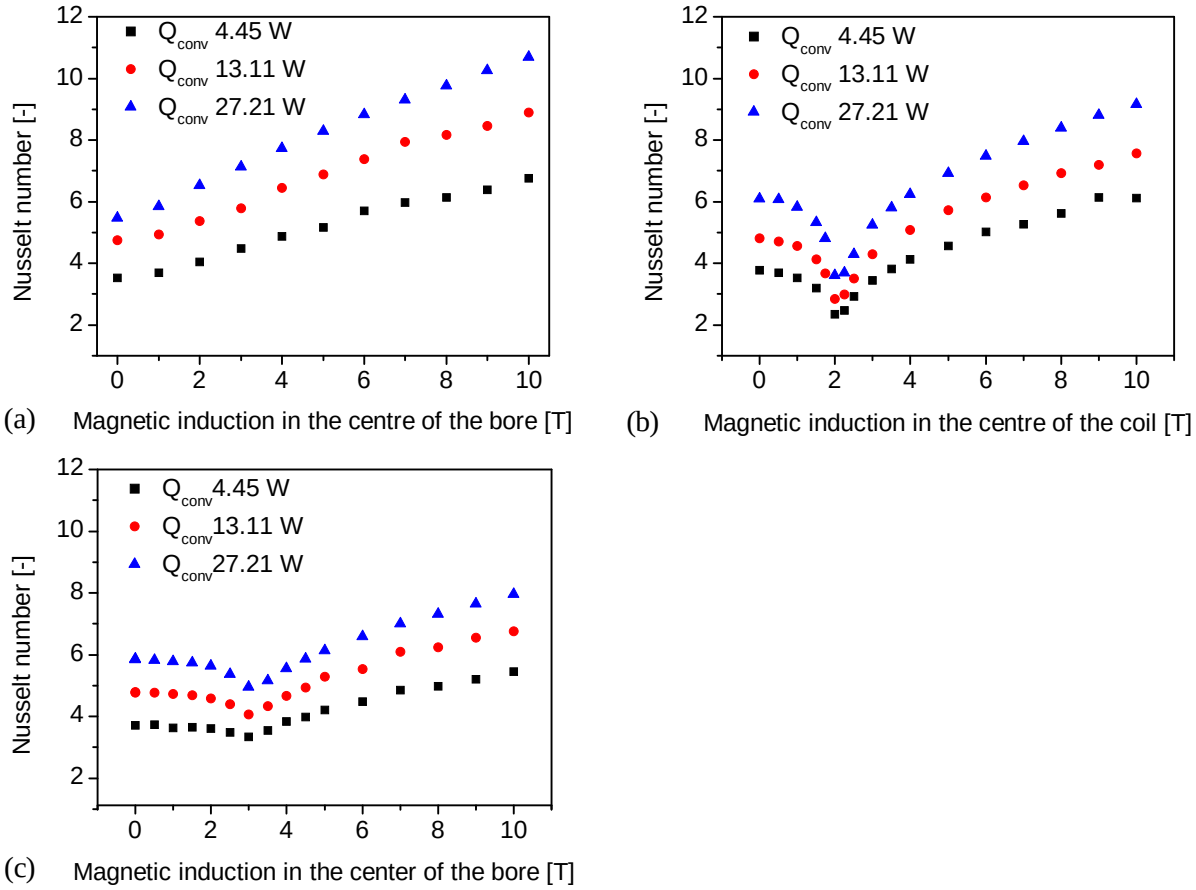

Figure 6. Experimental relationship between the Nusselt number and the magnetic induction: (a) experimental vessel in the configuration above the centre of coil, (b) vessel below the centre of the coil, (c) vessel in the centre of coil

In Fig. 6 the Nusselt number at magnetic induction of 0 T was equal for all studied positions, which indicates the results are repeatable. The results for position B (below the coil centre) and C (at the coil centre) show the minimum. For the position below the coil centre, the Nusselt number was minimal at magnetic induction of 2.0 T while in position at the centre at 2.5 T. A further increase in the magnetic induction in both cases caused the Nusselt number to increase. The highest Nusselt number values were obtained above the coil centre, while the lowest were obtained at position in the coil centre, which was understandable in light of the magnetizing force acting on the fluid in two opposite directions see Fig. 4c.

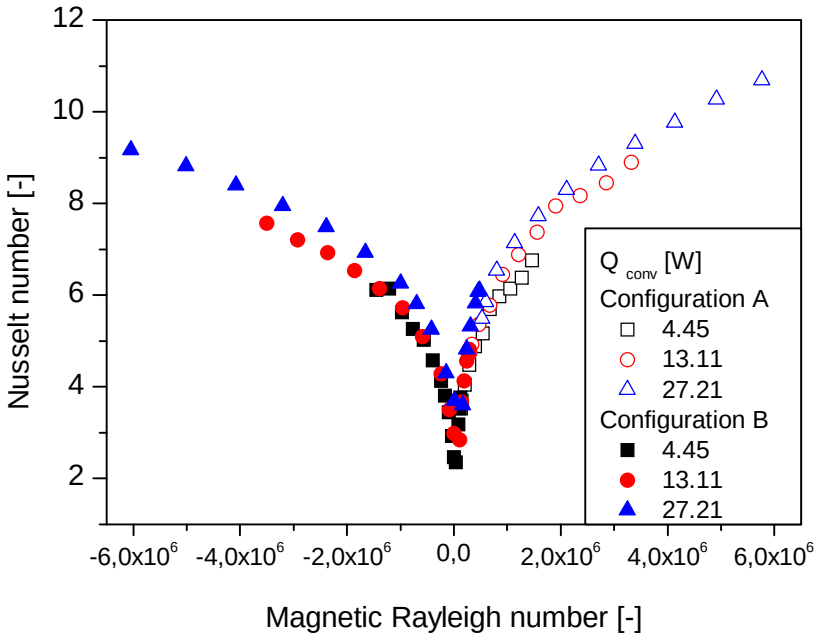

Figure 7. Plot of the Nusselt number versus magnetic Rayleigh number for data obtained in configuration A and B at various values of magnetic induction

Figure 7 presents the Nusselt number versus the magnetic Rayleigh number. The negative values of the Rayleigh number show that the gravitational and the magnetizing forces acted in opposite directions, though the magnetizing force did start to dominate in the system. The magnetic Rayleigh number equal to 0 corresponds to the situation when the gravitational and magnetizing force are equal to each other but moved in opposite directions. The combined data shows that the magnetic Rayleigh number is a parameter which can quantitatively describe the behavior of the fluid in the presence of the magnetic field and temperature gradient.

CONCLUSIONS

The results show that magnetizing force effects the heat transfer rate. A strong magnetic field can control the magnetic convection of paramagnetic fluid. Depending on the direction and the strength of magnetic field, either the enhancement or suppression of convective motion will be observed. The magnetic Rayleigh number is a parameter which can be used to characterize behavior of the fluid in the magnetic field. However, its definition needs to be studied thoroughly, because the behavior of the fluid in the vessel placed in C configuration (in the centre of coil) has not been clearly described.

A RAYLEIGH - BÉNARD CONFIGURATION OF A CUBICAL ENCLOSURE UNDER VARIOUS ORIENTATIONS OF MAGNETIC INDUCTION SQUARE GRADIENT

Ł. Pyrda[1*], E. Fornalik[1], J. S. Szmyd[1]
[1]AGH – University of Science and Technology, Krakow, Poland

ABSTRACT. In the present investigation the influence of a strong magnetic field on paramagnetic fluid is described. The cubical enclosure in the Rayleigh-Bénard configuration was chosen for study. The enclosure was heated from the bottom wall and cooled from the top one. All other walls were adiabatic. The natural convection in this geometry is quite well known. Therefore the influence of magnetic field with various orientations of $\nabla\vec{b}^2$ on the convection phenomena was distinguished easily. The high temperature gradients under a strong magnetic field were also examined.

Keywords: *thermomagnetic convection, strong magnetic field, paramagnetic fluid, cubic enclosure, heat transfer rate*

INTRODUCTION

The influence of temperature gradients on the density of fluid is known, as is that in systems with a temperature gradient, buoyancy forces occur. Such phenomena are commonly called free or natural convection. Control of convection phenomena is important for many heat transfer issues such as mixing devices, air conditioning systems or controlling crystal growth [1]. The buoyancy forces can control the convection but this control is limited. Utilization of magnetic force (Kelvin force) to control convection yields gives more possibilities. Bai et al. [2] formulated their magnetic force equation as follows:

$$F_{mag} = \frac{\chi_v \mu}{2} \nabla \vec{h}^2 \tag{1}$$

where: $\vec{h}$ is the magnetic field [A/m], χ_v is the volume magnetic susceptibility ($\chi_v = \chi_m \cdot \rho$) [-], χ_m is the mass magnetic susceptibility [m^3/kg], ρ *is* density [kg/m^3], and μ is the magnetic permeability [H/m]. This equation is inserted:

$$\mu = \vec{b} / \vec{h} \tag{2}$$

where: $\vec{b}$ is the magnetic induction [T]. According to Curie's law and Bussinesq approximation, the magnetic force equation (1) can be rewritten

$$F_{mag} = -\left(1 + \frac{1}{\beta\theta_0}\right) \frac{\rho_0 \chi_m \beta(\theta - \theta_0)}{2\mu_0} \nabla \vec{b}^2 \tag{3}$$

where β is the thermal expansion coefficient [1/K], θ_0 is the reference temperature [K], θ is the temperature [K], and μ_0 the magnetic permeability of vacuum [H/m].

The authors studied the influence of strong magnetic field on paramagnetic fluid in an enclosure variously heated. They chose to use a cubical enclosure with a Rayleigh-Bénard configuration in which the bottom wall was heated while the top wall was cooled. They also studied the influence the magnetic field exerted on the heat transfer rate, which is very important from the point of view of engineering. Therefore various relationships between the buoyancy gravitational force and magnetic force were also studied. The reciprocal relationship of these forces was obtained by introducing changes into the enclosure position in the magnet bore. Various phenomena were observed. The high temperature gradients under the influence of the magnetic field from 1 [T] to 10 [T] were also examined. Results are presented and discussed below.

EXPERIMENTAL SYSTEM

Experimental vessel

Figure 1 shows an experimental vessel.

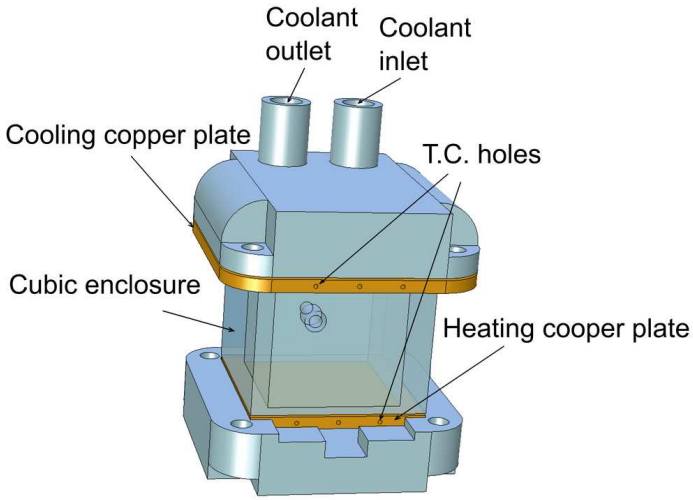

Figure 1. Experimental vessel [3]

The experimental apparatus consists of five elements: two copper plates with three holes in each for T-type thermocouples, cooling and heating chambers and a plexiglass cubical cavity. The cubic cavity had an internal size of 0.032 [m]. The bottom copper plate was heated with a resistance wire placed in the ceramic heating chamber. This wire was connected to a DC power supply which was constantly controlled. The upper copper plate was cooled by water flowing through the cooling chamber from the thermostating water bath. The cubic cavity contained a small hole into which the experimental fluid was injected. The cubical enclosure was placed in the superconducting magnet's bore which generated a strong magnetic field up to 10 [T] of magnetic induction. The assembled experimental setup is shown in Figure 2.

Experimental fluid

An 80% mass glycerol aqueous solution with crystals of gadolinium nitrate hexahydrate ($Gd(NO_3)_3 \times 6H_2O$) was selected as the working fluid. The density and mass magnetic susceptibility were obtained experimentally and the other properties were taken from [3]. Density was measured with a pycnometer. The measurements of mass magnetic susceptibility utilized Magnetic Susceptibility Balance; the magnetic susceptibility measurements were based on Evan's method. The balance measured the force with which the probe was attracted to the pair of permanent magnets and then the magnetic susceptibility was calculated. The properties of the working fluid are listed in Table 1.

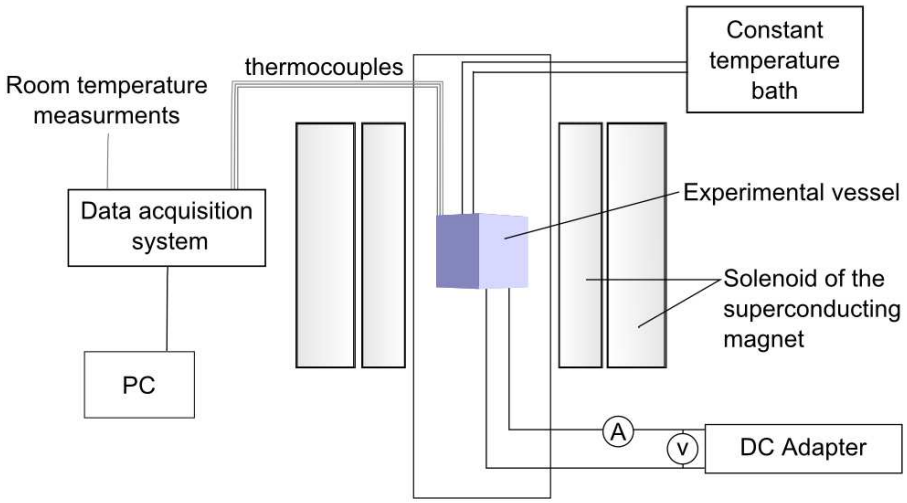

Figure 2. Experimental setup

Table 1. Properties of the fluid

Symbol	Value	Unit
α	1.01×10^{-7}	m^2/s
β	0.52×10^{-3}	1/K
λ	0.3972	W/m·K
μ	86.89×10^{-3}	kg/m·s
ν	5.9×10^{-5}	m^2/s
ρ	1453	kg/m^3
χ	21.776×10^{-8}	[-]

EXPERIMENTAL PROCEDURE

In the first step, a cubical enclosure filled with air was placed in the bore of the turned off magnet in order to measure the amount of heat lost to the environment. Power from the electrical heater attached to the bottom copper plate was set up at chosen levels and a constant temperature of 18 [^{0}C] was set for the cooling bath. After setting one value of power, the whole system was left to reach a steady state, which took roughly 30 minutes, at which point all measured quantities were recorded. Then a new value was set for the power supply, and the system again reached the steady state. This procedure was repeated for various power supply values. The results were used to find the relationship between temperature difference and heat loss. In the second step, convection phenomena under a strong magnetic field were investigated. Figure 3 shows three studied configurations of the system. Position A, placed 0.11 [m] above the centre of the solenoid, corresponded to the maximum of $\nabla \vec{b}^2$ while position B, placed in the centre of the solenoid, corresponded to the maximum value of magnetic induction $\vec{b}$. Position C, placed 0.11 [m] below the centre of the solenoid, corresponded to the second maximum of $\nabla \vec{b}^2$. For this experimental step, the cubic enclosure was filled with working fluid. The temperature of the cooling bath and power supply attached to the heater were then set and the system was left to reach a steady state upon which all measured quantities were recorded. The strength of the magnetic induction was changed stepwise from 1 [T] to 10 [T], with the system each time left to reach a steady state. The entire process lasted approximately half an hour, after which all data were recorded. For each position and each value of the power supply the experimental procedure was the same.

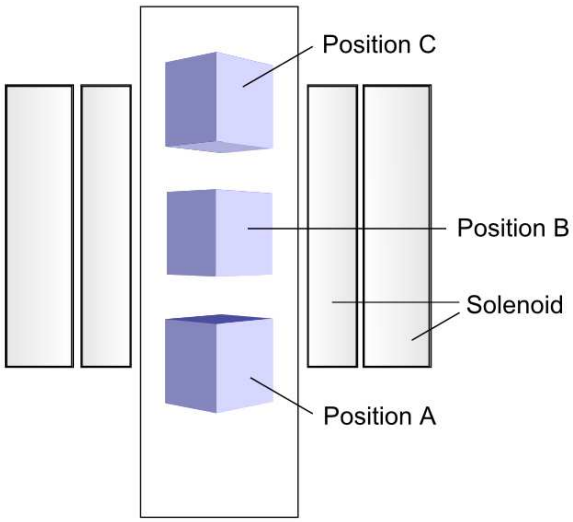

Figure 3. Investigated configurations

Heat transfer rates

To investigate the effect of the magnetic field on the heat transfer rate, thermal measurements were done in all the cases studied. The Nusselt number was calculated from this equation, according to a method invented by Ozoe and Churchill [4]:

$$\mathrm{Nu} = \frac{Q_{net\_convection}}{Q_{theor\_conduction}} \tag{4}$$

where: $Q_{net\_convection}$ is the net convection heat flux, and $Q_{theor\_conduction}$ the theoretical conduction heat flux. The net convection heat flux was obtained as the difference between supplied power ($Q_{convection}$) and the heat loss (Q_{loss}) and

$$Q_{convection} = I \cdot U \tag{5}$$

$$Q_{net\_convection} = Q_{convection} - Q_{loss} \tag{6}$$

The heat loss was estimated from the conduction experiment described in the "Experimental procedure" chapter. It was calculated as the difference between the conduction heat flux and theoretically calculated net heat flux:

$$Q_{loss} = Q_{conduction} - Q_{theor\_conduction} \tag{7}$$

$$Q_{theor\_conduction} = A\lambda(\theta_{hot} - \theta_{cold})/l \tag{8}$$

where A is the conduction area of cross section ($A=l^2$), θ_{hot} is the temperature of the heated wall, θ_{cold} is the temperature of the cooled wall. The definition for the form of the Nusselt number can be rewritten:

$$\mathrm{Nu} = \frac{Q_{convection} - Q_{loss}}{l\lambda(\theta_{hot} - \theta_{cold})} \tag{9}$$

Figure 4 shows the calculated heat losses of the experimental setup for various temperature differences. The data was linearly approximated and the following expression then obtained

$$\Delta\theta = 13.23 Q_{loss} + 0.05 \tag{10}$$

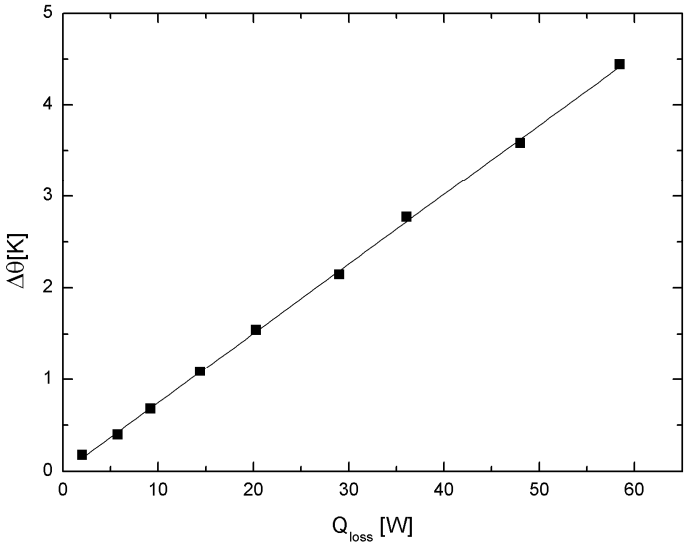

Figure 4. Linear fit of setup heat losses

RESULTS AND ANALYSIS

Figure 5 presents the Nusselt number as a function of magnetic induction in the centre of the bore. Diamonds represents the Nusselt number obtained for the enclosure in Position A (above the solenoid centre) and triangles represents the Nusselt numbers for the enclosure in Position B (in the centre of solenoid), both with about 0.4 W power supply directed to the heating wire.

The Rayleigh number is a very important parameter in the convective heat transfer. It characterise type of flow. It is a product of Prandtl number and Grashof number and near the vertical wall, this number can be defined as:

$$\mathrm{Ra} = \frac{g\beta(\theta_{hot} - \theta_{cold})l^3}{\alpha\nu} \tag{11}$$

where: α is the thermal diffusivity [m^2/s], g the gravitational acceleration, and ν the kinematic viscosity [m^2/s]. The Rayleigh number without magnetic field was equal to Ra = 103025. In Position A, the vectors of ∇b^2 were directed opposite to the gravitational acceleration vector, which produced a convection suppressing effect. From 3 [T] up to 10 [T] of magnetic induction, the Nusselt number was about 1.

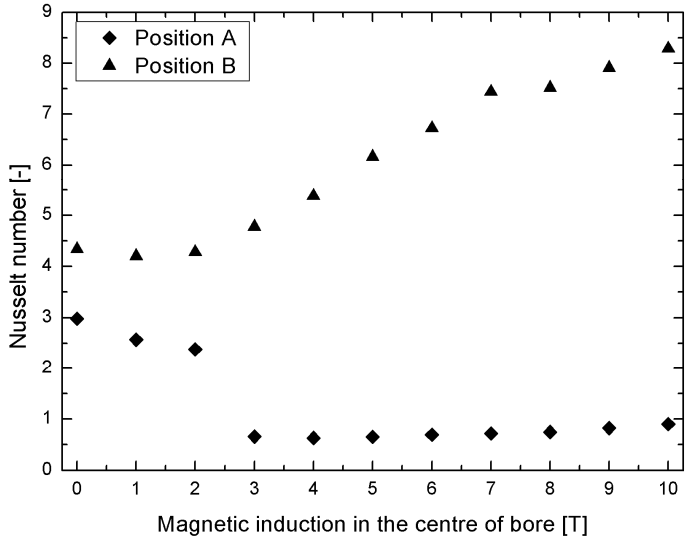

Figure 5. The Nusselt number as a function of magnetic induction in the bore centre for the enclosure placed below (Position A) and in the centre of solenoid (Position B)

In Position B the Nusselt number decreased slightly at 1 [T] of magnetic induction, but for all other values of that number it rise noticeably. It then reached a value two times higher than it was without magnetic field. At 7 [T] of magnetic induction the room temperature dropped and influenced the measurements. Room temperature was roughly 2 [°C] higher than the heated wall, which effected the results. In Figure 6 the Nusselt number values were obtained for the enclosure placed below the solenoid centre in Position C. Here the power supply was ten times higher than it was in other positions. The Nusselt number constantly grew, with increasing magnetic induction reaching a value 2.5 times higher than those without magnetic field. The authors expected the flow type to change from from laminar to transient. However, the data indicated very stable laminar flow even when the Rayleigh was quite high. It would seem that the fluctuations were suppressed and only the mean flow was enhanced.

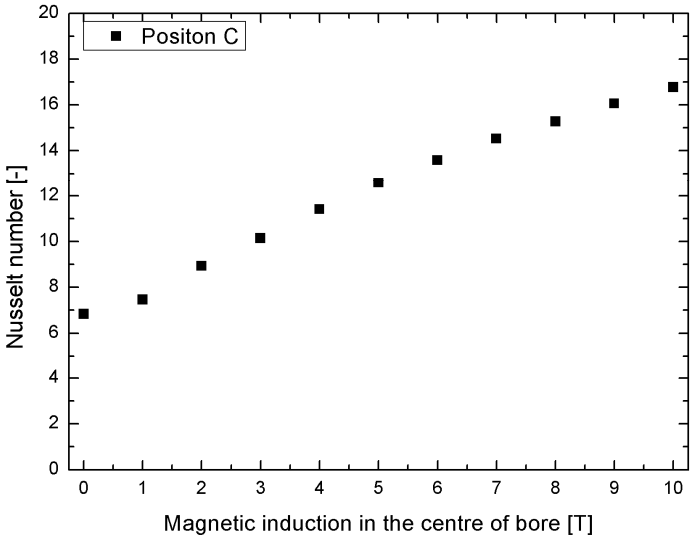

Figure 6. The Nusselt number as a function of magnetic induction in the centre of bore for the enclosure placed below the solenoid (Position C)

CONCLUSIONS

This paper has looked at the influence of a strong magnetic field on the behaviour of paramagnetic fluid in a variously heated cavity. Three different positions of cubical enclosure heated from the bottom and cooled from the top were examined. Enhanced convection was observed in Positions B (the solenoid centre) and C (above the solenoid centre), while the suppression of convection was observed in Position A. The flow was laminar even at a quite high Rayleigh number.

ABSTRACT The consequences of rotation on the flow-structuring and the corresponding heat transfer in a cylindrical volume of fluid subjected to a destabilising temperature gradient and rotation about the vertical axis were studied numerically and experimentally. A second order finite volume method was used for direct numerical simulation of the turbulent flow. At small rotation rates the convection is dominated by a large-scale circulation. Conversely, at high rotation rates the flow develops a number of thermal plumes that are strongly localized and roughly aligned along the vertical. The heat transfer is found to be increased by up to about 15% compared to the non-rotating case, which is closely connected to the effect of Ekman pumping in the boundary layers near the upper and lower boundaries. At the highest rotation rates the convective flow is found to be suppressed, as is the heat transfer.

INTRODUCTION

More than a century ago, Henri Bénard performed an intriguing experiment in which he heated very thin layers of fluid from below. He observed convective motions that took the shape of a regular pattern of hexagonal cells. The subsequent theoretical analysis of the convective instability of a layer of fluid was due to Lord Rayleigh who pointed out the importance of the temperature gradient, which is nowadays described in dimensionless form by the Rayleigh number. Thus Rayleigh-Bénard convection was coined for the motion of a fluid confined between horizontal plates and heated from below. The addition of rotation in the convective system induces a number of changes. The critical Rayleigh number for the onset of convection is increased with rotation. Furthermore, it is well-known that near solid boundaries in rotating flows active boundary layers are formed that can influence the flow even far away from boundaries, unlike boundary layers in non-rotating flows. An effect that is relevant for strong rotation is described by the Taylor-Proudman theorem: for slow motions in inviscid, strongly rotating flow the vertical gradient of velocity is zero, i.e., a columnar or sheet-like two-dimensional flow is observed. For an overview of literature see [1]. Hence, rotation may induce a macroscopic modulation of turbulence.

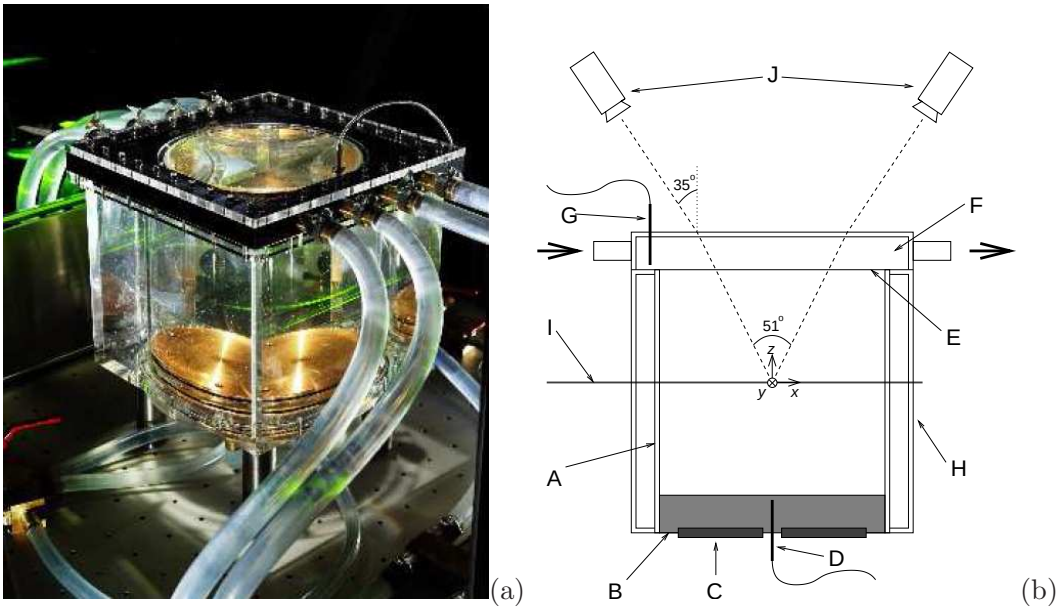
Fluid flow driven by buoyancy is ubiquitous in nature and technology. In many cases the density differences within the fluid come from differences in temperature, thus the designation thermal convection. Furthermore, some classes of fluid flows are additionally shaped by a rotation. A prime example comes from large-scale motions in the Earth's oceans, which are driven by temperature induced buoyancy, and at the same time have length-scales such that the rotation of the Earth plays a role in the development. An important example is open-ocean deep convection: in winter, in the Arctic and Antarctic seas surface cooling may lead to long-lived vortical downward flow. This deep convection is of paramount importance for the global thermohaline circulation.
A key consequence of the modulation of turbulent flow due to rotation is the change in the capacity of the system to transfer heat. This is the main area of attention in this paper. Ever since the first experiments by Rossby [2], it is known that rotation can have unexpected effects on the heat transfer. Rossby found that, for convection in water, there is a certain range of rotation rates for which the Nusselt number Nu, denoting a dimensionless heat flux, is *increased* relative to its static non-rotating value. The increase was about 10%. Such an increased Nusselt number is counter-intuitive, as it was shown that rotation stabilizes convection (the critical Rayleigh number is increased by rotation). Hence, a reduction of the heat transfer would be expected. At sufficiently high rotation rates, Rossby indeed measured a strongly decreased heat flux. The mechanism behind the increase in Nu in an intermediate range was hinted at by Rossby as being related to so-called Ekman pumping. The boundary layers in rapidly rotating flows have been described by Ekman [3]. These layers can actively influence the surrounding flow: if vorticity is found in the outer fluid the boundary layers will subsequently enact a vertical velocity (Ekman pumping). Since these boundary layers are very thin, the fluid pumped away from the wall will have considerably higher/lower temperature than the surrounding fluid. Thereby the heat-transfer can be enhanced.



(a) (b)

Figure 1: Impression of the physical experiment (a) and a sketch of the components of the set-up (b) in which two cameras (J) are placed above the vessel that is heated through a copper plate (B) and cooled with a lid (G-F) in between which a laser-sheet is defined (I).

The physics of rotating convection can be investigated in great detail using an experimental set-up as depicted in Fig. 1(a) and sketched in Fig. 1(b) [4]. A cylindrical vessel is heated from below and cooled from above. At different heights through the domain a laser sheet can be generated. The total equipment is placed on a rotating table. Seeding the fluid with tracer particles and adopting two cameras on top of the vessel allows to record all three components of velocity in the illuminated sheet. This stereo PIV (particle image velocimetry) approach allows a precise recording of the instantaneous flow as well as to generate data for a statistical analysis of the flow. Such non-intrusive physical experimentation is complemented with detailed direct numerical simulation.

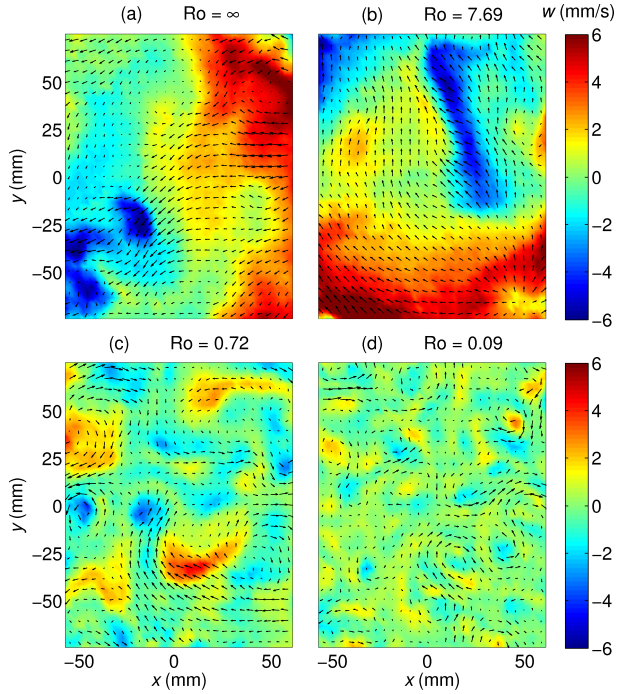


Figure 2: Typical velocity snapshots taken at height $z = 0.8H$, and Rayleigh number $Ra = 1.11 \times 10^9$. Snapshots at four different Rossby numbers Ro are shown. The background coloring depicts the out-of-plane vertical velocity component, while the arrows depict in-plane horizontal motions (only one fourth of the horizontal-velocity arrows is drawn for clarity).

The flow structure that corresponds to the altered heat-transfer display striking features. In fact, flow visualizations in turbulent rotating convection showed that many vertically aligned vortices are formed. An impression of the flow-organization as obtained from the physical experiments is collected in Fig. 2. The colors indicate the level of the vertical velocity w and the arrows correspond to the in-plane velocity components. As the rotation-rate increases (expressed by decreasing Rossby numbers Ro, denoting a dimensionless inverse rotation rate) more localized vortical structures are formed that are pre-dominantly aligned with the axis of rotation. In this paper we will present in some detail the dominant flow structuring, through numerical simulation. We will consider turbulent rotating convection in a cylinder, which can be directly compared to these physical experiments.

The organization of this paper is as follows. In the next Section we present the Boussinesq ap-

proximation to the governing equations and sketch the numerical method used to simulate the flow. Three-dimensional flow in a rotating cylinder that is heated from below and cooled on top is described subsequently. Concluding remarks are contained in a final Section.

MATHEMATICAL MODEL AND NUMERICAL APPROACH

In this section we first describe the mathematical model and then sketch and illustrate the numerical procedures that were adopted.

Mathematical model

The changes in density arising from modest temperature differences are correspondingly small. In this regime the dynamics of fluid flow subject to buoyancy and rotation may be expressed using the Boussinesq approximation. In vector notation the dimensionless set of governing equations can be written as:

$$\begin{aligned} \partial_t \mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \frac{1}{Ro}\mathbf{e}_z \times \mathbf{u} &= -\nabla p + T\mathbf{e}_z + \sqrt{\frac{\sigma}{Ra}}\nabla^2\mathbf{u} \\ \partial_t T + (\mathbf{u}\cdot\nabla)T &= \frac{1}{\sqrt{\sigma Ra}}\nabla^2 T \\ \nabla\cdot\mathbf{u} &= 0 \end{aligned} \tag{1}$$

These equations describe the evolution of velocity $\mathbf{u}$, temperature T and pressure p on the basis of conservation of momentum, energy and mass. Here $\mathbf{e}_z$ denotes the unit vector in the vertical z-direction.

The description of the flow behavior can be done succinctly with dimensionless numbers that give the ratios of different forces in the flow. For horizontally unbounded rotating Rayleigh-Bénard convection, there are six parameters involved, i.e., $\{(g\alpha), \nu, \kappa, \Omega, \Delta T, H\}$ denoting respectively the product of the gravitational acceleration g and thermal expansion α, the kinematic viscosity ν, the thermal diffusivity κ, the rotation rate Ω, the temperature difference between the plates ΔT and the distance between the plates H. These six parameters are formulated in three basic physical dimensions (length, time and temperature) - hence three dimensionless groups arise. A convenient velocity scale is $U = \sqrt{g\alpha\Delta T H}$ in terms of which we have for the Rayleigh Ra and Prandtl number σ:

$$Ra = \frac{g\alpha\Delta T H^3}{\nu\kappa} \quad , \quad \sigma = \frac{\nu}{\kappa} \tag{2}$$

The Rayleigh number is a ratio of buoyancy and dissipation. Diffusive properties of the fluid are described by the Prandtl number. The third basic dimensionless group is the Rossby number defined as

$$Ro = \frac{U}{2\Omega H} \tag{3}$$

which compares inertial and Coriolis forces. For slow rotation ($Ro \gg 1$) buoyancy is dominant, while for strong rotation ($Ro \ll 1$) Coriolis forces are stronger. For convective flow in bounded domains such as a cylinder, it is useful to define an additional parameter, the aspect ratio $\Gamma = D/H$ in which D denotes the diameter of the cylinder.

Numerical approach and validation

For a comparison of numerical simulation results to experiments in a rotating cylinder heated from below it is important to take into account the geometry of the experiment. The choice to perform

simulations in a cylindrical domain is obvious. To match with the experimental conditions the following boundary conditions are applied:

$$\begin{aligned} \text{Bottom plate} \quad (z=0) \quad &: \mathbf{u} = \mathbf{0} \;, \quad T = 1 \\ \text{Top plate} \quad (z=1) \quad &: \mathbf{u} = \mathbf{0} \;, \quad T = 0 \\ \text{Sidewall} \quad (r=1/2) \quad &: \mathbf{u} = \mathbf{0} \;, \quad \partial_r T = 0 \end{aligned} \tag{4}$$

indicating that all walls are no-slip, the bottom and top plates are kept at constant temperatures, and the sidewall is adiabatic.
In cylindrical coordinates the governing equations possess terms that include a factor $1/r$. These need special treatment to be evaluated at the cylinder axis $r = 0$. Verzicco & Orlandi [5] propose to rewrite the equations in terms of $q_r = ru_r$, $q_\phi = u_\phi$ and $q_z = u_z$. This, in combination with the use of a staggered grid, alleviates the discretization problems since $q_r(0, \phi, z) = 0$ and this is the only velocity component that needs to be evaluated at $r = 0$ since the other components are stored all off the axis. The equations are discretized on the staggered grid by central finite-difference formulations of second order accuracy. The solution uses a fractional-step procedure with the elliptic equation inverted using trigonometric expansions in the azimuthal direction and a direct solver for the other two directions. The numerical approach was validated by conducting simulations at a number of gradually finer resolutions. In literature various criteria for 'adequate' resolution were put forward - at a typical resolution of $N_r \times N_\phi \times N_z = 193 \times 385 \times 385$ we verified that these criteria were all satisfied for the simulations conducted. At the range of Rayleigh (10^8-10^{10}), Prandtl (4 and 6.4) and Rossby numbers (0.045 to 11.52) considered, the flow can be well resolved using direct numerical simulation - a systematic parameter-study was compiled.
In the next section we present simulation results of turbulent rotating convection in a cylinder.

ROTATING RAYLEIGH-BENARD CONVECTION IN CYLINDRICAL DOMAIN

We will focus on the numerical prediction of the large-scale flow structuring that occurs in the cylindrical convection cell, its consequences for the various length-scales that are present in the solution, and ultimately in the effect rotation has on the overall heat transfer.
In the physical experiments an organization into coherent structures was observed. Since the numerical simulations provide more detailed velocity and temperature data the development of the vortical plumes and their effect of the flow can be obtained. In order to appreciate the effect of rotation on the flow-structuring we consider the vortex structure in more detail. The vortical plumes that are detected for $Ro < 1$ are the most active components in the flow, as almost all of the vertical transport of fluid and heat is found in the interior of the vortices. Their size and number density are hence important for the total vertical transport through the fluid layer. In order to quantify such vortical structures we adopt the so-called Q-criterion. In [6] a vortex is identified with a spatial region where

$$Q \equiv \frac{1}{2}\Big(\|\mathbf{W}\|^2 - \|\mathbf{S}\|^2 \Big) > 0 \tag{5}$$

where $\mathbf{W}$ and $\mathbf{S}$ denote the symmetric and the antisymmetric parts of the velocity gradient tensor, and $\|\mathbf{A}\| = \sqrt{Tr(\mathbf{A}\mathbf{A}^T)}$ is the Euclidean norm.
A comparison of snapshots of Q at various Ro is presented in Fig. 3. Four Rossby numbers are included: $Ro = 0.09, 0.18, 0.36$ and 0.72. At lower rotation rates (higher Ro) considerably increased vertical variations are found. The columnar flow as expected from the Taylor-Proudman theorem

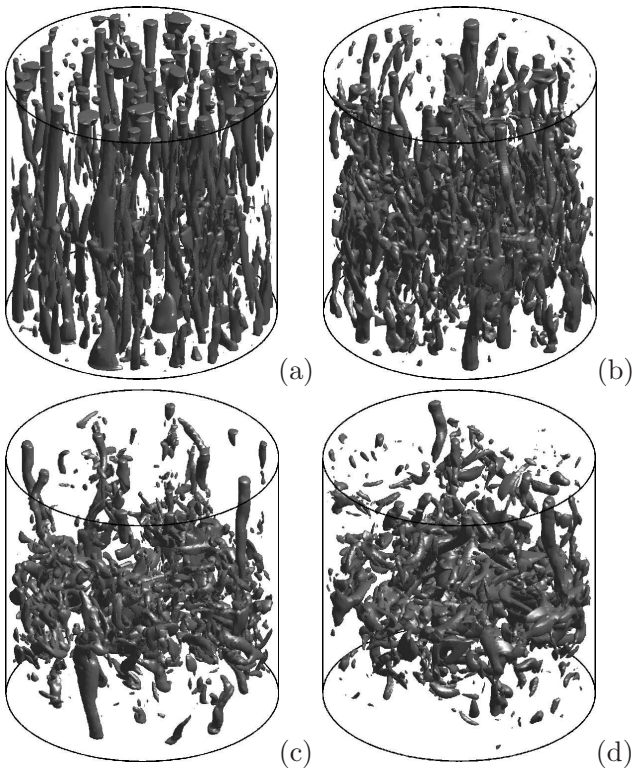

Figure 3: Snapshots of Q isosurfaces at (a) $Ro = 0.09$, (b) $Ro = 0.18$, (c) $Ro = 0.36$, and (d) $Ro = 0.72$.

is only found at the lowest Ro. Especially in the central part of the cylinder an intricate network of entangled tubes is found. Another difference is found in the average thickness of the vortices. It is clear that this is best measured closer to the plates, as there the vortical tubes are still aligned vertically. The average thickness decreases as Ro decreases. The vortex number density shows opposite behavior: more vortices are found at lower Ro.

We have seen that rotation has a profound influence on the phenomenology of turbulent convection. Therefore we also expect considerable changes in the turbulence statistics due to the rotation. The strength of the turbulent fluctuations may be represented by the root-mean-square values of, e.g., velocity, vertical vorticity and temperature. In Fig. 4 we collected the root-mean-square of two velocity components, extracted near the axis. The results correspond at small Ro approximately to a scaling $\sim Ro^{0.2}$ as was also observed in the physical experiments. At very high rotation rates the fluctuations decrease even more rapidly. For the temperature fluctuations the opposite was seen. At high rotation rates the RMS of temperature even increases with $\sim Ro^{-0.32}$. Under rotation the vortical plumes that develop need considerably more thermal contrast to break out from the boundary layer into the bulk fluid, as the critical Ra has increased.

We finally turn to the consequences of rotation for the vertical convective heat transfer as expressed in dimensionless form with the Nusselt number Nu. In Fig. 5 the Nusselt number Nu is presented as function of Ro and scaled with its value at $Ro = \infty$ (no rotation). At very high rotation rates this heat transfer clearly is hindered and Nu decreases. However, next to this asymptotic range, there is a set of rotation rates where Nu is even larger than in the non-rotating situation. The

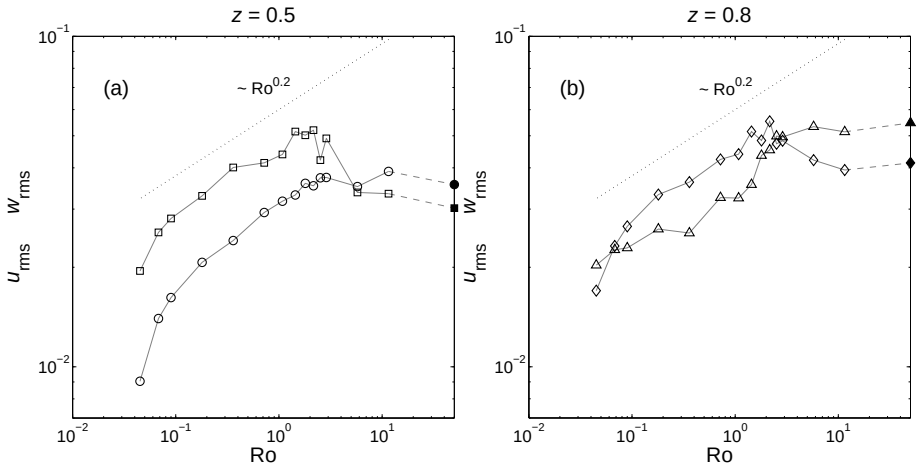

Figure 4: Root-mean-square velocities and their variation with Ro. (a) At $z = 0.5$ the horizontal rms values u_{rms} are indicated with circles and the vertical rms values w_{rms} with squares. (b) At $z = 0.8$ the horizontal components u_{rms} are plotted with triangles, the vertical rms values w_{rms} with diamonds. The filled symbols on the right-hand side of both figures are at $Ro = \infty$. A representative power-law dependence $Ro^{0.2}$ is given by the dotted line.

Ekman pumping taking place inside the vortical plumes is an efficient mechanism for entrainment of boundary-layer fluid (with strong temperature contrast) into the vortical plumes and subsequent transport of this fluid to the vertically opposite side. At higher rotation rates the stabilizing effect of the rotation becomes more and more prevalent and Nu approaches one, for a conductive state with zero flow velocity and a linear temperature gradient over the fluid.

CONCLUDING REMARKS

The problem of rotating Rayleigh-Bénard convection has been investigated through physical experimentation and numerical simulation. Direct numerical simulation has proved to be an excellent tool in the study of turbulent rotating convection in a cylindrical geometry. The agreement of DNS with the physical experiments was very strong. Hence, the phenomenology of rotating turbulent convection could be studied in much more detail, having full access to all flow properties at high spatial and temporal resolution. The effects of rotation on many aspects of the flow could be described and further understood. From the numerical results, a tentative separation into three regimes based on the Rossby number is suggested:

- $Ro \gtrsim 2$ In this range of Rossby numbers the flow behavior is dominated by the presence of the large-scale circulation (LSC). Variation of Ro has only minor effect. The LSC is hardly affected in strength although signs of instability are found near $Ro = 2$.
- $0.1 \lesssim Ro \lesssim 2$ The LSC is replaced by vortical columns as the dominant flow structure. However, in the central region of the cell still a disordered turbulent state is found: the vortices generally do not penetrate far into the fluid bulk. The number of vortices rises when Ro is decreased, and their mean radius decreases. In this range the turbulence intensity drops as rotation is increased. The Nusselt number, is larger than without rotation.
- $Ro \lesssim 0.1$ In the entire fluid volume the vortical plumes are found. Rotation has a more

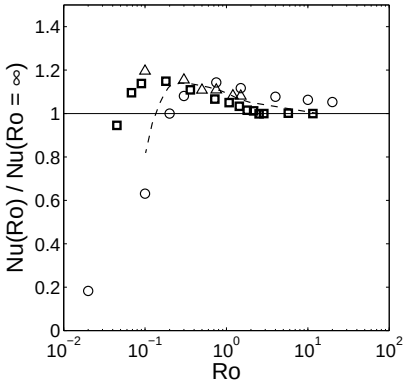

Figure 5: Relative Nusselt number $Nu(Ro)/Nu(Ro = \infty)$ as a function of Ro. The current simulation results are included with squares. The dashed line is taken from [2] at $Ra = 2.5 \times 10^6$, $\sigma = 6.8$, $\Gamma > 6$. Triangles represent results of [7] at $\sigma = 6.3$ and $\Gamma = 0.78$ (cuboid cell), extrapolated to $Ra = 1 \times 10^9$. Circles are taken from [8] at $Ra = 2 \times 10^8$, $\sigma = 0.7$, $\Gamma = 0.5$.

pronounced influence on the turbulence intensities, including vorticity: a considerably steeper dependence on Ro is reported in this range. The heat transfer is also adversely affected by the rotation; for Rossby numbers below 0.1 it is abruptly reduced.

The division into three regimes matches with the classification given in [9]: these authors label the first regime 'thermal turbulence', the second regime 'irregular geostrophic turbulence' and the last regime '(quasi-)regular vortex grid'. Many comparisons between the current numerical results and those from our experiments have been performed. Qualitatively a very good agreement was found. Quantitatively the discrepancies are well-described by stating that turbulent fluctuations in the experiments were generally less intense than in the simulations. The experimental conditions are obviously not as well-defined as in the numerical setting with idealized boundary conditions.

NUMERICAL ILLUSTRATIONS OF THE COUPLING BETWEEN LBM AND FINITE-TYPE MACRO-NUMERICAL METHODS

H.B. Luan, H. Xu, L. Chen, Y. L. He, W.Q. Tao*

Xi'an Jiaotong University, Xi'an, China

ABSTRACT Recently, multiscale approaches have had a tremendous impact on the analysis of complex problems in science and engineering. One widely adopted numerical method is "solving in different region individually and coupling the solutions at the interface". The major difficulty for macroscale and micro/mesoscale coupling is how to transform the macroscopic results into the dependent variables adopted in the micro/mesoscale methods. An analytic expression has been proposed by our research group for the exchange from velocity of finite-type method to the single-particle distribution function of lattice Boltzmann method (LBM). In this paper, lid driven cavity flow is selected to implement the coupling between the results of LBM and the finite-volume method (FVM). The final results show that the smoothness and consistency of the streamlines and velocity fields in the coupled region is very good. In addition it is also revealed that for the confirmation of good smoothness and consistence of solutions coupling at the interface vorticity contour distribution is a more appropriate parameter to ensure the quality.

Keywords: *multiscale computation, numerical method, couple method, LBM, FVM*

INTRODUCTION

Challenging multiscale phenomena or processes are widely existed in, e.g., material science, fluid flows, electrical and mechanical engineering [1,2,3]. Examples of multiscale problems include: turbulent fluid flow and heat transfer; transport phenomenon in proton exchange membrane of fuel cell; cooling process in data centre and so on. Multiscale problems can be divided into two categories: multiscale system and multiscale process. By multiscale system we refer to a system that is characterized by large variation in length scales. The processes at different scales are not very closely related and can be studied separately with certain connection. Cooling in data centre is a typical multiscale system problem. The length scale in cooling stream in house is in order of meter, while the cooling process of a chip is in order of millimeter. By multiscale process we mean that the overall behavior is governed by processes occur at different length and/or time scale, and they are inherently connected by process itself. Process in PEMFC, launching a spacerocket from earth surface to outer space and turbulent heat transfer are examples for multiscale process. From simulation point, study of the multiscale processes is more challenging and attractive. The focus of the present paper is in the multiscale process.

It is usually accepted that different scale problem should have different numerical method which is most applicable to that scale. Broadly speaking, there are three levels of simulation methods for fluid flow and heat transfer, the macroscale, mesoscale and microscale. The macro-scale numerical methods include the finite difference, finite volume, finite element and finite analytic methods. The basic feature of the four methods is that the smallest unit for computation is a cell with finite dimension. Thus they can be called finite-type methods. The mesoscale numerical methods include

the lattice Boltzmann method(LBM), direct simulation of Monte-Carlo method(DSMC). These two methods adopt a concept of computational particles which is much larger than an actual molecular but act as a molecule (simulation molecule). The micro numerical methods include molecular dynamic simulation (MDS) and quantum molecular simulation(QMS). In MDS every molecule is simulated according to the Newton's law of motion. A quantum molecular dynamics simulation solves the coupled time-dependent Schrodinger equations for all particles in the system[4]. This method is largely limited by the present computer source, hence, various approximations have to be used. In this paper QMS will not be concerned.

Recently, Abraham [5] have applied three level schemes FE-MD-QM (finite-element, molecular dynamic, quantum mechanical) to study crack dynamics. Nie et al. [6] adopted MDS and FVM for the lid-driven cavity flow in which the two vertexes are single point in math. Dupuis et al. [7] proposed LB-MD model in simulations of flows of liquid argon past and through a carbon nanotube. Wu et al. [8] proposed a scheme of coupled DSMC-NS using the unstructured mesh. One frequently encountered coupling is the one between some macro numerical method and meso numerical method, such as LBM and/or DSMC. The macro numerical methods usually are the finite-type methods (FDM, FVM, FEM, FAM). In this paper, the adopted method for the multiscale computation is the one in which different regions are solved individually and then the results are coupled at their interfaces.

In the following, we first present a brief overview of the lattice Boltzmann model and the finite volume model in Section 2. Then, we illustrate the basics and implement procedures of the couple strategy in Section 3. After that, we employed this couple strategy to solve the lid driven cavity flow in Section 4. Finally, some conclusions are given in Section 5.

LATTICE BOLTZMANN MODEL AND FINITE VOLUME MODEL

Lattice Boltzmann model

A popular kinetic model adopted in the literature is the single-relaxation-time (SRT) approximation, the so-called Bhatnagar-Gross-Krook(BGK) model [9,10]

$$\frac{\partial f}{\partial t}+\zeta\cdot\nabla f=-\frac{1}{\lambda}\left(f-f^{(eq)}\right) \tag{1}$$

where f is the single particle distribution function, ∇f is the gradient of the function f, ξ is the particle velocity vector, $f^{(eq)}$ is the equilibrium distribution function (the Maxwell-Boltzmann distribution function), and λ is the relaxation time due to collision.

To solve for f numerically, Equation (1) is first discretized in the velocity space using a finite set of velocities $\{\xi_\alpha\}$ without affecting the conservation laws [11, 12],

$$\frac{\partial f_\alpha}{\partial t}+\xi_\alpha\cdot\nabla f_\alpha=-\frac{1}{\lambda}\left(f_\alpha-f_\alpha^{(eq)}\right) \tag{2}$$

In the above equation, $f_\alpha(x,t)\equiv f(x,\zeta_\alpha,t)$ is the distribution function associated with the αth discrete velocity ξ_α and $f_\alpha^{(eq)}$ is the αth equilibrium distribution function. The nine-velocity square lattice model D2Q9 [12] (Figure 1) has been successfully used for simulating 2-D flow. The nine velocities which denoted by $\boldsymbol{e}_\alpha$ are given by:

$$\boldsymbol{e}_0=0, \tag{3a}$$

$$\boldsymbol{e}_\alpha=c\left(\cos\left((\alpha-1)\pi/4\right),\sin\left((\alpha-1)\pi/4\right)\right)\qquad \text{For } \alpha=1,3,5,7 \tag{3b}$$

$$\boldsymbol{e}_\alpha=\sqrt{2}c\left(\cos\left((\alpha-1)\pi/4\right),\sin\left((\alpha-1)\pi/4\right)\right)\qquad \text{FoR } \alpha=2,4,6,8 \tag{3c}$$

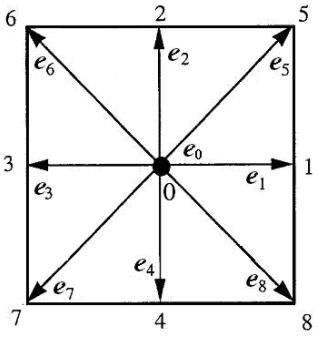

Figure 1. A 2-D, 9-velocity(D2Q9) lattice model

where $c = \delta x / \delta t$, δx is the lattice spacing step size and δt is the time step size. The equilibrium distribution function is given by:

$$f_i^{(eq)} = \omega_\alpha \rho \left[1 + \frac{3}{c^2}(\boldsymbol{e}_\alpha \cdot \boldsymbol{u}) + \frac{9}{2c^4}(\boldsymbol{e}_\alpha \cdot \boldsymbol{u})^2 - \frac{3}{2c^2} u^2 \right] \tag{4}$$

with the weights $\omega_0 = 4/9, \omega_1 = \omega_3 = \omega_5 = \omega_7 = 1/9, \omega_2 = \omega_4 = \omega_6 = \omega_8 = 1/36$ .The macroscopic density ρ and velocity vector $\boldsymbol{u}$ can be evaluated as

$$\rho = \sum_{\alpha=0}^{8} f_\alpha \tag{5a}$$

$$\rho \boldsymbol{u} = \sum_{\alpha=0}^{8} \boldsymbol{e}_\alpha f_\alpha \tag{5b}$$

The pressure of an ideal gas can be calculated from $p = \rho c_s^2$ with the speed of sound being $c_s = c/\sqrt{3}$. In the LBM, Equation (2) is discretized both in time and space, and the completely discretized equation (also the evolution equation) is

$$f_\alpha(\boldsymbol{x}_i + \boldsymbol{e}_\alpha \delta t, t + \delta t) - f_\alpha(\boldsymbol{x}, t) = -\frac{1}{\tau}\left[f_\alpha(\boldsymbol{x}_i, t) - f_\alpha^{(eq)}(\boldsymbol{x}_i, t) \right] \tag{6}$$

with the time step δt , space step $\delta x = \boldsymbol{e}_\alpha \delta t$, $\tau = \lambda / \delta t$ and x_i being a point in the discredited physical space.

Finite volume method

For multiscale simulation a fast converged algorithm of continuum method is highly required. The continuum methods include the finite difference, finite volume, finite element and finite analytic methods. FVM is the most widely adopted one in numerical heat transfer for its conservation properties of discretized equation and clear physical meaning of coefficient. Generally speaking, the macroscale methods (or called continuum methods hereafter) obey the fundamental laws of: mass conservation, momentum conservation and energy conservation.

The corresponding differential equation of the conservation law is:

$$\frac{\partial}{\partial \mathrm{t}}(\rho\phi) + \mathrm{div}(\rho \boldsymbol{U}\phi) = \mathrm{div}(\Gamma_\phi \mathbf{grad}\phi) + S_\phi \tag{7}$$

where ϕ is the dependent variable (such as velocity, temperature), U is the velocity vector, ρ is the fluid density. Γ is the nominal diffusion coefficient and S_ϕ is the source term.

In 1972, Patankar and Spalding proposed a solution procedure called SIMPLE, which is the most widely adopted algorithm for dealing with the coupling between velocity and pressure. There are two major assumptions in the simple algorithm: (1) The initial pressure and initial velocity are independently assumed, leading to some inconsistency between p and u, v ; (2) When the velocity

correction equation is derived, the effects of the neighboring grids velocity corrections are totally neglected.

These two assumptions do not affect the final solution but affect the convergence rate. The first assumption has been overcome by SIMPLER of Patankar(1980) [14]. Researchers have done many efforts to overcome the 2nd assumption, such as SIMPLEC by van Doormaal and Raithby (1984) [15], PISO by Issa (1986) [16], Explicit correction step method by Yen and Liu(1993) [17], MSIMPLER by Yu et al. (2001) [18]. None of the above revised versions could successfully overcome the second assumption. In the recent four years, our group developed CLEAR [19,20], and IDEAL [21,22]. They completely delete the 2nd assumption, making the algorithm fully-implicit. In both the CLEAR and IDEAL algorithms, the improved pressure and velocity are solved directly, rather than by adding a correction term to the intermediate solution. A further improvement of the solution procedure is conducted in the IDEAL algorithm making its convergence rate and robustness better than that of CLEAR.

In this article, the 2-D IDEAL collocated grid algorithm is adopted [23] using the SGSD scheme for the descretization of the convective term [24].

THE PRINCIPLE OF COUPLING LBM AND FINITE TYPE METHOD

First we present a general framework for designing a numerical method that couples marco methods and meso/micro methods. Assuming that a macroscale process is described by a state variable U, and a microscopic process is described by a state variable u. The two processes and state variables are related to each other at the interface of the macro and micro models by compression and reconstruction operation, denoted by Q and R respectively, as follows [1]:

$$U(x,t) = Q\big(u(x,t)\big) \tag{8}$$

$$u(x,t) = R\big(U(x,t)\big) \tag{9}$$

The two operators have the property $QR = I$, where I is the identity operator.

Generally speaking the reconstruction operator does not unique. In fact, the reconstruction procedure leads to a one-to-many mapping, because the microscopic simulator contains more information than that of the macroscopic simulator. In the opposite, the compression operation is usually a local/ensemble average through which a unique parameter can be resulted from lot of micro/meso-scale information. Thus for the coupling between the results from macroscopic and mesoscopic methods the major difficulty is how to transform the macroscopic results, such as velocity, into the dependent variables adopted in the micro/meso-scale methods, for example from velocity of finite-type method to the single-particle distribution function of LBM.

Recently an analytic expression has been derived by our research group which couples the lattice Boltzmann method(LBM) with finite-type macro numerical method as follows [25]

$$f_i = f_i^{(eq)}\{1 - C_s^{-2}\tau\delta t U_{i\beta}(U_{i\alpha}\partial_\alpha u_\beta + \nu\partial_\alpha^2 u_\beta + \nu\frac{1}{\rho}\partial_\alpha \rho S_{\alpha\beta})\} \tag{10}$$

where f_i represent the single-particle distribution function along the direction i, $f_i^{(eq)}$ is the equilibrium distribution function, C_s is the speed of sound of the model, ρ, u denote the density and velocity, respectively, τ is the relaxation time, ν for viscosity, and α, β represent the two coordinate directions.

To illustrate the basic idea, the lid-driven cavity flow is simulated by the coupled LBM-FVM method. The computational domain is decomposed in two regions in which the LBM and FVM methods are used respectively (Figure 2). We can control the coarseness and fineness of grids according to the zone spatial scale in each region. When the grid systems at the interface of the

subregions are not identical, space interpolation at the interface is required when transferring the information at the interface. In this paper, we choose the FVM grid space equals to lattice space for

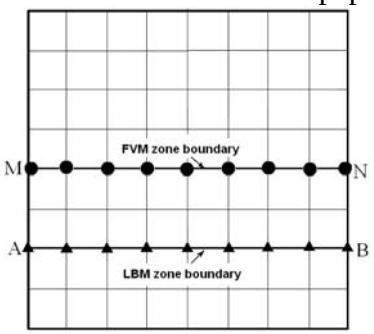

Figure 2. Interface structure between two regions of FVM and LBM

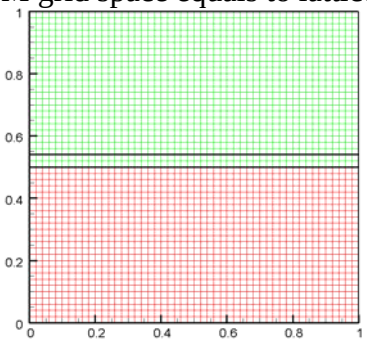

Figure3. Grid layout for a 2-D lid-driven cavity(200×200).

convenience to avoid the spatial interpolation. Line $\overline{MN}$ is the FVM region boundary located in the LBM subregion, while line $\overline{AB}$ is the LBM region boundary located in the FVM subregion. Hence the subdomain between the two lines is the overlapped region (often called hand-shaking region) where both LBM and FVM methods are adopted. This arrangement of the interface is convenient for the information exchange between the two neighboring region.

The coupled computations are conducted as follows. First with some arbitrary assumed velocity at the line $\overline{MN}$, the FVM simulation in the lower region is performed. After a temporary solution is obtained the information at the line $\overline{MN}$ is transformed into the single particle distribution function. The LBM simulation is carried out in the upper region. Then, the temporary solution of LBM at the line is then transported into the macro velocity at the line $\overline{AB}$ and the FVM simulation is repeated. Such computation is repeated until the results at the two lines are remained the same within an allowed tolerance.

RESULT AND DICUSSION

The grid layout is shown in Figure 3. Numerical simulations were carried out for cavity flow using the lattice Boltzmann method for *Re*=100, 400, 1000 on a grid of 200×200. The length of squared cavity is $L=1$. The boundaries of the cavity are still walls, except the upper boundary for which a uniform tangential velocity is prescribed as $u_{Re=100}=3.33\times10^{-3}$, $u_{Re=400}=1.33\times10^{-3}$, $u_{Re=1000}=3.33\times10^{-2}$ for the three Reynolds numbers, respectively.

Figure 4 shows plots of the stream function for the Reynolds number considered. These plots give a clear picture of the overall flow pattern and the effect of Reynolds number on the structure of the recirculating eddies in the cavity. The smoothness of the stream function distribution, especially around the hand-shaking region confirms the correctness of the information transfer at the interface.

To quantify these results, the velocity profiles along the vertical and horizontal centrelines of the cavity are shown in Figure 5 and Figure 6, and the centre locations of the primary vortices, bottom left vortices and bottom right vortices are listed in Table 1. The results are in close agreement with the benchmark solution [26]. As *Re* increases, the primary vortex centre moves towards the right and increasingly becomes circular.

The whole region vector plot is shown in Figure 7. We are interested in the smoothness and consistency of velocity distribution in the "hand-shaking" region. For this purpose, Figure 8 is presented where a local, enlarged view of the vector plot in the rectangle zone of Figure 7 is shown. Clearly, the vectors in the overlap region are quiet consistent between the LBM results and the FVM results, especially the vector arrows at the same location from the two methods in the hand shaking region are almost identical. Figure 9, 10 shows the contours of u_velocity, v_velocity. It is seen that these physical quantities are all smooth across the interface.

Finally the contours of vorticity distribution are presented in Figure 11. It can be observed that at *Re*=100, there is some un-smoothness at the interface in the left half of the cavity. This un-

smoothness may be caused by the un-completeness of iteration for this Reynolds number. This observation gives us a hint: to confirm a good smoothness and consistence when coupling of

numerical solutions at the interface is investigated, the quality of the vorticity contour plot is more sensible to that of velocity. This is because vorticity is the first derivative of velocity, its smoothness requirement is more strict than that of velocity. The stream function is an integral of the velocity, hence its smoothness is the easiest to be reached.

CONCULUSIONS

In this paper, an coupling approach is used to couple the solutions of LBM and FVM for simulating the fluid flow problems. A reconstruction operator is adopted to lift the macroscopic velocity fields of FVM to mesoscopic distribution functions of LBM. The numerical investigations validate the proposed reconstruction operator and the coupling method.

To confirm a good smoothness and consistence of solutions coupling at the interface the vorticity contours are suggested apart from the velocity distributions. The stream function contours are the most easiest to be smoothed.

HEAT AND FLUID FLOWS IN GAS SPRINGS

U. Lekić*, J.B.W.Kok
University of Twente, Enschede, The Netherlands

ABSTRACT. Thermo-mechanical processes and fluid flow phenomena occurring in an unlubricated piston-cylinder gas spring are investigated. Accurate prediction of the compressed gas thermal behaviour, energy transfer and the fluid flows, together with the heat transport in the surrounding solid structures is of high industrial importance, especially where tight tolerances and the absence of a lubricant are required (e.g. cryo-cooling industry). Existing heat transfer correlations are not applicable for the closed cyclically-compressed volumes. Research on transient fluid and heat flows is done with the use of the ANSYS CFX finite-volume numerical package, modelling the closed fluid domain and the surrounding solid in a valveless piston-cylinder gas spring. Measured pressure and heat-flux data from an unlubricated piston-cylinder experimental setup are compared to the numerically simulated values; very good agreement is observed. Analyses have been made on the forming and propagation of the thermal boundary layer towards the core gas, as a function of the varying operating speed. An analytical expression that determines the boundary layer thickness on the basis of operating conditions is presented.

Keywords: *transient heat transfer, DNS, fluid flow phenomena, boundary layers.*

MOTIVATION

Piston-Cylinder Combinations are in use in a very broad range of industrial applications. Examples are internal combustion engines in the automotive, marine and aerospace applications, compressors in the cooling devices for domestic and commercial applications, for the gas liquefaction, medical purposes and superconductivity technology in electronics. All of them are intrinsically characterized by the reciprocating pistons moving inside cylindrical volumes and compressing the enclosed operating fluid. These parts are conventionally lubricated to reduce the frictional forces and wear and cool the contacts; but unfortunately lubricants also pollute the working medium. In the internal combustion engines this is acceptable in reasonable limits (the lubricant is combusted and removed), but when it comes to the closed cooling-cycle systems, one wants to avoid any presence of impurities in the thermal carrier. Ways to achieve this are thorough filtering of the operating medium and shortening of the maintenance intervals. The other direction, proposed through this project is to omit the lubrication itself and so eliminate the related decrease of performance and increase of the operating costs.

Accurate thermal analysis is crucial in this sort of considerations. Thermal expansion, internal thermal stresses and distortion of the projected geometrical relations can lead to adverse frictional stresses, delamination and destruction of the exposed and interacting parts, wear and fatigue. The oil-free constructions, investigated here, demand extremely narrow tolerances of the functional parts, which again requires much work on understanding and describing the fluid-flow and heat transfer phenomena occurring in the gas and the surrounding solid parts.

NUMERICAL HEAT FLUX versus EXPERIMENTS

Conventional Nu-Re correlations, as derived for the steady state developed boundary layer flows, are not applicable for the transient heat transfer from the gas rapidly compressed and expanded, to the surrounding walls. A phase shift can be observed between the peak instantaneous heat flux at the gas spring walls and the peak bulk gas temperature; the peak heat flux precedes the temperature maximum up to as much as 45° (Figure 1), [1, 2, 3]. Attempts have been made and reported in the literature [1, 3, 4] to include this phenomenon in the bulk gas temperature-heat transfer correlation by adding a complex phasing part. This, however, has not lead to a generally applicable correlation. For this reason, in the presented work, numerical heat transfer modelling is performed using computational fluid dynamics, applied on flow and heat transfer in a closed flow domain with transiently changing volume.

The commercially available finite-volume code ANSYS CFX11.0 is used for solving the conservation equations and the numerical modelling of the gas flow field, wall heat flux and heat conduction in the solid wall. A Direct Numerical Simulation (DNS) approach is adopted; no approximating turbulence models are being used. Underlying governing equations are the standard compressible Navier-Stokes conservation equations set up in CFX. In the previous work, [5], k-ω, SAS and LES models were applied, but this was abandoned for the absence of actual developed turbulence in the compressed fluid. Latter will be explained in the following chapter.

Mass and energy conservation in the numerical model are verified with an adiabatic simulation and results are validated with the adiabatic thermodynamic analogy over a period of 10 operating cycles (Figure 2). Discretised models were verified to be sufficiently temporally and spatially refined, to ensure accurate and grid-independent solutions. Subsequently, models are generated also for non-adiabatic cases. These are compared to the available experimental database. Measurements have been performed by A.A.Kornhauser at Massachusetts Institute of Technology-MIT [3], who made the database available to the authors. The experimental setup was a single piston-cylinder crankshaft driven gas spring (no suction/exhaust valves). The geometry of the experimental machine was DxS=50.2x76mm for the compression ratio 2 [3], *S* being the piston stroke. Kornhauser also did experiments with higher compression ratios, but due to the reported uncertainty in the measurement results these will not be discussed here. Two operating-speed test-cases were 2 and 1000 RPM. Measured property was the absolute pressure; the heat flux in [3] and [6] was evaluated as a direct function of pressure, volume and the enclosed mass of the operating fluid, with the use of global thermodynamics (the First Law of Thermodynamics and the Clapeyron equation - ideal gas law). The results of the simulations, as compared to the measurements, are presented in the following pages.

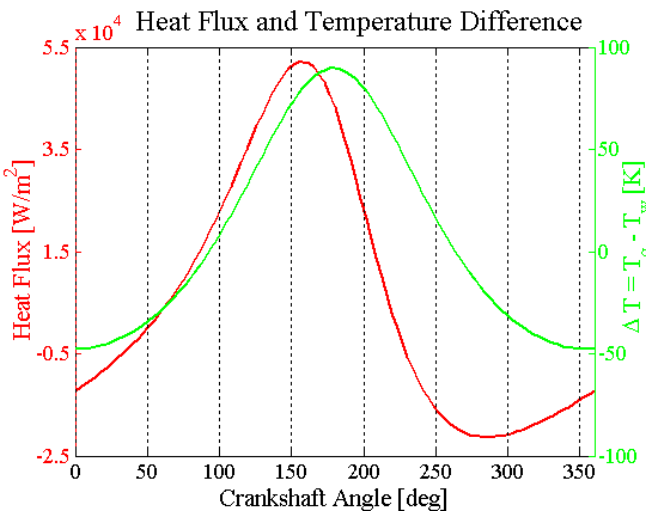

Figure 1. Temperature and heat flux phase shift

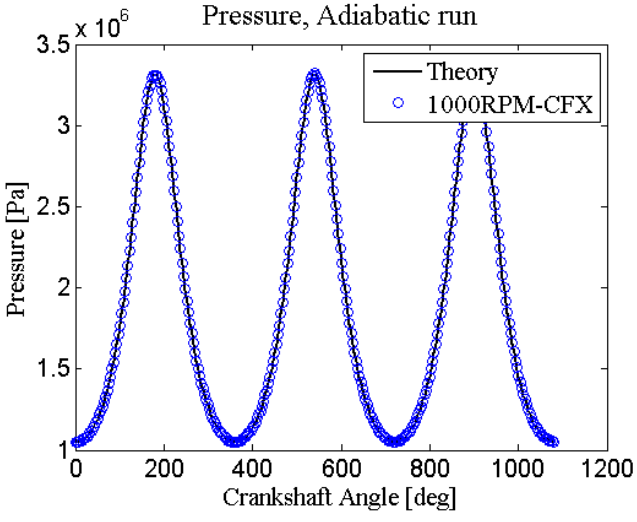

Figure 2. Numerically calculated pressure for an adiabatic run

Results

The CFX-model geometry and mesh are dimensioned according to the MIT experimental setup. For computational time reduction, and assuming the flow to be axi-symmetric, only a 5° cut of the compressed domain is modelled. The moving mesh is uniform, the piston is the only moving boundary (lower boundary) and the mesh elements are allowed to deform and redistribute in axial direction. Every node displacement is specified through an explicit function in order to ensure the uniform cell-distortion and avoid occurrence of negative-volume elements. After consecutive spatial and temporal refinements, the compression-ratio 2 model is optimized to ~28000 nodes (~20000 elements) and 1000 timesteps per cycle. The compressed gas is helium, as in the experiments. In the following discussion 2RPM runs will be regarded to as "*slow*" and 1000RPM as "*fast runs*".

Identical geometry and mesh are used for both slow and fast runs (mesh is optimized on the critical, fast run). All the walls surrounding the gas have a no-slip boundary condition. The piston surface (moving boundary) is set as an adiabatic wall and the cylinder and top (head) walls are defined to have a constant temperature of 295K, equal to the temperature of the coolant on the other side of the gas-spring walls. This assumption was made due to the very small actual oscillations in the wall temperature. This was measured for motored piston engines by several researchers [7, 1], and shown to be lower than ±3K, due to the large thermal time constant of the walls. Validity of this assumption was also examined by [6], and here too it was shown that the wall temperature can be assumed to be constant with a view to the effect on the wall heat flux.

Initial conditions are set to comply with Kornhauser's measured data; the runs are started from the bottom-dead-centre position. Kornhauser's measurements were recorded once the gas spring has reached the cyclic steady state in its operation, i.e. when the mean cycle pressure remained constant (less than 1% deviation). Results of measurements and simulations for the slow runs are presented in Figure 3 and Figure 4, and in Figure 5 and Figure 6 for the fast runs. Please note that *r* in the figure caption denotes the compression ratio and *f* stands for the operating frequency.

Slow runs. As can be seen in Figure 3, the numerically simulated pressure comes very close to the exact measured values. Properties are plotted against the crankshaft angle, 0° being the bottom-dead-centre (BDC) and 180° the top-dead-centre (TDC). The pressure in the steady state is oscillating periodically between approximately 78kPa and 160kPa; the maximum pressure is reached at the TDC. Figure 4 shows the wall heat flux to be well predicted at 0-210° and 300-360° crank angle. It is

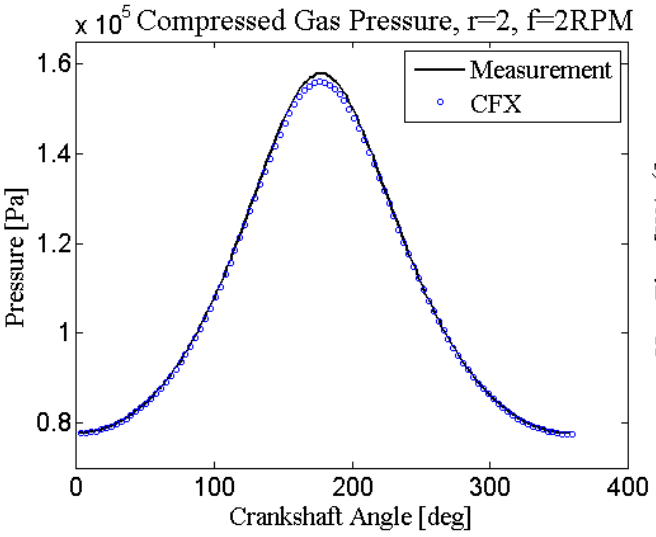

Figure 3. Measured and simulated gas pressure for the slow run, r=2

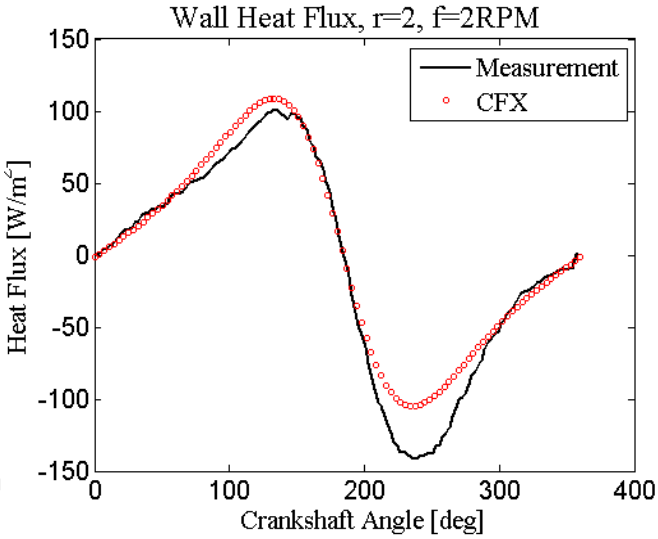

Figure 4. Measured and simulated wall heat flux for the slow run, r=2

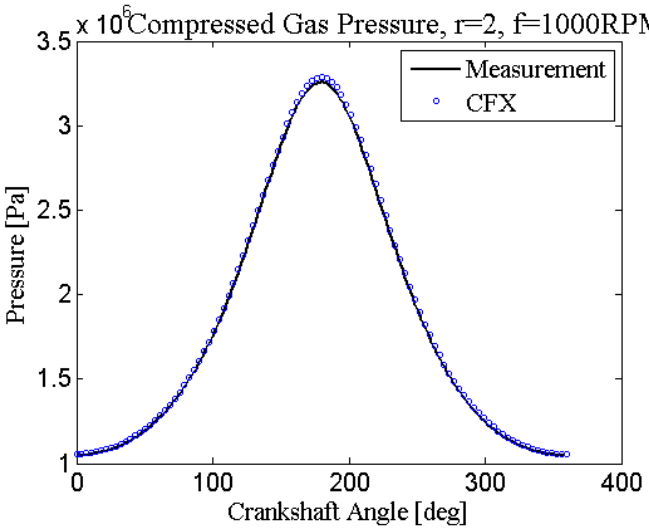

Figure 5. Measured and simulated gas pressure for the fast run, r=2

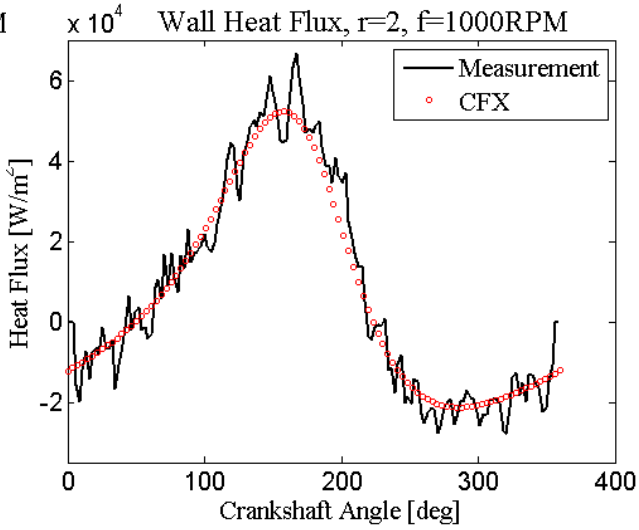

Figure 6. Measured and simulated wall heat flux for the fast run, r=2

positive in the compression phase of the cycle, positive being the heat release from the gas to the cylinder walls. There is no phase shift between the volume and mass averaged temperature and the heat flux for the slow runs (not shown here). Past the top-dead-centre the expansion starts and the heat flux becomes negative, with a negative maximum at approximately 235 degrees crank angle. Here the numerical model under-predicts the reported measured values; the maximum negative heat flux is underestimated by 50%. There is some uncertainty in the measurements at this point, as it appears that more heat is being cyclically accumulated than released. That way the gas spring would actually be producing work while the mean compressed-gas temperature is higher than the environmental (not shown here). Nevertheless, it can be concluded that CFD is very well able to predict the transient pressure and wall heat flux for the slow operating motored gas spring.

Fast runs. Measurements of the fast runs done by Kornhauser are at 1000 RPM and report turbulent flows inside the spring (the latter is discussed in the subsequent chapter). The boundary conditions in this CFD simulation are identical to those in the slow runs. The initial conditions are adapted to the experimental data; starting steady-state pressure is 1.05MPa. The obtained results for pressure and wall heat flux are presented in Figure 5 and Figure 6. The pressure on Figure 5 is observed to vary between 1 and 3.3MPa, with the maximum at the top-dead-centre, 180 degrees crank angle. Wall heat flux is plotted on Figure 6; the amplitude varies from plus 50 kW/m^2 to minus 20 kW/m^2, with the peak heat flux in the compression stroke preceding the temperature by approximately 25° crank angle. With very little error this is reproduced, and in view of the good comparison for the both characteristic test cases, it can be concluded that for the low compression ratio r=2, the CFX numerical model can successfully predict the energy flows and gas properties of the compressed medium in a valveless gas spring.

CYLINDER THERMAL BOUNDARY LAYER THICKNESS CORRELATION

The cylinder's boundary layer characteristics determine the rate of heat transfer and it's phasing with respect to the gas pressure and the bulk-gas temperature. In addition, the boundary layer at the bounding walls carries a significant part of the volume-enclosed gas mass (30-40%, [8]), and its size and shape prediction is a step to the better understanding of the transient instantaneous local heat flux. Here are presented the analysis on the development and propagation of the thermal boundary layer from the convoluting walls towards the centre of the domain. The work is based on the CFX11.0 numerical simulations as elaborated above and the analytical work, for two different piston-cylinder geometries.

Numerical models

The first modelled geometry is the above described Kornhauser's gas spring, while the second is according to the experimental setup built at the University of Twente - UT, Netherlands. Diameter and the piston stroke in the UT setup are 50mm and 52mm, respectively, compression ratio is two. The numerical model is optimized following the same routine as for the first geometry, resulting in ~8500 nodes (~6500 elements) and 1000 timesteps per cycle. The initial pressure in the UT gas spring model was set to 1.5bar and the simulations for every set case were run until the steady state is reached. Investigated operating frequencies for both geometries are 2, 10, 100, 500, 1000 and 1500RPM.

Boundary layers are usually conceptually correlated to the presence of turbulence. Although the swirling motion can be observed in the flow domains for the fast runs discussed above when the piston is at the top and bottom dead centre (Figure 7; left vertical line represents the symmetry axis of the domain 2-D snapshot), no developed turbulence is actually present here for either of the set operating frequencies. This is obvious from the turbulence parameters (eddy-viscosity, Reynolds number), and is in contrast with the reported work of Kornhauser [3]. Computed eddy frequency for the fast runs is in the order 10^3 smaller than the dynamic (molecular); in developed turbulent pipe flows it is three orders higher than the dynamic viscosity [9]. At the same time, Reynolds number is peaked at ~2000. There are no published studies on critical Reynolds numbers in this type of geometries; but it is well known that for pipe flows turbulence is ensured only for $Re>10^4$. Nevertheless, a viscous shear layer with the heat flux affected temperature and a bulk core in inertial motion can be distinguished. During the high speed runs, the shear layer thickness is much smaller than the characteristic length-piston diameter. In the slow runs the shear layer grows to the order of magnitude of the piston diameter.

Typical temperature profiles along the half-diameter, as derived from the computed temperatures for every node, are displayed on Figure 8 and Figure 9. Temperatures are sampled at 3 radius heights (discussed later) between the TDC and the cylinder top, and in the moment of the maximum piston velocities through the cycle (79° and 80° before TDC). Temperatures on these plots are sampled 38.1 and 26mm below the cylinder top (Kornhauser and UT geometry, respectively). As obvious from the figures, the forming and "shrinking" of the boundary layers as the operating frequency of the gas spring rises can be observed. For the fairly slow runs, 2&10RPM, the time scale of the temperature propagation velocity (heat and mass transfer in the gas) is larger than the axial velocity time scale, resulting in the Gaussian-like temperature profile. As the piston speed grows, two regions in the compressed (expanded) volume appear: the distinguished viscous boundary layer and the undisturbed turbulent-like core. Thermal and velocity boundary layers are formed as the consequence of the finite thermal conductivity of the gas and the discrete value of the molecular viscosity, that with the no-slip condition at the wall cause the momentum imposed by the piston displacement to be biased and diffused. Being that there is a time scale related to the propagation of this shear effect, in the fast runs, the turbulent-like core is basically the bulk gas uniformly displaced in the axial direction.

Analytic correlation

Dimensional analysis was used to develop a correlation for the growth of the thermal boundary layer at the cylinder walls. An expression by Lyford-Pike and Heywood [8] for a spark-ignition engine is revised to correlate the thermal boundary layers in the gas springs; the "analytical" boundary layer thickness $\delta_{T,A}$ is fitted to the numerically determined value $\delta_{T,N}$. The question arises what should be defined as the actual boundary layer, i.e. where the transition point should be set. Here, it is proposed to be the point where the temperature gradient dT/dx is changed by 25% when differentiating from the gas core towards the wall (Figure 10). It is very interesting to notice that the shape of the boundary layer through all these runs always follows the rule that this point falls extremely close to three times the distance of the peak-temperature BL thickness (Figure 10). The following quantities were taken as the relevant parameters: gas thermal conductivity k, density ρ, specific heat at constant pressure c_p, viscosity μ, time t, cylinder diameter D and the piston stroke S. All gas properties were evaluated for the mean of the bulk gas and the wall temperature.

The local gas velocity v was evaluated as in [8], varying linearly from the piston velocity v_p to zero at the cylinder head:

$$v = v_p \cdot (x_0/x) \qquad (1)$$

where x_0 is the distance from the sampling point to the cylinder top, and x between the piston crown and the cylinder top. Reynolds number is calculated as $Re = \rho v x_0/\mu$, and the thermal diffusivity $\alpha = k/(\rho c_p)$. Elapsed time for the boundary layer thickness expression begins when the piston passes BDC for the compression, and when it passes TDC for the expansion stroke. The set of sampling locations x_0, as distances from the cylinder top, is quoted in Table 1.

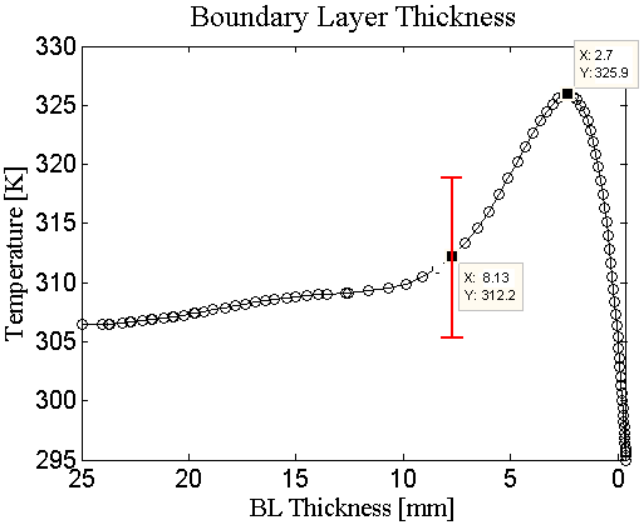

Figure 10. Boundary layer definition

An analytical correlation for the developed boundary layer thickness can be derived and shown to fit the numerically calculated values, during the compression stroke as defined by equation (2):

$$\delta_{T,A,comp} = 4.6\sqrt{\alpha \cdot t} \cdot \frac{1}{\left(Re \cdot \frac{S}{D}\right)^{0.03}}, \qquad (2)$$

and for the expansion stroke by equation (3):

$$\delta_{T,A,exp} = 3\sqrt{\alpha \cdot t} \cdot \frac{1}{\left(Re \cdot \frac{S}{D}\right)^{0.03}} \qquad (3)$$

On Figure 11 are plotted correlations for 3 sampled positions, both geometries and the specified range of operating frequencies. Figures show very satisfactory results for all test cases.

CONCLUSIONS

Numerical models have been developed with the use of the finite-volume numerical package ANSYS CFX11.0, to simulate the thermodynamic phenomena occurring in a compression ratio 2 helium gas-spring. Characteristic properties such as the mass and energy conservation, pressure of the compressed gas and the heat transfer from the gas to the solid are examined and compared to the experimental database obtained at MIT. For typically slow and fast runs: 2RPM and 1000RPM operating frequency, numerical model very successfully predicts the measured values of pressure and heat-flux, with very little error introduced.

In view of the relevance to the thermodynamic processes and convective heat transfer, the timescale and the depth of the penetration of the thermal boundary layer are analysed in numerical models for two different helium gas-spring geometries and a range of operating frequencies. Derived analytic expressions for determining the thermal boundary layer thickness at the cylinder walls fit the numeric data adequately for various test cases: both compression and expansion stroke, different geometries, charge pressures and operating speeds. It can be concluded that the presented correlation is a good approximation and can be used generally.

Nomenclature:

r – compression ratio, [/], $r=V_{BDC}/V_{TDC}$
f – operating frequency, [RPM]
TDC – Top Dead Centre
BDC – Bottom Dead Centre
$\delta_{T,N}$ – numerically determined boundary layer thickness, [mm]
$\delta_{A,N,\,comp}$ – analytically determined boundary layer thickness during the compression stroke, [mm]
$\delta_{A,N,\,exp}$ – analytically determined boundary layer thickness during the expansion stroke, [mm]
S – piston stroke, [mm]
x_0 – distance from the sampling point to the cylinder top, [mm]
x – distance from the piston crown to the cylinder top, [mm]

A STUDY OF PARTICLE FEEDBACK IN TURBULENT GAS-PARTICLE FLOWS

T. Strömgren*, G. Brethouwer, G. Amberg and A.V. Johansson
Linné Flow Centre, KTH, Stockholm, Sweden

ABSTRACT. The upward turbulent gas-particle flow in a channel was studied using an Eulerian-Eulerian two-phase model taking into account the feedback from the particles on the gas-phase. The objective is to study the influence of particles with different diameters and volume fractions on the flow and particularly on the accumulation of particles in the near wall region due to the turbophoretic effect. The results were obtained with a two-phase flow model that is presented. The accumulation of particles in the near-wall region was found to be strongest for particles with $\tau_p^+ = 13$. The model also shows that varying the particle diameters leads to different feedback of the particles on the turbulent flow.
Keywords: *Turbulent gas-particle flows, modelling, particle feedback, turbophoresis*

INTRODUCTION

The interaction between turbulent flows and inertial particles is important in both natural and industrial processes. For instance in particulate dispersion in the atmosphere and in processes to remove pollutants generated by power plants fired by fossil fuels. The effect of particles on the turbulence is very complex and it is of importance to increase the understanding of this phenomenon.

Particles tend to accumulate in regions with low turbulence intensity, e.g. in the near wall region of wall-bounded flows, due to the turbophoretic effect [1]. The turbophoretic particle drift caused by gradients in the turbulent kinetic energy is counteracted by turbulent diffusion that transports particles down concentration gradients [2]. These phenomena have been extensively studied by [1, 3, 4, 5, 6].

We have developed a model that takes into account the feedback from the particle-phase on the gas-phase [7]. We use the model to simulate the fully developed turbulent gas-particle flow in a vertical channel. The aim is to study the interaction between the particle-phase and the gas-phase and the accumulation of particles in the near wall region for different particle diameters and mass loadings.

The present paper is organized as follows: first a description of the model and the governing equations are given, then the simulation setup is explained followed by the discussion of the results and the conclusions.

MATHEMATICAL FORMULATION

Model equations

An Eulerian-Eulerian model, developed by [7], is used to study turbulent gas-particle flows assuming that the particle-phase can be considered as a continuum. The model is found to be in good agreement with both DNS-data and experiments [7]. The volume fraction weighted averaged continuity equation of the particle-phase can be written as

$$\frac{\partial \Phi_g}{\partial t} + \frac{\partial}{\partial x_i}(U_{gi}\Phi_g) = \frac{\partial}{\partial x_i}(\nu_p \frac{\partial \Phi_g}{\partial x_i}) \tag{1}$$

where Φ_p is the mean particle volume fraction, U_p is the particle velocity and ν_p is the viscosity due to particle-particle collisions. The volume fraction weighted averaged momentum equations for gas- and particle-phase are, respectively

$$\begin{aligned}&\frac{\partial}{\partial t}(\rho_g \Phi_g U_{gi}) + \frac{\partial}{\partial x_j}(\rho_g \Phi_g U_{gi} U_{gj}) = -\Phi_g \frac{\partial P}{\partial x_i} + \\ &\rho_g \frac{\partial}{\partial x_j}((\nu_{tg} + \nu_g)(\Phi_g(\frac{\partial U_{gi}}{\partial x_j} + \frac{\partial U_{gj}}{\partial x_i}))) - \frac{\partial}{\partial x_j}(\frac{2}{3}\rho_g \Phi_g \delta_{ij}(K_g + \nu_{tg}\frac{\partial U_{gl}}{\partial x_l})) \\ &- (1 + 0.15Re_r^{0.687})\frac{\rho_p}{\tau_p}\Phi_p(U_{gi} - U_{pi})\end{aligned} \tag{2}$$

$$\begin{aligned}&\frac{\partial}{\partial t}(\rho_p \Phi_p U_{pi}) + \frac{\partial}{\partial x_j}(\rho_p \Phi_p U_{pi} U_{pj}) = -\Phi_p \frac{\partial P}{\partial x_i} \\ &+ \rho_p \frac{\partial}{\partial x_j}(\Phi_p(\nu_p + \nu_{tp})(\frac{\partial U_{pi}}{\partial x_j} + \frac{\partial U_{pj}}{\partial x_i})) - \frac{\partial}{\partial x_j}(\frac{2}{3}\rho_p \Phi_p \delta_{ij}(K_p + \nu_{tp}\frac{\partial U_{pl}}{\partial x_l})) \\ &+ (1 + 0.15Re_r^{0.687})\frac{\rho_p}{\tau_p}(\Phi_p(U_{gi} - U_{pi})) + \Phi_p(\rho_p - \rho_g)g_i\end{aligned} \tag{3}$$

where U_g, ρ_g, Φ_g, P, K_g, ν_{tg}, and ν_g are the mean velocity, density, mean volume fraction, pressure, mean turbulent kinetic energy, turbulent viscosity and kinematic viscosity of the gas-phase, respectively. ρ_p, K_p and ν_{tp}, are the density, mean turbulent kinetic energy and turbulent viscosity of the particle-phase. The model takes into account the feedback from the particles on the gas-phase through the drag term (last term on the right hand side (R.H.S.) of equation (2)) with a correction term for higher Reynolds numbers according to [8], where $Re_r = D_p|U_p - U_g|/\nu_g$ is the relative Reynolds number, $\tau_p = \rho_p D_p^2/(18\rho_g \nu_g)$ is the particle response time and D_p is the particle diameter.

To model the gas- and particle Reynolds stresses the Boussinesq assumption is used. The turbulent viscosities are modelled according to $\nu_{tg} = K_g/\omega$ [9] and $\nu_{tp} = \nu_{tg}/(1+(\tau_p/T_L)^2)$ [10], where ω is the inverse time scale of the turbulence and T_L is the Lagrangian time scale of the gas-phase. A low Reynolds number K-ω model is used to compute K_g and ω [9]. The equations for K_g and ω are given by

$$\begin{aligned}&\rho_g \frac{\partial K_g}{\partial t} + \rho_g U_{gj}\frac{\partial K_g}{\partial x_j} = 2\rho_g \nu_{tg} S_{ij} S_{ij} - \rho_g C_\mu \omega K_g \\ &+ \frac{\partial}{\partial x_j}[\rho_g(\nu_g + \frac{\nu_{tg}}{\sigma_K})\frac{\partial K_g}{\partial x_j}] - (1 + 0.15Re_r^{0.687})\frac{\rho_p}{\tau_p}\Phi_p(\overline{u'_{gi}u'_{gi}} - \overline{u'_{pi}u'_{gi}})\end{aligned} \tag{4}$$

$$\rho_g \frac{\partial \omega}{\partial t} + \rho_g U_{gj}\frac{\partial \omega}{\partial x_j} = 2\rho_g \alpha S_{ij} S_{ij} - \rho_g \beta \omega^2 + \frac{\partial}{\partial x_j}[\rho_g(\nu_g + \frac{\nu_{tg}}{\sigma_\omega})\frac{\partial \omega}{\partial x_j}] \tag{5}$$

where

$$S_{ij} = \frac{1}{2}(\frac{\partial U_{gi}}{\partial x_j} + \frac{\partial U_{gj}}{\partial x_i}) \tag{6}$$

Equation (4) is derived from the momentum equation of the gas-phase (2). The last term in (4) represents the interaction between the gas-phase and the particle-phase. The model parameters are defined by

$$\alpha = \frac{5}{9}\frac{\alpha_o + Re_T/R_\omega}{1 + Re_T/R_\omega}(\alpha^*)^{-1} \tag{7}$$

$$\alpha^* = \frac{\alpha_o^* + Re_T/R_k}{1 + Re_T/R_k} \tag{8}$$

$$C_\mu = \frac{9}{100}\frac{5/18 + (Re_T/R_\beta)^4}{1 + (Re_T/R_\beta)^4} \tag{9}$$

where $Re_T=K_g/(\omega\nu_g)$. The constants we use are $\beta=3/40$, $\sigma_K=\sigma_\omega=2$, $\alpha_0^*=\beta/3$, $\alpha_0=1/10$, $R_\beta=8$, $R_K=6$ and $R_\omega=27/10$.

ω is decomposed according to

$$\omega = \tilde{\omega} + \omega_w \tag{10}$$

where $\omega_w = 6\nu_g/(\beta y^4)$ and y is the distance to the wall. The rapid variation in the near-wall region is captured by ω_w, whereas the former part is the dominating term far from the boundary [11].

The mean turbulent particle kinetic energy and the fluctuating gas-particle velocity correlation are modelled as

$$\overline{u'_{pi}u'_{pi}} = \overline{u'_{pi}u'_{gi}} = \frac{2K_g}{1 + \frac{\tau_p}{T_L}} \tag{11}$$

where $T_L = (C_\mu\omega)^{-1}$. This closure relation is also used by [12, 13, 14].

In the near wall region, where the particle concentration can be high in dilute gas-particle flows, the viscosity due to particle-particle collisions can be important as shown by [15, 16] through LES and DNS, respectively. To model the particle-particle collisions we adopt the shear induced particle diffusion model by [17]

$$\nu_p = \frac{1}{4}\Phi_p D_p^2 \frac{dU_p}{dy} \tag{12}$$

where dU_p/dy is the shear in the wall normal direction. The model gives a significant contribution only in the near wall region where the velocity gradient dU_p/dy is large and the particle concentration Φ_p can be high.

Simulations

The described Eulerian-Eulerian model is used to simulate the upward turbulent gas-particle flow in a vertical channel. Where channel flow is the flow between two infinite flat plates, so there is only variation in the wall normal direction. The channel half-width δ=0.05 m, ρ_g = 1.3 kg/m^3, ρ_p = 910 kg/m^3 and D_p is varied from 20 to 120 μm. The Reynolds number, $Re=U_{gc}\delta/\nu_g$,= 18500 in all simulations. Here U_{gc} is the centreline velocity of the gas-phase. The velocity components of the gas-phase have a no-slip condition at the wall. The streamwise particle-velocity has a free-slip condition at the wall $dU_p/dx=0$. In the normal direction the particle velocity is zero implying that the net flux of particles at the wall is zero [6]. The pressure and particle volume fraction have Neumann conditions at the wall. We assume that the flow is fully developed in the streamwise direction. Therefore, cyclic boundary conditions are imposed. The model is implemented into a finite element code [18] with grid refinement close to the wall. There are at least 10 grid points in the region below $y^+ = 1$ in order to resolve the steep particle concentration gradients near the wall. Here $y^+=u_\tau y/\nu_g$ where $u_\tau=(\tau_w/\rho_g)^{1/2}$ is the friction velocity and τ_w is the wall shear stress. The simulations are run until a steady state is reached. Simulations are carried out for six particle diameters varying from 20 to 120 μm and four different particle volume fractions.

RESULTS

In figure 1, Φ_p normalised with the initial particle volume fraction, $\Phi_{0,}$ is shown as a function of the wall distance for six different D_p and two different initial particle volume fractions. The particles accumulate in the near-wall region as shown by the large values of Φ_p/Φ_0. This accumulation is due to the turbophoretic effect, which is modelled by the gradient of the mean kinetic energy, i.e. the third term on the R.H.S. in equation (3) [19]. The magnitude of Φ_p/Φ_0 decreases quite substantially with increasing Φ_0, which is explained by an increasing attenuation of K_g for increasing Φ_0, se figure 4.

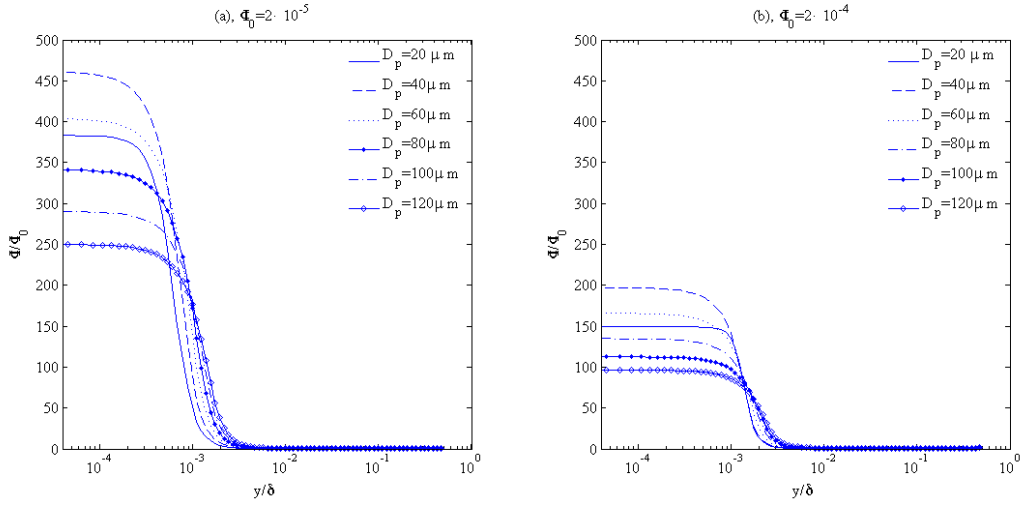

Figure 1. Mean particle volume fraction normalised with the initial particle volume fraction for six different particle diameters and two different particle volume fractions $\Phi_0=2\cdot10^{-5}$ (a) and $\Phi_0=2\cdot10^{-4}$ (b). Note the logarithmic scale in the wall normal direction.

The maximum values of Φ_p/Φ_0 as a function of D_p for four different Φ_0 are shown in figure 2a. The maximum values of Φ_p/Φ_0 occur at the wall due to the turbophoretic effect shown in figure 1. It increases quite substantially for decreasing Φ_0, although K_g changes quite moderately between

$\Phi_0 = 2 \cdot 10^{-5}$ and $1 \cdot 10^{-4}$, see figure 4. The accumulation of particles near the wall due to the turbophoretic effect is strongest for D_p=40 μm, for this particular parameter range, whereafter it decreases. This phenomenon is related to the particle response time. For increasing Reynolds numbers the strongest effect of the turbophoresis will occur for larger D_p.

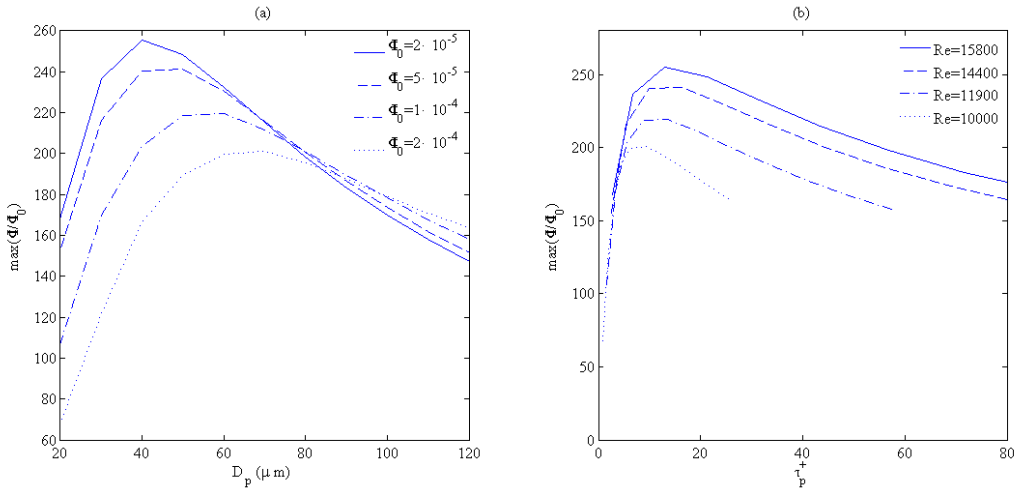

Figure 2. The maximum value of the mean particle volume fraction normalised with initial particle volume fraction as a function of D_p for four different Φ_0 (a) and as a function of τ_p^+ for four different Reynolds numbers with $\Phi_0 = 1 \cdot 10^{-4}$ (b).

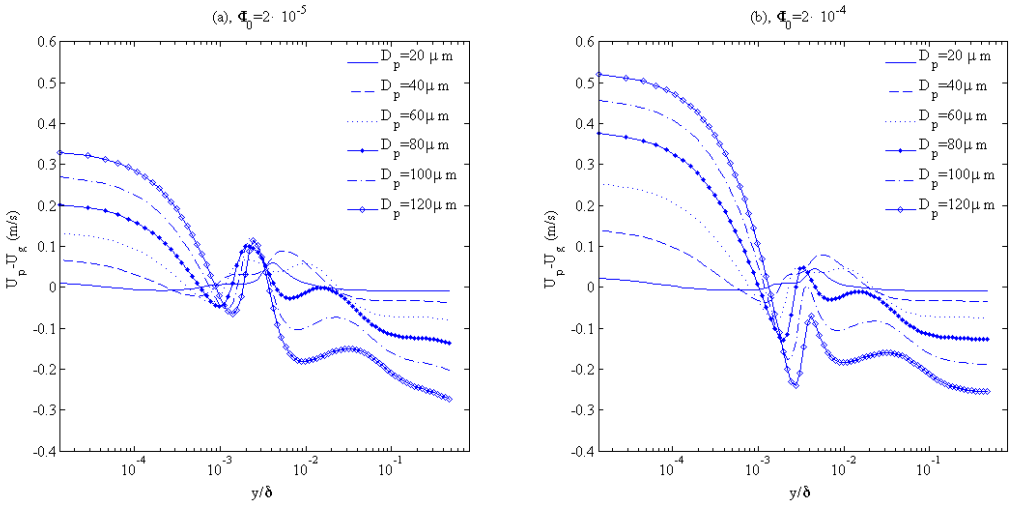

Figure 3. Mean slip velocity between particle- and gas-phase for six different particle diameters and two different particle volume fractions $\Phi_0 = 2 \cdot 10^{-5}$ (a) and $\Phi_0 = 2 \cdot 10^{-4}$ (b). Note the logarithmic scale in wall normal direction.

In figure 2b the maximum value of Φ_p/Φ_0 is shown as a function of τ_p^+ for four different Reynolds numbers, where $\tau_p^+ = \tau_p u_\tau^2/\nu$. Φ_p/Φ_0 reaches a maximum for τ_p^+ around 13 for all Reynolds numbers except for Re=10 000 where the maximum occurs at $\tau_p^+ = 9$. The turbophoretic effect is significant for particles that respond to turbulence but do not perfectly follow the turbulent flow field. This implies

that the turbophoretic effect is weak for particles with large or small τ_p^+, i.e. large or small D_p, because large particles are not affected by the turbulence while very small ones follow the turbulence perfectly.

Figure 3 shows the slip velocity between the particle- and the gas-phase for the same cases as in figure 1. In the core of the channel the particles lag the flow due to gravity. However, in the near-wall region the particles lead the flow due to the inertia the particles gained in the core of the channel [20]. The maximum slip velocity is at the wall since the particles have a free-slip condition at the wall. The slip velocity at the wall increases slightly with increasing particle volume fraction. The magnitude of the slip velocity increases for increasing D_p as shown by figure 3. In figure 4a the mean kinetic energy of the gas phase is shown for D_p=100 μm for four different Φ_0 and for one simulation without particles. Increasing the mass loading leads to a stronger damping of the gas-phase turbulence as shown by the figure. The same behaviour is seen for all D_p between 20 and 120 μm. In figure 4b the mean kinetic energy is shown for $\Phi_0=2\cdot10^{-4}$ for four different D_p. It is seen that K_g decreases with increasing Φ_0. The peak of the turbulence kinetic energy close to the wall is most strongly damped by particles with Dp=20μm. Particles with D_p=120μm have the least effect on K_g. However, at D_p=60μm the maximum value of K_g decreases more than at D_p=40μm. On the other hand, in the centre of the channel particles with D_p=120μm has the largest decrease on K_g and particles with D_p=40μm have the least effect on K_g. The magnitude of the decrease is smaller in figure 4b compared to figure 4a because mass loading is constant in figure 4b. Results with a different diameter have thus a different feedback effect on the gas-phase turbulence even though the mass loading is the same.

Changing the particle diameter D_p gives rise to three different physical mechanisms that counteract each other. A smaller D_p for constant mass loading leads to a larger surface area that increases the friction between the phases. On the other hand, smaller particles have a smaller slip velocity as shown by figure 3, leading to decreased drag. These two effects have opposing effects on the magnitude of the drag term (last term in equation (2)) and the interaction between the gas-phase turbulence and the particle-phase (last term in equation (4)). These terms also depend on Φ_p, which changes with D_p as shown by figure 2a. Therefore the relation between the damping of the gas-phase turbulence and the particle diameter is complex.

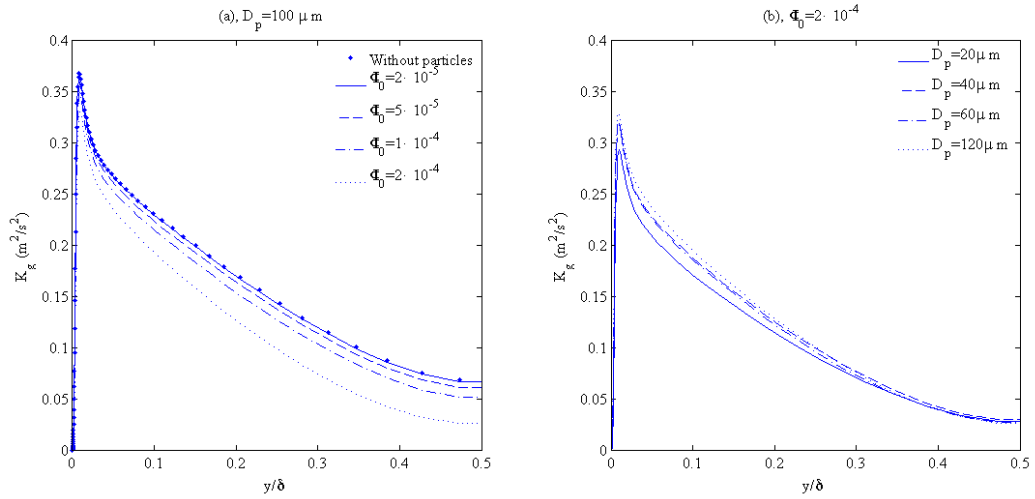

Figure 4. Mean turbulent kinetic energy of the gas-phase. For four different initial particle volume fractions with D_p=100μm (a) and for four different D_p with $\Phi_0=2\cdot10^{-4}$ (b).

The particle velocity in the wall normal direction is shown in figure 5 for the same cases as in figure 4a. We see that the particles move towards the wall in the near wall region whereas in the core of the channel the particles move towards the centreline. The change in sign of the wall normal particle velocity appears where K_g has its peak-value, which clearly shows that the drift of particles in the wall-normal direction is strongly influenced by the gradient in the mean turbulent kinetic energy [19].

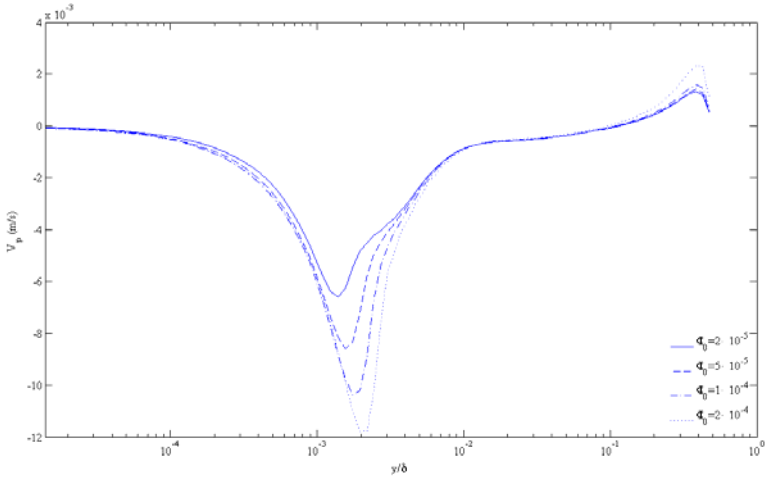

Figure 5. Mean particle velocity in the wall normal direction for four different initial particle volume fractions. Note the logarithmic scale in wall normal direction.

CONCLUSIONS

Upward particle laden turbulent channel flow was studied using an Eulerian-Eulerian two-phase flow model which takes into account the feedback of the particle-phase on the gas-phase. A low Reynolds number K-ω model was used to describe the gas-phase turbulence. Simulations for different particle diameters and particle volume fractions were carried out at constant Reynolds number.

The turbophoresis effect was found to decrease for increasing particle volume fraction. It has a maximum effect for particles with τ_p^+=13. Increasing the particle diameter was found to increase the slip velocity, which increases the drag between the phases. However, increasing the particle diameter decreases the friction between the phases, which decreases the drag. Therefore, the relation between particle diameter and the drag between the phases and the gas-phase turbulence intensity is quite complex.

In this study the centreline velocity of the gas-phase is kept constant between the different cases by changing the pressure gradient. However, when the pressure gradient is kept constant the mean flow will be strongly affected and decreases for decreasing D_p, see [7].

NUMERICAL SIMULATION OF TURBULENT FLOW WITHIN A PRECESSING JET NOZZLE

J. W. Zhou*, L. P. Geng, R. Tao
Dept. of Thermal Engineering, China Jiliang University, Hangzhou 310018, China

ABSTRACT. Numerical simulation of unsteady turbulent flow within a precessing jet nozzle is carried out in this paper. The nozzle model comprises of an axisymmetric inlet tube and a large cylindrical chamber. The flow features of a self-excited precessing jet are numerically studied using the large eddy simulation (LES) approach. The simulations show that the precession in axisymmetric sudden expansions develops naturally when the nozzle configuration is within suitable geometric ratios. The bulk axial velocity of the precessing jet is decreased significantly because of the entrainment of ambient air. The swirling flow, the wall attachment effect and the reverse flow region within the nozzle are also found in the numerical flow field and these results accord well with the previous analysis. The simulated oscillating frequency spectrum is also in general agreement with the experimental data.

Keywords: *precessing jet, flow field, large eddy simulation, power spectral analysis*

INTRODUCTION

The precessing jet has found lots of applications in many engineering aspects, such as burners and spray dryers. The precession phenomenon was initially observed in swirling flows. However, the imparted swirl has proved not to be a prerequisite for the generation of a precessing flow instability. Nathan et al. [1] discovered the self-excited precession of an initially axisymmetric jet generated by a fluidic precessing jet nozzle, which has proved beneficial in combustion applications [2]. The precessing jet nozzle in its simplest form is a sudden expansion cylindrical chamber from a small axisymmetric inlet [3, 4]. After entering the chamber via the inlet, the jet expands through entrainment of chamber fluid and reattaches asymmetrically to the chamber wall (see Figure 1). That is the so-called wall attachment effect of fluid (also called Coanda effect). The asymmetric entrainment also feeds back to reinforce an azimuthal pressure difference which causes the reattachment point of the primary jet to move azimuthally around the inner surface of the chamber. This rotating pressure field within the chamber causes the reattaching flow to precess around the inside wall of the chamber and this also produces a precessing exit flow. Simultaneously, external fluid is drawn into the chamber to replenish what is entrained by the primary jet. Thus, the flow emerging from the exit plane is highly three-dimensional and unsteady, with both the exit angle and precession frequency exhibiting considerable cycle-to-cycle fluctuations.

It is important to note that to produce the jet precession the nozzle configuration must be conditioned with the inlet expansion ratio, chamber length-to-diameter ratio and some other parameters [1, 3, 4]. Nathan et al. [1] discovered that, two flow modes, i.e., an instantaneously

highly asymmetric "precessing jet" (PJ) and a quasi-symmetric "axial jet" (AJ), existed simultaneously within the nozzle chamber. The temporal probability (proportion of time) of the PJ mode depends on the nozzle geometry and Reynolds number.

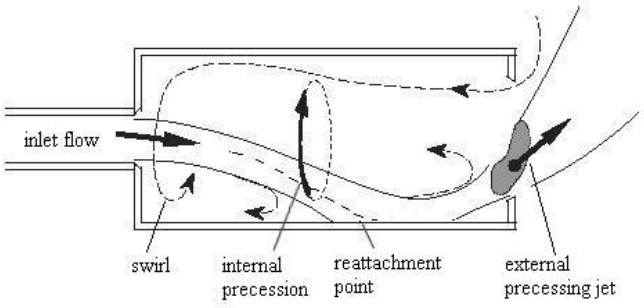

Figure 1. A simplified representation of the flow in a precessing jet nozzle [3, 4]

The configuration of the nozzle usually should be within specific geometric ratios, usually D/d=3.5~6 and L/D=2~3.5 to enable the jet precession although expansion ratio as small as 1.94 or as large as 10 has also been reported [5, 6]. The precessing flow within the nozzle chamber is complex and very sensitive to the geometry. Any alteration to the chamber configuration is expected to cause a significant change to the flow behaviour such as the precession frequency.

Much research has been invested to study the precession behaviour of this naturally oscillating jet flow so far [3, 4]. The particle image velocimetry (PIV) and laser-Doppler anemometry (LDA) techniques are also used to experimentally measure the velocity in the near external field of the precessing jet nozzle [7]. Due to the complexity of the phenomenon, the precessing instability is very difficult to study and the fundamental understanding has thus far remained rather incomplete. There have been relatively few simulation studies of this type of instability [8, 9]. Computational fluid Dynamics (CFD) can be used to provide a better understanding of the complex fluid physics and to provide predictive models for engineering analysis. On the other hand, it is also not easy to get the global information of flow field inside the precessing jet nozzle with experimental approach. Thus, this paper is concerned with the numerical simulation of unsteady turbulent flows behind sudden expansions without inlet swirl. A commercial CFD package, Fluent, is used to simulate the three dimensional, time-dependent flow within precessing jet nozzle in order to explore the phenomena better.

NUMERICAL APPROACH

Mathematical equations

Turbulent flows are extremely complex and time-dependent. Most fluid flows can be described by the full Navier-Stokes equations, which comprise equations for conservation of mass and momentum and, in a non-isothermal flow, energy. Many numerical methods have been developed to simulate the turbulent flow. Among the various methods, the Direct Numerical Simulation (DNS) is only used for low Reynolds numbers in simple geometries and a Reynolds averaging (time-averaging) method (RANS) is usually used to solve for the mean quantities rather than for all details of the turbulence[10,11]. However, swirling or precessing flows are difficult to model with Reynolds-averaged methods due to the effects of mean flow streamline curvature [12]. The Large Eddy Simulation (LES) approach, in which only the small-scale turbulent fluctuations are modelled

and the larger-scale fluctuations are computed directly, is a promising approach for simulation of complex, high Reynolds number turbulent flows. It is especially suitable to the analysis of the precessing flow in abruptly changed geometry channel. Thus LES is used to solve the problems in our study.

There are two key characteristics, i.e., the filter function and the subgrid scale stress (SGS) model, in LES approach. In Fluent, some common filters such as the Fourier cut-off filter, the box filter and the Gaussian filter, are provided and a finite volume method is applied to solve the differential equations. Applying the filtering operation, the governing equations (i.e., the equation of mass conservation and equation of the momentum conservation) are obtained

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho \bar{u}_i) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho \bar{u}_i) + \frac{\partial}{\partial x_j}(\rho \bar{u}_i \bar{u}_j) = \frac{\partial}{\partial x_j}(\mu \frac{\partial \bar{u}_i}{\partial x_j}) - \frac{\partial \bar{p}}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} \tag{2}$$

where an overline - denotes filtering variables at a computational cell; i (= 1, 2, 3) indicates the spatial dimension; p is pressure; ρ and μ are the fluid density and viscosity, respectively; u is the resolved velocity field; τ_{ij} is the subgrid scale stress defined by

$$\tau_{ij} = \rho \overline{u_i u_j} - \rho \bar{u}_i \bar{u}_j \tag{3}$$

The subgrid scale stresses resulting from the filtering operation are unknown and require modeling. The majority of the SGS models in use today are eddy viscosity models. The most basic of SGS models is proposed by Smagorinsky and further developed by Smagorinsky and Lilly. Most of the other SGS models are the Smagorinsky type variations. In our study the standard Smagorinsky–Lilly SGS model is applied to simulate the complex fluid flows.

Physical model

The geometry in simulation is shown in Figure 2. The ratio of the larger diameter D to the inlet tube diameter d is defined as the expansion ratio E. The inlet tube diameter d is chosen as 3.5mm. The simulation region has been taken as $l=5d$ and the length of the large chamber $L=2\sim4D$. The x-axis of the Cartesian coordinates is on the axis of the pipes and the origin point is defined as the orifice entrance. U_i and U_0 denote the axial bulk velocities for the inlet and outlet.

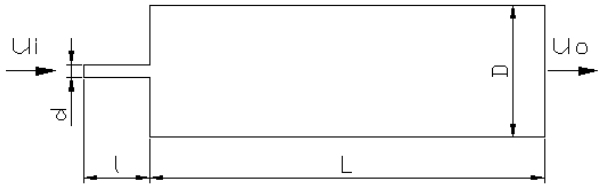

Figure 2. A schematic diagram of the physical model

Drawing and gridding the physical model is the first basic step in a CFD simulation. Fluent offers another software package, GAMBIT, to accomplish the model drawing and meshing. A fully three-dimensional non-structured grid has been used in simulation. The total number of element nodes is approximately between 144000 and 487000 depending on the geometric parameters in the physical model.

Boundary conditions and numerical considerations

Another basic step involved in a CFD simulation is to apply boundary conditions and to solve the problem. For the inlet flow, the velocity is assumed to be parallel to the inlet tube axis without any cross-stream components, with the volumetric flow rate being specified, i.e.,

$$U_{in} = \frac{4Q_{in}}{\pi d^2},\ V_{in} = 0,\ W_{in} = 0 \qquad (4)$$

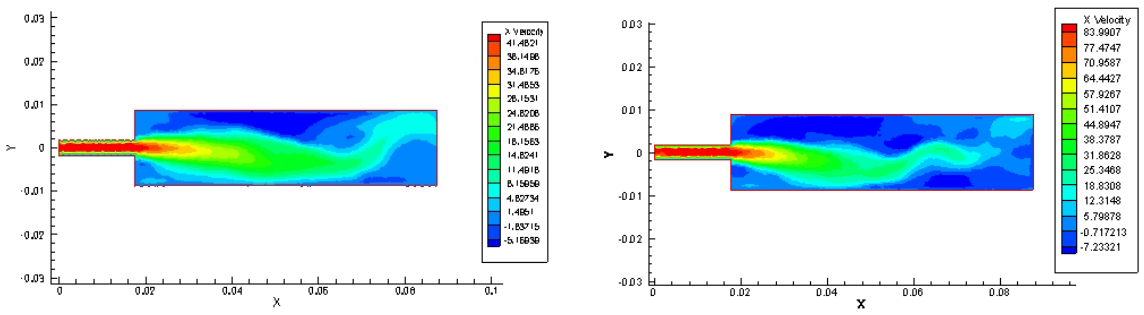
U, V and *W* denote the averaged velocity components. Q_{in} is the volumetric flow rate and *d* is the inlet diameter.

Neumann boundary conditions are imposed for the outlet, which mean that the velocity components and turbulence quantities are assumed to be fully developed and have a zero normal gradient for the outflow. The relative pressure is set to zero at the outlet. No-slip boundary conditions are applied at the solid walls. A universal log-law wall function is applied for all walls.

A finite volume formulation is used to discretize the Navier-Stokes equations. The PISO algorithm is used for pressure correction. In this algorithm, a second pressure correction equation is solved in order to improve the solution of momentum equations while maintaining continuity and thus reducing the number of global iterations for convergence. Air, assumed to be incompressible and Newtonian gas, is chosen as the working fluid. The physical properties of air are assumed to be constant. The grid and time step independence tests are performed on the above 3-D physical model before the numerical experiments.

RESULTS AND DISCUSSIONS

Although the instantaneous flow field changes with time, the fundamental features remain the same. Many numerical experiments are carried out for various expansion ratios *E*, chamber length *L* and *Re* number in this study. Figure 3 presents the instantaneous axial velocity contour in a plane across the centreline of precessing jet nozzle for the case of *E=5*, *L=4D* at $Re=1\times10^4$ and $Re=2\times10^4$, respectively. From the simulation results, the naturally oscillating phenomena of this turbulent flow are easy to be identified. Because of the instabilities of the flow, the fluid emanating from the inlet tube separates at the expansion, departs from the central axis and moves toward the wall of large cylindrical chamber. It reattaches asymmetrically to the wall and then bends inward toward the other side of the wall. A reverse flow region exits in the flow field and a rapid decay of the bulk axial velocity, due to the strong mixing with ambient air, is found from the simulated results.



(a) $Re=1\times10^4$ (b) $Re=2\times10^4$

Figure 3. Instantaneous velocity contour maps in PJN (*E=5*, *L=4D*)

Figure 4 shows the instantaneous velocity vectors in a cross-sectional plane just behind the expansion surface (0.2D downstream from the sudden expansion). A non-uniform tangential flow in the circumferential direction is formed although the magnitude of tangential velocity is much smaller than the axial velocity. A significant mixing between the upstream and downstream flows, as well as tangential mixing, is expected inside the precessing jet nozzle.

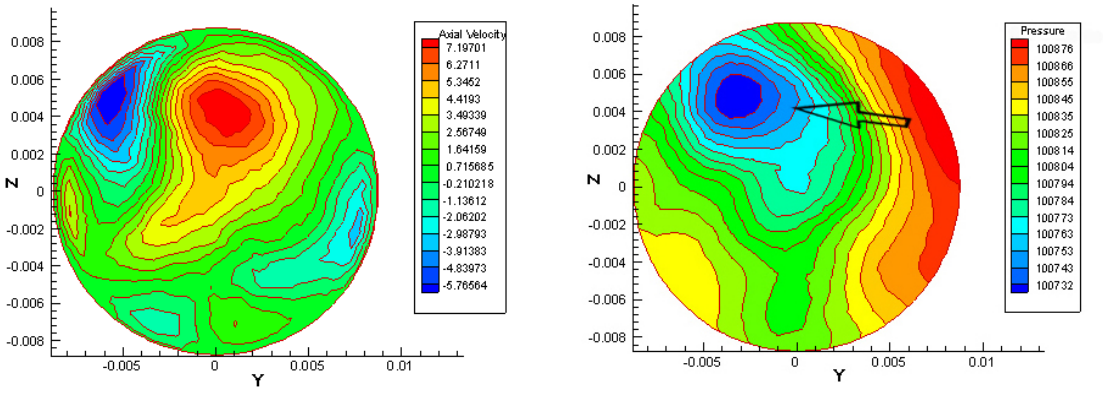
Figure 4. Instantaneous velocity vectors in a plane 0.2D downstream from the expansion ($E=5$, $L=4D$, $Re=2\times10^4$)



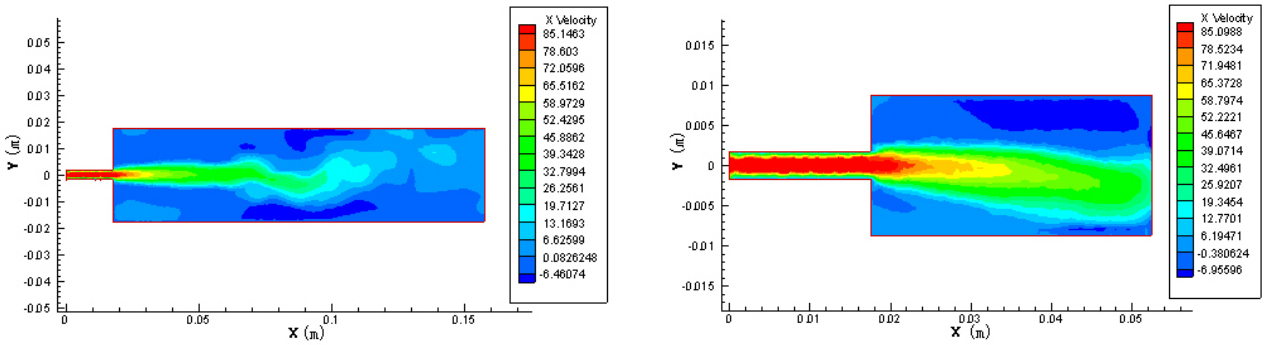
(a) axial velocity (b) pressure

Figure 5. Contour maps in a plane 3.4D downstream from the expansion ($E=5$, $L=4D$, $Re=2\times10^4$)

Figure 5 shows the instantaneous velocity and pressure contour maps in a cross-sectional plane 3.4D downstream from the expansion (i.e., close to the exit of the nozzle). At this moment, the position of the jet and the reverse flow are quite clear in axial velocity contour map (Figure 5(a)). It can be seen, from the corresponding pressure contour map (Figure 5(b)), that the higher pressure occurs on the wall near the jet reattaches and the low-pressure zone locates between the jet and the reverse flow core. A pressure gradient is created across the primary jet (as the arrow shown in Figure 5(b)) and this gradient may drive the jet to move towards the other side of the wall at an oblique angle.

Figure 6 shows two examples of the instantaneous velocity contour maps for different nozzle geometric parameters at $Re=2\times10^4$. Although the flowfield looks not so perfect, the inherent instability or the wall attachment effect of the fluid can be easily found. It demonstrates that the jet

precession within a nozzle depends mainly on the geometric configuration (i.e., ratio of *D/d* and *L/D*) as well as the Reynolds number.



(a) E=10, L=4D (b) E=5, L=2D

Figure 6. Velocity contour maps for different nozzles (Re=2×10^4).

The self-oscillating features of a flow can be characterized by the precession frequency. Some variables, e.g., the velocity and pressure, at a specific location can be monitored during the process of the transient calculation and the resulting time series can be used to the analysis of power spectral density (PSD). The PSD curve obtained from the simulated velocity is compared with the actual experimental PSD result obtained from the same spot hot-wire measurement data. The experimental data was previously obtained from a precessing nozzle with similar geometry and configuration parameters [6]. The results are typically shown in Figure 7(a) and 7(b), respectively. Results show in general agreement between the simulations and the experiments in the sense of the quasi-periodically oscillating features.

CONCLUSIONS

In this study, the LES turbulence model is used to simulate the complicated turbulent flows within a precessing jet nozzle. The simulations demonstrate that the asymmetry and subsequent oscillations are inherent phenomena within an expansion flow. Strong self-sustained precession can be induced and a reverse flow region can be generated within a precessing jet nozzle. A pressure gradient across the jet in both radial and tangential directions may be the driving force for the precessing motions. The precession phenomena significantly depend on the configuration

parameters of the nozzle and the Reynolds number. The simulated features of self-excited precessing jets are generally consistent with the previous investigations and analysis.

ABSTRACT. The present paper describes comprehensive experimental and numerical investigations of evolution of disturbances generated in the hypersonic viscous shock layer on a flat plate by external acoustic waves and by perturbations introduced into the shock layer from the surface of model. All experiments are performed in the hypersonic nitrogen wind tunnel T-327A based at the Khristianovich Institute of Theoretical and Applied Mechanics with a free-stream Mach number $M_\infty = 21$ and Reynolds number $Re_L = 1.44 \times 10^5$. Direct numerical simulations of propagation of disturbances are performed by solving Navier-Stokes equations with the use of high-order shock-capturing schemes. The results obtained show that periodic blowing and suction of the gas near the leading edge can be used for active control of the transition to turbulence in a hypersonic shock layer through suppressing, by means of destructive interference, the development of instability arising under the action of acoustic perturbations of the free stream. Based on this scheme, wind tunnel experiments on controlling the intensity of density fluctuations in a hypersonic shock layer on a flat plate at a zero angle of attack are performed.

INTRODUCTION

When a flying vehicle moves with a high velocity in the upper atmospheric layers, the regime of a viscous shock layer persists even at a large distance from the leading edges. The viscous shock layer consists of a thick boundary layer and a thin zone of inviscid flow behind the bow shock wave. Disturbances formed in the shock layer are entrained in the downstream direction and affect the evolution of fluctuations and the laminar-turbulent transition in the hypersonic boundary layer on a flying vehicle as a whole.

Understanding the mechanisms of receptivity and instability of the viscous shock layer is a necessary condition for the development of effective methods for controlling the laminar-turbulent transition on flying vehicles in a hypersonic flow.

This problem has not been adequately addressed yet. The previous results of experimental [1-3] and theoretical [4-5] research and control methods developed refer to the boundary-layer flow and cannot be directly transposed to a hypersonic shock layer. The flow in a hypersonic shock layer has some specific features: the influence of a closely located shock wave on the evolution of disturbances, significant nonparallelism of the flow, and a high degree of rarefaction.

The present paper describes the results of a comprehensive numerical and experimental study of a hypersonic viscous shock layer on a flat plate at a zero angle of attack. Based on the data obtained, numerical and experimental modeling of controlling the intensity of fluctuations in the shock layer on a plate model was performed.

EXPERIMENTAL EQUIPMENT AND DIAGNOSTIC METHODS

The experiments were performed in the hypersonic nitrogen wind tunnel T-327A based at the Khristianovich Institute of Theoretical and Applied Mechanics (Siberian Branch, Russian Academy of Sciences). A flat plate model 240 mm long with a sharp leading edge 100 mm wide was inserted into a hypersonic flow with a Mach number $M_\infty = 21$, unit Reynolds number $Re_{1\infty} = 6\cdot10^5$ m^{-1}, and stagnation temperature $T_0 = 1200$ K; the temperature factor of the surface was $T_w/T_0 = 0.26$. The distributions of mean density and the characteristics of density fluctuations were measured by the method of electron-beam fluorescence of nitrogen [6].

The external acoustic disturbances excited in the experiments were slow acoustic waves generated by the turbulent boundary layer formed on the nozzle walls [7]. Internal perturbations localized near the leading edge were generated by an obliquely cut cylindrical aerodynamic whistle located under the plate [8].

NUMERICAL STATEMENT OF THE PROBLEM

With allowance for the moderate magnitude of local Reynolds numbers typical of the viscous shock layer, the most adequate approach to the problem of numerical simulation seems to be the direct numerical simulation (DNS) of disturbances on the basis of solving the full unsteady Navier-Stokes equations. Two-dimensional Navier-Stokes equations were written in the form of conservation laws:

$$\frac{\partial Q}{\partial t}+\frac{\partial F}{\partial x}+\frac{\partial G}{\partial y}=\frac{M_\infty}{\mathrm{Re}_L}\left(\frac{\partial F^v}{\partial x}+\frac{\partial G^v}{\partial y}\right) \tag{1}$$

Here t is the time, x and y are the coordinates along and across the plate, Q is the vector of conservative variables, F, G are the vectors of inviscid fluxes, and F^v, G^v are the vectors of viscous fluxes:

$$Q=\begin{pmatrix}\rho\\ \rho u\\ \rho v\\ e\end{pmatrix},\qquad F=\begin{pmatrix}\rho u\\ \rho u^2+p\\ \rho uv\\ (e+p)u\end{pmatrix},\qquad G=\begin{pmatrix}\rho v\\ \rho uv\\ \rho v^2+p\\ (e+p)v\end{pmatrix},$$

$$F^v=\begin{pmatrix}0\\ \tau_{xx}\\ \tau_{xy}\\ u\tau_{xx}+v\tau_{xy}+\kappa\dfrac{\partial T}{\partial x}\end{pmatrix},\qquad G^v=\begin{pmatrix}0\\ \tau_{xy}\\ \tau_{yy}\\ u\tau_{xy}+v\tau_{yy}+\kappa\dfrac{\partial T}{\partial y}\end{pmatrix}, \tag{2}$$

$$\tau_{xx}=\mu\left(\frac{4}{3}\frac{\partial u}{\partial x}-\frac{2}{3}\frac{\partial v}{\partial y}\right),\quad \tau_{xy}=\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right),\quad \tau_{yy}=\mu\left(\frac{4}{3}\frac{\partial v}{\partial y}-\frac{2}{3}\frac{\partial u}{\partial x}\right).$$

The system is closed by the equation of state of a perfect gas

$$p=\rho T/\gamma\,. \tag{3}$$

In Eqs. (1)-(3), u, v are the x and y components of the velocity vector, p is the pressure, ρ is the density, T is the temperature, $e=p/(\gamma-1)+\rho(u^2+v^2)/2$ is the total energy per unit volume, γ is the ratio of specific heats, μ is the dynamic coefficient of viscosity, and $\kappa=\dfrac{\mu}{(\gamma-1)\mathrm{Pr}}$ is the coefficient of thermal conductivity. The viscosity was calculated with the Sutherland formula $\mu=T^{1.5}\dfrac{1+T_S/T_\infty^*}{T+T_S/T_\infty^*}$, where T_∞^* is the free-stream temperature and T_S is the Sutherland constant

equal to 106.67 K for nitrogen. The Reynolds number Re_L was based on the free-stream parameters and the plate length L^*, and the Prandtl number was Pr= 0.72. Hereinafter, the asterisk indicates dimensional quantities. In writing Eqs. (2), (3) in dimensionless form, the density, temperature, and viscosity were normalized to their free-stream values; the other scaling quantities were the velocity of sound c_∞ for velocity, $\rho_\infty c_\infty^2$ for pressure, and the plate length L for geometric sizes.

Two-dimensional Navier-Stokes equations are solved by high-order shock-capturing schemes. Details of the numerical method can be found in [7,9].

The computational domain was a rectangle with some part of the lower side coinciding with the plate surface. The left (inflow) boundary was located at a distance of a few computational cells upstream from the leading edge of the plate. The height of the computational domain was chosen under the condition that the bow shock wave emanating from the leading edge did not interact with the upper boundary. The right (outflow) boundary was separated from the trailing edge of the plate by some distance so that the flow in the exit section was completely supersonic.

The steady basic flow was first calculated with a uniform hypersonic flow being imposed on the left and upper boundaries. The solution on the right boundary was extrapolated from inside the computational domain. The boundary conditions on the plate took into account the velocity slip and the temperature jump. The results of modeling a steady flow demonstrated good agreement with the values of the Mach number and mean density measured in the shock layer [7].

Then the problem of interaction of a viscous shock layer with external acoustic disturbances propagating in the streamwise direction was solved. The variables on the left boundary were set as a superposition of the steady main flow and a planar monochromatic acoustic wave:

$$\begin{pmatrix} u' \\ v' \\ p' \\ \rho' \end{pmatrix} = A \begin{pmatrix} \pm\cos\theta \\ \mp\sin\theta \\ 1 \\ 1 \end{pmatrix} \exp\left[i\left(k_x x + k_y y - \omega t\right)\right].$$

Here u', v', p', ρ' are the fluctuations of the longitudinal and transverse velocity, pressure, and density, respectively, θ is the angle of propagation of the external acoustic wave, A is the disturbance amplitude, t is the time, $k_x = k\cos\theta, \quad k_y = -k\sin\theta$ are the components of the wave vector related to the frequency $\omega = 2\pi f L / c_\infty$ by the dispersion expression $k = \dfrac{\omega}{\left(M_\infty \cos\theta \pm 1\right)}$. In the above-given relations, the upper (lower) index corresponds to the fast (slow) acoustic wave. In dimensionless relations, the density and temperature disturbances are normalized to their free-stream values, the velocity perturbations are normalized to the velocity of sound in the free stream c_∞, and the pressure disturbances are normalized to $\rho_\infty c_\infty^2$.

In the experiment, artificial disturbances in the form of periodic injection and suction were locally introduced from the leading edge of the plate. In the numerical solution of the problem, they were modeled by imposing the following boundary condition for the transverse flow rate at a certain part of the surface near the leading edge of the plate:

$$\rho v'\big|_{y=0} / \rho_\infty c_\infty = A \sin\left(\pi \frac{x - x_1}{x_2 - x_1}\right) \sin \pi f t$$

Here v' are the velocity fluctuations in the direction normal to the plate surface, ρ is the local density, A is the amplitude, and x_1 and x_2 are the boundaries of the region where the controlled disturbances were introduced.

After introduction of disturbances, the Navier-Stokes equations were integrated until the unsteady solution reached a steady periodic regime. The uniform grid used contained $N_x = 1050$ cells in the streamwise direction and $N_y = 240$ cells in the transverse direction. Up to 20 processors of the Siberian Supercomputer Center were used in the computations.

The simulations of density fluctuations turned out to be in good agreement with the measurements of characteristics of density fluctuations in the shock layer [7,9] and with the computations by the locally parallel linear stability theory with allowance for the influence of the shock wave [10] for the wall temperature of the model T_w = 300 K.

RESULTS

In a hypersonic shock layer under the action of external acoustic waves of slow and fast modes, the main wave processes occur on the shock wave and on the upper boundary of the hypersonic

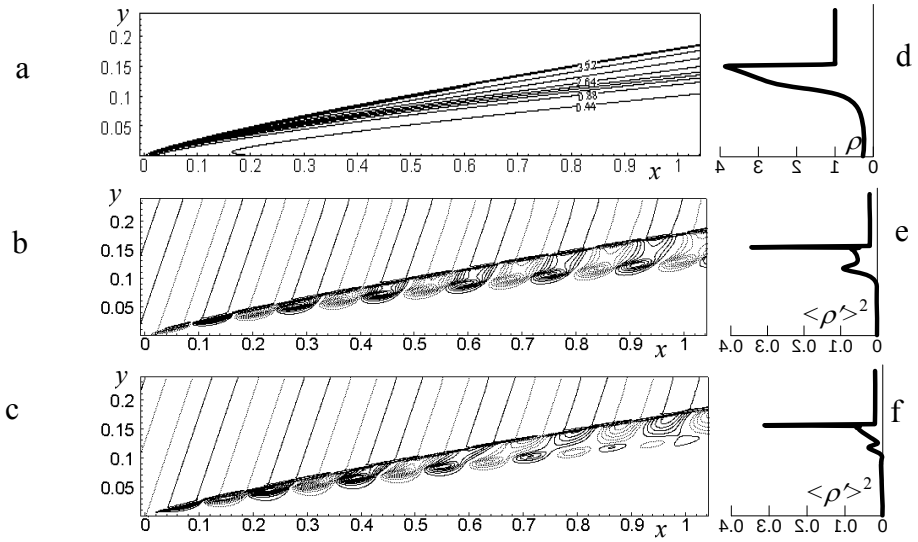

Figure 1. Field of mean density contours (a) M_∞ = 21, $Re_L = 1.44 \cdot 10^5$, field of instantaneous density fluctuations (b,c), and distributions of the root-mean-square fluctuations in the cross section x=0.8 (d,e,f): b,e – disturbances induced by a slow acoustic wave with θ = 20°, A = 0.028, and f=38.4 kHz; c,f – disturbances induced by a fast acoustic wave with θ = 20°, A = 0.028, and f=38.4 kHz.

boundary layer (BL) with vortex disturbances dominating [6,7,]. The fluctuating characteristics of the flow in the hypersonic shock layer have a typical form with two maximums; the greater maximum is located on the SW, and the location of the second maximum coincides with the BL edge (Fig. 1). This is clearly seen both in the field of instantaneous contours of density fluctuations (Fig. 1b,c) and in the distributions of the mean-square fluctuations (Fig.1e,f). For angles of propagation of external acoustic waves θ close to zero, vortex disturbances dominate in the spectrum of disturbance modes in the shock layer [7,9], which agrees with the linear theory of interaction of disturbances with the SW [11]. It should be noted that the prevalence of the entropy-vortex mode is not typical of the boundary layer at moderate hypersonic Mach numbers, where the acoustic instability mode is mainly developed [4,12].

The computations showed that the fields of the mean density and density fluctuations generated by a source of the blowing-suction type are similar to the fields of fluctuations under the action of external acoustic disturbances on the shock layer. Figure 2 shows the instantaneous density fluctuations in the shock layer on a flat plate (a), generated by a blowing-suction source at a frequency f = 20 kHz, which were obtained in direct numerical simulations (a) and in experiments (b). It is seen that the field of intense fluctuations occupies the region between the SW and the BL edge, which corresponds to the maximum gradient of the mean density, as in the case of external acoustic perturbations.

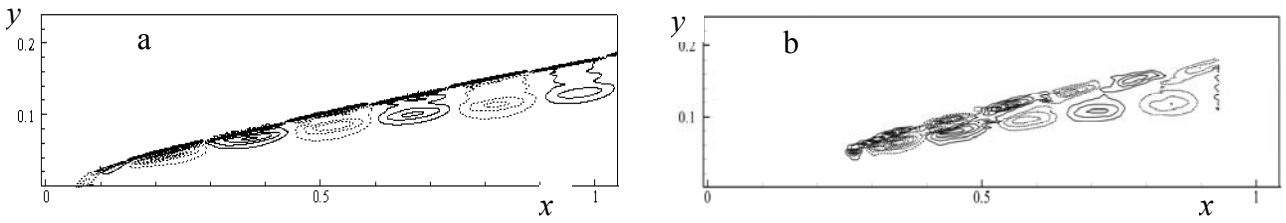

Figure 2. Instantaneous density fluctuations induced by periodic blowing-suction perturbations at a frequency f = 20.5 kHz: a – DNS, A=0.028, b – experiment.

The measurements and the computations of the fields of density fluctuations for disturbances, which are generated by acoustic waves in the external flow, confirmed the similarity of the spatial structure of density fluctuations generated in the shock layer by means of blowing-suction. In particular, there are two maximums of the intensity of density fluctuations; one of the maximums (the greater one) is located on the SW, and the second maximum (the smaller one) is located on the BL edge, and the phases of density fluctuations on the SW and on the BL edge are shifted by 180°. The magnitude of density fluctuations in the shock layer as a function of the amplitude A of the introduced disturbances is considered in the present paper. Such information is important for controlling the intensity of fluctuations in the shock layer by means of injection and suction.

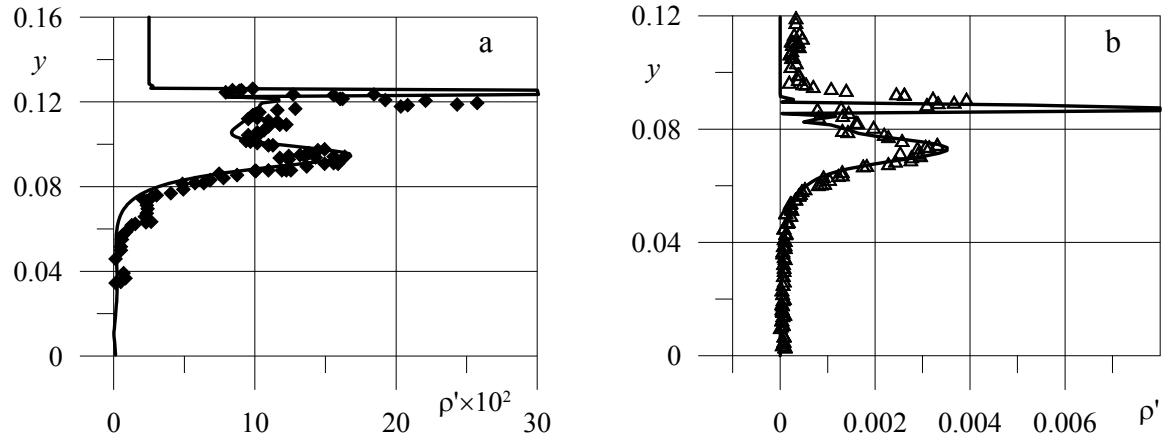

Figure 3. Profiles of density fluctuations across the shock layer for M_∞ = 21 and $Re_L = 1.44 \times 10^5$, which are generated by slow acoustic waves in the external flow ($\theta = 0°$, A = 0.028 and f=38.4 kHz) in the cross section x=0.63 (a) and by a blowing-suction source (f = 20 kHz and A=0.0286) in the cross section x=0.42: the symbols – experimental data; solid curves – computed results.

The computed distributions of density fluctuations across the shock layer are in good agreement with the measured results (Fig.3). A comparison of the data in figure 3b with the distribution of density fluctuations in the shock layer, which are generated by acoustic waves in the external flow (Fig.3a), shows that these profiles also coincide. The position of the maximums of fluctuations correspond to the maximums of the transverse gradient of the mean density, and their intensity corresponds to the magnitude of the local gradient. Thus, the field of density fluctuations is formed by normal-to-the-plate-surface fluctuations of the mean density field in the shock layer, caused by vortices arising behind the SW under the action of external flow perturbations and blowing-suction source.

Thus, the main features of the mechanism of formation of the field of density fluctuations due to shock-layer interaction both with external acoustic perturbations and with blowing-suction perturbations on the plate surface is the emergence and domination of entropy-vortex disturbances inside the shock layer. The spatial structures of disturbances under the action from outside and inside the shock layer are fairly similar. Under these conditions, it is possible to use active methods of disturbance control, which work well in subsonic boundary layers. Oscillations generated by

external perturbations can be suppressed by artificial perturbations introduced, if an appropriate phase and amplitude are chosen for blowing and suction [13].

In the present activities, the possibility of such control was demonstrated numerically and experimentally. Figure 4a shows the calculated field of instantaneous density fluctuations in the shock layer on a flat plate under the action of slow-mode acoustic waves propagating at a zero angle to the external flow centerline. Hereinafter, for the sake of illustration, the field of isolines is supplemented by the root-mean-square (averaged over the period) dependence of density fluctuations on the transverse coordinate y in the cross section x=0.8 (Fig.4e,f,g,h). Figure 4b shows the field of instantaneous density fluctuations in the shock layer on a flat plate, which were generated by blowing-suction of the gas. Qualitative similarity of the fields of fluctuations and quantitative coincidence of the amplitude of density fluctuations on the BL edge are observed. Fig. 4c shows the field of instantaneous density fluctuations in the shock layer on a flat plate under a joint action of external and internal sources of perturbations, when these sources operate exactly in the opposite phases. It is well seen that the density fluctuations on the BL edge decrease substantially, though the oscillations of the shock wave proper remain almost unchanged. For the sake of illustration, Fig.4d shows the field of instantaneous density fluctuations in the case of in-phase operation of the sources of perturbations. As it was expected, the amplitude of fluctuations on the BL edge is doubled.

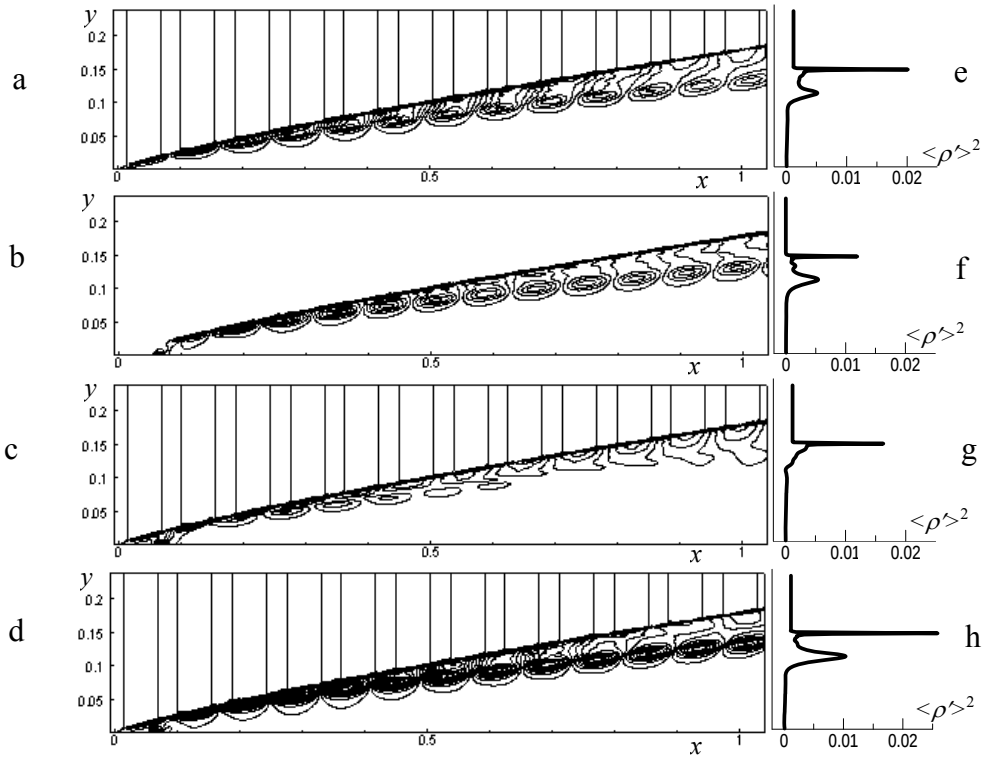

Figure 4. Instantaneous density fluctuations in the shock layer (a,b,c,d) and root-mean-square density fluctuations in the cross section x=0.8 (e,f,g,h) for M_∞ = 21, $Re_L = 1.44 \times 10^5$, $\theta = 0°$, and f=38.4 kHz: a,e) fast acoustic wave A = 0.0017; b,f) blowing-suction of the gas from the plate surface A = 0.0694; c,g) anti-phase action; d,h) in-phase action.

The possibility of controlling the intensity of fluctuations in a hypersonic shock layer on a flat plate was also demonstrated in experiments for fast external acoustic waves. The idea of this experiment is illustrated in Fig.5. Periodic acoustic waves are generated in a hypersonic flow, which interact with the shock layer on the plate and generate fluctuations in the shock layer. The oblique gas-dynamic whistle located under the plate near its tip also excites periodic pressure perturbations in the shock layer. If the frequencies of external flow disturbances and of perturbations excited by the whistle are identical, a certain relation between the phases of these disturbances may lead to

interference suppression (amplification) of fluctuations in the boundary layer on a flat plate. As an illustration, Fig. 5 shows suppression of density fluctuations in the shock layer at the time when the perturbations excited by the whistle have covered half of the plate length

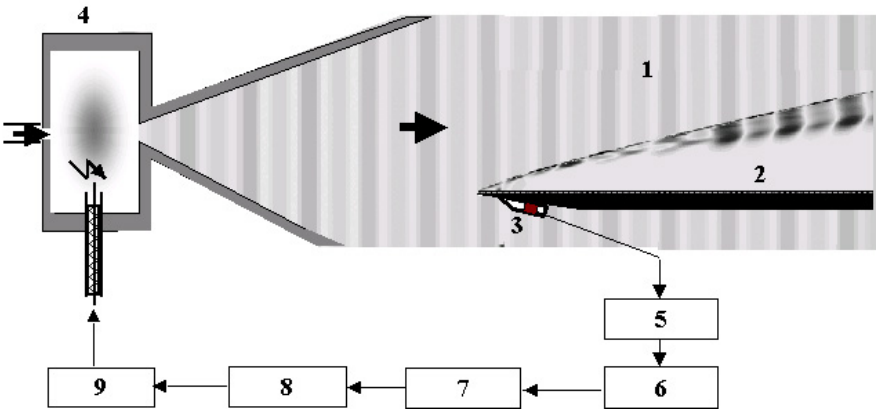

Figure 5. Arrangement of the experiment. 1 – acoustic waves in the external flow; 2 – flat plate; 3 – oblique whistle; 4 – settling chamber; 5 – amplifier; 6 – narrow-band filter; 7 – frequency divider; 8 – generator of pulses for electric discharge initiation; 9 – power unit for the discharge.

For a frequency f = 37.5 kHz, Fig. 6 shows the experimental curves for the amplitude of density fluctuations on the edge of the boundary layer on the plate ρ''/ρ'_{max} in the cross section x/L = 0.63 versus the time shift $\Delta\tau$ between external flow disturbances and perturbations generated by the whistle. Here ρ'_{max} is the level of density fluctuations on the boundary-layer edge in the case of an in-phase action of the external acoustic wave and periodic blowing/suction. The relation between the amplitudes of external and internal disturbances allows almost complete suppression of perturbations in the shock layer. The solid curve in Fig. 6 approximates the experimental values in accordance with the law of interference of two sinusoidal waves of identical frequency and amplitude.

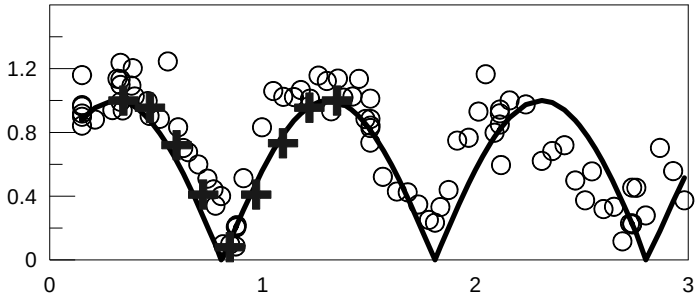

Figure 6. Amplitude of density fluctuations on the boundary-layer edge versus the delay of the initial disturbances.

CONCLUSIONS

The present paper describes comprehensive numerical and experimental studies of receptivity and of disturbance evolution in a hypersonic viscous shock layer on a flat plate at a very high Mach numbers and moderate Reynolds numbers.

It is shown that the main specific feature of the mechanism of formation of the field of fluctuations in the case of shock-layer interaction with external acoustic disturbances and with perturbations of the blowing-suction type is generation and propagation of entropy-vortex perturbations inside the shock layer.

The field of fluctuations induced in the shock layer by external flow perturbations was shown to be similar to the field of fluctuations generated by blowing-suction perturbations; the streamwise phase velocities of fluctuations generated by these sources in the shock layer also coincide. Owing to these features, it became possible to implement interference-based controlling of the intensity of fluctuations in the shock layer by affecting them with the help of controlled perturbations with certain amplitudes and phases.

The interference-based flow-control method was realized both numerically and experimentally. Periodic acoustic waves were introduced into the external flow and generated entropy-vortex disturbances in the shock layer. The latter were suppressed or amplified by periodic perturbations with the opposite phases, which were generated by a blowing-suction source (in numerical simulations) or by an oblique whistle located near the plate tip (in the experiments). Fluctuations on the boundary-layer edge were almost completely suppressed, and fluctuations in the shock layer as a whole were substantially attenuated.

This work was supported by the Russian Foundation for Basic Research (grant 09-08-00557) and by ADTP RNP 2.1.1/3963. The computer time for computations was allocated by the Siberian Supercomputer Center.

ABSTRACT. The joint composition probability density function (PDF) transport equation is widely used for turbulent combustion simulation. Due to the high number of dimensions, traditional finite methods are not suitable for solving this joint PDF transport equation (their computational time increases exponentially with the dimensionality). Monte Carlo methods, on the other hand, yield a linearly growing effort with dimensionality. Eulerian Monte Carlo (EMC) methods are based on stochastic fields that evolve through stochastic partial differential equations (SPDEs) statistically equivalent to the the joint PDF transport equation. EMC methods may be formulated either in non conservative or in conservative forms of SPDEs.
In this paper we devise a new hybrid finite volume/EMC method based on the conservative form of EMC methods, for both stationary and non-stationary turbulent reactive flows. The mean velocity and turbulence fields are solved in the frame of a RANS solver while the species concentrations and enthalpy are treated using SPDEs. The coupling is performed through an additional equation for the mean pressure, in which the source term is calculated using the scalar fields taken from SPDE solver. We validate our algorithm by computing a premixed flame stabilized behind a backward facing step and by comparing with some experimental data obtained in ONERA subsonic combustion rig.

Keywords: *turbulent combustion, probability density function, Eulerian Monte Carlo method, stochastic fields, premixed flame*

INTRODUCTION

In turbulent flames, phenomena of interest, such as pollutant production, soot formation or extinctions/ignitions, mainly arise from a conjunction of rare physical events (peak temperature, weak mixing conditions, ...) and finite rate chemistry effects. Predicting these phenomena thus requires a precise knowledge of the one-point statistics of the species concentrations and temperature, as well as an accurate description of chemical reactions. Regarding both aspects, the one-point joint composition probability function (PDF) appears as a relevant tool: it transports the detailed one-point statistical information of the turbulent scalars and allows chemical source terms to be treated exactly [1].

These advantages are nonetheless counterbalanced by a severe numerical constraint: the composition PDF possesses a potentially high number of dimensions, which induces heavy computational costs. In particular, the finite methods traditionally employed in computational fluid dynamics (CFD) cannot be used, as their cost increases exponentially with dimensionality. Monte Carlo methods, on the other hand, yield a linearly growing effort and are more adapted to solve PDF equations.

So far, in the field of turbulent combustion, Monte Carlo methods have mostly been considered under their Lagrangian form, following the impulsion given by the seminal work of Pope [1]. Numerous publications document the convergence and accuracy of Lagrangian Monte Carlo (LMC) methods. They have been used in many complex calculations (including LES), and for several years now, they have been implemented in commercial CFD codes. However, the development and evaluation of an alternative Eulerian (Field) Monte Carlo (EMC) method is also useful and stimulating, since the competition between LMC and EMC methods could push both approaches forward.

EMC methods are based on stochastic Eulerian fields, which evolve from stochastic partial differential equations (SPDE) stochastically equivalent to the PDF equation. These SPDEs are the Eulerian counter-part of the stochastic ordinary differential equations (SODEs) used in LMC methods. Their application to simulate the composition PDF in turbulent reactive flows only seems to be dating back from Valiño's work [2], in which the method is named Field Monte Carlo formulation. Sabel'nikov and Soulard [3] proposed a new path to derive SPDEs for solving composition PDF equations. They also presented the details of the theoretical and numerical issues concerning EMC methods. The SPDEs proposed in [3] are written in a non-conservative form. A conservative formulation was later proposed in [4].

In this paper a novel hybrid composition EMC-FV (Finite Volume) algorithm is developed based on the conservative formulation of SPDEs [4]. Correction techniques, time averaging procedure and coupling strategy efficiency are evaluated. This algorithm was implemented into the industrial CFD code ONERA CEDRE. Then, EMC-RANS algorithm was applied to simulate a turbulent premixed methane-air flame stabilized by backward facing step. Computations results were compared with experimental data [5]. The results were found to compare favourably with experimental data.

HYBRID EMC-RANS ALGORITHM

For variable density flows, working with density-weighted (Favre) statistics is a widespread technique. We denote the one-point Favre composition PDF as $\widetilde{f}(\boldsymbol{\Psi}; x, t)$, where $\boldsymbol{\Psi}$ is the vector in the "phase space" for the scalar variables $\boldsymbol{Y}$, where Y_k, $1 \leq k \leq N_s$ are species mass fractions and $Y_{N+1} = h_t$ is the total enthalpy. The exact transport equation for is derived from the species and energy conservations equations, using standard techniques [1]. Mean advection and chemical source terms in this equation are treated exactly, whereas the effects of molecular diffusion and turbulent advection require modelling. Turbulent advection is modelled with an isotropic gradient diffusion assumption. Molecular diffusion effects (micromixing term) are usually described by the simplest model - the interaction by exchange with mean (IEM) [1]. As a result, the following modelled transport equation is obtained for $\widetilde{f}(\boldsymbol{\Psi}; x, t)$:

$$\frac{\partial}{\partial t}\left(\langle\rho\rangle\,\widetilde{f}\right) + \frac{\partial}{\partial x_j}\left(\langle\rho\rangle\,\widetilde{U}_j\,\widetilde{f}\right) = \frac{\partial}{\partial x_j}\left(\langle\rho\rangle\,\Gamma_T\,\frac{\partial \widetilde{f}}{\partial x_j}\right) + \frac{\partial}{\partial \Psi_k}\left(\langle\rho\rangle\,\langle\omega_c\rangle\left(\Psi_k - \widetilde{\Psi}_k\right)\widetilde{f}\right) - \frac{\partial}{\partial \Psi_k}\left(\langle\rho\rangle\,S_k\,\widetilde{f}\right) \tag{1}$$

In this equation, Γ_T is the turbulent diffusivity , $\langle\omega_c\rangle$ is the mean mixing frequency , and $\widetilde{\boldsymbol{U}}$ is the Favre averaged velocity. These quantities are computed from a RANS solver [6].

The Favre averaged continuity and momentum equations are solved and a standard $k-\epsilon$ model is used to compute the turbulent stresses, with k the turbulent kinetic energy and ϵ the turbulent dissipation.

$$\begin{array}{lcl} \textit{Continuity} & : & \frac{\partial \langle\rho\rangle}{\partial t} + \frac{\partial}{\partial x_j}\left(\langle\rho\rangle \tilde{U}_j\right) = 0 \\ \textit{Momentum} & : & \langle\rho\rangle \frac{D\tilde{U}_i}{Dt} = -\frac{\partial \langle P\rangle}{\partial x_j} + \frac{\partial \sigma_{ij}}{\partial x_j} \\ \textit{Turb. kin. energy} & : & \langle\rho\rangle \frac{Dk}{Dt} = \frac{\partial}{\partial x_j}\left(\langle\rho\rangle \frac{\nu_t}{Pr_k}\frac{\partial k}{\partial x_j}\right) + P_k - d_k \\ \textit{Turb. dissipation} & : & \langle\rho\rangle \frac{D\epsilon}{Dt} = \frac{\partial}{\partial x_j}\left(\langle\rho\rangle \frac{\nu_t}{Pr_\epsilon}\frac{\partial \epsilon}{\partial x_j}\right) + P_\epsilon - d_\epsilon \end{array} \tag{2}$$

$\frac{D}{Dt}$ is the substantial derivative. It stands for $\frac{\partial}{\partial t} + \tilde{U}_j \frac{\partial}{\partial x_j}$. σ_{ij} models the turbulent stresses with an eddy viscosity hypothesis:

$$\sigma_{ij} = -\frac{2}{3}\langle\rho\rangle k\delta_{ij} + \langle\rho\rangle \nu_t \left(\frac{\partial \tilde{U}_i}{\partial x_j} + \frac{\partial \tilde{U}_j}{\partial x_i} - \frac{2}{3}\frac{\partial \tilde{U}_k}{\partial x_k}\delta_{ij}\right) \tag{3}$$

P_k and d_k (respectively P_ϵ and d_ϵ) are the production and dissipation terms of the turbulent kinetic energy (resp. dissipation). Standard expressions are used for these terms, as found for instance in [6]. The eddy viscosity is given by $\nu_t = C_\mu \frac{k^2}{\epsilon}$. Standard values are chosen for the $k-\epsilon$ model constants, as given in [6].

The statistics of species mass fractions Y_k and total enthalpy h_t are computed with an EMC solver using SPDEs derived in non-conservative form [3] :

$$\begin{array}{lcl} \textit{Mass fraction} & : & \frac{\partial Y_k}{\partial t}dt + \left(\tilde{U}_j - \frac{1}{2}\frac{\partial \Gamma_T}{\partial x_j} - \frac{1}{\langle\rho\rangle}\frac{\partial\langle\rho\rangle}{\partial x_j}\Gamma_T\right)\frac{\partial Y_k}{\partial x_j}dt \\ & & + \sqrt{2\Gamma_T}\frac{\partial Y_k}{\partial x_j} \circ dW_j(t) = -\langle\omega_c\rangle (Y_k - \tilde{Y}_k)dt + S(Y, h_t)dt \\ \textit{Total enthalpy} & : & \frac{\partial h_t}{\partial t}dt + \left(\tilde{U}_j - \frac{1}{2}\frac{\partial \Gamma_T}{\partial x_j} - \frac{1}{\langle\rho\rangle}\frac{\partial\langle\rho\rangle}{\partial x_j}\Gamma_T\right)\frac{\partial h_t}{\partial x_j}dt \\ & & + \sqrt{2\Gamma_T}\frac{\partial h_t}{\partial x_j} \circ dW_j(t) = -\langle\omega_c\rangle (h_t - \tilde{h}_t)dt + \frac{1}{\langle\rho\rangle}\frac{dP_0}{dt} \end{array} \tag{4}$$

or in conservative form [4] :

$$\frac{\partial}{\partial t}\mathtt{r}\, Y_k + \frac{\partial}{\partial x_j}\left(\mathtt{r}\, Y_k \circ (\widetilde{U}_j + \mathcal{U}^*_j)\right) = -\mathtt{r}\, \langle\omega_c\rangle (Y_k - \widetilde{Y}_k) + \mathtt{r}\, S_k(Y, T) \tag{5}$$

$$\frac{\partial \mathtt{r}\, h_t}{\partial t} + \frac{\partial}{\partial x_j}\left(\mathtt{r}\, h_t \circ (\widetilde{U}_j + \mathcal{U}^*_j)\right) = -\mathtt{r}\, \langle\omega_c\rangle (h_t - \widetilde{h}_t) + \frac{dP_0}{dt} \tag{6}$$

$$\mathcal{U}^*_j = \Gamma_t \frac{1}{\langle\rho\rangle}\frac{\partial\langle\rho\rangle}{\partial x_j} + \frac{1}{2}\frac{\partial \Gamma_t}{\partial x_j} + \sqrt{2\Gamma_t}\dot{W}_j \tag{7}$$

where P_0 is a reference pressure.

In the enthalpy equation, a unity Lewis number assumption has been made and acoustic interactions, viscous dissipation, and body forces were neglected under a low Mach number assumption. In these equations, the turbulent diffusivity is defined by $\Gamma_T = \nu_t / Sc_t$, where Sc_t is a turbulent Schmidt number supposed here to be unity. The mixing frequency is defined by $\langle\omega_c\rangle = C_\phi \frac{\epsilon}{k}$ where C_ϕ is a constant supposed to be equal to 0.7.

For the non-conservative formulation (4), the Favre averaged values of the species mass fraction and total enthalpy are computed by: $\tilde{Y}_k = \frac{1}{N}\sum_{real.} Y_k$ and $\tilde{h}_t = \frac{1}{N}\sum_{real.} h_t$, where the sums are taken over N realisations of the stochastic fields.

For the conservative formulation (5)-(7), the Favre averaged values of the species mass fraction and total enthalpy are computed by: $\widetilde{Y}_k = \sum_{real.} rY_k / \sum_{real.} r$ and $\widetilde{h}_t = \sum_{real.} rh_t / \sum_{real.} r$ where the sums are taken over the N realisations.

Information is transmitted from the RANS solver to the EMC solver via $\langle\rho\rangle$, $\tilde{U}_j$, ν_t and $\langle\omega\rangle$. The influence of the EMC solver on the RANS solver is achieved in the mean momentum equation, through the gradient of the mean pressure, which is computed from the equation of state :

$$\langle P\rangle = \langle\rho\rangle R_0 \sum_k \frac{\widetilde{Y_k T}}{M_k} \tag{8}$$

In this formula, R_0 is the gas constant and M_k is the molecular weight of the species k.
This way of coupling the EMC and RANS solver worked directly for the non-conservative formulation. However, for the conservative formulation, this coupling does not allow to get satisfactory convergence rates. The statistical fluctuations from $\langle \mathtt{r}\rangle_s = \frac{1}{N}\sum_{real.} \mathtt{r}$ and $\widetilde{Y_k T}$ in (8) are large and prevent the convergence. To overcome this difficulty, an equation is considered for the following quantity:

$$\Phi_\gamma = \frac{\langle P\rangle}{\langle\rho\rangle} + \frac{\langle\gamma\rangle - 1}{2}\widetilde{U}_i\widetilde{U}_i \tag{9}$$

where γ is the ratio of specific heats. With some approximation, the following equation is used for Φ_γ:

$$\frac{\partial \langle\rho\rangle \Phi_\gamma}{\partial t} + \frac{\partial}{\partial x_j}\left(\langle\rho\rangle \Phi_\gamma \widetilde{u}_j\right) = \frac{\partial}{\partial x_j}\left(\langle\rho\rangle \Gamma_T \frac{\partial \Phi_\gamma}{\partial x_j}\right) - \sum_k \langle(\gamma - 1)h_k S_k\rangle \tag{10}$$

where h_k is the specific enthalpy of species k and γ is its specific heat ratio. The source term in equation (10) are obtained from the EMC solver. This way of coupling allows to improve the stability and the statistical convergence.

NUMERICAL ASPECTS

Numerical scheme

To be consistent with the Stratonovitch interpretation used in equations (4)-(6), one must respect a "mid-point" rule in temporal integration [7]. For instance, fully explicit schemes are not consistent when used to discretize equations (4)-(6). Another important point is that precision must be evaluated in a weak sense: we are concerned with the error done in solving the PDF equation, not the SPDE.
Thus, we must adapt existing numerical schemes. First, we address the issue of temporal integration. We recast equations (4)-(6) in an SODE form; this allows the use of traditional SODE techniques [7]. An explicit first order scheme is chosen, with a predictor-corrector procedure generalizing the Heun scheme [7].
As for spatial discretization, scalar fluxes are interpolated with a second order Essentially Non-Oscillatory (ENO) scheme and a decentered procedure is used for the advection term. Decentering derivatives yields a correlation between the white noise and the discretization error. As a result, despite being second order accurate for the individual stochastic fields, the numerical scheme only discretizes the PDF equation with a first order spatial accuracy. Higher order numerical schemes can also be constructed.
The timestep is set according to a CFL criterion, built on the stochastic velocity. This guarantees the linear stability of the overall scheme. Because, the advection velocity is stochastic, the CFL criterion that we obtain is different from the usual one, and resembles an advection/diffusion stability criterion.

Boundary conditions

The issue of boundary conditions is also a crucial one. It should be noted that a diffusion equation like the one for the PDF requires boundary conditions to be specified on all the domain frontiers, whereas an hyperbolic equation only requires boundary conditions to be specified on certain parts of

the frontier. Furthermore, the stochastic advection term of SPDEs (4)-(6) can change the specification of boundary conditions in time. The boundaries alternatively become inflow boundaries, with a specified value of the stochastic field or outflow boundaries, with a value of the stochastic field computed from the interior of the domain. A more general discussion on boundary conditions is given in [3].

Correction algorithms

The hybrid algorithm is consistent at the level of the governing equations (i.e. $\langle \mathtt{r} \rangle_s = \langle \rho \rangle$). However due to the limited number of stochastic fields and the accumulation of numerical errors, the condition $\langle \mathtt{r} \rangle_s = \langle \rho \rangle$ may not always be respected during the calculation. In order to limit the statistical error, a correction diffusion term is added to SPDEs (5):

$$\frac{\partial}{\partial t}\mathtt{r}Y_k + \frac{\partial}{\partial x_j}\left(\mathtt{r}Y_k \circ (\widetilde{U}_j + \mathcal{U}_j^*)\right) = -\,\mathtt{r}\,\langle \omega_c \rangle\,(Y_k - \widetilde{Y}_k) + \mathtt{r}S_k(Y,T) + \frac{\partial}{\partial x_j}\left(\langle \rho \rangle\,\Gamma_T \frac{\partial}{\partial x_j}\left(\left|\frac{\langle \mathtt{r} \rangle_s - \langle \rho \rangle}{\langle \rho \rangle}\right| Y_k\right)\right) \tag{11}$$

The correction diffusion term is equal to zero once $\langle \mathtt{r} \rangle_s = \langle \rho \rangle$. The second correction concerns the velocity $\mathcal{U}_j^*$. In theory, the Favre average of this velocity is equal to zero:

$$\left\langle \mathcal{U}_j^* \right\rangle_{\mathtt{r}} = \frac{\left\langle \mathtt{r}\mathcal{U}_j^* \right\rangle_s}{\langle \mathtt{r} \rangle_s} = 0 \tag{12}$$

In the calculations, due to stochastic and numerical errors, condition (12) is not satisfied. To respect condition (12), we correct $\mathcal{U}_j^*$ by substracting its Favre average, as done for LMC methods in [8]. The new stochastic velocity is:

$$\mathcal{U}_j = \mathcal{U}_j^* - \sum_{real.} \mathtt{r}\mathcal{U}_j^* / \sum_{real.} \mathtt{r} \tag{13}$$

To reduce statistical noise, we also applied a time averaging technique similar to the one described in [8].

SIMULATION OF A BACKWARD FACING STEP WITH A HYBRID EMC-RANS ALGORITHM

The EMC-RANS solver described above was validated against experimental data [5] on a configuration consisting in the turbulent combustion of a pre-mixed stoichiometric methane-air mixture. The flame was stabilized by a recirculation zone in a plane channel with a sudden expansion (backward facing step).

Configuration

The physical domain is $L = 1m$ horizontally and $H = 0.1m$ vertically. The height of the step, placed at the lower wall, is $h = 0.035m$, and its extremity is located at $0.2m$ inside the computational domain. Positions will hereafter be given using the step extremity as the origin.

At inlet, a methane/air mixture is injected at $U_0 = 58m/s$ and $T_0 = 525K$, with a stoichiometric equivalence ratio $\phi = 1$. The inlet values of the turbulent quantities are $k_0 = 60m^2/s^2$ and $\epsilon_0 = 800m^2/s^3$. At outlet, the pressure is fixed: $P_s = 1bar$. The geometry and inlet conditions correspond to the experimental ones [5].

At the upper and lower wall, wall functions are applied for k and ϵ, while the enthalpy and mass fractions are set by assuming that the walls are adiabatic. However, the measurements of the temperature in [5] were done in a water-cooled combustion facility. Thus, in the experiment, there were wall heat

fluxes and the redistribution of the heat through metal walls by means of thermal conductivity. As a consequence, the approximation of adiabatic walls overestimates temperature at the lower wall, and underestimates the temperature at the upper wall. This remark has to be taken into account when comparing computed and experimental data.
Methane combustion in air was modeled by a global single-step chemical reaction, which describes complete combustion of methane, the resultant products being CO_2 and H_2O [9]. Though the single-step reaction offers only an approximate description of methane oidation and, in particular, over-predicts the temperature T, it was used for preliminary testing of the hybrid EMC-RANS algorithm developed here.

Results and discussion
The EMC method in non-conservative form (4) was applied to the calculation of the methane-air flame described above in [10]. Comparison against experimental data yielded a qualitatively good agreement between mean temperatures and temperature variances. Statistical and spatial errors were thoroughly analyzed in [10]. It was shown that a grid resolution of $\Delta x = 10^{-2}m$ and $\Delta y = 2.4 \cdot 10^{-3}m$ is sufficient to capture the flame structure.
In this section, we present some results obtained with the EMC method in conservative form (5)-(6). SPDEs (5)-(6) in conservative form yield almost the same restults as those published in [10] with the non-conservative formulation. This is not surprising because the conservative and non-conservative formulations are statistically equivalent to the same PDF equation (1).
Table recapitulates the resolution of the four grids we used. The grid refinement was performed in the near step nose region.

Table 1
Grid Resolution. x: horizontal direction; y: vertical direction

	$\Delta x_{min}(m)$	$\Delta y_{min}(m)$	$N_x \cdot N_y$
Mesh 1	$1.5 \cdot 10^{-2}$	$5 \cdot 10^{-3}$	900
Mesh 2	$6 \cdot 10^{-3}$	$5 \cdot 10^{-3}$	1600
Mesh 3	$4 \cdot 10^{-3}$	$3 \cdot 10^{-3}$	4000
Mesh 4	$1.5 \cdot 10^{-3}$	10^{-3}	8000

We first analyze stochastic convergence. We perform five calculations on *Mesh 3* with $N = 5$, $N = 10$, $N = 25$, $N = 50$, and $N = 100$ stochastic fields. We compare the results once a statistical convergence is attained. This is the case for times on the order of $10L/U_0 = 0.15s$. To better characterize the statistical convergence, we introduce two integrals: $E_1 = \frac{\int |\widetilde{T} - \widetilde{T}_{ref}| dxdy}{\int \widetilde{T}_{ref} dxdy}$ and $E_2 = \frac{\int |\sqrt{\widetilde{T'^2}} - \sqrt{\widetilde{T'^2_{ref}}}| dxdy}{\int \sqrt{\widetilde{T'^2_{ref}}} dxdy}$ where $\widetilde{T}_{ref}$ and $\widetilde{T'^2_{ref}}$ are computed from a high resolution solution with $N = 100$ stochastic fields. Figure (a) shows the evolution of E_1 and E_2 against the number of stochastic fields. A convergence is indeed observed : E_1 decays as $N^{-0.8}$ and E_2 decays as $N^{-0.7}$. These decay rates are slightly higher than the theoretical $N^{-0.5}$ rate that we could expect.
We now analyze spatial convergence. Calculations are done with $N = 50$ stochastic fields, and the number of computational cells is varied from *Mesh 1* to *Mesh 4*. The computation done with *Mesh 4* is considered as a reference solution against which other calculations are compared. The integrals E_1 and E_2, with $\widetilde{T}_{ref}$ and $\sqrt{\widetilde{T'^2_{ref}}}$ computed from *Mesh 4*, are used for this comparison. Figure (b) shows the evolution of E_1 and E_2 against the number of computational cells. Comparison of figures (a) and (b) shows that for $N_c = 4000$ cells the spatial error is on the order of the stochastic error obtained with $N = 50$ fields. Thus, by choosing the most refined mesh $N_c = 8000$ cells for our calculations, we

(a) (b)

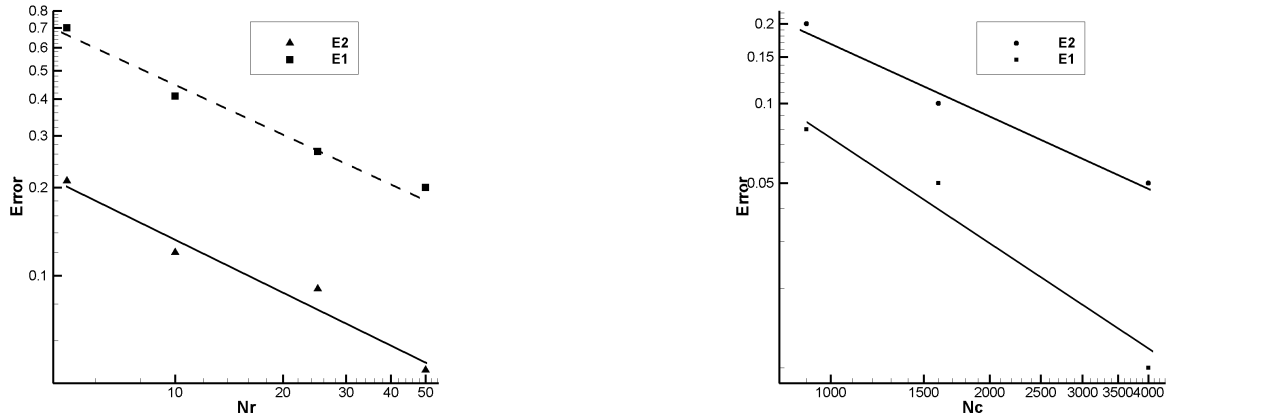

Figure 1: Errors E_1 and E_2 against (a) : the number of stochastic fields N; (b): the number of cells

expect the spatial discretization error to be much smaller than the stochastic error. It then becomes useless to refine further the grid without adding more stochastic fields.
Thus, in the remaining calculations, we will choose *Mesh 3* and $N = 50$ fields as a compromise between precision and calculation cost. Mean and RMS temperature vertical profiles at a given location are shown on figure 2. They are compared against the experimental results obtained by [5]. The main point of this comparison is the satisfactory agreement found between the calculation and the experiment. In particular, the peak location of the calculated RMS temperature is close to the experimental one. The temperature PDFs were also computed and found to compare favorably with experimental data [5]. This comparison is not presented here, but can be found in [10].

CONCLUSIONS

Eulerian (Field) Monte Carlo (EMC) methods are employed to construct hybrid algorithms to resolve the composition PDF equations. The composition PDFs in EMC methods are represented by stochastic Eulerian species fields. Stochastic partial differential equations (SPDEs) are statistically equivalent

to the PDF equations. Numerical issues emerging in the solution of the SPDEs are discussed and numerical schemes are adapted. A hierarchy of numerical validation tests is performed. A novel hybrid composition EMC-FV (Finite Volume) algorithm is developed based on the conservative formulation of SPDEs. Correction techniques, time averaging procedure and coupling strategy efficiency are evaluated. This algorithm was implemented into the industrial CFD code ONERA CEDRE. Then, EMC-RANS algorithm was applied to simulate a turbulent premixed methane-air flame stabilized by backward facing step. Computations results were compared with experimental data. The results were found to compare favourably with experimental data.

LARGE EDDY SIMULATIONS OF PARTICLE-LADEN TURBULENT CHANNEL FLOWS

M. Jaszczur
AGH University of Science and Technology, Kraków, Poland

ABSTRACT The particle-turbulence interaction is one of the key phenomena important to have a very accurate prediction and a good understanding of the physical process. Due to the interactions with turbulence, the distribution of the particles and their properties can be highly influenced. That behaviour can have serious consequences on the efficiency and direction of many chemical and industrial processes. In presented paper Large Eddy Simulations for the case of flows laden with a large number of small particles were performed. Eulerian-Lagrangian point-particle approach was used to study of the particle-turbulence dynamics. The objective of this work was the analysis of influence of the Smagorinsky constant and wall function on the particle statistics. The influence of the constant models was tested in a comparison between the results obtained with Direct Numerical Simulations and Large Eddy Simulations using a standard Smagorinsky model or combined with Van Driest wall-damping model. Due to the complexity of the particles behaviour, only some computed average profiles of the dispersed phase from the LES simulations show good agreement with the DNS data. Phenomena like clustering and concentration was very difficult to reproduce properly with LES and additional sub grid scale model for dispersed phase seems to be required.
In particular, even though the models reproduces more accurately results for the continuous phase in comparison to results obtained by DNS the properties of the dispersed phase computed using LES do not match the DNS results. The particles tends to be highly concentrated in the region close to the wall but concentration is always lower than for DNS. Moreover, the properties of the particles in terms of concentrations and velocity fluctuation profiles do not show large improvement with the use of different models for LES. This mean that additional model concerning proper preproduction of the dispersed phase needs to be implemented.

Keywords: *LES particle laden flow, multiphase flow, turbulent channel flow*

INTRODUCTION

The multiphase flow laden with a large number of particles has recently received considerable attention due to its relevance to large number of chemical and engineering applications. It is well know that depending on the particle Stokes number and density of the particles the turbulent flow structure can be low or highly influence by the presence of the particles. Numerical computations can play an important role in understanding fundamental interaction between particles and turbulence but is often limited to low Reynolds number cases (Direct Numerical Simulations). To overcome this limitation Large Eddy Simulations has been more often used but in that case suitable subgrid scale model needs to be introduced. In the present work particle transport in fully developed turbulent wall-bounded flow has been investigated with the fluid-particle one way interaction

approach and Large Eddy Simulations approach. LES of the incompressible flow, combined with Lagrangian particle tracking technique has been performed to study problem.

Numerical computations using DNS as well as experimental measurements shows that shear flow, mean gradient in the fluid and velocity of the particles have complex effect on the particle fluctuations. In wall-bounded shear flow Rouson and Eaton[1], Pedinotti[2] have shown that particle are preferentially concentrated in the low speed streaks and near-wall region. McLaughlin[3] has shown that particles accumulate in the near wall region.

In order to design industrial devices involving particle-turbulence interaction it is important to have a very accurate prediction of particles behavior in selected processes. Small heavy particles immersed in a turbulent flow tend to accumulate, creating non-homogeneities in concentration [1] in contrast to more welcome for many chemical processes uniformity. This can have important consequences on the direction and efficiency of many chemical and industrial processes. Number of research has been done to study the influence of particle inertia on the dispersion phenomena [2-4]. Most of simulations do not promise to have high reliability and applicability and fail to provide more accurately analysis of the flow.

Several important aspects of particle-turbulence interactions have been analyzed by Maxey and Riley [5], Kulick [6], Fessler and Eaton [7], Chung [8], and Portela [9] among others.

In the most study Direct Numerical Simulations has been used to overcome problem of additional numerical modeling but Large Eddy Simulation method has been also used for particle-laden flows and several work have been published over the last years [9-11]. But the issue is still perceived as open and further work is needed to understand the effect of sub grid-scale fluid flow on particle motion and vice versa. In particular, seems to be very important to model properly the carrier flow. One of the several available models in LES is the Smagorinsky model, which has been widely applied to many different situations. However, one of the main problems of this model is the dependence on a model coefficient, which has to be determined a priori.

In presented paper Large Eddy Simulations for the case of flows laden with a large number of small particles were performed and the objective of this work was the analysis of influence of the Smagorinsky constant and wall function on the particle statistics (dispersed phase). The influence of the constant models was tested by the comparison of the results obtained with Direct Numerical Simulations (performed also here and in reference paper Jaszczur et. al. [12]) and Large Eddy Simulations using a standard Smagorinsky model or combined with Van Driest wall-damping model.

The problem analyzed the transport of small heavy particles in a closed-channel flow coupled with Lagrangian Particle Tracking. The last is done using the point-particle technique, and considering only a one-way coupling situation, i.e., the influence of the particles on the turbulence and particle collisions were not taken into account. Due to the complexity of the particles behavior, only some computed average profiles of the dispersed phase from the LES simulations show good agreement with the DNS data. Phenomena like clustering and concentration was very difficult to reproduce properly with LES and additional sub grid scale modeling for continuous or dispersed phase seems to be required.

MATHEMATICAL MODEL

Equations of motion

In turbulent channel flow laden with particle two different phases can be recognized in the domain: a continuous phase (gas phase) and a dispersed phase (particle phase). Assuming the flow is isothermal, Newtonian and incompressible, for the case of Large Eddy Simulations, the continuous phase can be represented by the filtered Navier-Stokes equations for continuity and momentum presented below:

$$\nabla \cdot \mathbf{u} = \mathbf{0} \tag{1}$$

$$\frac{D\mathbf{u}}{Dt} = -\frac{\nabla P}{\rho_f} + \upsilon \nabla^2 \mathbf{u} + \nabla \cdot \boldsymbol{T} \tag{2}$$

where **u** and P are the fluid velocity and pressure, ρ_f , ν respectively the fluid density, and kinematic viscosity. The stress-tensor, $\boldsymbol{T}$ represented the influence of the sub grid scales on the resolved fluid-velocity. One of the most popular sub grid scale (SGS) stress model is the Smagorinsky model [13]. Even though this relatively easy model has been successfully applied to many different turbulent flows. But there are two limitations on the application of the Smagorinsky model. First of limitation to industrial application is essentially dissipative character of the model, and second more importantly, the value of the Smagorinsky constant C_s has to be defined a priori.
In the standard Smagorinsky model, the residual stress tensor is denoted by $\boldsymbol{\tau}$, and is defined as follows:

$$\tau_{ij} = \overline{u_i u_j} - \bar{u}_i \bar{u}_j \tag{3}$$

This tensor **τ** is parameterized by an eddy viscosity model, as follows:

$$\tau_{ij} - \frac{\delta_{ij}}{3}\tau_{kk} = -2\nu_r \overline{S_{ij}} \tag{4}$$

This is incorporated in the pressure term and the coefficient of proportionally to ν_r and it is modelled by analogy to the mixing length hypothesis as:

$$\nu_r = C\Delta^2 \left|\overline{S}\right| \tag{5}$$

where C is the Smagorinsky constant, $\overline{\Delta}$ is the filter width, and $\left|\overline{S}\right|$ is the magnitude of the large scale strain rate tensor $\overline{S}_{ij}$. Last tensor can be defined as bellow:

$$\overline{S}_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{6}$$

where the magnitude of the strain-rate tensor can be defined as:

$$|\bar{S}| = \left(2\bar{S}_{ij}\bar{S}_{ij}\right)^{1/2} \tag{7}$$

For the numerical simulations recommended value of the Smagorinsky constant was C=0.01 sometimes defined as C_s=0.1 or in more advanced models this coefficient can be not fixed but determine dynamically (Germano [14]). Also in the case of the standard Smagorinsky model, wall functions has to be implemented to ensure proper values of viscosity at the wall. Influence of the wall function model was tested in the present computation and several simulations was performed with the standard Van Driest wall-damping model, with parameter A=25 and without wall model .

In general the forces acting on the particle immersed in a flow are described properly by Maxey and Riley equations[5]. But in the case of the small heavy particles considered here, the dominant forces acting on the particles are the drag force and gravity force (in order to study fluid particle interactions gravity force will be neglected). With the above assumption the equation of motion for a particle can be written as:

$$\frac{dv}{dt} = C_d \frac{Re_p}{24}\frac{1}{\tau_v}(\boldsymbol{u} - \boldsymbol{v}) \tag{8}$$

where **v**, **u** are the particle velocity and the velocity of the fluid (interpolated at the geometrical center of the particle). The particle Reynolds number Re_p, and the particle relaxation time τ_v, are defined as follow:

$$Re_p = \frac{|(\boldsymbol{u}-\boldsymbol{v})|\, D_p}{\upsilon}, \quad \tau_\upsilon = \frac{\rho_p}{\rho}\frac{D_p^2}{18\upsilon}, \quad C_d = \frac{24}{Re_p} \tag{9}$$

where ρ_p, ρ_f are the density of the dispersed phase (particle) and the continuous phase (fluid), D_p is the diameter of the particles and C_d is the drag coefficient for Stokes flow (valid for small Re_p).

Numerical methods

Figure 1 shows the geometry of the computational domain used in Large Eddy Simulation of a particle-laden channel flow. Mean flow is driven by a streamwise pressure gradient.

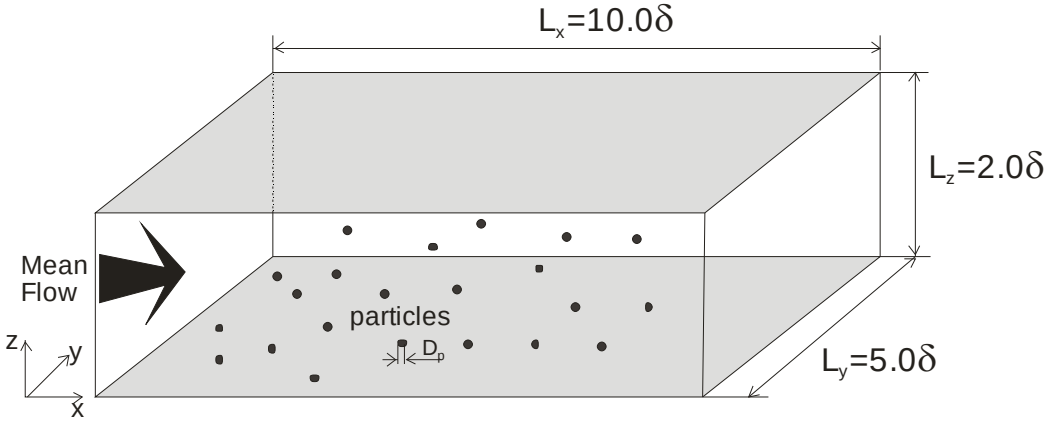

Figure 1. Sketch of computational domain.

The size of the domain, flow and particle quantities are normalized by the channel half-width, δ, and the friction velocity u_τ.

The numerical algorithm was a standard finite-volume method on a staggered grid where the continuous phase was solved using a predictor-corrector solver, with a second-order Adams-Bashforth scheme. The time step was obtained using the Courant stability criterion. In the streamwise and spanwise directions periodic boundary conditions were used.

For the discrete phase, particle equation of motion was integrated using an explicit second-order Runge-Kutta scheme. Tri-linear interpolation has been used to calculate the fluid velocity at the particle position. The time step size for the particles was always equal to or smaller than the fluid time step (a particle can't travel more than ½ of grid cell per iteration). All the conditions for the dispersed phase were the same as in the DNS from Jaszczur et.al. [12]. This means, no model was used to mimic the unresolved flow scales. More details of the code can be found in Portela and Oliemans [9].

RESULTS

Large Eddy Simulations where performed for Re_τ = 150, with the Reynolds number based on the shear velocity and half-channel height. The size of computational domain was 10x4x2δ base on half-channel height and the grid resolution was 64x64x48, with uniform grid spacing in the stream and span-wise directions, and a hyperbolic-tangent stretching in the normal-wise direction, with a high number of grid points in the near-wall region. The simulations started from fully developed DNS (grid size 128x128x64, and domain size 6.4x3.2x2.0) velocity field and particles randomly distributed in computation domain.

When a statistically steady state flow field was obtained, small and heavy particles (density ρ_p=800[kg/m^3]) with particle Stokes number St=1 were introduced in the domain. In order to obtain good statistics for particle the simulations presented here was performed with 1.5x10^5 particles. Their initial velocity assumed to be the same as the fluid in the center of particles location. The particles need to adapt to the new velocity which usually takes few particle response times. But in order to get statistically-steady state for particles conditions much longer time (longer than for flow field) is required. The particles where tracked for t* = 800, and both fluid and particles properties where averaged from t* = 300 till t* = 800. The particle properties were obtained by averaging over a rectangular slices using simple linear model.

Figure 2 presents the mean streamwise velocity profiles for fluid and various constants of LES and compare to DNS as well as no model simulations (C_s=0). On the left hand side are the profiles for model using wall function (Van Driest), while on the right hand side without wall function. Very good agreement between the DNS and LES profiles for mean streamwise velocity was obtain with the use of the wall function model and C_s=0.1. Relatively poor results was obtain without any model C_s=0 or without wall function.

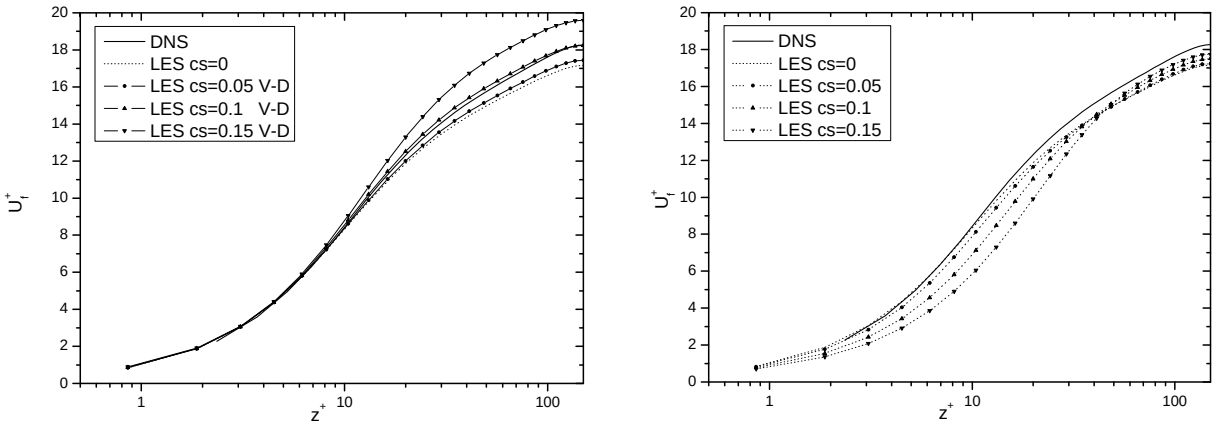

Figure 2: Mean streamwise fluid velocity profiles for LES and DNS and for Re_τ = 150, V-D denotes Van Driest wall function model with A=25.

Figure 3 presents the mean streamwise particle velocity profiles for various constants of LES and DNS. On the left hand side are the profiles for model using wall function while on the right hand side without wall function. Similar to figure 2 very good agreement compare to DNS was obtain with the use of the wall function model and C_s=0.1.

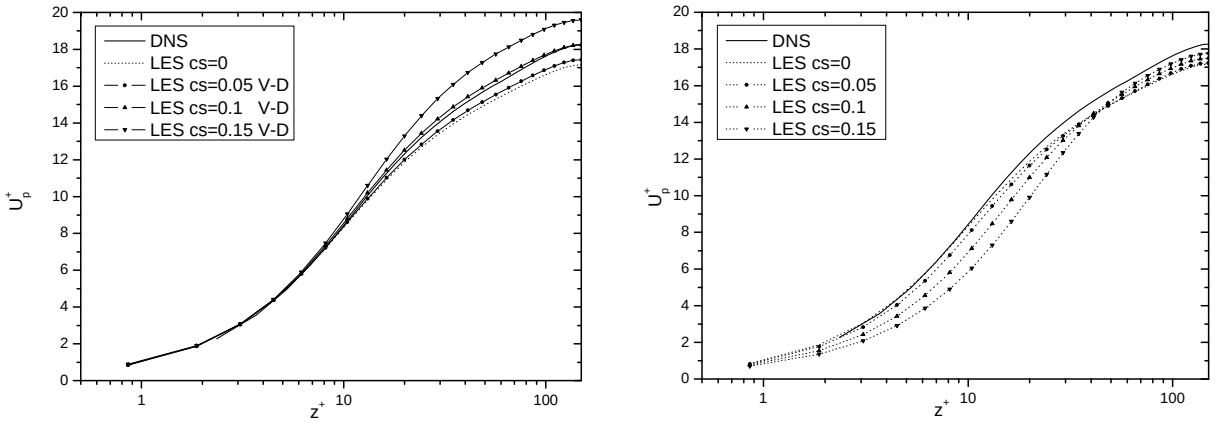

Figure 3. Mean streamwise particle velocity profiles for LES and DNS and for Re_τ = 150, St=1, V-D denotes Van Driest wall function model with A=25.

In contrast to the mean velocity field (where the mean velocity for continuous and for dispersed part computed with DNS and LES shows good agreement for optimal model constant) the stresses differs quite a lot. On figure 4 we can see that value obtained by LES for optimal constant (C_s=0.1) are higher for fluid and lower for particle compare to DNS for correlation <uu>. For the <vv> correlation for continuous phase best result give model with C_s=0.05. This value without wall function model gives better results than for C_s=0.1. Independent of model and constants in all cases prediction of $<w_p w_p>$ and $<u_p w_p>$ is much lower compare to DNS results. Level of fluctuations play key role in particle distributions and, as can be seen from figure 6, large eddy simulation results gives in all cases much lower concentration of the particles close to the wall. This can be in relation to lower fluctuation of the particle in that region. But it need to be emphases that fluid fluctuations depending on model can be relatively well reproduces there. Also, as can be seen on figure 5, the predicted slip velocity with LES is much higher than for DNS. This can be also cause by much smaller particle fluctuation.

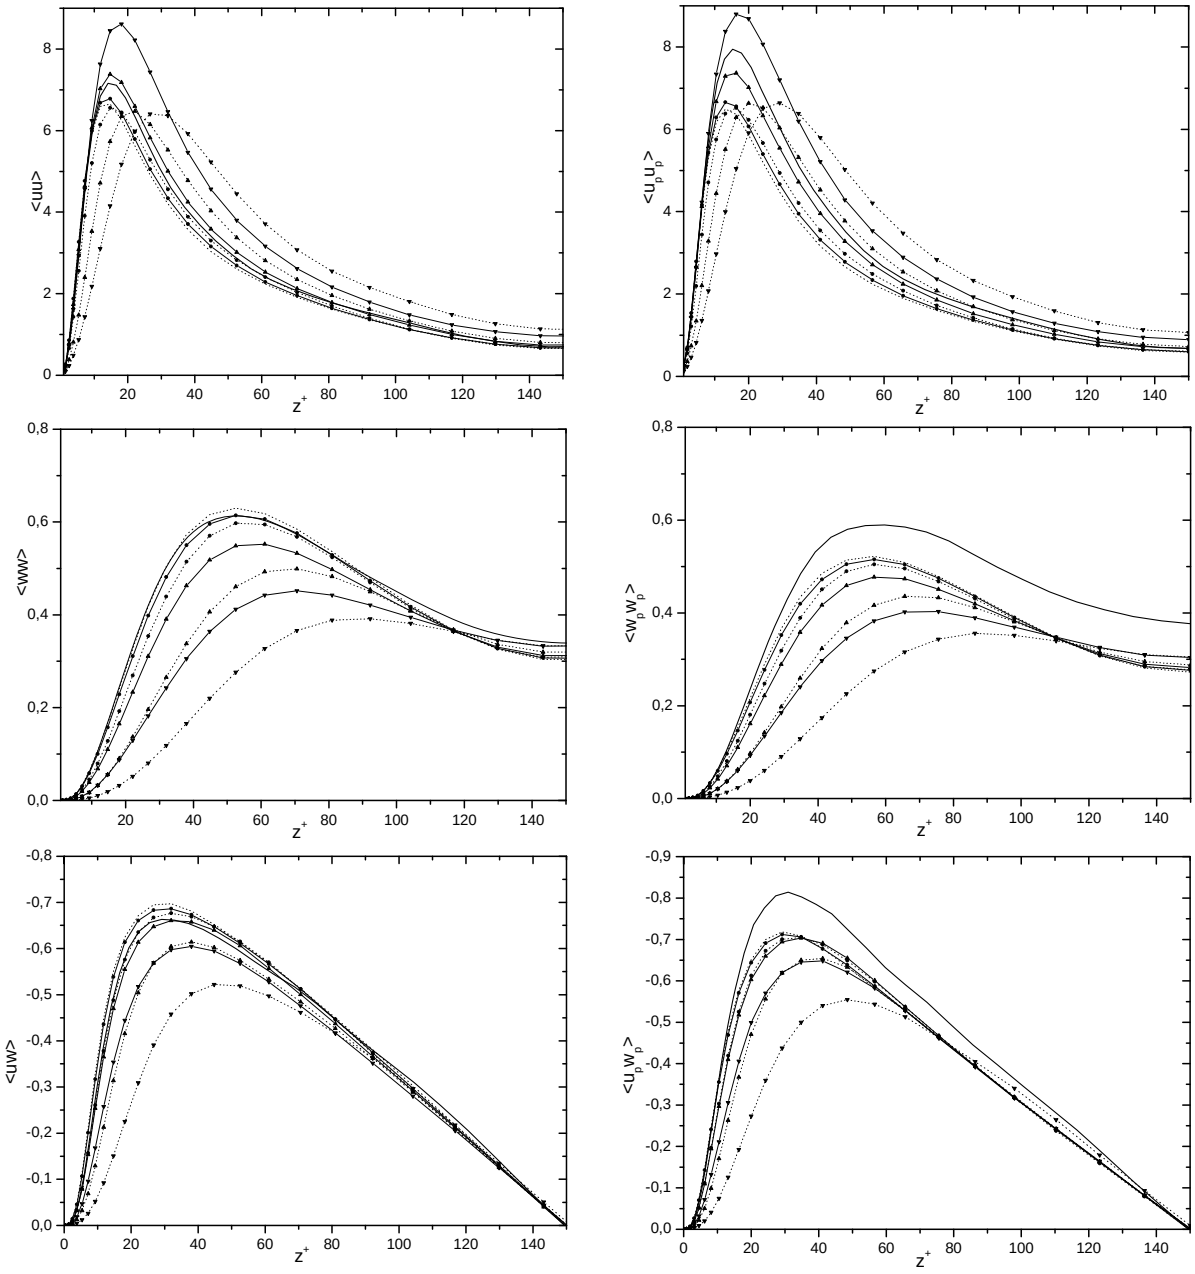

Figure 4: Fluid and particles velocity fluctuation profiles for DNS and large eddy simulations for Re_τ = 150 and St=1(for details see legend on figure 3).

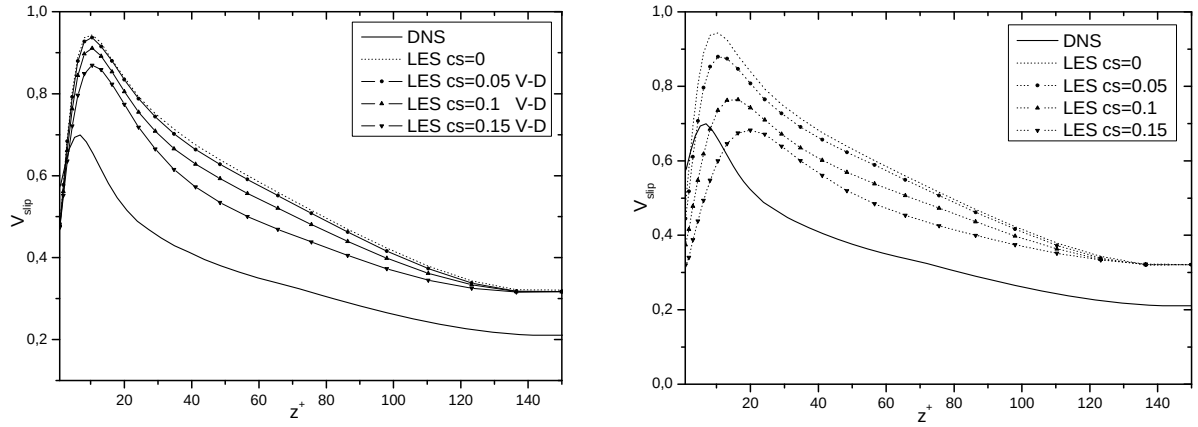

Figure 5: Slip velocity profiles for DNS and large eddy simulations for Re_τ = 150 and St=1, left – with wall model, right – without wall model.

In reference to the fluid and particles fluctuations concentrations for particles in the near wall region is predicted best without any subgrid scale model and with models with Smagorinsky constant C_s=0.05. This tendency is true also for cases without wall-function where predicted concentrations are shifted for all the cases of about 0.25 lower for the first presented point.

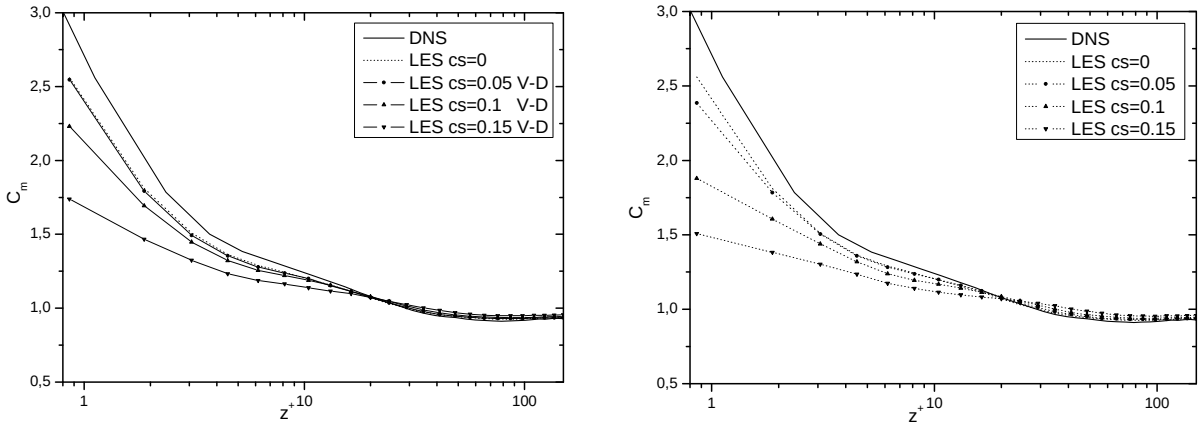

Figure 6: Concentration profiles for DNS and large eddy simulations for Re_τ = 150 and particle Stokes number St=1.

To avoid difference between LES and DNS results due to numerical model, the same procedure was used for particle computation and post-processing (particle statistics). Different numerical model can cause large difference in particle concentration at the wall. This was obtain in benchmark solution [15] where particle concentration at the wall for St=1 and z^+=0.2 was between 3.5 and 7.3 depending on numerical procedure. To avoid influence of averaged time several analysis was done but the difference between results (if statistically steady state was obtain) were very small.

CONCLUSIONS

This paper has shown an analysis of the particle transport in a particle-laden channel flow using Large Eddy Simulations and a point-particle Lagrangian particle tracking. Several statistical quantities for particle velocity and concentrations for both the continuous and the dispersed phase were obtained from the calculations. The results for the fluid phase (mean fluid velocity and correlations) show a good agreement with results obtained by other researchers using DNS for proper model constant. However, the properties of the particles computed from LES do not match DNS results for most properties at all. It was observed that for results obtained using Direct Numerical Simulations particles tend to be highly concentrated in the region close to the wall. This was as a results of particle fluctuation, higher for DNS than with any LES model. Even though the qualitatively behavior of the particles are the same in LES and DNS, this study showed quantitatively differences in the velocity fluctuation and concentration profiles. Moreover, the

properties of the particles in terms of concentrations and velocity fluctuation profiles are not so sensitive to the use of different models for LES, like the standard and can also appears for dynamical models.

Calculations with LES for particle laden flow are still perceived as an open problem, and further work is warranted on the effect of sub grid-scale fluid flow on particle motion. Particle motion similar to continuous phase for proper evaluation of key properties e.g. kinetic energy, preferential concentration, collision statistics, deposition velocity etc, required additional models which will take into account not only local but also global structure of particles. Regarding the treatment of the dispersed phase the way how the fluid velocity is interpolated to the center of the particle can be very important and probably higher order or different method should be introduced. Particles with higher Stokes number can filter itselves velocity field due to high relaxation time and requirement for the sub-grid scale modeling can be less important than in this work.

Miscellaneous Applications

HIDRODYNAMICS OF JETS FROM GUILLOTINE STEAM GENERATOR TUBE RUPTURE

J.L.Muñoz-Cobo[1,*], L.E.Herranz[2], A.Escrivá[1], A.Geraldo[1]
[1]Universidad Politécnica, Valencia, Spain
[2]CIEMAT, Centro de Investigaciones Energéticas, Madrid, Spain

ABSTRACT. In this work we study the hydrodynamics of characteristic gas jets resulting from guillotine breaks of steam generator tube rupture sequences (SGTR), in pressurized nuclear power reactors. As an initial step towards describing an "in-bundle" gas jet, a hydrodynamic model of free gas jets emerging from a guillotine breach under prototypical SGTR conditions have been developed. The model estimates variables such as trajectories, centreline velocities, and velocity distributions. We have performed model comparisons with experimental data for different experimental conditions with different mass flow rates, and we have found good agreement of the model with the experimental results. Additionally, an "ad-hoc" expression has been derived for the centreline jet velocity ($u_c(s) = C_c / s^{0.92}$), which has been experimentally confirmed. Consistently with data, the model predicts no outflow near the jet centre.

Keywords: *guillotine tube rupture jets, jets in enclosures, hydrodynamics of jets, SGTR*

INTRODUCTION

Steam generators (SG) of nuclear power plants consists of around 4000 U inverted tubes, inside these tubes water flows at high pressure (140 bar) and temperature. These tubes under normal operating conditions are submerged in water at lower pressure (70 bar) and temperature than inside the tubes, the compartment where the tubes are submerged is known as the secondary side of the SG. The heat is transferred by convection and conduction from the primary side of these tubes to the secondary of the SG as result the subcooled water that enters the SG becomes heated and at a given height from the bottom reach saturation conditions, so the heat transferred from the tubes beyond this height is invested only in steam production. Under normal operating conditions the SG secondary is flooded with a biphasic water/steam mixture, so a breach or tube rupture (TR) in one of the tubes produces a discharge of steam into the biphasic mixture and most of the steam condenses and radioactive impurities carried by the steam get absorbed into the secondary side pool. However under accident conditions (SGTR meltdown sequences) the secondary side water level can be located under the tube breach. In this last case a gaseous jet at high velocity and temperature is discharged into the secondary side of the SG. This jet carries radioactive aerosols particles from the primary to the secondary. So the understanding of the hydrodynamics of the jets produced in the tube breach is essential to asses the safety consequences of the tube rupture inside the SG especially when the rupture takes place over the secondary water level. Several experiments in conjunction with computational and analytical studies have been performed in CIEMAT and UPV on this subject as part of the ARTIST international project [1]. This paper shows the accomplishments in modelling the jets produced in SGTR scenarios and the comparison with experimental data.

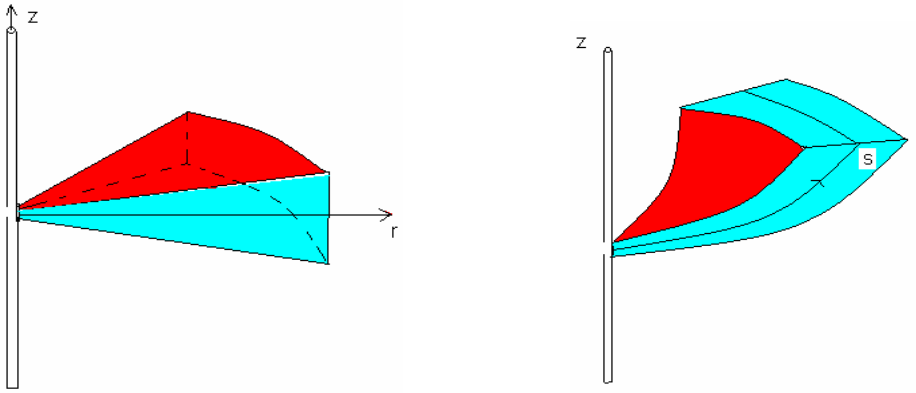
HIDRODYNAMICS OF JETS FROM GUILLOTINE TUBE RUPTURE

In a first step we analyse the hydrodynamics of free jets from guillotine tube rupture, in a second step we will assume that the jet is produced inside an enclosure of the dimensions of an SG and open in the upper part.

Hydrodynamics of a free jet from a tube with radial symmetry

First we start with the most simple case i.e. a jet from a tube with radial symmetry and free, we will assume that there are not forces that can bend the jet and the initial velocity of the jet has only radial component, the geometry of this jet is displayed in figure 1-a



(a) (b)

Figure1 Geometry of a jet from a steam generator tube rupture (SGTR), figure (a) is for an ideal free jet produced in a guillotine tube rupture with only velocity radial component, figure (b) is for a jet with initial velocity components in the radial and axial direction and forces that bend the jet.

If $u_r(r,z)$ denotes the radial velocity component then assuming that the total momentum M_j of the jet in the radial direction is conserved we can write:

$$M_j = 2\pi r_0 \rho u_j^2 D_r = \rho \int_{-\infty}^{+\infty} u_r^2(r,z) 2\pi r \, dz \qquad (1)$$

where u_j is the initial velocity of the jet, and r_0 is the tube radius, and D_r the height of the breach. If we assume that the radial component of the velocity follows a Gaussian distribution [2]:

$$u_r(r,z) = u_c(r) exp\left(-\frac{z^2}{(\delta(r))^2}\right) \qquad (2)$$

where $u_c(r)$ is the centre jet velocity at a distance r from the rupture and $\delta(r)$ is the jet width. From equations (1) and (2) it is deduced:

$$M_j = \rho u_c^2(r)\delta(r)\sqrt{2}\,\pi^{3/2} r \qquad (3)$$

Assuming that the jet width increases linearly with the distance r, i.e. $\delta(r) = c_1 r$, it is obtained from equation (3) that the velocity at the jet centre is given by:

$$u_c(r) = \sqrt{\frac{M_j}{\sqrt{2}\pi^{3/2}\rho}} \frac{1}{\sqrt{c_1 r}} = \frac{C_c}{r} \qquad (4)$$

The continuity equation on account of the symmetry of the problem can be written as follows:

$$\frac{1}{r}\frac{\partial}{\partial r}(r\,u_r(r,z)) + \frac{\partial}{\partial z}(u_z(r,z)) = 0 \qquad (5)$$

And the momentum equation in the radial direction is:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\,u_r^2(r,z)\right) + \frac{\partial}{\partial z}\left(u_z(r,z)u_r(r,z)\right) + \frac{\partial}{\partial z}\left(\overline{u_z'(r,z)u_r'(r,z)}\right) = -\frac{1}{\rho}\frac{\partial p}{\partial r} \qquad (6)$$

Where the Reynolds stress is given by $\tau_{Rey} = -\overline{\rho u_z'(r,z) u_r'(r,z)}$. The next step is to integrate the continuity equation between 0 and z, assuming that the axial velocity component is zero at the jet centre, this operation yields the following result for the axial velocity component $u_z(r,z)$:

$$u_z(r,z) = -\int_0^z \frac{1}{r}\frac{\partial}{\partial r}(r\,u_r(r,z))dz = u_c(r)c_1\left(\xi\, exp\left(-\xi^2\right) - \frac{\sqrt{\pi}}{2} erf(\xi)\right) \qquad (7)$$

Where $erf(\xi)$ is the error function and $\xi = z/\delta(r)$. If we plot the ratio $u_z(r,z)/u_c(r)$, of the axial velocity component and the velocity and the jet centre, versus ξ, we obtain the upper curve of figure 2, displayed with (o) circles. We observe that the axial velocity component only shows incoming flow or "inflow" toward the jet from the surrounding, also we observe that the incoming flow velocities from the upper and lower parts of the jet have the same absolute value and opposite directions. The prediction of this model is that it do not occurs outflow in the jet centre. We remind that in the study performed by Agrawad and Prassad [2] with a jet with planar symmetry, they found the existence of "outflow" from the jet centre up to a relative distance of $\xi = 1$. Then the results of the tube rupture with radial symmetry are at this point different from the case of a jet discharge with planar symmetry.

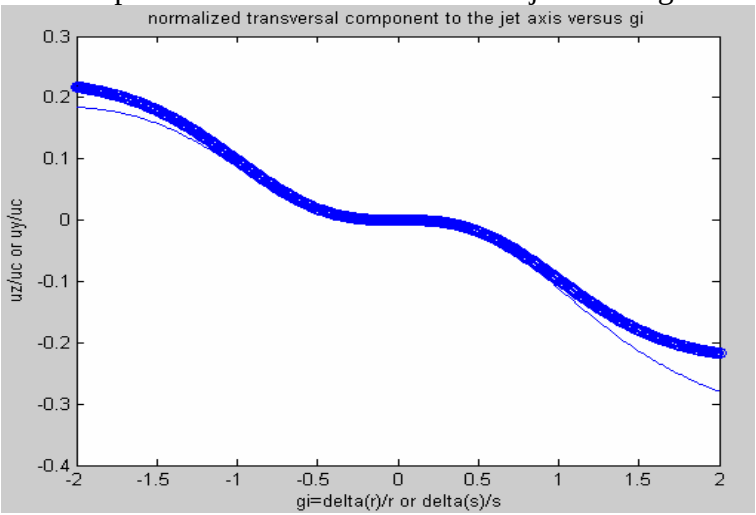


Figure 2 Normalized transversal velocity component to the jet axis versus ξ .The upper curve displays $u_z(r,z)/u_c(r)$, versus $\xi = \delta(r)/r$ for the free radial jet from a SGTR with only radial component at the rupture. The lower curve (thinner line) displays the normalized velocity component $u_y(s,y)/u_c(s)$ versus $\xi = \delta(s)/s$, for a curved jet with radial symmetry.

The next step is to compute the Reynolds stress by integrating equation (5) from jet centre up to the distance z, and assuming that at the jet centre the Reynolds stress vanished by symmetry . This calculation yields:

$$\overline{u_z'u_r'}(r,z) = -\frac{1}{r}\int_0^z \frac{\partial}{\partial r}\left(u_r^2\, r\right) dz - u_z(s,r)u_r(s,r) = c_1 u_c^2(r)\frac{\sqrt{\pi}}{2} exp\left(-\xi^2\right) erf(\xi) \qquad (8)$$

The profile of the normalized shear stress i.e $\overline{u_z'u_r'}/u_c^2$ is the same one that for the planar jet.

Hydrodynamics of a curve jet from a tube with radial symmetry

This case of the jet bending up is displayed in figure 1-b. This is the situation observed experimentally by Velasco, Del Prá, and Herranz [3]. The causative mechanism of the jet bending is that the jet initial velocity has two components one radial and other axial in the positive direction of the z axis, and when it penetrates in the surrounding gas loss radial momentum by friction and because the enclosure is open in the upper part there is an up-flow that produces a drag effect on the jet provoking a progressive jet bending with a pseudo-parabolic trajectory.

To solve the problem we adopt the curvilinear coordinates (natural) displayed in figure (3), i.e. the distance s along the jet centreline, the distance y along the orthogonal to the jet centreline, and the polar angle ϕ. Assuming that this problem has polar symmetry the conservation equations are:

Continuity equation

$$\frac{1}{r}\frac{\partial\left(r\,u_s(s,y)\right)}{\partial s}+\frac{1}{r}\frac{\partial\left(r\,u_r(s,y)\right)}{\partial y}=0 \tag{9}$$

Momentum conservation equation in the jet (stream) direction:

$$\frac{1}{r}\frac{\partial\left(r\,u_s^2\right)}{\partial s}+\frac{1}{r}\frac{\partial\left(r\,u_s\,u_y\right)}{\partial y}=-\frac{1}{r}\frac{\partial}{\partial y}\left[r\left(\overline{u_s'\,u_r'}\right)\right]-\frac{1}{\rho}\frac{\partial p}{\partial s} \tag{10}$$

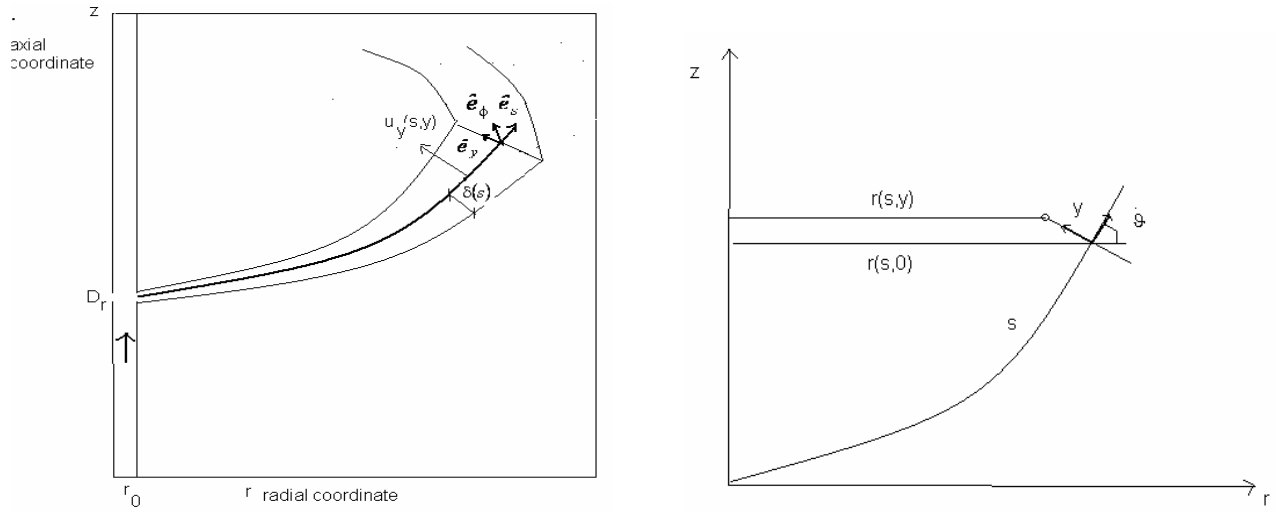

Figure 3 Natural curvilinear coordinates for a jet produced in a guillotine SGTR.

The experiments performed by Velasco et al [3] confirm that 60 mm away from the discharge point, the velocity profile in the direction of the stream is practically Gaussian and symmetric with respect to the jet centreline. We have assumed that the jet width $\delta(s)$ increases linearly with s, this approximation is a standard one for turbulent jets [4]. To have an approximate analytical solution we assume that the velocity component in the stream direction i.e $u_s(s,y)$, can be approximated by a Gaussian distribution, also we assume that the jet momentum is conserved in the s direction. Therefore we write:

$$u_s(s,y)=u_c(s)\,exp\left(-y^2\Big/(\delta(s))^2\right) \tag{11}$$

And the conservation of the jet momentum in the s direction gives:

$$M_j=\rho\int_{-\infty}^{+\infty}u_s^2\,2\pi r(s)dy=\rho\,u_c^2(s)\int_{-\infty}^{+\infty}\left(exp\left(-\frac{y^2}{\delta(s)}\right)\right)^2 dy=\sqrt{2}\;\pi^{3/2}\rho\,(u_c(s))^2\,r(s)\delta(s) \tag{12}$$

The assumption of linear variation of the jet width $\delta(s)$ with the distance s leads to the following expression for the jet centreline velocity:

$$u_c(s)=\sqrt{\frac{M_j}{\sqrt{2}\,\pi^{3/2}\rho}}\;\frac{1}{\sqrt{c_1}\,\sqrt{r(s)}\,s^{0.5}} \tag{13}$$

Next we need to compute the expression that gives the radial distance in terms of s, distance to the jet exit along the jet trajectory. Performing a dimensional analysis similar to the one performed by Ramaprian and Haniu [5], it is found that the jet trajectory obeys the following equation:

$$\frac{z-z_0}{l_m}=C\left(\frac{r}{l_m}\right)^{\alpha} \tag{14}$$

Where z is the axial coordinate assuming the origin in the break point, r is the radial coordinate, and l_m is the momentum length scale, defined for this particular case as the momentum per unit of circumferential length divided by the square of the reference velocity:

$$l_m = \frac{\left(M_j / 2\pi r_0\right)}{v_{j,0}^2} = \left[1 + \left(\frac{u_{j,0}}{v_{j,0}}\right)^2\right] D_r \tag{15}$$

$u_{j,0}$, and $v_{j,0}$ are the radial and axial components of the jet velocity at the tube rupture.

Equation (14) can be used to compute the arc length along the jet trajectory that yields:

$$s(r) = \int_{r_0}^{r} \sqrt{1 + \left[z'(r_1)\right]^2}\, dr_1 = \frac{2}{3b}\left[(1 + br)^{3/2} - (1 + br_0)^{3/2}\right] \tag{16}$$

Where, b is given by the expression:

$$b = \frac{C\,\alpha^2}{(l_m)^{2(\alpha-1)}}, and\ br_0 << 1 \tag{17}$$

From equation (16) it is obtained that de dependence of $r(s)$ with the arc length s is given by:

$$r(s) = \frac{1}{b}\left[\left(1 + \frac{3}{2} b\, s\right)^{2/3} - 1\right] \tag{18}$$

The value of b is approximately equal to 6.7 10^{-3} mm when s is expressed in mm. therefore for small values of s expanding $(1 + 1.5\, b\, s)^{2/3}$ in Taylor series it is obtained that varies linearly with s, however from equation (18) it is deduced that for large values of s, r(s)~$s^{2/3}$. Therefore the velocity at the jet centre diminishes with the law $s^{-\beta}$, where $\beta \in [0.83, 1]$. We have chosen for the decaying parameter β the middle value of the interval i.e. $\beta = 0.92$. As a consequence we have assumed that the velocity at the jet centre follows the law:

$$u_c(s) = C_c\, s^{-\beta},\ with\ \beta = 0.92 \tag{19}$$

The next step is to integrate the continuity equation (9), to do this we need to obtain r(s,y), that according to figure (3-b) is given by:

$$r(s,y) = r(s,0) - y\, sen\vartheta = r(s) - y\frac{\left(\frac{\partial z}{\partial r}\right)}{\sqrt{1 + \left(\frac{\partial z}{\partial r}\right)^2}} = r(s) - c_y\, y \tag{20}$$

To obtain the velocity component $u_y(s,y)$ orthogonal to the jet trajectory , we integrate the continuity equation between the coordinate y=0 at the jet centre and y, and we take on account the fact that at the jet centre the velocity component in the $\vec{e}_y$ direction is zero, so we write:

$$u_y(s,y) = -\frac{1}{r(s,y)}\int_0^y \frac{\partial}{\partial s}\left(u_s(s,y')\, r(s,y')\right) dy' = -\frac{1}{r(s,y)}\int_0^y dy'\left(r(s,y')\frac{\partial u_s}{\partial s} + u_s\frac{\partial r(s,y')}{\partial y'}\right) \tag{21}$$

Performing the calculations that appear in equation (21) with the help of equations (11), (19), and (20) it is obtained after some calculus the following result:

$$u_y(s,y) = \frac{u_c(s) c_1}{4}\frac{r(s)}{r(s,y)}\left\{4\,\xi\, exp\left(-\xi^2\right) - 2\left[(1-\beta) + \frac{\left(\partial r(s)/\partial s\right)}{\left(r(s)/s\right)}\right]\right\}\sqrt{\pi}\, erf(\xi) +$$

$$+ \frac{u_c(s) c_1\, \delta(s)}{r(s,y)} c_y(s)\left\{\left(1 - \frac{\beta}{2}\right) - \left[\left(1 - \frac{\beta}{2}\right) + \xi^2\right] exp\left(-\xi^2\right)\right\} + \frac{u_c(s)\delta^2}{r(s,y)}\frac{\partial c_y(s)}{\partial s}\left\{1 - exp\left(-\xi^2\right)\right\} \tag{22}$$

Equation (22) gives the transversal velocity $u_y(s,y)$ of the curved radial jet, this equation reduces to equation (7) for the free radial jet from a guillotine SGTR if we assume no curvature $c_y(s)=0$, s=r and $\beta=1$.

If we plot $u_y(s,\xi)/u_c(s)$ versus ξ, in the interval [-2, 2], it is obtained the lower curve of figure 2 (thinner line). We observe that in this case we have only incoming flow toward the jet centre, as in the free radial jet from a guillotine SGTR. Also this case differs from the planar jet studied by Agrawal and Prasad that showed outflow near the jet centre. The main differences between the results of the radial free jet from a guillotine SGTR, with only radial velocity component at $r=r_0$ and the case of the curved jet is the loss of symmetry for the inflow velocity from the upper and lower parts of the jets at displayed in figure 2. The inflow transversal velocities are higher at the upper part of the jet or concave side (positive values of ξ), than in the lower part of the jet or convex (negative values of ξ) as displayed in figure 2. This fact has been confirmed experimentally by Velasco et al. [3] that found that the resulting pseudo-parabolic jet gives rise to a non-symmetric gas entrainment around it where suction is more intense at the concave side.

MODEL COMPARISON WITH EXPERIMENTAL DATA AND DISCUSSION

In this section we obtain the model parameters from the experimental data of Velasco et al. [3]. Velasco at al carried out a set of experiments on jets produced in guillotine tube rupture with and without other tubes. The first set of experiments were performed with an isolated tube with a guillotine rupture of height D_r=0.24 D, and a tube diameter D=19.05 mm. Because the upper part of the tube is closed, the flow leaves the tube through the rupture expanding in the enclosure containing the tube. Five runs were performed (see table 1) denoted by its volumetric air flows Q_{air}. As seed material Velasco used TiO_2, injected as aerosol particles. The aerosol generator is based on the fluidized bed technology and allows the injection of 9.75 kg/hr of N_2 doped with aerosol particles of micrometer size. Table 1 displays the experimental conditions.

We performed a fit of the experimental jet trajectories to the curve of equation (14). The value of l_m was obtained from equation (15) and was set equal to 38.86 mm for all the runs. The parameter values C, α and z_0 obtained for the different runs are displayed at table 2, the last column of this table gives the relative error of the fit.

Table 1

Table 1 Experimental conditions for the free jet inside a enclosure [3]

Run Number	Q_{air} Nm^3/hr	p_{in} bar	p_{pri} abs bar	p_{sec} abs bar	T_{pri} ºC	ρ Kg/Nm^3	$\dot{W}_{air}$ Kg/h	$\dot{W}_{air}+\dot{W}_{N_2}$ Kg/h
1	150	3	2	1.3	17.5	1.29	193.88	203.63
2	75	1.9	1.2	1.1	15	1.29	96.94	106.69
3	100	1.3	1.4	1.1	16	1.29	129.25	139.00
4	180	3.2	2.1	1.4	16	1.29	232.20	232.20
5	189	3.2	2.5	1.4	15	1.29	244.28	254.03

Table 2

Parameter values for the trajectories of the jets

Run	C	α	z_0 mm	Relative error %
75	0.456	1.227	6.0	3.24
100	0.345	1.508	8.0	6.24
150	0.283	1.531	9.0	7.90
180	0.285	1.552	9.1	10.55
189	0.295	1.561	10.0	12.03

Figure 4a displays the experimental data for the jet trajectory for run 3 with $Q_{air} = 100\, Kg/hr$, the bubbles are the experimental data, while the continuous line is the result of the fit to equation (14). Due to the inertia of the TiO_2 particles and because they change of direction at the tube rupture, they move near the tube exit at lower velocity than the carrier gas, and the measurements performed with the PIV in the first 30mm from the breach are not reliable. For this reason we use to compute the centreline velocity $u_c(s)$ only the jet velocity data that are 30 mm away from the breach. The expression used to fit the data is $u_c(s) = C_c / s^{0.92}$. The value of C_c for the case of 100 Nm^3/hr was 1006.62. Also we have compared this result with the one obtained using the planar model velocity that for the planar case (x,z) gives $u_c(s) = 176 / \sqrt{s}$ as displayed in the blue line of figure 4-b We can see that the radial model for the curved jet of this paper fits much better the experimental data except at short distances from the break where the TiO_2 particles have not attained the carrier gas velocity.

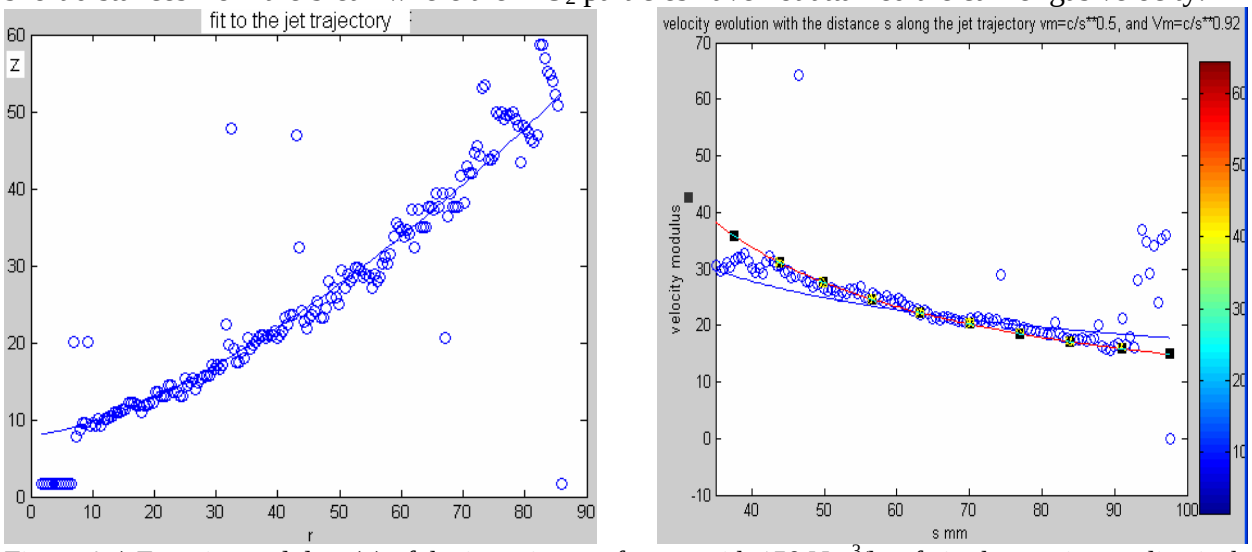

Figure 4 a) Experimental data (o) of the jet trajectory for run with 150 Nm^3/hr of air, the continuous line is the fit with the model of this paper, b) Centre jet velocity for the radial model of this paper (red line), the planar model (blue line) and the experimental data for the run of 100 kg/hr of air flow

.

For the case with an air flow of 75 Nm^3/hr it is clearly seen at figure (5-a) that the radial geometry model of this paper (red line) fit much better the experimental data for the jet centre velocity than the planar jet model. The expression obtained for the radial model was $u_c(s)=769.34/s^{0.92}$, and for the planar model (blue line) $u_c(s)=138/s^{0.5}$.

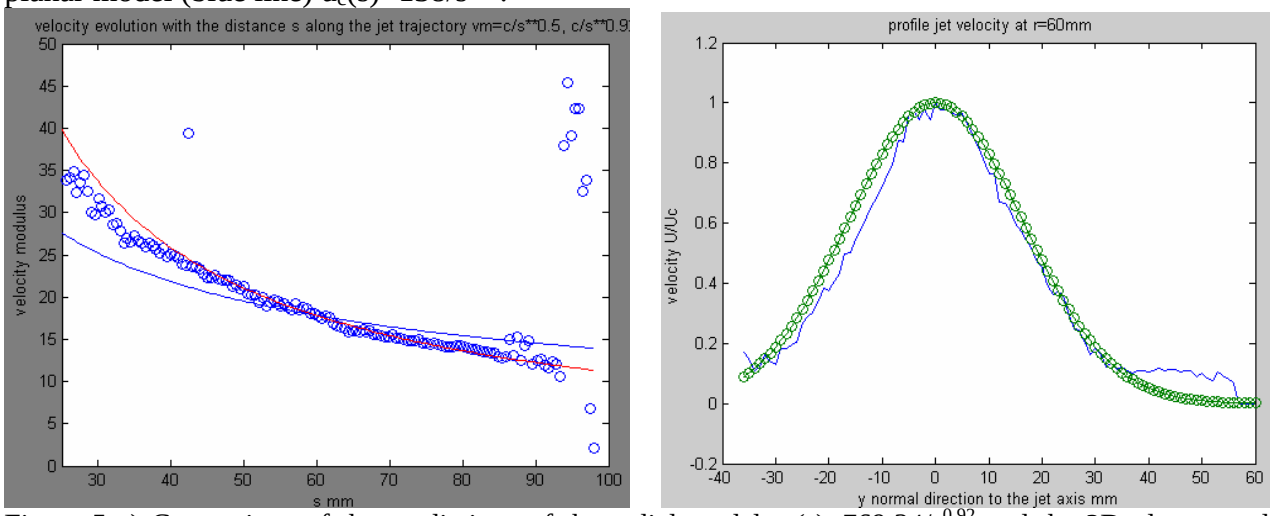

Figure 5 a) Comparison of the predictions of the radial model $u_c(s)=769.34/s^{0.92}$ and the 2D planar model $u_c(s)=138/s^{0.5}$ (blue line) with the experimental data (o). b) Normalized velocity distribution in the jet direction at 70 mm from the rupture for run 75. The experimental data are displayed in blue.

The last issue to be studied is the velocity distribution in the jet direction i.e $u_s(s,y)$. We have seen that at distances equal or bigger than 60 mm from the rupture the shape of the distribution is nearly Gaussian. The value of $\delta(s)$ was obtained by interpolation from the experimental data at 70 mm from the rupture using the spline method and looking for the point where the velocity it is reduced by a factor 1/e. Because we have assumed that $\delta(s) = c_1 s$, we obtain immediately the value of c_1 for this run. Figure (5-b) displays the velocity distribution in the jet direction at 70 mm from the tube rupture for run 75, we see that the distribution is practically Gaussian except at the end of the right hand side.

CONCLUSIONS

The understanding of the hydro-dynamics of jets coming from tube rupture is important to assess the consequences of SGTR accident scenarios of nuclear power plants. Also is important to have analytical expressions for the jet trajectories and velocities in order to have simple models to implement in the reactor safety codes under guillotine tube rupture scenarios. During the SGTR a high velocity steam jet is produced, this jet expands with the distance bending upward due to the initial velocity component in the axial direction, and to the fluid drag produced by the fluid leaving the SG at the dome upper part. We have found that the centre jet velocity diminishes with distance for all the cases with the law $u_c(s) = C_c / s^{0.92}$**,** this law has been compared with experimental data with good results. When we are far away 60mm from the rupture the velocity profile is practically Gaussian, however such symmetry breaks down near the rupture point.

It has been experimentally observed that the gas streamlines over and below the jet are attracted toward the jet producing an incoming transversal velocity toward the jet or inflow that fosters the development of the jet and diminishes the jet velocity at the centreline [3]; the model presented above is capable of capturing with reasonable accuracy gas ingestion and its effects. We have verified also this conclusion by CFD calculations performed with the ANSYS-CFX code. Therefore the tube guillotine SGTR jets display only inflow in the transversal direction to the jet. This behaviour is different in the planar jets that display an outflow region near the jet centre and then beyond $\xi = 1$display inflow.

ABSTRACT. There are different organic chemical reactions placed in processes of hydrocarbons refining such as a pyrolysis, oxidation, dehydratation, polymerization, nitration and others. Modelling and improvement of these processes is actual task for chemical industry and science. The efficient use of delivered energy, optimization of gas flows and heat transfer are still remains topical problems.

A flow reactor with the reactants heated by continuous CO_2 laser radiation is proposed for studying the gas phase homogeneous reactions. Ethane pyrolysis yielding ethylene is considered as an example of such chemical process. For this process, a mode of 'energetic catalysis' is feasible, where increasing energy absorption in the volume is related with the increased content of target product. The mode of 'energetic catalysis' was implemented at transformation of laser energy into thermal power using the sensitization properties of ethylene. In the pyrolysis reaction zone, temperature measurements were made for a gas mixture in the laser radiation field with a power density up to 10^2 W/cm^2. The walls and windows were isolated from the high-temperature zone by argon feeding and configuration of the reactor. Three-dimensional calculation of the gas-dynamics reactant flows and their mixing made with the FLUENT software package showed the presence of the modes where reaction zone with a high content of C_2 hydrocarbons is localized in the centre of reactor, which was confirmed by experiments. High values of ethane conversion up to 80 vol. % were obtained at nearby 53% selectivity for ethylene.

Keywords: *ethane pyrolysis, fluent, fluid flow*

INTRODUCTION

Endothermic chemical processes are carried out in the reactors with energy input to the reaction zone. Such reactors are distinguished by the energy source, which can be represented by electric arc, heat from combustion of a part of feedstock with oxygen in reactor, cyclic heating of catalyst, inert gas at a high temperature, or reactor tubes. A wide variety of the heating methods and endothermic chemical processes implies special-purpose designs of chemical reactors: turbulent flow reactors, reactors with shock waves in a tube, and plasma reactors.

The above-listed reactors are used to run the endothermic chemical processes like cracking and pyrolysis of hydrocarbons. However, the efficient use of delivered energy still remains a topical problem. For instance, when acetylene is obtained from methane by electric arc heating, only 30%

of supplied energy can be put into the energy of bond cleavage and formation of new chemicals bond. In this process, high rates of energy input provide fast heating of the reactants, which leads to a temperature gradient in the reaction zone up to 100 - 200 K/mm. However, in this case, spatial heterogeneity of the medium is observed, which decreases the selectivity for target products due to a pronounced temperature dependence of chemical reaction constants.

Another problem is related with optimization of reactants' residence time in the reaction zone to prevent the involvement of target products in secondary reactions. Thus, thermal dehydrogenation of C_2 - C_4 hydrocarbons yielding ethylene and propylene is characterized by high reactivity of these products at the temperatures of pyrolysis. This imposes specific constraints on the reactor design.

The use of laser radiation for heating the reaction medium makes possible the direct input of energy to the gas with the power density of $10^2 W/cm^2$, which exceeds by one and a half - two orders of magnitude the values attained in reactors with metal walls. This circumstance allows decreasing the time of reactants' pyrolysis to milliseconds. Possibility of using laser energy as a powerful energy source for the chemical reactors gives impact to the scientists for studying endothermal chemical processing. There are many different trends initiated in gas-core reactions studying, catalyst preparation, polymer films synthesis, heat-and-mass transfer, interaction between laser energy and gas environment, impact of laser energy on chemical reactions during 70-80 years of twenties century. At the power density below $10^5 \div 10^6 W/cm^2$, energy absorption and reaction occurrence at atmospheric and higher pressures follow the thermal mechanism. A necessary condition for application of laser radiation is that the reaction medium comprises a component which absorption spectrum contains the bands coinciding with the region of laser generation. In this case, the absorbed energy of laser radiation is transmitted at collisional relaxation to the reaction medium, thus heating it. When studying the process kinetics, it is important to provide the gas-phase occurrence of the reactions. A necessary thermal insulation of the reaction zone can be provided by buffer gas supercharging at the sites of laser radiation input and by a relatively cold mixture of reactants in the rest near-wall region of convectively cooled reactor. For cylindrical geometry, such mode can be implemented via a smaller section of laser beam as compared to reactor section.

This work presents results of the study of a flow reactor with laser input of energy for endothermic reactions exemplified by ethane pyrolysis. The reactions were conducted under homogeneous conditions at atmospheric pressure in the reactor with the reaction mixture components heated by the laser energy flux delivered directly into the gas. Ethylene, being among the main reaction products, served as the laser energy absorber. This created the mode of 'energetic catalysis'. Here, increasing energy absorption in the volume is related with the increased content of the reaction product.

The FLUENT software program tested with the experimental data of laboratory setup will allow using numerical methods to search for the reactor design, which will be further implemented in a pilot prototype.

REACTOR DESIGN

A schematic diagram of reactor indicating the temperature gauges layout is displayed in Figure 1. Reactor is made of a quartz tube with the inner diameter 20 mm and length 70 mm. Four inlets (8-1, 4, 5, 9) were used for Ar feeding into reactor to protect optical parts and decrease the effective length of the reaction zone. For the same purpose, stainless steel diaphragms (16) with straight-through diameter 12.5 mm were mounted in the chamber. The ethane-ethylene mixture was fed into reactor via inlet (8-7) in the central section.

Radiation power meter LM-2 unit. 6. Diffusing window (NaCl). 7. InfraLUM FT-801 Fourier transform spectrometer unit. 8-1,4,5,9 - Ar inputs. 8-2,3 - Gas mixture output. 8-7 - Ethane-ethylene mixture input. 8-6,8 - Closed plugs. 9. Radiation power meter TI-3 unit. 10. Chromatographs Crystal 2000M and LHM-80MD units. 11. UFGP-4 gas flow former. 12. Vacuum manometers. 13. Forevacuum pump unit. 14. CO_2 laser energy absorber. 15. Al mirror of the reactor. 16. Diaphragms.

Four inlets (8-2, 3, 6, 8) symmetric about the central axis were used to remove a mixture of reaction products with argon. In the same section, with a 90° shift, temperature gauges (17) were placed: a heat-insulated Mo plate 50 mkm in thickness and 2.5 mm in diameter - for pyrometric measurements, or a spiral thermistor made of copper wire 70 mkm thick, with coil diameter 3 mm and 0.4 Ω impedance. The axis of six-turn copper spiral and the plane of molybdenum gauge are oriented along the laser beam axis. In the same section with the gauges, a thermocouple is mounted in the chamber to measure the gas temperature at a distance of 0.5÷1 mm from the lateral wall of reactor.

To measure the brightness temperature and calculate the absolute temperature, we used an EOP-66 optical pyrometer with effective wavelength 0.655 mkm. The operating temperature range of pyrometer was 800-10000°C. The total rated measurement error for the luminance temperature in sub-range 800-1400°C did not exceed ±8°C. A correction for determination of the absolute (true) temperature related with the value of spectral radiative ability of Mo in the temperature range 800÷1000°C, $\varepsilon \approx 0.4$, was equal to +(45-60)°C. Irradiation of the pyrometric gauge was recorded through the quartz wall of reactor using a rotary mirror at a distance of nearby 2 m.

There are several reasons for choosing the copper thermistor for temperature measurements. First, the temperatures under consideration range from 300 to 1000°C. Second, thermistor should not affect the

processes in reactor. Third, the thermistor material should be resistant to CO_2 laser radiation with power density up to 200 W/cm^2 and have a low level of radiation absorption. It is necessary also to provide time resolution of ca. 1 s and the possibility of operation with standard measuring equipment.

MODELLING RESULTS

The mixing of gas flows in the 3D reactor geometry was calculated with the FLUENT software package. For all flows, FLUENT solves conservation equations for mass and momentum. Full description of mathematical model that used in FLUENT described in [1]. That was many tests on numerical model with different parameters of reactant and buffer gas flows, radiation model.

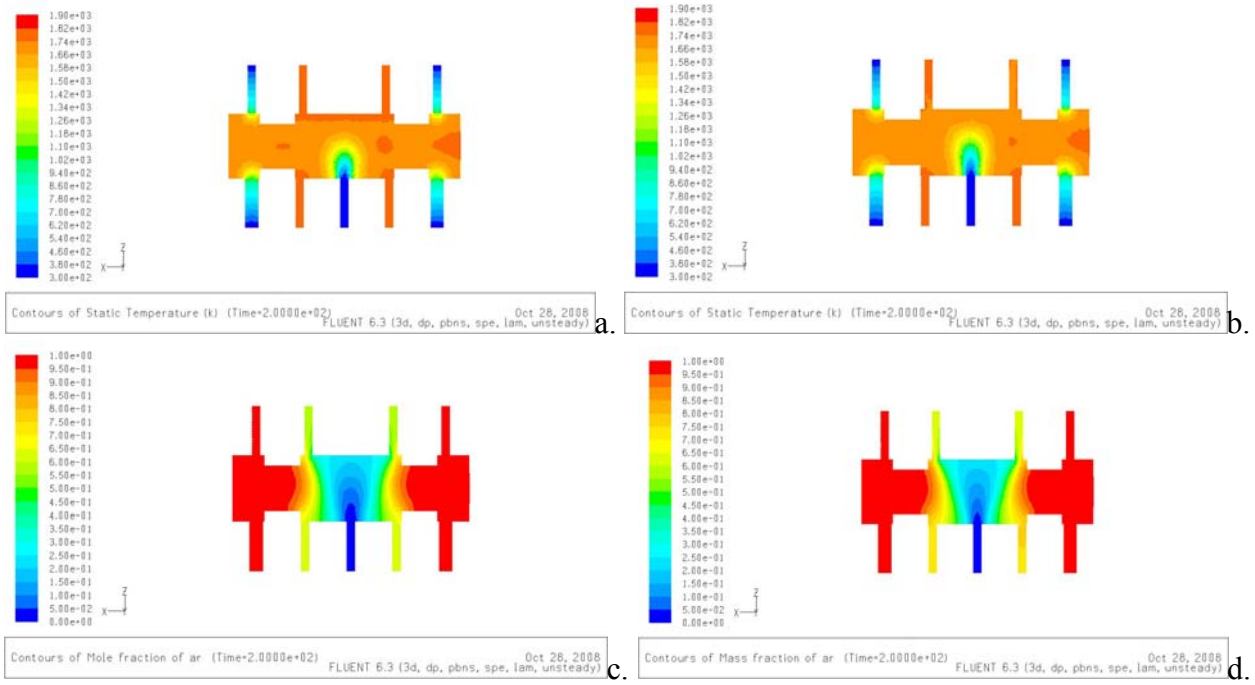

Figure 2. Contours of temperature (a,b) and Ar mass fraction (c,d) for C_2H_6-C_2H_4 mass flow rates 1.1 L/h (a,c), 2.1 L/h (b,d) and Ar mass flow rates 2.5L/h (a,c), 3.45L/h (b,d) at time 200s.

Results of mathematical modelling on the Figure 2 received with using of constant absorption coefficient (absorption of laser energy by reactants gases). This model does not equal to experiment because absorption coefficient depends on C_2H_4 concentration. But we can get the results of modelling gas flows very quickly (2-3 hours of FLUENT work on standard double cores processor) with a 20-30% error to experiment. We can see that Argon block reactant gases from windows 4, 15 on the Figure 1. It means that reaction products did not fall out on the windows and windows will be clear during chemical process.

Results on Figure 3 received with variable absorption coefficient that depends on C_2H_4 concentration. The user defined function for variable absorption coefficient was developed for FLUENT. This scheme is closer to the experiment. But the time of calculation is two times bigger than constant coefficient. The temperature in reaction zone is 1100-1200K that enough for starting of chemical reactions. Concentration of reactants and temperature at windows are very small for starting of chemical reactions.

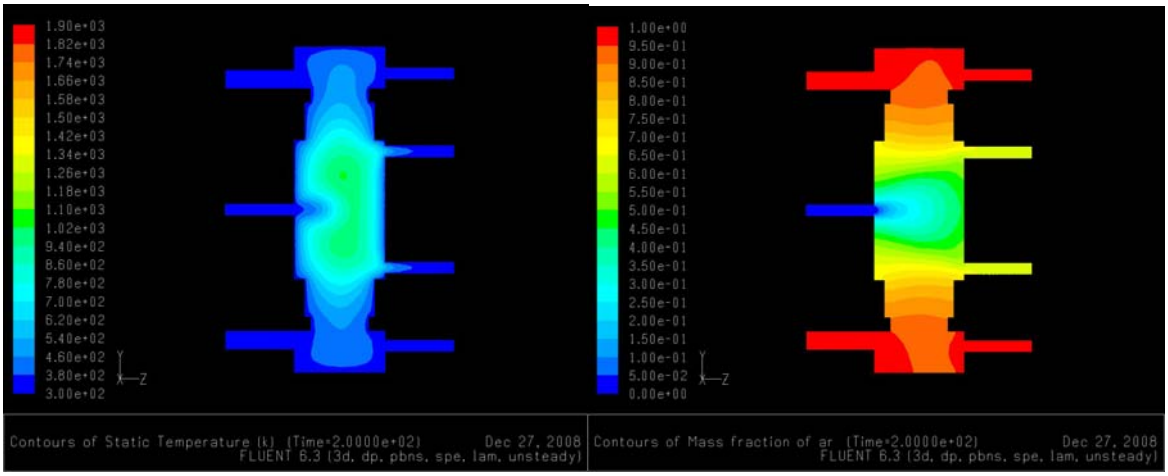

Figure 3. Contours of temperature and Ar mass fraction for C_2H_6-C_2H_4 mass flow rate 1.1 L/h and Ar mass flow rate 2.5L/h at time 200s.

EXPERIMENTAL RESULTS

In the experiments, total flow rate of argon was set at 3 L/h, and that of the ethane-ethylene mixture - at 1.7 L/h, with the 30% content of ethylene. Mixing of the gas flows was studied at 20°C and atmospheric pressure. For the reactor with diaphragms, the fraction of hydrocarbons near the reactor faces was found to be 17%. The axial distribution of hydrocarbons in reactor in the Ar-C_2H_6-C_2H_4 mixture is shown in Figure 4. Dark points correspond to experimental measurements. One may see that in the central part of reactor the fraction of hydrocarbons makes up 60% and far exceeds their amount near the face walls. More widely experiment was described in [2].

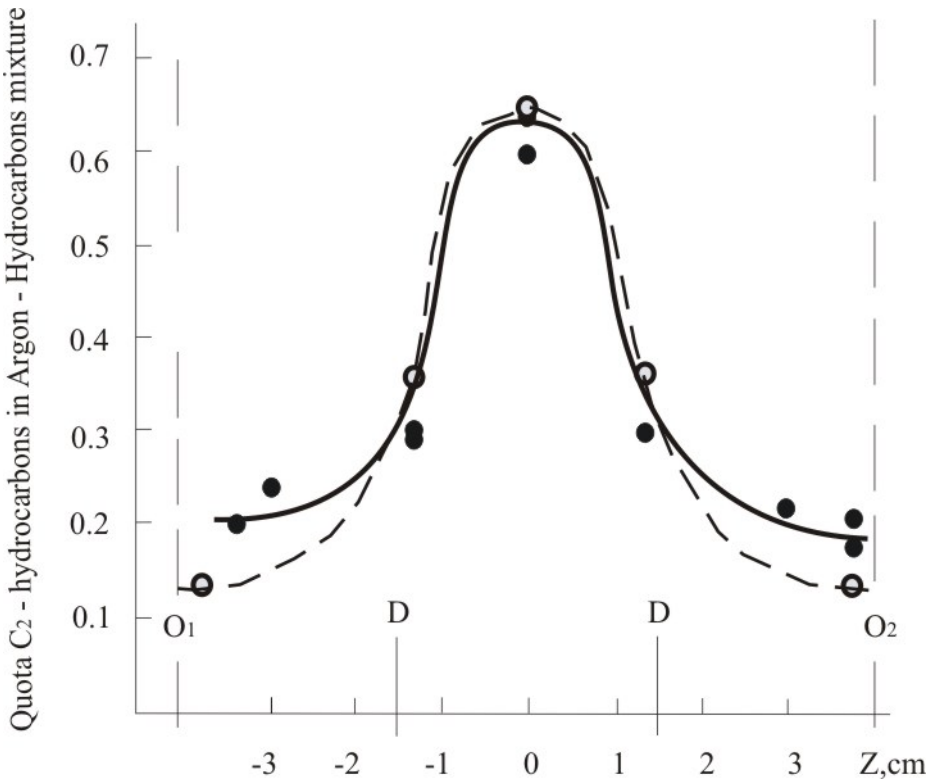

Figure 4. Distribution of hydrocarbons over the length of reactor in the experiments. O1 and O2 - reactor faces, D - diaphragm boundaries in the reaction zone. Dark points - experimental data. Hollow points - calculated data obtained with the FLUENT software.

CONCLUSION

A flow reactor with laser input of energy providing the homogeneous conditions for chemical process occurrence has been devised for the study of gas-phase reactions. Three-dimensional modelling of the gas flow mixing and heat transfer was made using the FLUENT program package for the reactor with geometrical dimensions corresponding to the pilot sample. A qualitative agreement between the calculated and experimental data was obtained. This confirmed applicability of FLUENT for designing of these type reactors. Formation of the reaction zone in the centre of reactor insulated from the chamber face walls with the buffer gas was demonstrated experimentally and supported by numerical modelling. A decreased temperature of the near-wall gas mixture indicates that the reaction zone is insulated also from other reactor walls. Ethylene was shown to be an efficient converter of laser energy to heat power at ethane pyrolysis.

Thus, ethane pyrolysis was performed in the mode of 'energetic catalysis', where energy absorption for endothermic reaction increased with increasing content of the reaction products. In the process, ethane conversion attained 80% at ethylene yield of 43%. As ethane conversion decreased to 70%, ethylene yield increased to 56%. Effective laser energy absorption in reaction zone was from 30% to 70% of total laser energy.

ABSTRACT. There are different thermodynamic models that have been applied for modeling of asphaltene precipitation in various crude oils. However, there is no reported experience in the literature that has compared the predictions of thermodynamic micellization model and solid model under pressure depletion and composition alteration conditions. Moreover, the impacts of different characterization methods on the accuracy of model predictions along with the effects of model parameters are not well understood. In this work, two computer codes which are based on two different asphaltene precipitation thermodynamic models, 1-Thermodynamic Micellization Model and 2- Solid Model, have been developed, and, used for predicting of asphaltene precipitation data reported in the literature under gas/solvent injection condition. The model parameters obtained from sensitivity analysis as well as various characterization methods, were applied in the thermodynamic models. The developed computer code of solid model is able to predict the asphaltene precipitation data under gas/solvent injection condition with a close agreement. Especially, for the maximum value of asphaltene precipitation and for the trend of the curve after the peak point, good agreements were observed which could rarely be found in the available literature. It has been observed that the thermodynamic micellization model, which is more complex than solid model, is able to predict the trend of the asphaltene precipitation curve for gas titration condition reasonably well. Also, its predictions matched well with more experimental data points in comparison to the solid model predictions.

Keywords: *Asphaltene Precipitation, Thermodynamic Modeling, Thermodynamic Micellization Model, Solid Model.*

INTRODUCTION

Asphaltenes are a solubility class of crude oils and are defined as the fraction that precipitates upon the addition of an n-alkane (usually n-pentane or n-heptane), but dissolves in aromatic solvents such as toluene. Asphaltenes can precipitate upon a change in pressure, temperature, and/or composition. For example, when pressure is drawn down around and within a wellbore, asphaltenes can precipitate and significantly reduce production.

For efficient process design, it is important to know *when* and *how much* asphaltene precipitation may affect the production of petroleum in all facets of field development. To predict precipitation, it is useful to develop thermodynamic models for describing the precipitation properties of dead and live oil fluids. Various thermodynamic models such as solubility model, solid model and thermodynamic micellization model have been reported in literature [1, 2, 3]. However quantitative representation is still far from satisfactory.

The simplest model for precipitated asphaltene is the single-component solid model that was tried by Gupta [4] and Thomas et al. [5]. Nghiem et al. [2] used solid model along with a robust flash calculation procedure for vapor/liquid/asphalt systems to predict asphaltene precipitation data from the literature and the industry under pressure depletion, gas or solvent injection conditions. They observed that their proposed model could not exhibit the correct behavior with increasing solvent concentration under gas/solvent injection condition.
Victorov and Firoozabadi [6] proposed a thermodynamic model that considers that asphaltene precipitation from petroleum fluid is a micellization process. This model has shown promising results in explaining most of the experimentally observed results. However, their proposed approach could not predict asphaltene precipitation data under gas titration condition with a close agreement.
In this work, various characterization methods, including different techniques for estimation of critical properties and acentricities of SCN's and pseudo components, were applied in both thermodynamic micellization model and solid model. The obtained values for matching parameters from sensibility analysis along with the chosen techniques for estimation of critical properties and acentricities of SCN's and pseudo components have been used and the ability of both models to reproduce correct behavior of asphaltene precipitation under gas titration condition has been improved. Finally, the improved ability of the thermodynamic micellization model for predicting asphaltene precipitation data under gas/solvent injection condition has been compared with the enhanced solid model ability.

THERMODYNAMIC MODELING

Solid model

Solid representation of precipitated asphaltene. The precipitate asphaltene is represented as a pure solid. For a given temperature T and pressure P assuming that the solid is incompressible, the fugacity of the solid phase is:

$$\ln f_s = \ln f_s^* + \frac{v_s\left(P - P^*\right)}{RT} \tag{1}$$

where $f_s, f_s^*, P, P^*, R, v_s, T$ are solid fugacity [kPa], reference solid fugacity [kPa], pressure [kPa], reference pressure [kPa], gas constant [$8.314\ kPa\, m^3/kmol\ ^oK$], solid molar volume [$m^3/kmol$], and temperature[$^oK$], respectively.

Oil and gas phases. The oil and gas phases are modeled with a cubic EOS with volume shift parameters. The PR-EOS is used for all calculations in this work. The fugacity of component i in phase j ($j = o, g$) is:

$$\ln f_{ij} = \ln f_{ij}^0 + \frac{s_i b_i P}{RT}; i = 1,...,n_c \quad j = o, g \tag{2}$$

where f_{ij}, f_{ij}^0, s_i are fugacity of component i in phase j with volume shift [kPa], fugacity of component i in phase j without volume shift [kPa], and dimensionless volume shift, respectively and b_i is the EOS "b" parameter for component i, i.e.

$$b_i = \frac{\Omega_b RT_{ci}}{P_{ci}} \tag{3}$$

where P_{ci}, T_{ci}, Ω_b are critical pressure of component i [kPa], critical temperature of component i [^oK], and dimensionless EOS parameter, respectively. The molar volume of phase j with volume shift is:

$$v_j = v_j^0 + \sum_{i=1}^{n_c} y_{ij} s_i b_i ;\ j = o, g \tag{4}$$

where v_j^0 is the EOS molar volume without volume shift.

Representation of asphaltene component. In a mixture of n_c components, let the asphaltene component be the $n_c - th$ component. When a gas phase, an oil phase and a solid phase coexist, the following thermodynamic equilibrium equations are satisfied:

$$\ln f_{ig} = \ln f_{io};\ i = 1,..., n_c \tag{5a}$$

$$\ln f_{n_c o} = \ln f_s \tag{5b}$$

The crucial step in the modeling of asphaltene is the split of the heaviest component in the oil (e.g, C_{31+}) into a non-precipitating component (C_{31A+}) and a precipitating component (C_{31B+}). These two components have identical critical properties and acentric factors, but different interaction coefficients with the light components. The precipitating component has larger interaction coefficients with the light components. Interaction coefficients between components are important parameters for phase behavior predictions. In this work, the interaction coefficients between hydrocarbons are calculated from:

$$d_{ik} = 1 - \left(\frac{2 \cdot v_{ci}^{1/6} \cdot v_{ck}^{1/6}}{v_{ci}^{1/3} + v_{ck}^{1/3}} \right)^e \tag{6}$$

where $d_{ik}, e, v_{ci}, v_{ck}$ are interaction coefficients between component i and k [*dimensionless*], adjustable parameter [*dimensionless*], critical volume of component i [$m^3/kmol$], and critical volume of component k [$m^3/kmol$], respectively. The interaction coefficients between the precipitating component (e.g. C_{31B+}) and the light components (e.g, C_1 to C_5) are set to a constant value, i.e.:

$$d_{ik} = \delta \tag{7}$$

while the interaction coefficients with the remaining heavier components are set equal to zero.

Flash calculations with a solid phase. Given a pressure *P*, a temperature *T*, and a mixture with global composition $z_i (i = 1,..., n_c)$, flash calculations determine the phase molar fraction and composition by solving equation (1). The complexity of multi phase flash calculations is due to the fact that the number of phases in equilibrium is not known a priori. More details can be found in previous works [2, 7].

Thermodynamic micellization model

Victorov and Firoozabadi [6] assumed in their model that an asphaltene-resin micelle is composed by n_1 aggregated asphaltene molecules forming a micellar core, and n_2 bipolar resin molecules which are adhered to the surface of the core. The material balance equations for the case of monodispersed micelles are given by:

$$N_a = N_{a1} + n_1 N_m(n_1, n_2) \tag{8}$$

$$N_r = N_{r1} + n_2 N_m(n_1, n_2) \tag{9}$$

With the precipitation of the asphaltene phase, the material balance equations should include the amount of precipitate. If the precipitated phase (phase γ) contains only pure asphaltene, equation (8) turns out to be:

$$N_a = N_a^{\gamma} + N_{a1} + n_1 N_m(n_1, n_2) \tag{10}$$

In the above equations, N_a and N_r are the number of asphaltene and resin molecules in the crude. N_{a1} and N_{r1} are the number of asphaltene and resin monomeric species, and N_m (n_1, n_2) is the number of micelles containing n_1 asphaltene molecules and n_2 resin molecules.
The micellar-monomer equilibrium equations that govern the aggregation process are:
Micelle chemical potential:

$$\mu_m = n_1 \mu_{a1} + n_2 \mu_{r1} \tag{11}$$

Monomeric resin and monomeric asphaltene chemical potentials:

$$\mu_{a1} = \mu_{a1}^* + kT \ln X_{a1} \tag{12}$$

$$\mu_{r1} = \mu_{r1}^* + kT \ln X_{r1} \tag{13}$$

and

$$\mu_m = G_M^{00} + kT \ln X_m \tag{14}$$

for the micelles.
In above equations, X_i is the mole fraction of species i, μ_{a1}^*, μ_{r1}^* and G_M^{00} are the standard chemical potentials. Equations (12), (13) and (14) lead to:

$$X_m = X_{a1}^{n1} X_{r1}^{n2} \exp(\Delta G_M^{00} / kT) \tag{15}$$

in which

$$\Delta G_M^{00} = n_1 \mu_{a1}^* + n_2 \mu_{r1}^* - G_M^{00} \tag{16}$$

is the standard Gibbs free energy of micellization. It represents the standard free energy difference between all asphaltene and resin molecules present in a micelle.
The standard Gibbs free energy of micellization, ΔG_M^{00}, represents various specific features of the micelle-formation process. These features have been represented in previous works [6, 8]. As the final result, ΔG_M^{00} can be calculated from:

$$\frac{\Delta G_M^{00}}{RT} = n_2 f(\theta) - n_1 \ln X_{a1}^{ons} \tag{17}$$

$$f(\theta) = \ln(1-\theta) + \frac{\Delta U_r}{RT} - \frac{\sigma_0 a(1-\theta)}{RT\theta} \tag{18}$$

θ, the fraction of micellar core covered by resins, can be calculated from:

$$\ln\left(\frac{X_{a1}}{X_{r1} X_{a1}^{ons}}\right) - \frac{\Delta U_r}{RT} - \frac{\sigma_0 a}{RT}(1+b) = \ln(1-\theta) - \frac{\theta}{1-\theta}(1+\theta b) \tag{19}$$

where $b = \frac{v_a}{a}\left(\frac{8\pi}{an_2^s}\right)^{1/2}$.

In above equations, ΔU_r is the energy of desorption per resin molecule, σ_0 is the interfacial tension between a micelle and the petroleum fluid at zero adsorption of resins onto a micelle, a is the surface area of the resin molecule polar head, v_a is the asphaltene molecular volume, n_2^s is the maximum number of the resin molecules which can be accommodated on the flat surfaces of a micellar core and X_{a1}^{ons} is the concentration of asphaltene monomers in the crude in equilibrium with the pure solid asphaltene phase. This last parameter is a characteristic of a given crude and is adjusted from experimental data on asphaltene precipitation for each individual crude mixture.

Having X_{a10}^{ons} at a reference condition, X_{a1}^{ons} can be calculated for other conditions, by using an EOS (In this work, the PR-EOS is used), from equations (20) and (21):

$$X_{a1}^{ons}(T,P,ratio) = X_{a10}^{ons}(T,P,ratio=0)\frac{\varphi_{a10}^{\beta}(T,P,ratio=0)}{\varphi_{a1}^{\beta}(T,P,ratio)} \tag{20}$$

where φ_{a1}^{β} is the fugacity coefficient of monomeric asphaltene species in the petroleum fluid medium β and *ratio* is the dilution ratio.

$$X_{a1}^{ons}(P') = X_{a10}^{ons}(P)\frac{\varphi_{a10}^{\beta}(T,P,x)P}{\varphi_{a1}^{\beta}(T,P',x')P'}\exp\left(\frac{v_a(P'-P)}{RT}\right) \tag{21}$$

where x is the composition at P.

APPLICATION OF THERMODYNAMIC MODEL

In this work, the experimental data of Burke et al. [9] is used to illustrate the modeling of the phase behavior of asphaltene precipitation during gas/solvent injection condition. The behaviors of both models with respect to different techniques for estimation of critical properties and acentricities of SCN's and pseudo components as well as changes in different model parameters are investigated.

Table 1 reports the composition of the oil and the solvent from Burke et al. [9]. The oil was mixed with various amounts of the solvent.

Oil component characterization

Solid model. The plus fraction of the oil was first split into single carbon number components and all the components are then lumped into pseudo-components using the method of Li et al. [10].

Table 1
Burke et al. (1990) Oil and Solvent

Components	Oil Mole%	Solvent Mole%
N_2	0.51	3.17
CO_2	1.42	17.76
C_1	6.04	30.33
C_2	7.00	26.92
C_3	6.86	13.09
i-C_4	0.83	1.26
n-C_4	3.35	4.66
i-C_5	0.70	0.77
n-C_5	3.46	1.26
C_6	3.16	0.78
C_{7+}	66.68	

The heaviest fraction C_{31+} was split into two components: a non-precipitating component, C_{31+A}, and a precipitating component, C_{31+B}. The mole fraction of C_{31+B} is calculated from the average weight percent of total precipitate [2, 7]. Then, the mole fraction of C_{31+A} is calculated from the difference between the mole fractions of C_{31+} and C_{31+B}. The interaction coefficients between all hydrocarbon components up to and including C_{31+A} were calculated from equation (6). The interaction coefficients between C_{31+B} and the light hydrocarbon components up to C_5 are assumed to have the same value δ in equation (7). For gas titration condition, δ affected both the saturation pressures and the amount of precipitates, and had to be adjusted simultaneously.

Thermodynamic micellization model. For modeling the behavior of a crude, it is absolutely necessary to know its composition including the total fractions of asphaltenes and resins. Unfortunately, these data are often missing in the literature. For the considered crude, the total asphaltene weight percent was taken from experimental data. Then, the method of Li et al. [10] for oil component characterization, which is commonly used in the thermodynamic solid model, was used. In this method, the heaviest fraction, C_{31+} is divided into two parts: C_{31+A} and C_{31+B}. C_{31+A} is the non-precipitating and C_{31+B} is the precipitating component. Since in this work we assume no resin precipitation, the amount of C_{31+A} can be set as the resin content of the crude [2]. The interaction coefficients between C_{31B+} and the light hydrocarbon components up to C_5 are assumed to have the same value δ. δ is obtained from sensitivity analysis. We set the interaction coefficients between C_{31A+} and the other hydrocarbon components equal to zero.

RESULTS AND DISCUSSION

Model sensitivity analysis

*Solid model***.** Matching saturation pressure and precipitation data simultaneously, yields e = 1.75 and δ = 0.24. Figure 1 compares calculated and experimental saturation pressures and figure 2 shows the comparison between calculated and experimental precipitates for Burke et al. oil. For solvent concentration above 78 mole percent, the measurements indicated a substantial drop in the precipitate. Burke et al. [9] and Chabak [11] attributed the decrease in the precipitate at high solvent concentration to the switching of the mixture from a bubble-point fluid to a dew-point fluid.

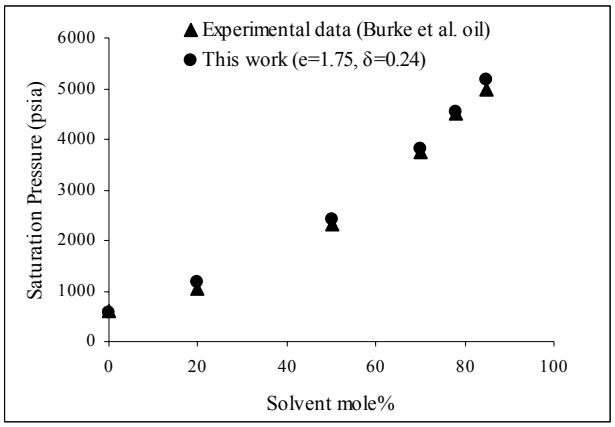

Figure 1. Saturation pressure of Burke et al. oil

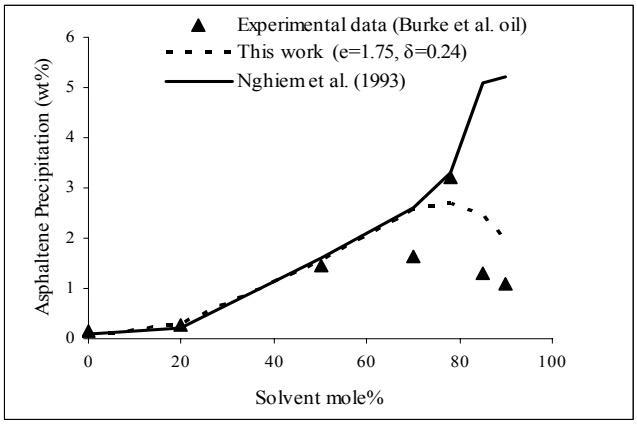

Figure 2. Model predictions for Burke et al. oil

The literature results [2] do not show a decrease in precipitation at high solvent concentration, but do exhibit a change in the precipitation behavior. Here, a significant improvement in model predictions can be observed. This work shows the decrease in amount of precipitation at high solvent concentrations. It can also predict the maximum of precipitation reasonably well. This improvement in the results is due to chosen characterization method including techniques used for estimation of critical properties and acentricities of SCN's and pseudo components, as well as the obtained values for matching parameters e and δ from sensitivity analysis. Various characterization

methods cause different values for fugacities of components and can make changes in final results. Since, at high solvent concentration, the mixture switches from a bubble-point fluid to a dew-point fluid [9], saturation pressure matching is a crucial step which can highly affect the accuracy of the model. Also, the matching is a difficult procedure due to this alteration. Figure 3 shows the effect of δ on model predictions. Larger value for δ, interaction coefficient parameter between C_{31B+} and light components, will cause larger amount of precipitation. Table 2 shows different runs with various characterization methods [12]. It can be found, from figures 4, 5 and 6, that the model is also sensitive to the chosen characterization methods, including techniques for estimation of critical properties and acentricities of SCN's and pseudo components.

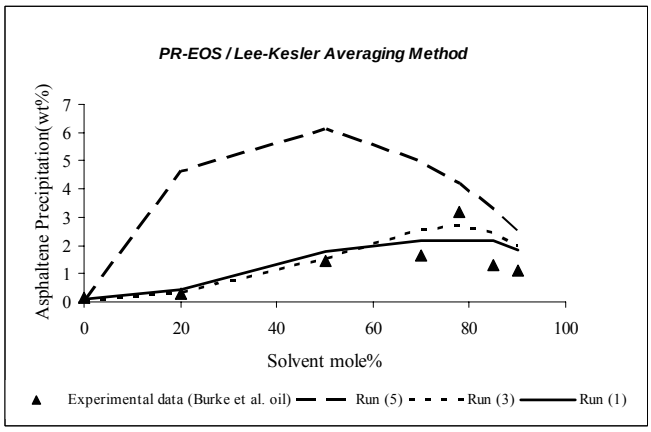

Figure 4. Effect of characterization methods

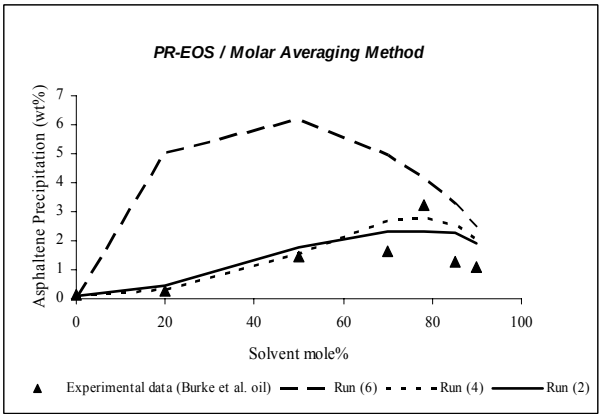

Figure 5. Effect of characterization methods

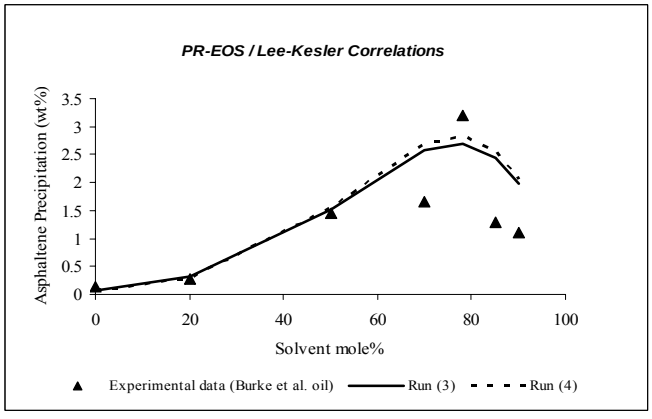

Figure 6. Effect of characterization methods

Thermodynamic micellization model. Figure 7 shows the model predictions using the micellization model parameters given in Table 3. The calculation procedure has been given previously [6]. By

sensitivity analysis, it can be found that the parameters ΔU_r and σ_0 play an important role in the micellization process. Lowering σ_0 will increase the stability of the aggregates. Hence, there is no precipitation for σ_0 = 0.045 N/m, and the model shows much more asphaltene precipitation at low mole percents of solvent with σ_0 = 0.080 N/m. The increase of the ΔU_r shifts the onset of asphaltene precipitation to the higher mole percents of solvent. At the value of 0.075 J/(mol.m^2) no precipitation can be observed. With ΔU_r = 0.065 J/(mol.m^2), the asphaltene precipitation at low mole percents of solvent would increase too much.

Figures 8 and 9 show the effect of chosen values for X_{a10}^{ons} and δ on model predictions. Figures 10 and 11 show the effect of temperature and resin content of the crude. Table 2 shows different runs with various characterization methods [12]. It can be found, from figures 12, 13 and 14, that the model is also sensitive to the chosen characterization methods, including techniques for estimation of critical properties and acentricities of SCN's and pseudo components.

Comparison of the thermodynamic micellization model and solid model

Figure 15 compares the asphaltene precipitation predictions of the thermodynamic micellization model and solid model under gas titration condition. It can be observed that both models are able to predict the experimental data reasonably well. The predictions of solid model, which is a simple model, show good agreements for the maximum value of asphaltene precipitation and for the trend of the curve after the peak point. In comparison to the solid model, the thermodynamic micellization model is a more complex model and its computational effort is more demanding than for the solid model. The thermodynamic micellization model is able to predict the trend of the asphaltene precipitation envelope reasonably well. It cannot predict the maximum of precipitation as well as the predictions of solid model but, its predictions matched well with more experimental data points in comparison to the solid model.

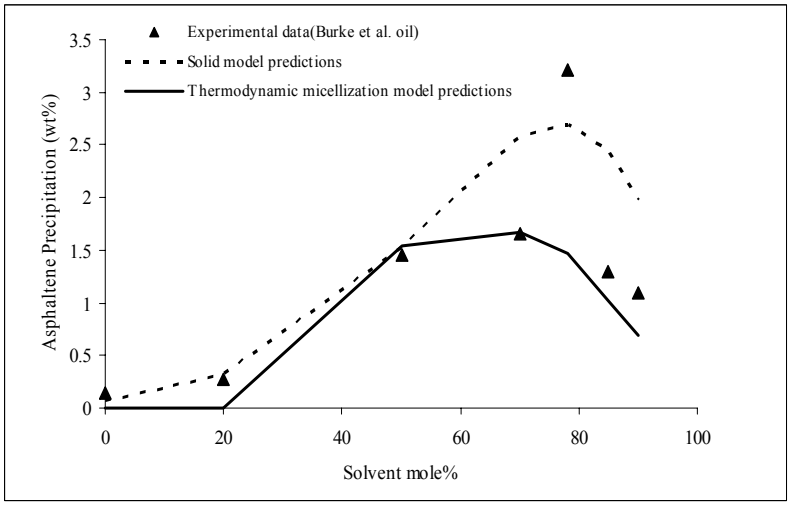

Figure 15. Comparison of the thermodynamic micellization model and solid model predictions

CONCLUSIONS

In this work, two computer codes which are based on two different asphaltene precipitation thermodynamic models, 1-Thermodynamic Micellization Model and 2- Solid Model, have been developed, and, used for predicting of asphaltene precipitation data reported in the literature under gas/solvent injection condition. The obtained values for matching parameters from sensibility analysis along with the chosen techniques for estimation of critical properties and acentricities of SCN's and pseudo components have been used and the ability of both models to reproduce correct behavior of asphaltene precipitation under gas titration condition has been improved. In the case of solid model, two adjustable parameters, e and δ, were required to match the experimental data.

Larger value for δ, interaction coefficient parameter between C_{31B+} and light components, will cause larger amount of precipitation. For thermodynamic micellization model, a characterization method which is commonly used in the thermodynamic solid model, has been applied for oil component characterization. This new approach showed a significant improvement in the thermodynamic micellization model predictions of asphaltene precipitation data under gas injection conditions. The sensitivity analysis on model parameters has shown that the model is highly sensitive to the resin content of the crude, ΔU_r, σ_0, X_{a10}^{ons} and δ. The last two parameters are our main adjustable parameters. The model sensitivity to the parameter δ is due to the new characterization method chosen for the thermodynamic micellization model. Also, it can be found from the sensibility analysis that both models predictions are highly sensitive to the chosen techniques for estimation of critical properties and acentricities of SCN's and pseudo components. Comparison of the thermodynamic micellization model and solid model showed that both models are able to predict the trend of asphaltene precipitation curve reasonably well. The thermodynamic micellization model cannot predict the maximum of precipitation as well as the predictions of solid model but, its predictions matched well with more experimental data points in comparison to the solid model. Also, it can be found that the thermodynamic micellization model is a more complex model and its computational effort is more demanding than for solid model.

ABSTRACT. Much is already known about the heat transfer characteristics of impinging air jets, and they are widely used in many engineering applications. There currently exist many correlations describing such characteristics. However, the complex internal structure of many nozzles can lead these to produce results which deviate from those predicted by correlations. One such nozzle is currently used in this research group to produce a water mist flow. This atomisation nozzle tends to produce a lower stagnation Nusselt number, but higher heat transfer for radial locations beyond two diameters from impingement.

Keywords: *Heat Transfer, Air Jet Cooling, Nozzle Geometry, Mist Jet Cooling*

INTRODUCTION

Length of paper
Impinging air jet nozzles have long been known to achieve superior heat transfer coefficients. The variation in their local heat transfer coefficients also lends itself to application in areas of large temperature gradients. Their ability to achieve effective cooling rates has led to their implementation in many situations including the replacement of lubricants in some machining operations. Previous work in the research group investigated their effect on grinding temperatures [1].

It is believed that the implementation of a fine water mist into the air stream has the potential to further increase the heat transfer rates. Indeed, Lee et al. [2] state that at droplet diameters of 30-80µm, a “superbly effective cooling scheme” is present. Convective heat transfer coefficients can increase by up to 10 times, through evaporation of an “ultra-thin” liquid film (50-100µm). The dispersal of water droplets into an air flow can be characterised as either spray cooling or mist jet cooling. A spray is obtained by pressurising the water in the nozzle in order to atomize it. Mist jets use the air pressure to atomize the water. Mist jets thus allow smaller droplet size [3]. The liquid flow can be controlled with less atomization constraints.

This paper seeks to compare time averaged heat transfer coefficients from two different nozzles. One nozzle is a simple round air jet nozzle, of diameter 4.5mm, made of copper piping. The other nozzle is an atomizing nozzle, Spraying Systems Co., involving a complex nozzle body, with air exiting through an annular hole, nominal diameter 3.5mm, figure 1. This nozzle will ultimately be used to investigate an air flow with entrained mist particles.

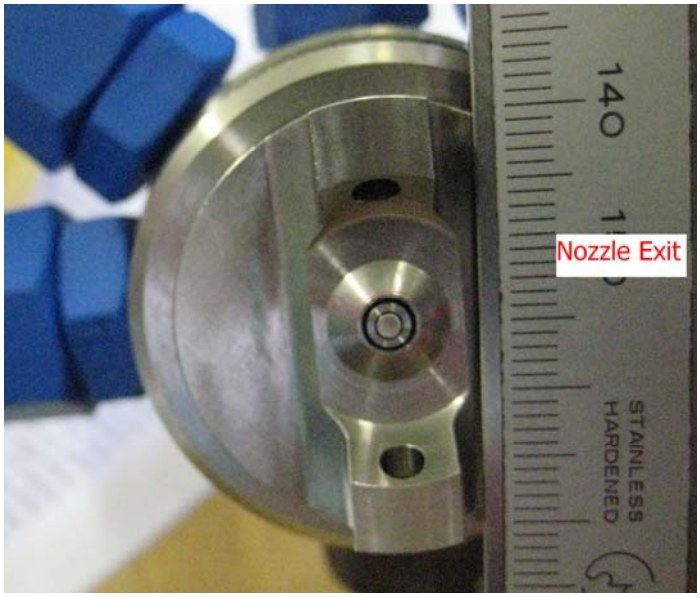

Figure 1. Nozzle profile

Nozzle geometry affects both the flow exit profile and the turbulence characteristics of the resulting flow. The flow structure will influence the local heat transfer distribution, through increased mixing of the thermal boundary layer. The effect of the nozzle exit shape on the velocity profile will also impact on heat transfer distributions [4]. Increased free stream turbulence has been noted by [5] due to the complex internal structure of the nozzle used in this investigation. Thus, the air jet itself is expected to give higher heat transfer coefficients than correlations predict [6, 7].

Chatterjee and Deviprasath [4] showed that the surface heat transfer coefficient can be influenced by the nozzle velocity distribution. The velocity distribution will be controlled by the nozzle exit conditions. Thus, nozzles of different geometries can have different heat transfer profiles. This effect becomes diminished at large H/D values. Kito et al [8] also showed the effect the contraction area ratio can have on surface heat transfer measurements.

The effect of angle of impingement is to relocate the maximum heat transfer coefficient. This occurs because the stagnation point is displaced in the direction of the angle, Goldsteain and Franchett (9)

Heat transfer coefficients tend to increase with increasing Reynolds numbers, in a similar manner to many correlations, e.g. the Lui and Sullivan [10]

$$Nu_0 = 0.585\,\mathrm{Pr}^{0.4}\,\mathrm{Re}^{0.5}$$
$$H/D < 2 \qquad (1)$$

It is expected that the complex nozzle will achieve similar dependencies.

EXPERIMENTAL SET-UP

A rig was built to investigate the effects of nozzle geometry on the heat transfer to an impinging jet. The test surface is an instrumented isothermally heated copper plate. In order to measure the local heat flux transferred from the surface to the jet flow, a hot film sensor and thermopile heat flux sensor are mounted flush with the copper plate. The thermopile sensor is used for obtaining time averaged data whereas the hot film sensor will be used at a later stage of the research to obtain fluctuating heat transfer measurements. Ambient, test surface, and nozzle fluid temperatures are

recorded by several thermocouples. A stepper motor is used to move the test surface with respect to the fixed nozzle, so as to achieve full field measurements.

Data acquisition is via a National Instruments chassis containing analogue and digital input and output modules and a thermocouple module. The microfoil sensors used are RdF 27036 sensors. The signal is amplified before being fed to the data acquisition system. Labview controls all the data handling. Figure 2 shows the schematic of the test apparatus, with H, the nozzle exit to plate distance.

The heat transfer measurement approach has been validated for an impinging air jet against known correlations described in the literature [10, 11, 12] and other experimental rigs. Extensive calibration was performed on the thermocouples with a factory calibrated RTD probe connected to an Omega thermometer. The microfoil sensor was calibrated using an air jet with circular nozzle of diameter 9.5mm. The nozzle was positioned at a jet-to-surface distance H/D of 1. The calibration was performed using the Liu and Sullivan correlation, relating the stagnation Nusselt number to the Reynolds number [10]. The Reynolds number was varied from 10,000 – 20,000.

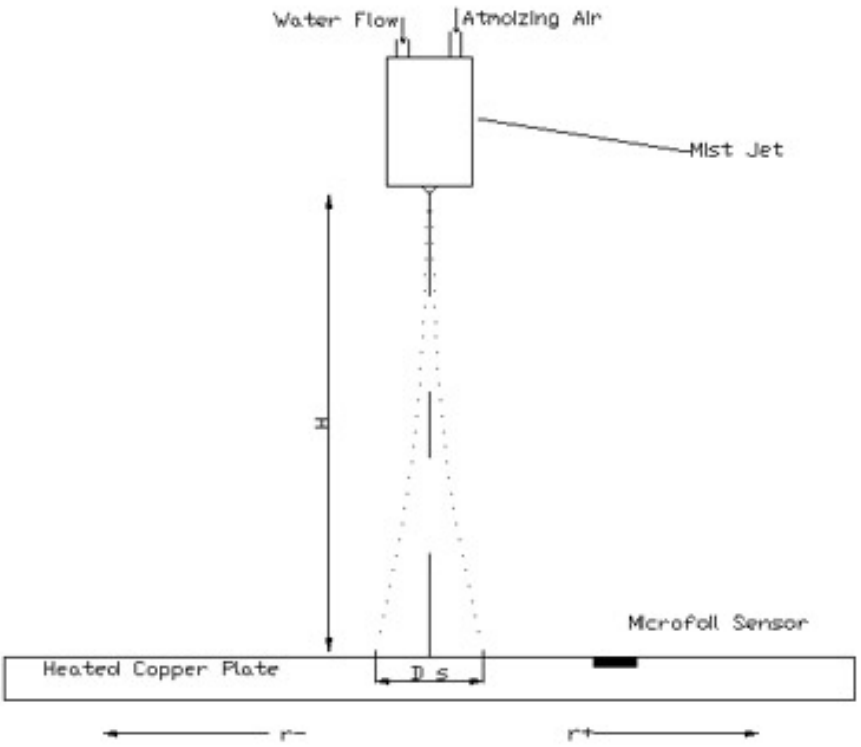

Figure 2. Schematic of the test apparatus

The hydraulic diameter, used for the atomizing nozzle has been defined as four times the cross sectional area (A) divided by the wetted perimeter (U) [13].

$$D = \frac{4A}{U} \tag{2}$$

This value is then used as the characteristic length (D) in all Reynolds number, H/D and r/D spacing. The nozzle exit profile can be seen in figure 1 and is of an annular profile. The nominal or hydraulic diameter has been calculated as 3.5mm. The pipe nozzle was chosen to be close in size to

it; it has a diameter of 4.5mm. As can be seen from figure 2, the nozzle can be varied relative to the test rig, so as to achieve full field measurements.

$$h = \frac{\ddot{q}_{conv}}{T_s - T_{jet}} \tag{3}$$

Heat transfer coefficients associated with the jets are based on the jet temperature of the air flow, eqn 3. This is measured by the air mass flow meter immediately upstream of the nozzle, and is typically 20°C.

The full extent of the rig consists of a water gear pump, pressure and flow meters. This enables water to be pumped to the atomising nozzle at high pressure. Water droplets are thus dispersed into an airstream, creating a mist flow.

RESULTS AND DISCUSSION

Analysis of both atomizing nozzle and pipe nozzle are presented for a range of Reynolds numbers and angles. Comparisons are provided to illustrate the difference in heat transfer obtainable through the complex atomizing nozzle.

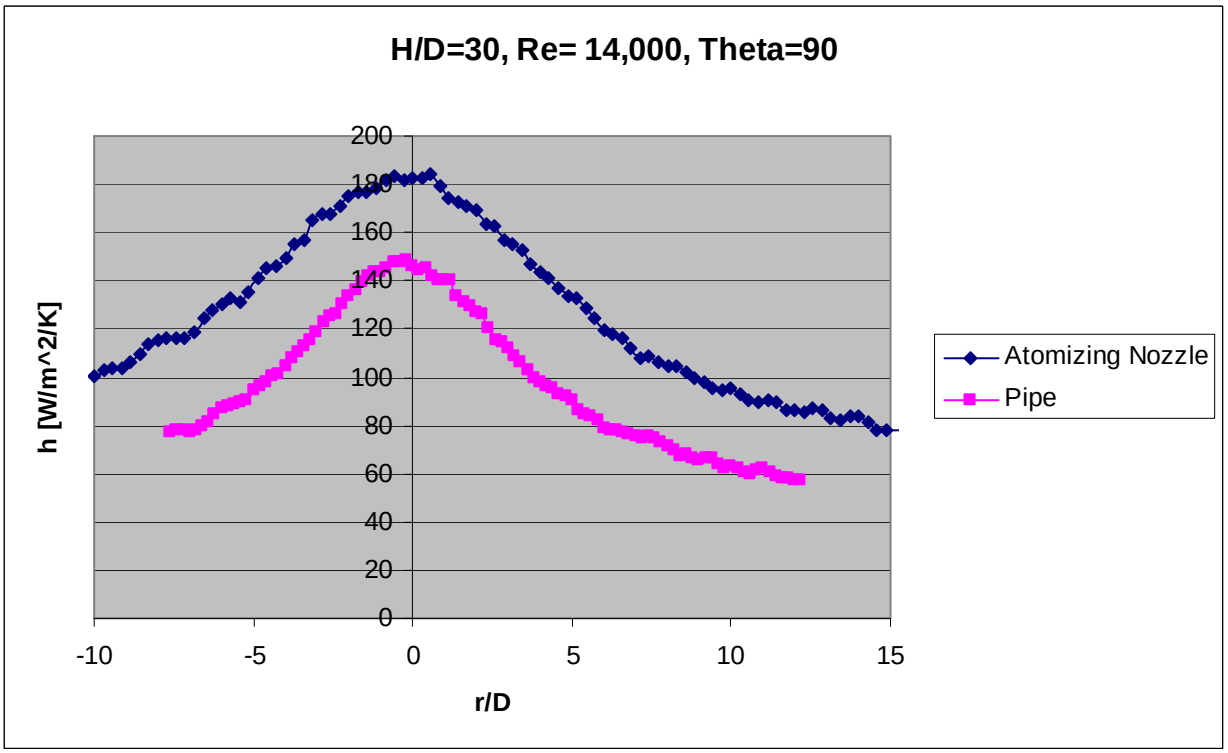

Figure 3. Atomizing vs Pipe Nozzle

Figure 3 shows the heat transfer profiles at a Reynolds number of 14,000, H/D of around 30 and an impingement angle of 90°. The atomizing nozzle shows higher convective coefficients across the r/D profile. It is interesting to note that since the data is for identical Reynolds numbers, yet different nozzle widths, the pipe jet actually has a 40% higher mass flow rate of air, yet achieves lower heat transfer coefficients. Although, corresponding stagnation Nusselt numbers (figure 4) are 10% higher in the pipe jet, and maintain an increase until an r/D of about 2. At such large H/D (>10), the annular exit

profile should not be impacting greatly on the stagnation region. (insert reference). Any potential core effects should have dissipated within 6 diameters, Hrycak et al [14]. Overall Nusselt numbers appear quite similar at large H/Ds similar to that noted by Chatterjee and Deviprasath [4].

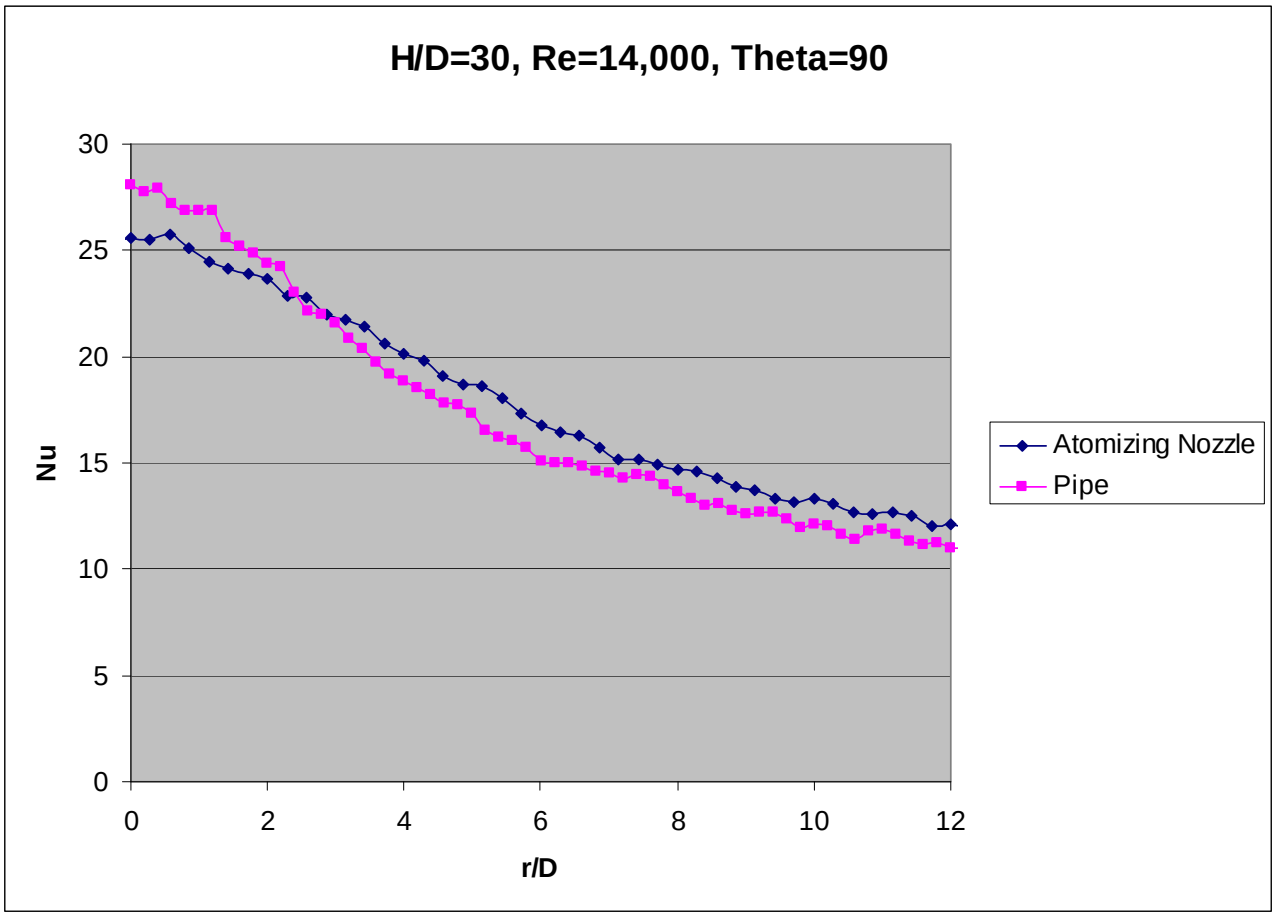

Figure 4. Nusselt number H/D =30

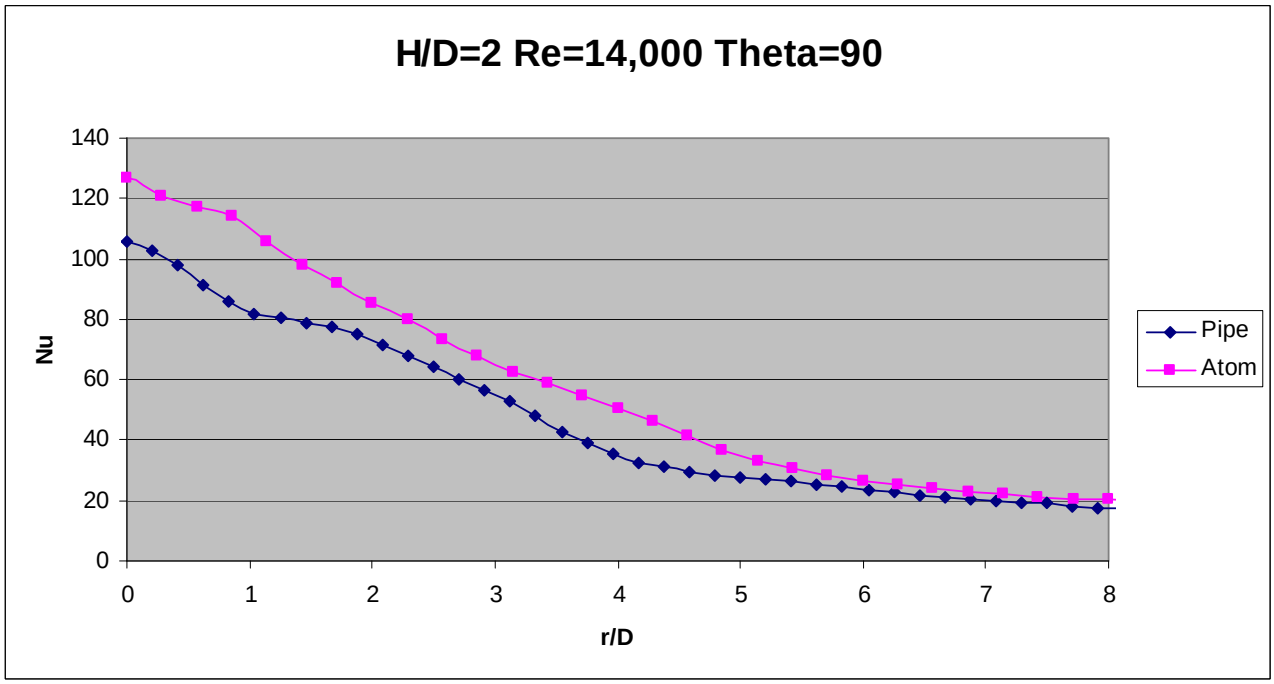

Figure 4b. Nusselt number H/D = 2

Figure 4b shows a comparison of Nusselt numbers for the pipe and atomizing nozzle at an H/D=2. The development of local secondary peaks at approximately one to two diameters can be seen. It is worth noting that the secondary peaks in the pipe nozzle are much more defined than that of the atomizing nozzle. In this case the atomizing nozzle outperforms the pipe nozzle across the radial distribution. The atomizing nozzle exists as an annular profile but shows none of their characteristics; offset maximum heat transfer and reverse stagnation point occurrence in the flow field noted by Chattopadhyay [15] although the Reynolds numbers used in this study are much higher.

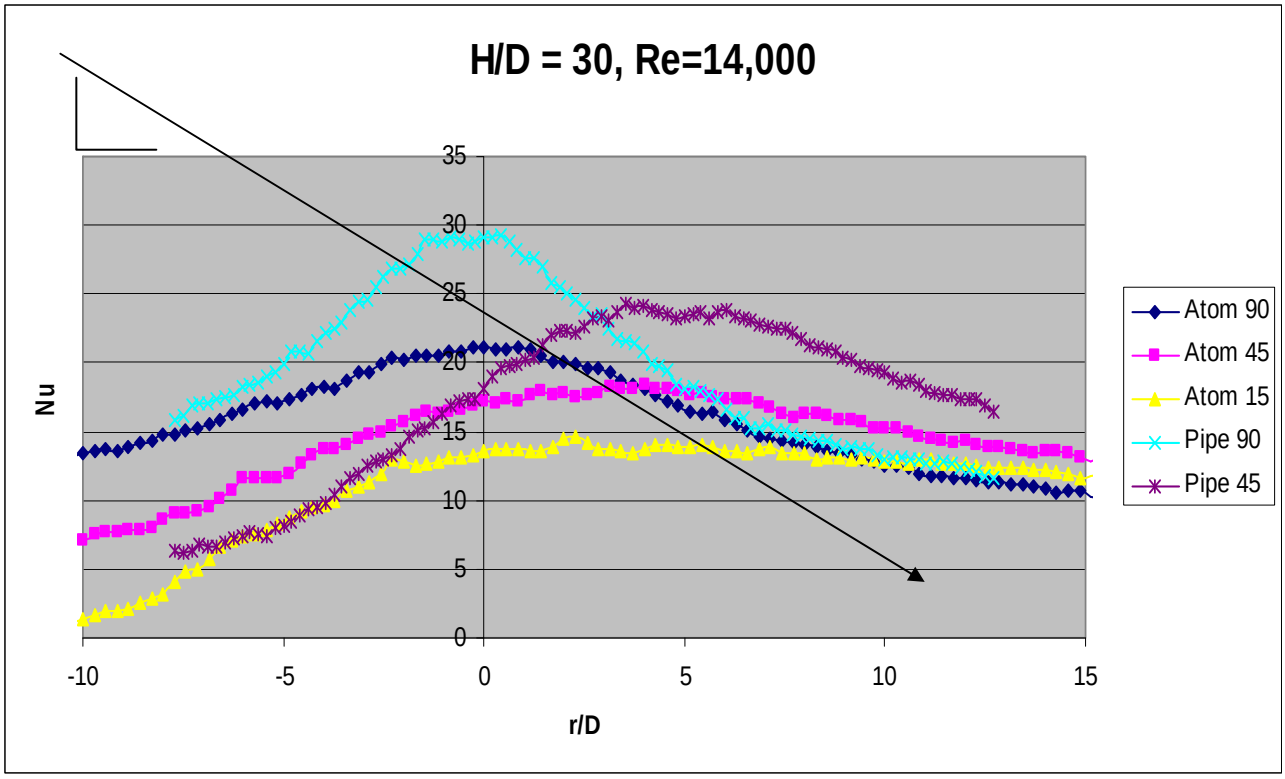

Figure 5. angle of impingement (add in pipe nozzles as well)

Figure 5 shows the variation in heat transfer coefficient against r/D for various angles of impingement. The direction of the angle is represented by the arrow. Again for all flow rates, the atomizing nozzle shows the bell shaped distribution. Upstream, the atomizing nozzle shows a decreasing cooling with increase in angle away from 90. A direct impingement angle has also shown the best degree of cooling in the stagnation region. This is due to a lower mass flux in both stagnation and upstream wall jet regions for angled nozzles. Conversely there is a higher mass flux downstream, and outside of a few diameters the 45 degree data shows an increase in heat transfer. The same is true for the 15 degree data outside approximately seven diameters. Again in these graphs, the stagnation Nusselt number is lower than that of the pipe nozzle.

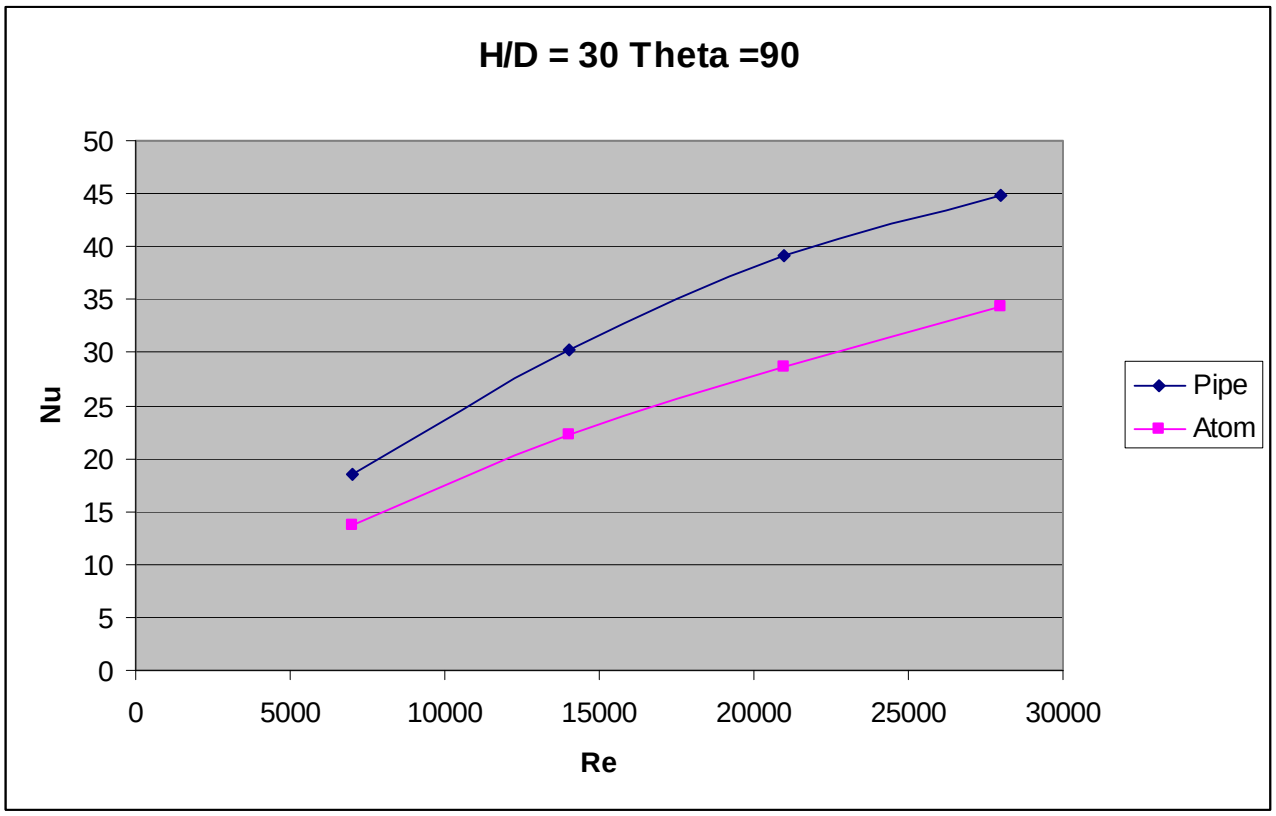

Figure 6. Reynolds number

The stagnation Nusselt numbers are consistently lower for the atomizing nozzle at various Reynolds numbers. It can be seen from figure 6 that the atomizing nozzle has a similar dependence on Reynolds number to that of the pipe nozzle and previous correlations [10].

The atomizing nozzle does appear to be following the typical bell-shaped distribution. Additionally, the effect of Reynolds number and angle of impingement show similar effects to both the pipe nozzle and previous literature (10, 11, 12). Overall Nusselt numbers appear similar, with around 10% higher for the pipe nozzle in the stagnation region at large H/D's. Thereafter the atomizing nozzle achieves higher levels of heat transfer. This effect is not noted at lower H/D's, where the pipe nozzle consistently underperforms.

The data recorded in this experiment has been used to compare a standard pipe nozzle to a more complex nozzle. The aim of these has been to characterise this complex nozzle, which will ultimately be used to generate a mist flow. This analysis has been used so as to determine how much of the increase in heat transfer is due to the mist and how much to that of the complex internal structure of the nozzle.

CONCLUSIONS

A study has been carried out to investigate the effects of nozzle geometry on local heat transfer from an impinging jet to a copper plate.

The atomizing nozzle has been shown to provide superior convective cooling at r/D's greater than two.

The atomizing nozzle has a lower stagnation Nusselt number and tends to be lower in the immediate stagnation region.

The effect of Reynolds number and H/D spacing has been shown to be consistent with that of a straight pipe nozzle.

Further analysis of the flow field, both at nozzle exit and at impingement, is important.

Furthermore, the measurement of fluctuating heat transfer parameters is expected to provide further information on the characteristics of the atomizing nozzle.

ABSTRACT. Thermal characteristics of laminar flow through square duct with periodic transverse ribs and through wire coil inserts have been studied experimentally. The duct is under uniform wall heat flux boundary condition. The effect of rib height, rib pitch, coil helix angle and coil wire diameter on axially averaged Nusselt number have been studied. It has been observed that the heat transfer increases with the increase of rib height and decrease of rib pitch, decrease of coil wire diameter and increase of coil helix angle.

Keywords: *Laminar Flow, Forced Convection, Ribbed Duct, Wire Coil Inserts, Enhanced Heat Transfer*

INTRODUCTION

Heat exchangers often operate at low flow velocity for many reasons, e.g. the heat transfer area is usually designed conservatively to be larger than actually needed so that the designed flow velocity is low; or the flow rate of heat exchanging fluid might not be enough; or the load is not full during production; etc. In these circumstances laminar flow occurs for which the heat transfer coefficient is very low. In these cases, different types of heat transfer enhancement techniques are used to increase the heat transfer rate, Webb and Kim [1]. In the present paper, results of experimental work on laminar flow heat transfer characteristics in a square duct with transverse periodic ribs of various height and pitch and through wire coil inserts with various coil helix angle and coil wire diameter have been presented.

EXPERIMENTAL SET UP, OPERATING PROCEDURE AND DATA REDUCTION

The schematic diagram of the experimental setup is shown in Figure 1 below.

1. The Storage Tank— It is a 900 mm×500 mm × 395 mm rectangular box made of PVC. The working fluid is the servotherm medium oil.

2. The Working Fluid Circulating Loop – The working fluid passes through one of the three rotameters, calming section, the test section, mixing chamber, heat exchanger and back to the storage tank. The vane pump pumps the working fluid.

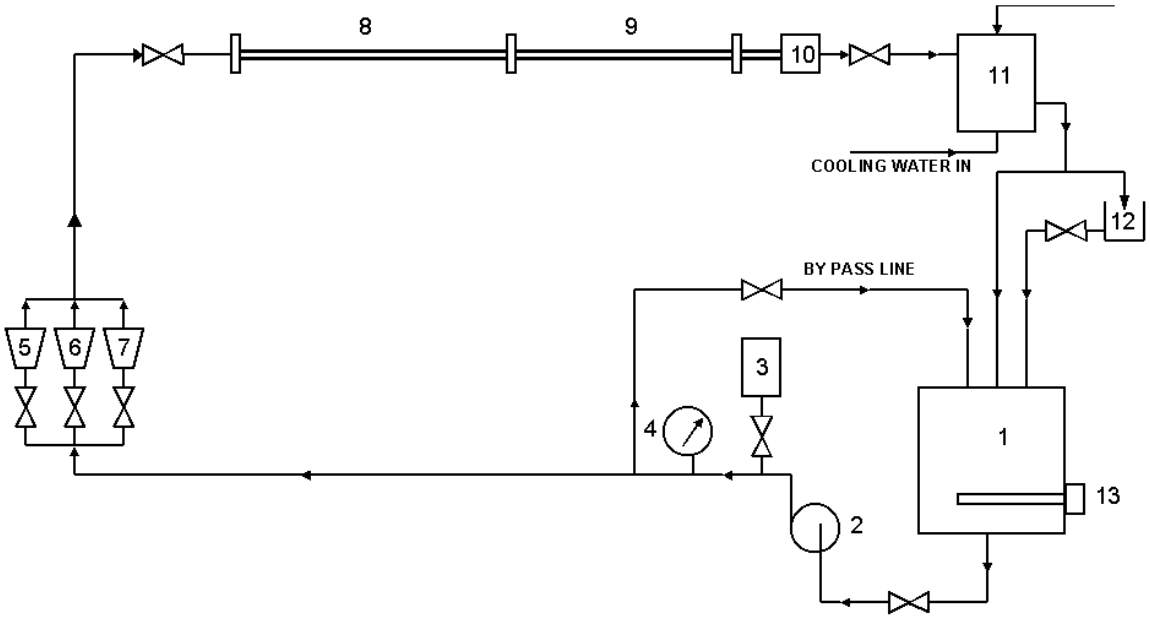

Figure 1.

1.	RESERVOIR	5, 6, 7.	ROTA METERS	11.	HEAT EXCHANGER
2.	PUMP	8.	CALMING SECTION	12.	WEIGHING PLATFORM
3.	ACCUMULATOR	9.	TEST SECTION	13.	HEATER
4.	PRESSURE GAUGE	10.	MIXING CHAMBER		

3. Test Section --- 13 mm × 13 mm square and [13 mm × 26 mm and 13 mm × 39 mm] rectangular SS heat transfer test section, all test sections 2 m long. Heat transfer test sections are wrapped with nichrome (20 gauge, 1.6 Ω /m) heater wire. Heat is supplied to the heat transfer test section by autotransformers. The power input is measured by digital voltmeter and ammeter. Ribs in the test section have heights (e) and pitch (P) such that e/D_h and P/e have pre-determined values, where D_h is the hydraulic diameter of the plain duct.
4. Calming Section – It is 25 mm OD and 1.2 m long GI pipe.
5. Mixing Chamber— It is 50 mm × 50 mm cross section 150 mm long GI piece with 12.5 mm × 12.5 mm helical plate at the centre having φ 6 mm holes in the plate.
6. Heat Exchanger --- Coil-in-shell type. The working fluid passes through the 10 mm ID and 12 mm OD and 15m long copper coil made into two coaxial coils having 150 mm and 120 mm PCD. The shell is a 190 mm OD 260 mm height MS drum with openings at top and bottom for the flow of the coolant.
7. Accumulator--- It is a 150 mm OD 115 mm height vertical MS drum to reduce pressure fluctuations.
8. Thermocouples --- 34 gauge Copper-Constantan, 28 in number; at seven locations (50mm, 500mm, 1000mm, 1250mm, 1500mm, 1750mm and 1950mm from the beginning of the heating); one each in the middle of each of the four edges.
9. Rotameters—3 in number—0.07 –0.7 kg/s; 0.0115—0.115 kg/s, 0.00175—0.0175 kg/s
10. Thermocouples are connected to the digital multimeter via 36-points selector switch box.
11. A centrifugal pump supplies the coolant raised from a reservoir to the overhead tank and then to the heat exchanger.

12. Heat transfer test section is electrically heated by nichrome heater wire giving uniform wall heat flux boundary condition. Nichrome heater wire is having porcelain bead insulation on it. There is no direct contact of the Nichrome heater wire with the duct wall. First, there is fibre glass tape insulation (electrical but not thermal) on the duct wall. Then the porcelain-bead covered Nichrome heater wire is wrapped on the duct wall. Two consecutive turns of the heater wire is seated side by side touching each other in each duct. The thermal conductivity of the duct wall material is high enough and the duct wall thickness is sufficient to ensure uniform wall heat flux. Asbestos rope and glass wool insulates the heat transfer test section after the heater wire. Finally the test section is covered with gunny bag.
13. Oil bulk-mean temperatures at inlet and outlet of the test section are also measured by copper-constantan thermocouples. The oil temperature at outlet is measured after the mixing chamber and this is uniform. The mixing chamber is a cylindrical box of rectangular cross-section. The mixing chamber has rectangular plates arranged inside in such a fashion that the working fluid moves in a serpentine path. This gives a uniform temperature of the working fluid at its exit plane. At other locations, the fluid bulk-mean temperatures are interpolated since the fluid bulk-mean temperature increases linearly for the uniform wall heat flux boundary condition. The duct wall temperature also rises linearly in the downstream fully developed region. Heat input to the test section is evaluated by measuring resistance of and voltage across the heater wires and the enthalpy rise of oil in its passage through the test duct. The electrical energy input and the enthalpy rise of the oil match within 3%. The enthalpy rise of the oil is taken as the thermal energy input to the heat transfer test section. Experimental uncertainty was determined by the method of Kline and McClintock [2]. The uncertainty in Reynolds number, Prandtl number and Nusselt number were $\pm$ 3%, $\pm$5% and ± 8%, respectively. The fluid temperature rise along the heated duct is not very high and fluid thermal properties being well documented, therefore, the uncertainties in fluid properties variation have been neglected without much loss in accuracy,
14. The axial local Nusselt number is determined from the peripherally averaged measured wall temperature and then the axially local Nusselt numbers at seven axial stations are axially averaged by trapezoidal rule.

RESULTS AND DISCUSSION

Figures 2-5 show the experimental heat transfer data. In Figure 2, it is seen that heat transfer is more for a square ribbed duct with wire coil inserts than that for a circular ribbed duct just as it happens for a plain duct. Also, for a larger rib height, the heat transfer is more than that in case of a smaller rib height. This observation is, however, more true for circular duct than that in case of square duct. The observed results can be explained by the fact that more recirculation, mixing with boundary layer separation and reattachment causes flatter temperature profile with increased Nusselt number and heat transfer. Figures 3-5 show the effects of rib pitch, coil wire diameter and coil helix angle, respectively on heat transfer. The larger the rib pitch, the less is the heat transfer as shown in Figure 3. This is true for both circular duct and square duct. The results are explained by the fact that, the number of occasions of boundary layer separation and reattachment is less with larger pitch and hence is the lower heater transfer. Figure 4 shows that the heat transfer is largely unaffected by the coil wire diameter. Figure 5 shows that heat transfer increases with the increase of coil helix angle. In Figures 2-5, X and Y are the multiplying factors.

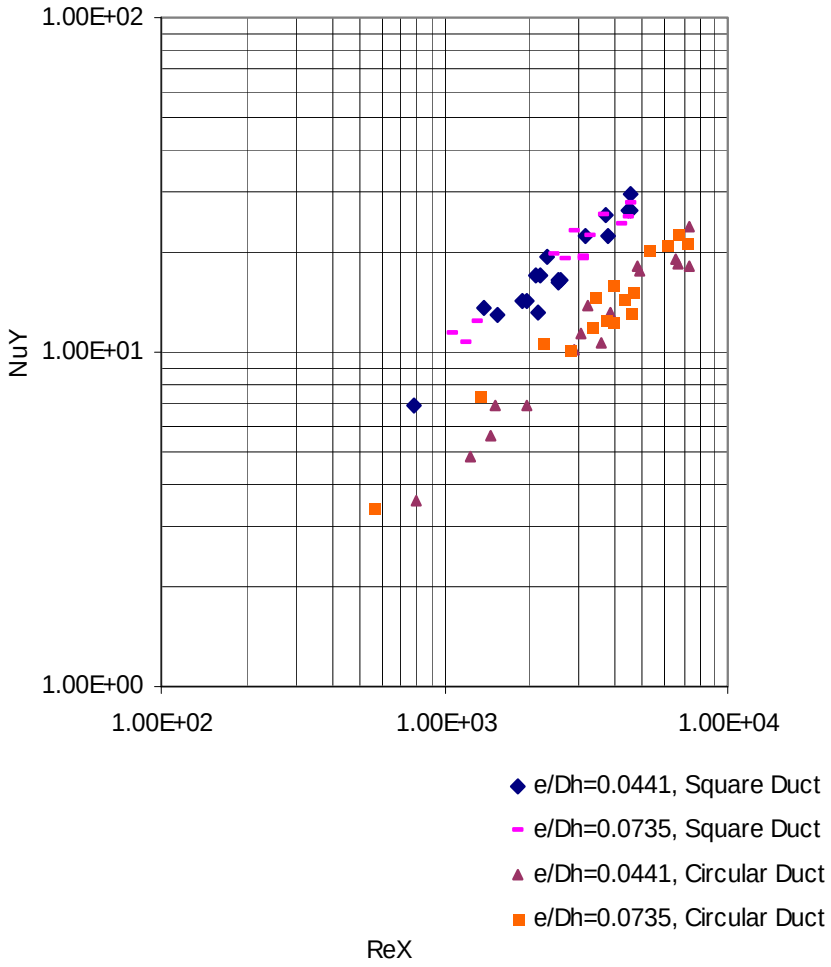

Figure 2. Effect of Rib Height on Nusselt Number---P/e=20, d/D_h=0.07692, Coil Helix Angle= 60^o

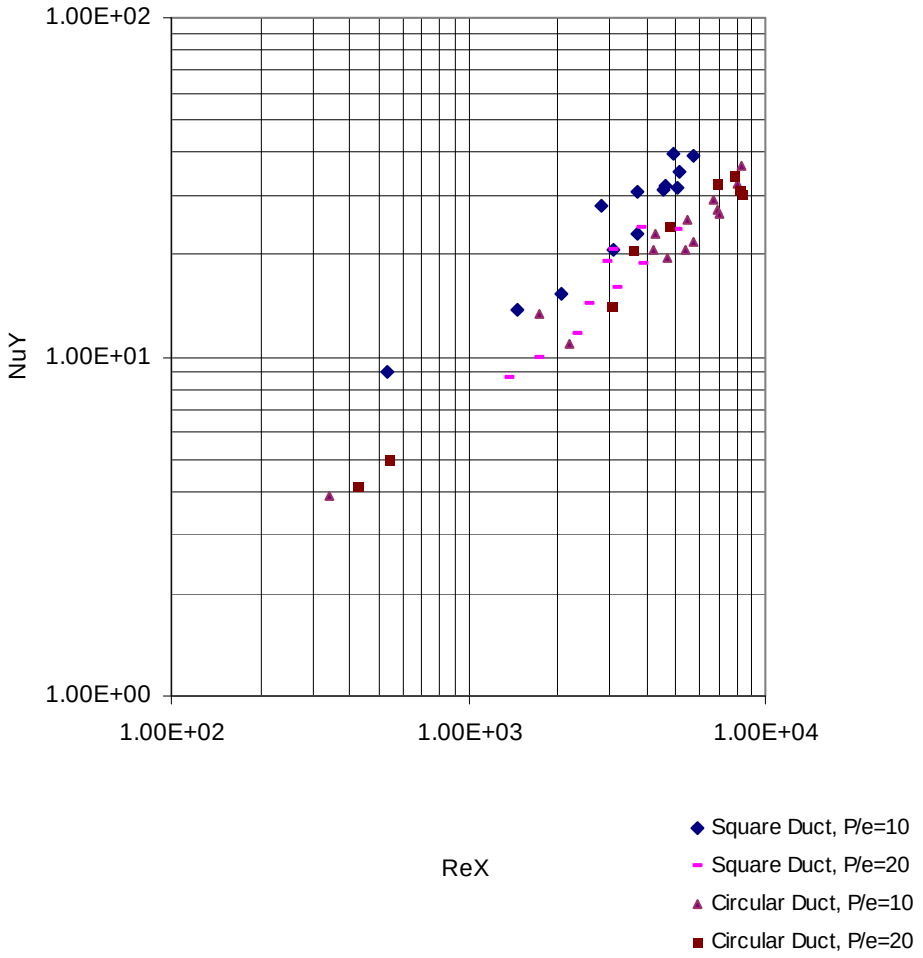

Figure 3. Effect of Rib Pitch on Nusselt Number--e/D_h=0.0735, d/D_h=0.07692, Coil Helix Angle=60^o

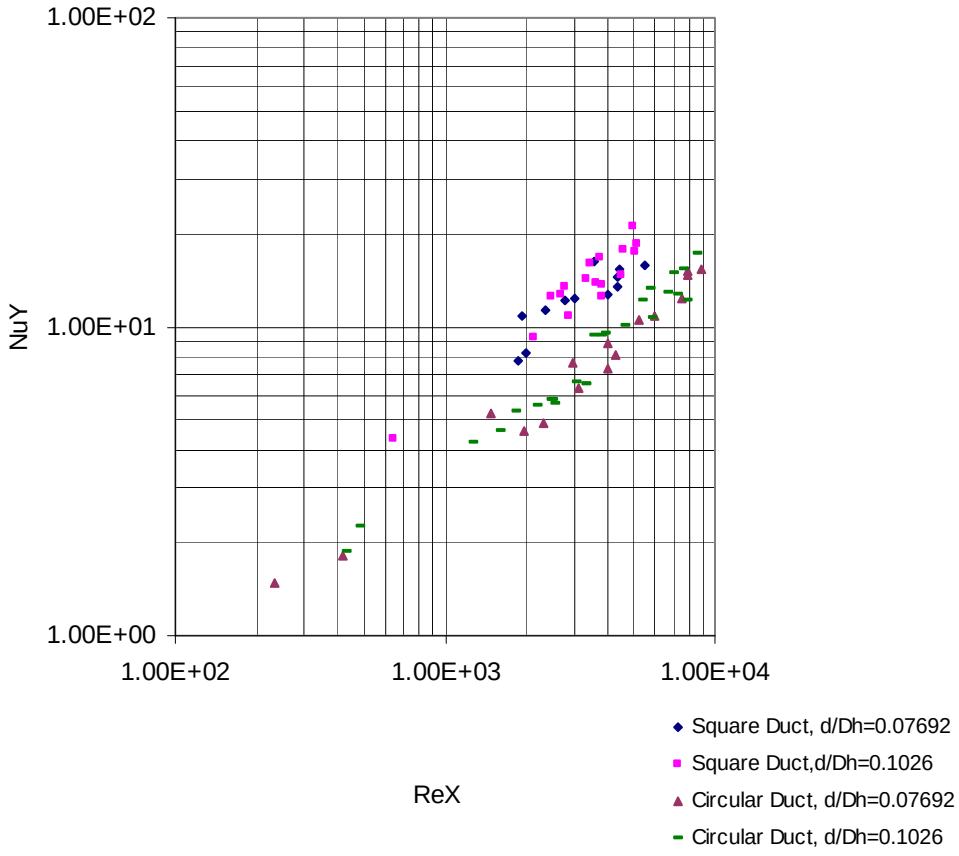

Figure 4. Effect of Coil Wire Diameter on Nusselt Number--e/D_h=0.0441, P/e=20, Coil Helix Angle=30^o

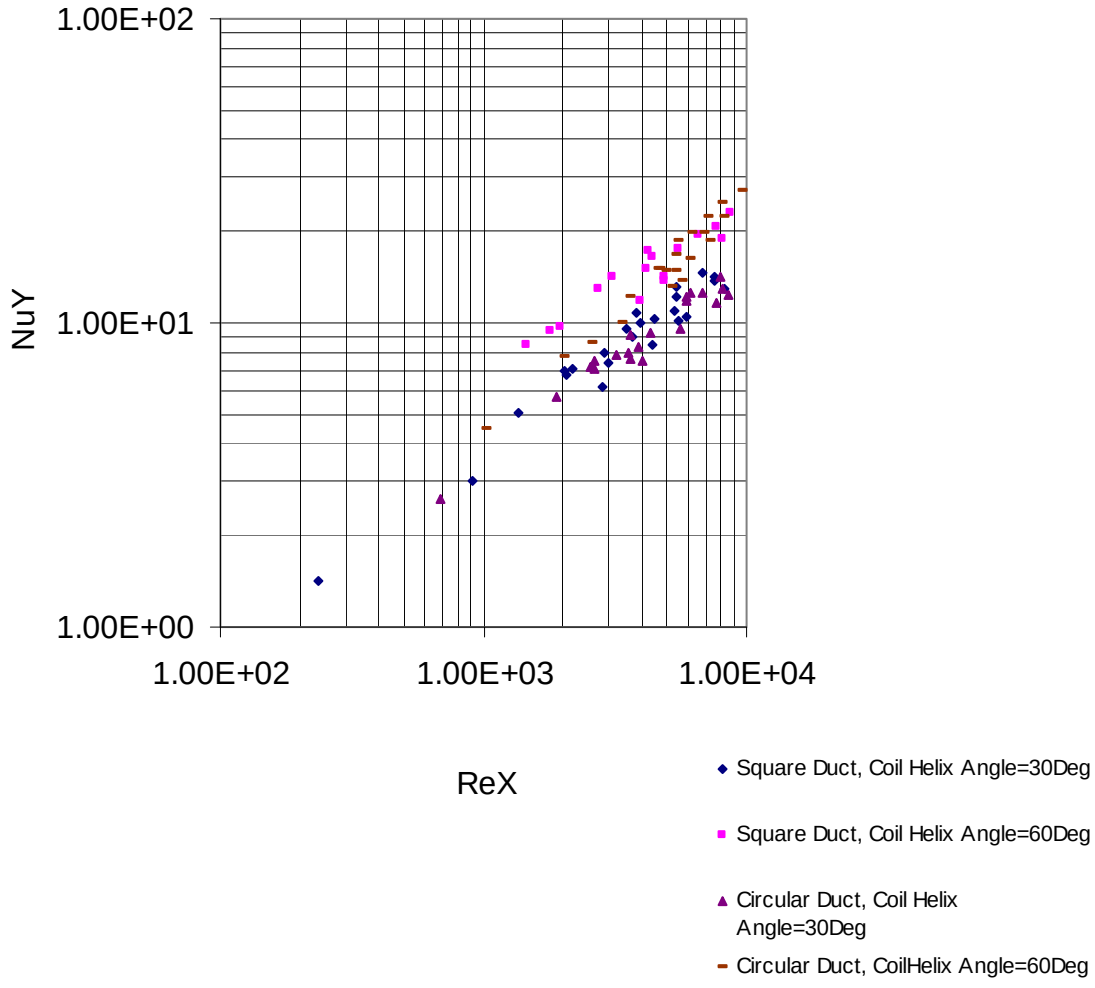

Figure 5. Effect of Coil Helix Angle on Nusselt Number--e/D_h=0.0441, P/e=20, d/D_h=0.07692

CONCLUSION

Thermal characteristics of laminar flow through square duct with periodic transverse ribs and through wire coil inserts have been studied experimentally. The duct is under uniform wall heat flux boundary condition. It has been observed that the heat transfer increases with the increase of rib height and decrease of rib pitch, decrease of coil wire diameter and increase of coil helix angle.

ABSTRACT. In this particular work is given experimental and numerical study results of temperature gradient influence on concentrating convection, evolving from diffusion in isothermal gas mixtures.

Experiment method is as follows: Binary mixture of helium and argon was blended with nitrogen on the arrangement, realized double-envelope method. The density of helium and argon mixture in the upper envelope at any temperature is less than thickness of nitrogen in the lower part of arrangement. The temperature of the upper envelope was changed in the range of 278-473 K. The temperature of the lower envelope was constant and equal to 298 K. The pressure was 2.5MPa. After every experiment endings the gas mixture structure from both envelopes was analyzed.

As from this experiment, in this system existing unsteadiness mixture mechanical balance. Argon and nitrogen function is considerably more than helium. While growing of temperature convection current intention is decreasing. Convection is discontinued under the temperature definite critical meaning and molecular function became dominant.

Numerical analysis on stability of triple gas mixture mechanical balance shows existence possibility of diffusion and convection. In Relley's terms determined "non-isothermal diffusion - concentrating convection" conversion limit. Results of calculation by non-isothermal diffusion and concentrating convection determination in triple gas mixture depending on channel's temperature, length and radius satisfactory conform to experimental facts.

Keywords: *convection, diffusion, mixtures, instability*

INTRODUCTION

In isothermal binary gas mixture instability of mechanical equilibrium may occur only in case heavier in density gas appears above. Due to Archimedes buoyant force the convection appears in the mixture: heavier gas descends and the lighter one ascends. Convection continues until the lighter gas appears above. Addition of the third component to the mixture may under certain conditions result in disruption of mechanical equilibrium stability and convection shall appear even in case of stable density stratification. This effect can be explained by the fact that in isothermal three-component system convectional currents are induced by two concentration gradients instead of the figure of one. The report will focus on experimental and numerical results related to the investigation of "diffusion – concentration gravitation convection" regimes change in isothermal binary gas mixtures.

EXPERIMENTAL DATA

Experiments on instability study were made on the basis of two-bulb method device (figure 1). Two bulbs of the same size were connected by a vertical canal. Pressure in the bulbs kept equal. The testing method corresponded to the classic scheme. Capillary to connect the bulbs opened and after certain time it was blocked. Mixture composition was being registered in both bulbs. The concentrations that appeared during testing were leveled to diffusions calculated in supposition.

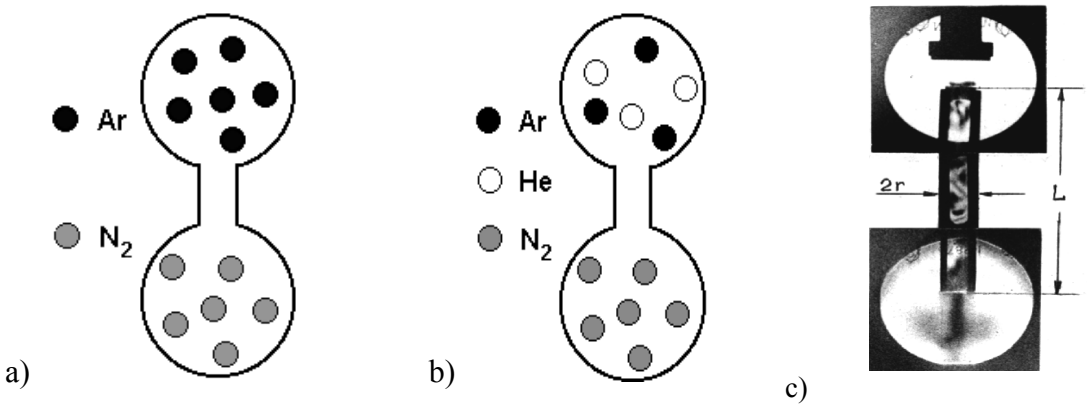

Figure 1. Scheme of diffusion cell.

Binary mixtures

The upper bulb contains gas (or gas mixture) which excels in density the component included into the lower bulb (figure 1a). Instability was studied when occurred as follows:

1) Variation of conditions was made by pressure change, all other thermodynamic parameters and geometrical characteristics of the instrument remained invariable;
2) All parameters were fixed, the system temperature varied;
3) Diffusion canal slope angle was changed relative to the vertical line under the same conditions.

Figure 2(a) shows typical dependence of the parameter thus achieved $\alpha = c_{\text{exp}} / c_{\text{theory}}$ on the pressure for the N_2 – He system. In case of $p < p_*$ pressures usual molecular diffusion occurs. In this case experimental values for concentrations are equal to the diffusion calculated in supposition. Dimensionless parameter α may be approximately equal to the figure of one. Upon pressure p_* =0,58 MPa α parameter exceeds figure of one. Mechanical equilibrium becomes unstable. Convection occurs.

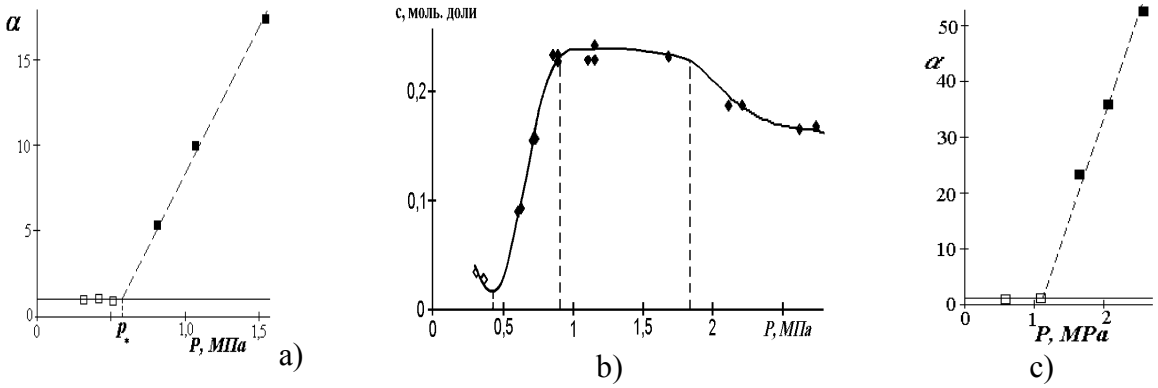

Figure 2. (a) Binary mixture N_2 – He, (gas – helium), T=298 K. □ – diffusion, ■ - convection. (b) System Ar – N_2, T=298 K., points ◇, ◆ – are experimental data for nitrogen. Firm line is the calculation using polynomial dependence. (c) Parameter α_{Ar} at various pressures in the mixture 0,4521 He + 0,5479 Ar – N_2, $T = 298{,}0$ K

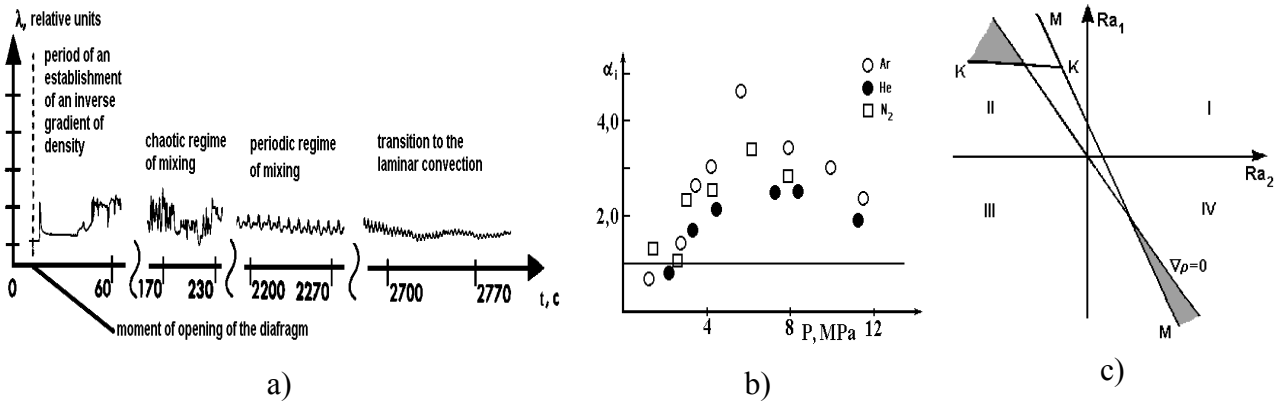
Further α starts increasing by linear dependence at the initial stage. Thereby, in binary systems upon certain pressure p_* "diffusion – concentration gravitation convection" change occurs. Further pressure increase results in break of linear dependence. Figure 2(b) shows dependence of gas transferred during experiment on the pressure for system Ar – N_2. After convection appears mass transfer intensity in the system increases drastically to p_{**} pressure. After reaching p_{**} intensity of convection transfer remains relatively constant despite pressure increase. Further, after reaching p_{***} pressure, convection decreases. The dependence of mass transfer intensity on the pressure may be explained by change of current structure in the canal after pressure reaches p_{**} and p_{***}.

Dependence of α parameter on temperature and slope angle are equivalent (figure 2a). The experiments have revealed that pressure increase suppresses convection instability in binary mixtures. Study of the boundary of "diffusion – concentration gravitation convection" change upon changing a canal slope angle in relation to the vertical line showed that canal slope angle increase results in decreasing of instable process intensity. Upon certain angle the system changes its unstable position to the stable one, i.e. diffusion.

Three-component mixtures

Experiments to study "diffusion – concentration gravitation convection" regime change were made by the method used for binary mixtures. The upper bulb included binary mixture of the lighter and heavier components. Medium in density gas was included into the lower bulb. In all cases concentrations of the lighter and heavier components were selected so that mixture in the upper bulb was of a lower density. Thus achieved concentrations were leveled to diffusions in supposition calculated under Stephen-Maxwell equations. Figure 2(c) shows dependence of thus achieved parameter $\alpha_i = c_{i\,\mathrm{exp}} / c_{i\,\mathrm{theor}}$ on the pressure for He + Ar – N_2 system. As it is seen in the figure, α_i parameter under certain critical pressure exceeds figure of one, i.e. mechanical equilibrium of the mixture becomes unstable. Anomalous concentration gravitational convection occurs.



a) b) c)

Figure 3. (a) Change of heat conductivity of a mixture in time, illustrating a change of regimes of convection, (b) Values α_i of rate of flux for various components of a mixture 0,47 *He* + 0,53 *Ar* – N_2, normalized on the settlement charge in conditions of a mechanical equilibrium at change of pressure. $T = 293{,}0$ K. (c) The diagram of stability of three-component system on a plane of partial Rayleigh numbers. Above the line MM the convectional stream in system is stationary, above the semi-infinite line KK the regime of convection is periodic. The straight line passing through the origin of coordinates, divides a plane into areas with negative (below a straight line) and positive gradient of concentration. The shaded areas correspond to conditions of abnormal convection

Studies made in [2-6] have revealed that shift from diffusion to convection mixture is determined by the following critical parameters: pressure, temperature, mixture viscosity, its original composition, difference in diffusion components ratio, geometrical canal characteristics and its orientation in relation to the vertical line. For the purpose of visual registration of shift boundary we used Tepler's shadow method which is based on that rays of light in turbulent layers are deflected in different ways. Canal with transparent walls and right-angled in section was lit by a beam of light. The screen behind the canal was registering heterogeneous light intensity which varied in time. Device construction allowed monitoring convection currents in the device bulbs (figure 1c). Convection regime change may also be registered by quick-response sensors which define gas local heat conductivity. Gas mixture's heat conductivity depends on the component concentration which enables to determine typical periods of regimes being studied (figure 3 a).

Figure 3(b) shows dependence of gas transferred during the test on pressure for system 0,47 He + 0,53 Ar – N_2. There is a certain range of pressures in which anomalous division of mixture components can be seen. Further pressure increase results in stabilization of convective regime.

Theoretical analysis for convective stability of the gas mixture

Boundary of "diffusion – concentration gravitation convection" regime change may be obtained from hydrodynamics equation joint solution. For isothermal three-component gas mixture they are presented as follows:

$$\rho\left[\frac{\partial\vec{u}}{\partial t}+(\vec{u}\nabla)\vec{u}\right]=-\nabla p+\eta\nabla^2\vec{u}+\left(\frac{\eta}{3}+\xi\right)\nabla div\vec{u}+\rho\vec{g},$$
$$\frac{\partial\rho}{\partial t}+div(\rho\vec{u})=0,\ \rho\left(\frac{\partial c_i}{\partial t}+\vec{u}\nabla c_i\right)=-div\vec{j}_i, \qquad (1)$$
$$\vec{j}_1=-\rho\left(D_{11}^*\nabla c_1+D_{12}^*\nabla c_2\right),\ \vec{j}_2=-\rho\left(D_{21}^*\nabla c_1+D_{22}^*\nabla c_2\right),$$
$$\sum_{i=1}^{3}\vec{j}_i=0,\ \sum_{i=1}^{3}c_i=1.$$

Where ρ – density, u – velocity, t – time, p – pressure, η and ξ – ratios of shear and volume viscosity, g- gravity acceleration, c_i –i component concentration, D_{ij}* – multi-component diffusion matrix ratio. Ratios D_{ij}*, η, ξ are not subject to the mixture composition. Equations (1) are added by equalization of conditions $\rho=\rho(c_1,c_2,p),\ T=const.$ After applying traditional procedures to the tasks related to stability studies, which are as follows:

- Use of Boussinesq approximation;
- Neglecting minor squared agitations;
- Minor differences between average mass and number average velocities agitations;
- Neglecting pressure differential as an agitated value;
- Linear distribution of concentration in the vertical canal;
- Selection of typical large measurement units;
- Shift to dimensionless values

The equation system (1) is leveled to agitation equations made as dimensionless ones:

$$\mathrm{Pr}_{22}\frac{\partial c_1}{\partial t}-u=\tau_{11}\frac{\partial^2 c_1}{\partial x^2}+\frac{A_2}{A_1}\tau_{12}\frac{\partial^2 c_2}{\partial x^2},$$
$$\mathrm{Pr}_{22}\frac{\partial c_2}{\partial t}-u=\frac{A_1}{A_2}\tau_{21}\frac{\partial^2 c_1}{\partial x^2}+\frac{\partial^2 c_2}{\partial x^2}, \qquad (2)$$
$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}+Ra_1\tau_{11}c_1+Ra_2c_2.$$

$Pr_{ii}=\nu/$ D_{ij}*– Prandtl number; $\nu=$ η/ρ; $Ra_i=g\beta_i A_i d^4/\nu$ D_{ij}*- Rayleigh number; $\tau\beta_i = -\frac{1}{\rho_0}\left(\frac{\partial\rho}{\partial c_i}\right)_{p,T,c_j\neq c_i}$, $_{ij}= D_{ij}$*/ D_{22}*; $A_i\gamma = -\nabla c_{i0}$, γ - unit vector.

Solution (2) results in definition of boundary lines of monotonous (MM) and oscillatory (КК) instabilities showed in figure 3c. Below of both lines the mechanical equilibrium is stable and above – unstable. Density is related to concentrations c_i of the components of

$\tau_{11}Ra_1 = - Ra_2$

In (Ra_1,Ra_2) this condition determines straight line going through origin of coordinates (figure 3б). Below the line $\nabla\rho<0$. Analysis (figure 3б) enables to reveal areas with negative density gradient but located above instability lines MM or КК. In figure 3c these areas are hatched. In the event of special selection of experiment conditions so that the system could appear in the given areas, anomalous convection shall occur. Comparison of experimental data with estimated ones under (1), (2) demonstrates well coordination.

CONCLUSIONS

Linear theory of stability, which takes into account an inversion of a gradient of density, adequately explains experimentally observed phenomenon. However, description of effects observed in the field of parameters considerably exceeding critical, lays out of its limits. To understand, how growing perturbations move over to convective structure it is necessary to refuse assumptions:

- small size of perturbations;
- Linear distribution of concentration on length of the channel.

ABSTRACT. Microchannels (smaller than 0.5 mm dia) are emerging geometries for heat and mass transfer applications. The major benefit is to obtain ultra high heat transfer coefficients with equal or somewhat higher pressure drop compared to mini channels and compact heat exchangers depending on the applications. Extensive research efforts are going on world wide to understand the phenomena and develop design data base. As of today, no commercial products are available that use microchannels. In this state-of-the art review, an attempt has been made to summarize heat transfer information for small diameter tubes since this is an area of newer applications to be emerged. The focus will be to summarize the phenomena and design information for single-phase flow, boiling and condensation. Also summarized will be the current challenges and opportunities.

KEYWORDS: *Microchannel Heat Exchanger, Single-phase Convection, Boiling, Condensation*

INTRODUCTION

Microchannels (circular and noncircular) and micropipes are emerging geometries for heat and mass transfer, controlled fluid transport and thermal control in about 0.5 mm and smaller size passages. Since many authors have defined microchannels different way, the definition by Thome (2004) appears to be more technical. He defines microchannels with upper and lower bound for geometrical dimensions as follows: The upper limit (the largest diameter) corresponds to confined bubble flow and the lower limit corresponds to the complete suppression of nucleation and hence threshold to nanochannels for two-phase flows.

Applications include many heat transfer simple and complex devices including microchannel heat sinks, microchannel heat exchangers, micropumps, microelectromechanical systems (MEMS) and biomedical and genetic engineering simulating biological and life science phenomena in the advancing technologies. Microprocessors generate increasingly larger amounts of heat with improved processing speeds from MHz to GHz. This heat must be removed so that the chip does not overheat and deteriorate in performance. In the review here, we will focus primarily on heat transfer and pressure drop aspects and design information in microchannels associated with single-phase and phase-change (two-phase, boiling and condensation) fluids, and will neglect the effects of electrokinetics and electroosmotic forces.

Why do we need microchannel flow passages? There are several reasons depending on the applications: (1) High and ultra high heat transfer rates per unit volume of the heat exchanger. This translates into low physical volume for the heat transfer device generally with lower total cost as the technology advances, and the same pressure drop as the macro heat exchanger if the design is done

E-mail address: celata@enea.it

properly, i.e., the number of microchannel passages is increased to maintain the same flow area and/or reduces flow length. (2) In microelectronic (PCs, servers, laser diodes, RF devices, etc.) and micromedical devices, higher heat dissipation than was possible in 1993 (~ 200 W/m^2), and this limit is pushed to about 1000 W/m^2 with the temperature differences for heat transfer becoming smaller to a few °C and microchannel size to few microns (Kandlikar and Garimella, 2006). (3) With emerging technology in many fields that use micro devices, they will require cooling where micro heat exchangers will become essential.

The materials used for mini/microchannels are polymers, metal, glass, and ceramics. The choice of material depends on the following factors: temperature resistance, corrosion resistance and thermal properties. Since this is evolving technology, small physical sizes involved and there are not enough applications, there are no codes and standards imposed on micro heat exchangers. The manufacturing technologies used are silicon technologies (dry and wet etching), wet chemical etching, mechanical micro machining, and laser machining. Microstructures like minichannels have many potential applications such as heat transfer, evaporation, mixing, generation of emulsions, and running chemical reactions in the lab-scale range (Brandner et al., 2007).

There are many techniques to realize miniaturized channels but four process technologies are imposing for system miniaturization:

- Micromechanical machining (such as diamond machining, laser processes, focused ion beam, microdrilling);
- X-ray micromachining (such as LIGA LItographie-Galvanoformung-Abformung);
- Photolithographic-based processes (such as Si chemical etching);
- Surface and surface-proximity-micromachining (epimicromachining) processing techniques.

Our focus in this paper will be to provide a state-of-the art review starting with some basic information followed by the recent developments in single-phase, two-phase (with no heat transfer), boiling and condensation heat transfer phenomena in circular and noncircular channels as well as some information on the actual heat exchangers being evaluated.

CLASSIFICATION OF MICROCHANNELS

Most classification methods are rules-of thumb classifications. Based on industrial application viewpoint, Shah (1981, 1998) defined a heat exchanger as compact, meso (laminar flow) or micro heat exchanger based on the surface area density β of the heat transfer surface on one fluid side of the exchanger as follows:

Compact heat exchanger: $\beta > 700$ m^2/m^3 or $D_h \le 6$ mm for gas flows
$\beta > 400$ m^2/m^3 for liquid flows

Laminar flow (or meso) heat exchanger: $\beta > 3000$ m^2/m^3 or $100\ \mu m \le D_h \le 1$ mm for gas flows

Micro heat exchanger: $\beta > 10000$ m^2/m^3 or $1\ \mu m \le D_h \le 100\ \mu m$

Mehendale et al. (2000) proposed the definitions of channels as follows:

Microchannels: $1\ \mu m < D_h \le 100\ \mu m$
Mesochannels: $100\ \mu m < D_h \le 1$ mm
Compact passages: 1 mm $< D_h \le 6$ mm
Conventional passages: $D_h > 6$ mm

Kandlikar and Grande (2002) defined various channel sizes as follows:

Conventional channels: $D_h > 3$ mm
Minichannels: 200 μm < $D_h \leq 3$ mm
Microchannels: 10 μm < $D_h \leq 200$ μm
Transitional Microchannels: 1 μm < $D_h \leq 10$ μm
Transitional Nanochannels: 0.1 μm < $D_h \leq 1$ μm
Molecular Nanochannels: $D_h \leq 0.1$ μm

Cheng and Wu (2006) provided the classification of the small channels based on the relative importance of the buoyancy force to surface tension force (going away from the rules-of-thumb classification), and showed that that this ratio can be translated to a ratio of the hydraulic diameter to the capillary length. This ratio is defined as Bond number as follows.

$$Bo_d = \left(\frac{D_h}{\ell_c}\right)^2 = \frac{g(\rho_\ell - \rho_v)D_h^2}{\sigma} \tag{1}$$

where $\ell_c = [\sigma/\{g(\rho_\ell - \rho_v)\}]^{1/2}$ is the capillary length; D_h is the hydraulic diameter of the channel; g is the gravitational acceleration; σ is the surface tension; and ρ_ℓ and ρ_v are the densities of the liquid and vapor, respectively. Cheng and Wu (2006) then proposed the definitions as

- Microchannel: $Bo_d \leq 0.05$ where the gravity effect can be neglected.
- Minichannel: $0.05 < Bo_d < 3.0$ where the surface tension effect becomes dominant and the gravity effect is small.
- Macrochannel: $Bo_d > 3.0$ where surface tension is small in comparison with gravitational force.

It is relevant to point out that the Bond number, defined by Eq. (1), has taken into consideration the effects of temperature, pressure, and physical properties of the fluid. According to the above classification, the minichannels have the hydraulic diameter 0.5–30 mm at 450 K and microchannels have the hydraulic diameter less than 0.5 mm (at 450 K) for phase change heat transfer if water is used as the working fluid.
It should be emphasized that most of the results presented in the literature do not conform to any of the above definitions, and simply consider any tubes having 2 mm or less hydraulic diameter as the microtube or microchannel!

HEAT TRANSFER AND PRESSURE DROP PHENOMENA AND CORRELATIONS

Single-Phase Flows

Flow and heat transfer phenomena in microchannels and minichannels are the same as those in macrochannels. Shah and Sekulić (2003) have presented extensive data on friction factors, Nusselt numbers, entrance lengths, additional pressure drops due to entrance length, etc. for a large number of flow passages for developed and developing laminar and turbulent flows in channels. Some basic information is provided in Tables 1-2.
Han and Kedzierski (2007) measured pressure drop in microtubes of diameters 97-260 μm and Reynolds number range of 30-3000. Tubes were made of three different materials: fused silica, polyetheretherketone and stainless steel. Three different fluids, distilled water, tap water and deionized water were used to investigate the effect of ionic composition of the fluids on the pressure drop. Other parameters investigated were: influence of surface polarity and the effect of micro-particles. With

systematic variations of tube length, material and diameter, as well as fluid type and filtering, they found that the measurements agreed with the classical theory of flow in a pipe, including no earlier transition from laminar to turbulent flow. They showed that the pressure drop dependence on Reynolds number is the same as that for macrotubes and the classical theory including no significant effect of viscous dissipation, microparticles or small surface roughness of the tubes.

Additional Effects on Single-Phase Performance due to Microscale of the Geometry

Two most important parameters come into picture for mini and micro channels are: surface roughness and channel straightness along the flow length of the flow passages. Generally, the effect of relatively non-straight flow length on heat transfer is small and is ignored since the tubes are generally not long. Otherwise, the results inferred from curved ducts may be considered. Also, the microchannels are usually short and the entrance length effect may not be negligible and may need to be taken into account.

Table 2. Transition and turbulent flow friction factor and Nusselt number correlations in circular and noncircular channels (Shah and Sekulić, 2003)

Type of Flow and Geometry	Correlations	Eq. No.	Remarks	Reference

Transition and turbulent flow, circular or non-circular duct	$\mathrm{Nu} = \phi\mathrm{Nu}_{\mathrm{lam}} + (1 - \phi)\mathrm{Nu}_{\mathrm{turb}}$ $\phi = 1.33 - (\mathrm{Re}/6000)$	(7.77) (7.78)	Use $\mathrm{Nu}_{\mathrm{turb}}$ from Eq. (7.74) or (7.76) and $\mathrm{Nu}_{\mathrm{lam}}$ from Table 7.3 Applicable for $2000 < \mathrm{Re} < 8000$	Taborek (1990)
Turbulent flow in a smooth duct	$\mathrm{Nu} = 0.023\mathrm{Re}^{0.8} \cdot \mathrm{Pr}^{0.4}$	(7.79)	So-called Dittus–Boelter correlation Used for approximate calculations	Winterton (1998)

What is considered a smooth tube ($\varepsilon/D_h = 0.0001$ at $\mathrm{Re} = 10^5$) for large diameter tubes (about 3 mm and larger) becomes increasing rough surface (for the same surface roughness height) as the diameter continues to go down in microns. This surface roughness essentially reduces the flow area and/or changes the effective flow cross section shape which in turn affects the fully developed friction factor and Nusselt numbers. Thus the effect of surface roughness should also be taken into account in laminar flow for microchannels by considering an effective diameter what Kandlikar names it as constricted diameter.

As in non-microchannels, the thermal boundary condition for heat transfer through microchannels is also ambiguous and falls in between constant wall temperature and constant heat flux boundary conditions. Not enough data are available to provide a correlation for this effect (Kandlikar and Garimella, 2006), as shown in table 3. Now we provide correlations for laminar and turbulent flow heat transfer and flow friction in microchannel passages.

Single-Phase Flow Friction in Laminar/Turbulent Flow

Kandlikar (2005) suggested to use the constricted diameter $D_{cf} = D - 2\varepsilon$ for the Reynolds number calculation and then use the Moody diagram for the determination of turbulent flow friction factors for microchannels. Here ε is the equivalent roughness and is the same as that used by Nikuradse. The transition Reynolds number reduces from about 2300 for a smooth tube to about 500 for a rough microtube having $\varepsilon/D_{h,cf} = 0.14$. Kandlikar then presented the following laminar-to-turbulent transition Reynolds number criteria as:

$$\mathrm{Re}_{t,cf} = 2300 - 18750\,(\varepsilon/D_{h,cf}) \qquad \text{for } 0 < (\varepsilon/D_{h,cf}) \le 0.08 \tag{2}$$

$$Re_{t,cf} = 800 - 3270\ (\varepsilon/D_{h,cf} - 0.08) \qquad \text{for } 0.08 < (\varepsilon/D_{h,cf}) \le 0.15 \tag{3}$$

Table 3. Fully developed laminar flow Nusselt numbers (Kandlikar and Garimella, 2007)

$\alpha_c = a/b$	$Nu_{fd,3}$	$Nu_{fd,4}$
0	8.235	8.235
0.10	6.939	6.700
0.20	6.072	5.704
0.30	5.393	4.969
0.40	4.885	4.457
0.50	4.505	4.111
0.70	3.991	3.740
1.00	3.556	3.599
1.43	3.195	3.740
2.00	3.146	4.111
2.50	3.169	4.457
3.33	3.306	4.969
5.00	3.636	5.704
10.00	4.252	6.700
>10.00	5.385	8.235

a – unheated side in three-side heated case.

Friction factors in the transition region for rough microtubes ($\varepsilon/D_{h,cf} \le 0.05$) at a given Reynolds number can be obtained by a linear interpolation of (i) the laminar friction factor $f_{cf} = 16/Re_{cf}$ and fully developed turbulent friction factor obtained from the following equations depending on the value of $(\varepsilon/D_{h,cf})$.

$$f_{cf} = \begin{cases} \dfrac{0.25\left[\log_{10}\left(\dfrac{\varepsilon/D_{h,cf}}{3.7} + \dfrac{5.74}{Re_{cf}^{0.9}}\right)\right]^{-2}}{4} & for\ 0 \le \varepsilon/D_{h,cf} \le 0.03 \\ 0.0105 & for\ 0.03 \le \varepsilon/D_{h,cf} \le 0.05 \end{cases} \tag{4}$$

Single-Phase Nusselt Numbers for Laminar/Turbulent Flow

For heat transfer, determine analytical Nusselt numbers for laminar flow through smooth rectangular passages with aspect ratio α_c (1 for square passages to 0 for parallel plates) from the correlations of Shah and Sekulić (2003) as follows for Ⓣ, Ⓗ1, and Ⓗ2 thermal boundary conditions.

$$Nu_T = 7.541(1 - 2.610\alpha_c + 4.790\,\alpha_c^2 - 5.119\,\alpha_c^3 + 2.702\,\alpha_c^4 - 0.548\,\alpha_c^5) \tag{5}$$

$$Nu_{H1} = 8.235(1 - 2.041\alpha_c + 3.0853\,\alpha_c^2 - 2.4765\,\alpha_c^3 + 1.0578\,\alpha_c^4 - 0.1861\,\alpha_c^5) \tag{6}$$

$$Nu_{H2} = 8.235(1 - 10.6044\alpha_c + 61.1755\,\alpha_c^2 - 155.1803\,\alpha_c^3 + 176.9203\,\alpha_c^4 - 72.9236\,\alpha_c^5) \tag{7}$$

It should be mentioned that the reduction in effective hydraulic diameter of a microchannel due to surface roughness would theoretically increase the heat transfer coefficient (for a constant Nusselt number). However, for conservative analysis and not knowing the effect of other factors on Nu, we generally ignore this effect and determine Nu based on the specified full diameter of the microchannels.

Since the rectangular cross section has four sides, the more common boundary condition for microchannel applications is the cross section heated on four sides; however, in experimental studies, heat transfer takes place from three sides and the fourth side has the cover of glass or some material bonded on the top side to form the microchannel. Hence, the fully developed laminar flow Nusselt numbers are presented in Table 3 for three and four side heated rectangular channels (Shah and London, 1978, Kandlikar and Garimella, 2006).
Longitudinal heat conduction in tube walls may not be important for microtubes because of thin walls and having short flow length. However, if the computer programs are used for the design/analysis purpose for a microchannel heat exchanger, this effect is generally taken care in most commercial software.
Kandlikar et al. (Kandlikar and Garimella, 2006) also present some information on enhanced (Offset strip fin geometry) microchannels, as shown in Fig. 1.

Two-Phase Flow in Microchannels: Transition from Macro to Microchannel Phenomena
There are several analytical approaches presented in the literature for quantitative evaluation of the transition regime based on the pertinent dimensionless groups. In the microscale, the surface tension is more important and the influence of gravity diminishes as the tube diameter reduces and hence no stratified flow exists.
Kew and Cornwell (1997) empirically proposed the transition from macro-to-microscale diameter d_{th} to occur at the Bond number Bd = 4. Here,

$$d_{th} = 2\left(\frac{\sigma}{g(\rho_L - \rho_G)}\right)^{1/2} \qquad Bd = \frac{g(\rho_L - \rho_G)d_i^2}{\sigma} \tag{8}$$

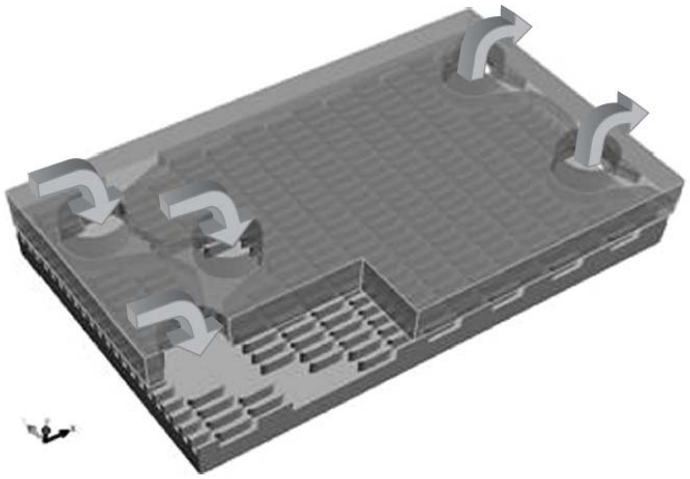

Figure. 1 - Three-dimensional rendition of the IBM enhanced silicon chip with short multiple fluid streams

The $d_{th} < 4$ represents the threshold to confined bubble flow (microscale flow). Some researchers use the confinement number Co instead of the Bond number. Note that Co = Bd/4 by definition.
Kawaji and Chung (2003) refined Kew and Cornwell criterion to include other dimensionless groups to take into account the comprehensive effect of all other acting forces as follows:

Bond number Bd <<4

Weber number $\quad We_{SL} = \frac{\rho_L U_L^2 d_i}{\sigma} << 1 \qquad We_{SG} = \frac{\rho_G U_G^2 d_i}{\sigma} << 1$

Reynolds number $\quad Re_{SL} = \frac{\rho_L U_L d_i}{\mu_L} < 2000 \qquad Re_{SG} = \frac{\rho_G U_G d_i}{\mu_G} < 2000$

Capillary number $\quad Ca_L = \frac{\mu_L U_L}{\sigma} << 1$

Superficial velocity: Gas $U_G = \frac{\dot{Q}_G}{A}$ $\qquad$ Liquid $U_G = \frac{\dot{Q}_G}{A}$

Ullman and Brauner (2007) suggested the transition from macro-to-microchannel threshold to occur at Bd ≈ 0.8, somewhat lower diameter than that of Kew and Cornwell (1997).

Two-Phase Flow Phenomena and Flow Regimes

As mentioned earlier, in the single-phase flow, there are no new fluid flow and heat transfer phenomena in two-phase flow (isothermal, i.e., without heat transfer) and boiling. The results for smooth macrochannels are also applicable to microchannels, except that one has to take into account the wall surface roughness introduced due to microchannel size. In the case of two-phase flow, boiling and condensation in microchannels, this is not the case since the flow regimes are somewhat different in microchannels, and the results for macrochannels may not be applicable to microchannels (D_h < 0.5 mm) due to underlying changes in the physics considerably. For example, surface tension effect (important primarily for condensation) becomes more important as the channel size reduces and the gravitational force becomes weaker. We will summarize these differences now.

Let us start first with the transition from macro-to-micro channel boiling phenomenon followed by the flow regimes. From the phenomena viewpoint, some flow regimes may be suppressed or become of secondary importance while some others may become important as the channel size reduces. These changes are usually gradual as the channel size reduces. Based on published flow visualization results, Thome (2008) concluded that the transition regime for stratified-wavy and fully stratified flow regimes in microchannels occurs in the range 0.5 – 2 mm tube diameter and below 0.5 mm tube diameter it becomes either annular flow or elongated bubble flow. Cheng et al. (2006) conducted an extensive study on flow regimes in vertical tubes (1.01–4.25 mm diameters) with R134a having the pressure range 6–14 bar. They found that none of the macroscale flow regime maps were able to predict their observations. They concluded 2 mm tube size as the boundary between large and small tube behavior with confined flow in the smaller tubes.

Chen et al. (2007) reported that isolated bubble (bubbly flow), confined bubble (plug/slug flow), annular flow and mist flow may exist during flow boiling in microchannels. In the stable flow boiling mode, vapor bubbles grow on the heated wall and carried away by the liquid. In unstable flow boiling mode with long-period oscillations, cyclic variations in pressure and temperature have been observed along with back and forth changing of bubbly flow and annular/mist flow with short-period oscillations.

Two-Phase Pressure Drop

Two-phase pressure drop data are not affected by going from macro-to-microscale in slug and annular flow, and the homogeneous flow model works very well (Thome, 2008).

The pressure drop during flow boiling in multi-microchannels was investigated for R236fa and R245fa, showing that R245fa yields higher pressure drops for chip cooling applications, due to its low vapour density. The total pressure drop was shown to increase almost linearly with vapour quality and as the square of the mass velocity, and to decrease with increasing saturation temperature. The homogeneous model correctly predicted these pressure drop trends and is recommended to be used together with the

inlet and outlet singular pressure drops to predict the total pressure drop in the present multi-microchannel configuration. Furthermore, an analysis showed that for the channel geometry and at the mass velocity and vapour quality required for a chip cooling application, the pressure drop is mainly controlled by the two-phase flow in the microchannels and not the headers with their orifices. However, the outlet pressure drop is not negligible and can represent up to 30% of the total pressure drop.

Flow Boiling

For flow boiling heat transfer in small channels, several studies indicated that as the diameter is reduced, the flow boiling heat transfer coefficient increases, again approximately the 2 mm diameter tube is the boundary between micro-to-macroscale transition, for low vapor quality about 0.25 or so.

Boiling in Microchannels

Thome (2006) provided a review of boiling and two-phase flow in microchannels. His conclusions were: more data are needed to understand and predict the flow boiling phenomena in microchannels: boundary between microchannels and macrochannels, critical heat flux data for circular and noncircular channels, fluid properties, inlet header geometry, two-phase flow transitions, flow instability and flow-induced fluctuations, etc.

Cheng et al. (2007) summarized Yen et al. (2003) work with the following three boiling modes in microchannels (based on the data for a microchannel of 0.186 mm diameter at an inlet subcooling of 35°C):

- Stable flow boiling with no periodic oscillation ($q/G < 0.96$ kJ/kg); isolated bubbles are generated.
- Unstable flow boiling with long-period oscillation (0.96 kJ/kg $< q/G <$ 2.14 kJ/kg); elongated bubbles expand upstream to near the inlet of the microchannel and makes the flow as annular/mist flow.
- Unstable flow boiling with short-period oscillations ($q/G >$ 2.14 kJ/kg) with annular and mist flow appearing alternately with time. Periodic dryout and rewetting has been observed.

Agostini et al. (2008a, 2008b, 2008c) conducted an experimental study in high heat flux flow boiling in silicon multi-microchannels using refrigerants R236fa and R245fa. Their findings were:

- At low heat flux, the heat transfer coefficient increases with vapour quality and is independent of heat flux and mass velocity.
- At medium heat flux, the heat transfer coefficient increases with heat flux as q0.67, is independent of vapour quality, increases slightly with mass velocity for R245fa or is independent of mass velocity for R236fa.
- At high heat flux, the heat transfer coefficient decreases with increasing heat flux and vapour quality and increases with mass velocity. The heat transfer coefficient is found to increase with saturation pressure, particularly for R236fa and the level of subcooling was found to have no influence for saturated boiling, while subcooled boiling data were below those for saturated boiling, similar to other previous studies.

Bertsch et al. (2008) compared 10 data sets on saturated flow boiling in channels of diameters range 0.16-2.01 mm. It included a total of 1847 points and eight fluids. These measured heat transfer coefficients were compared with the predicted values from 25 published correlations for flow boiling. They found a wide variation on the prediction of these experimental data. The best predictions had a

mean absolute error ±40%, less than half of the data were predicted within ±30%, and predictions from 12 out of the 25 correlations exceeded errors of 100%.

Critical Heat Flux

For saturated critical heat flux, the micro-to-macroscale transition occurs approximately in the same tube diameter range.

For the same test conditions, when the tube diameter is reduced from 0.530 to 0.050 and 0.251 to 0.050 mm (two studies), the void fraction deviated from the homogeneous void fraction law (higher void fraction) perhaps suggesting a new smaller scale transition.

Agostini et al. (2008a, 2008b, 2008c) detected CHF when the difference between the wall and the saturation temperatures was greater than 70 K. With increasing mass velocity, the wall critical heat flux also increased. The inlet saturation temperatures ($20.31°C < T_{sat,in} < 34.27$ °C) and the inlet subcoolings ($0.4 < \Delta T_{sub} < 15.3$ K) were found to have a negligible influence on the wall CHF. The best methods were Wojtan et al. (2006) correlation and Revellin and Thome (2008) model. They both predicted 100% of the experimental CHF results to within ±20% with the heated equivalent diameter taken as the characteristic diameter.

Calculating the critical vapor quality from the CHF, an annular-to-dryout transition is also obtained as a design limit in a diabatic microscale flow pattern map. Beyond this transition, damage from overheating would occur for the device being cooled by the microchannels.

Condensation

Condensation in minichannels and microchannels is substantially enhanced because surface tension plays a very important role by pulling the condensate film to the corners of the non-circular passages, more common in automotive air-conditioning condenser passages and some industrial applications. Thus the liquid film away from the corners is thinned out resulting in enhanced heat transfer coefficient in the regions away from the corners. Note that surface tension does not play an important role in boiling as it does in condensation. Some of the geometries investigated or used for condensation in automotive/industrial applications are shown in Fig. 2 (Webb and Ermis, 2001). Other applications of microchannel heat exchangers envisioned as good design data and information on fouling become available. In addition to reduced air-side pressure drop and improved heat transfer, the required refrigerant charge also reduces with minichannels in automotive condensers and some electronic components.

It should be emphasized that surface tension becomes important minichannels and the flow regimes that are dominated by surface tension are: slug, plug and bubble. In contrast, in larger tubes, shear stress dominates and associated flow regimes are mist, annular, wavy and stratified flow. We consider surface tension dominated flows when surface tension force is larger than the sum of shear force plus buoyancy force. As we will describe, in minichannels, the most important flows are intermittent (slug/plug) and annular.

Condensation is extensively studied experimentally in minichannels ($D_h \geq 0.44$ mm) while none in microchannels because of experimentation difficulty. Condensation heat transfer is significantly enhanced as the channel size (hydraulic diameter) becomes smaller and smaller, going from minichannels towards microchannels. We will briefly describe flow regimes in minichannels with circular, rectangular and square cross-sections.

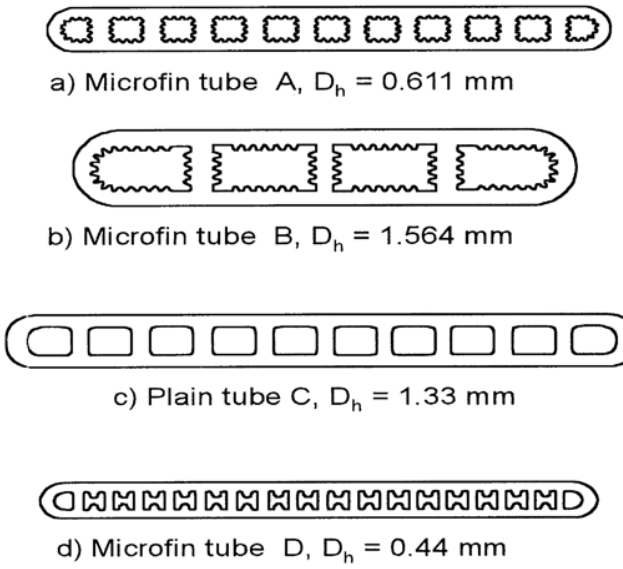

Figure. 2 - Microfin tubes: (a) A: 1.7-18-11M, D_h = 0.611 mm, (b) B: 3-16-4M, D_h = 1.564 mm, (c) C: 2-20 10P, D_h = 1.33 mm; (d) D: 1.4-18-18M, D_h = 0.44 mm (Webb and Ermis, 2001)

Condensation Flow Regimes

Garimella, et al. (2000, 2002, 2005) observed flow regimes during air-water adiabatic flow, and with R134a condensing at 51.7 °C in horizontal tubes and square minichannels with hydraulic diameters ranging from 4.91 to 0.5 mm. The following are their major findings:

- Hydraulic diameter has a substantial effect on flow pattern and transition, while tube shape is less significant.
- For G > 150 kg/m^{2}s, four regimes are identified: annular, wavy (influenced by gravity and with a wavy structure of the liquid film), intermittent (slug, plug), dispersed (bubble).
- As D_h decreases (D_h < 3 mm), overall range of annular flow increases, wavy regime decreases disappearing at D_h = 1 mm, while the intermittent regime increases. The model of intermittent flow is shown in Fig. 3.

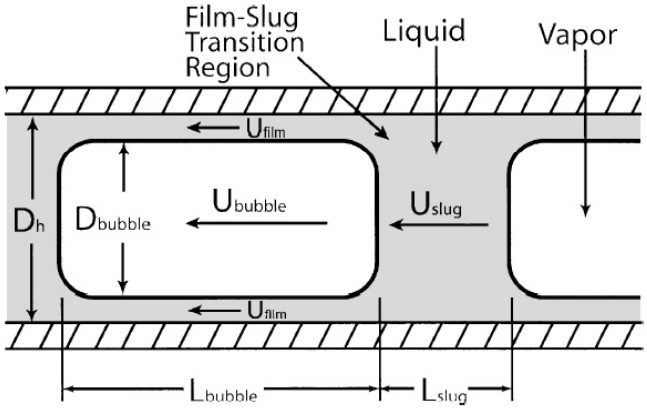

Figure. 3 - Schematic of intermittent flow, Garimella et al. (2005)

Coleman and Garimella (2000) and Garimella et al. (2002) proposed a map for the transition from intermittent to non-intermittent flow (wavy, annular mist, disperse flow) as shown in Fig. 4. This transition occurs at vapor quality x given by

$$x \leq \frac{a}{G + b} \tag{9}$$

where $a = 69.57 + 22.60 \exp(0.259\ D_h)$ and $b = -59.99 + 176.8 \exp(0.383 D_h)$. Here the hydraulic diameter D_h is in mm and G is the total mass flux in kg/m^{2}s.

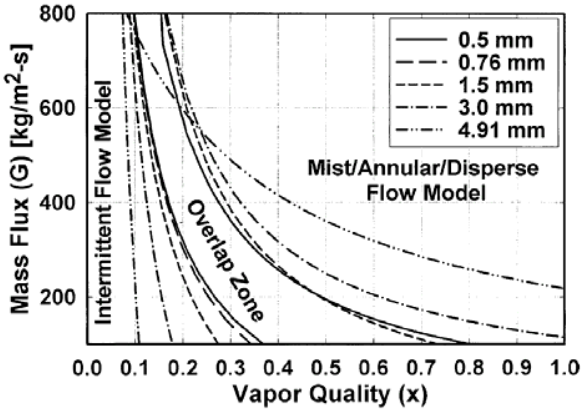

Figure. 4 – Flow regimes in minichannels (Garimella et al. 2002)

Cheng et al. (2007) identified four flow patterns in flow condensation: mist flow, annular flow, slug/plug flow (confined bubble) and bubbly (isolated bubble) flow.

Condensation Pressure Drop

Garimella et al. (2005) studied pressure drop during condensation of refrigerant R134a in horizontal circular channels of diameters range 0.5-4.91 mm. The pressure drops were measured for qualities 0-100% and the mass fluxes 150-750 kg/m^{2}s. Out of a total of 603 experimental data points, 77 data points were in the intermittent regime, 448 data points in disperse/annular/mist flow regime, and the remaining 78 data points in overlap region between the above two flow regimes (see Fig. 4 for flow regimes).

For the intermittent regime modeling, they considered the total pressure drop consisting of three components – the liquid slug ΔP_{slug}, the vapor bubble ΔP_{vb}, and the flow of liquid between the film and slug $\Delta P_{film\text{-}slug}$ as follows. Here it was idealized that the flow was reasonably uniform with large slugs of vapor bubble as shown in Fig. 4.

$$\Delta P_{total} = \Delta P_{slug} + \Delta P_{vb} + \Delta P_{film\text{-}slug} \tag{10}$$

$$\frac{\Delta P}{L} = \left(\frac{dP}{dx}\right)_{film\,bubble}\left(\frac{L_{bubble}}{L_{unit\ cell}}\right) + \left(\frac{dP}{dx}\right)_{slug}\left(\frac{L_{slug}}{L_{unit\ cell}}\right) + \Delta P_{one\,transition}\left(\frac{N_{unit\ cells}}{L}\right) \tag{11}$$

The term in the parenthesis of the last term on the right-hand side of the above equation is the same as $1/L_{unit\ cell}$ and can be determined from the slug frequency measurements or from the following correlation:

$$\frac{D_h}{L_{unit\ cell}} = 1.573\left(Re_{slug}\right)^{-0.507} \tag{12}$$

This model predicted 65% of the intermittent and discrete wave flow data within ±20%. If only intermittent flow regime points were considered, the model would predict 75% of the data within ±20%. In the disperse/annular/mist flow regime, the pressure gradient is given by

$$\frac{\Delta P}{L} = \frac{1}{2} f_i \frac{G^2 x^2}{\rho_V \alpha^{2.5}} \frac{1}{D} \tag{13}$$

where f_i is given by

$$\frac{f_i}{f_l} = A X^a Re_l^b \Psi^c \tag{14}$$

where the constants are given by

$A = 1.308 \times 10^{-3}$; $a = 0.427$, $b = 0.930$ and $c = -0.121$ for laminar region ($Re_l < 2100$)

$A = 25.64$; $a = 0.532$, $b = -0.327$ and $c = 0.021$ for turbulent region ($Re_l > 3400$)

For the transition region, the pressure drop is first independently calculated using the laminar and turbulent constants at the low and high values of the mass flux and quality representing the boundaries of the laminar and turbulent regions. Linear interpolation between these bounding values is then conducted separately based on the quality and mass flux in consideration. The average of these two pressure drops resulting from the interpolation based on G and x represents the two-phase pressure drop for the transition region data point. The above model predicts 87% of the data within ±20%, as shown in Fig. 5.

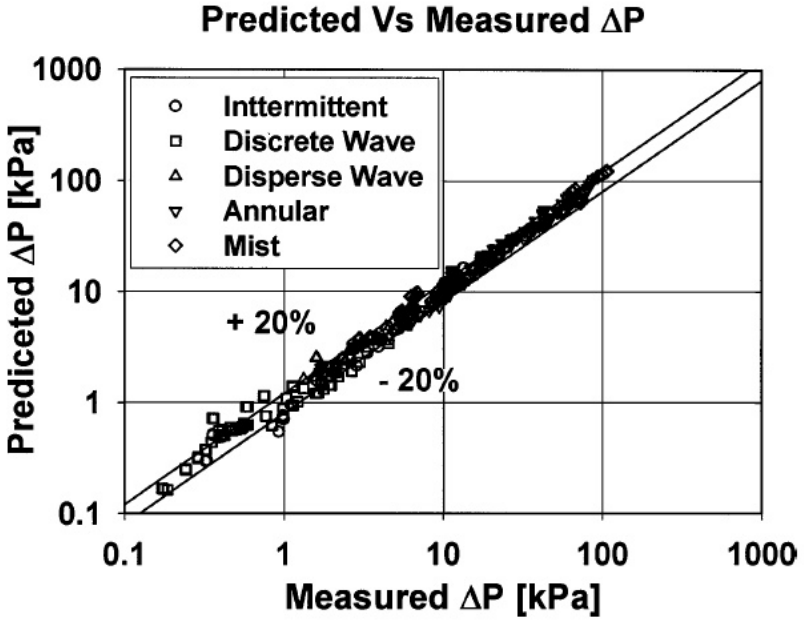

Figure. 5 - Comprehensive pressure drop model predictions (Garimella, et al. 2005)

Condensation Heat Transfer

Due to small channel size, surface tension and viscous dissipation effects become important which may not be that important for large channels.

Several condensation heat transfer studies have been reported in the literature. Cavallini et al. (2005a) reported condensation in a multiport tube (1.4 mm hydraulic diameter) as used in a modern condenser having flat multiport tube and corrugated multilouver air fins. They used R134a and R410a refrigerants and mass velocity range of 200-1000 kg/m^{2}s (for R134a) and 200-1400 kg/m^{2}s (for R410a) with the vapor quality varied as 0.75, 0.50 and 0.25. The measured data were compared with several correlations. There was good agreement of the frictional pressure drop with several published correlations, but the measured heat transfer coefficients were underpredicted by all models. The reason may be different flow regimes for the test results compared to the correlations for annular flow regime.

Cavallini et al. (2005b) extended their work (Cavallini et al. (2005a)) by condensing R134a, R410A and R236ea in 1.4 mm hydraulic diameter multiport tube. They then proposed the following correlation which agreed most of the experimental data within ± 20% in the shear dominated regime, as shown in Fig. 6.

$$Nu_{annular} = Nu_{LO}\,[1 + 1.128\,x^{0.817}(\rho_L/\rho_G)^{0.3685}(\mu_L/\mu_G)^{0.2363}(1-\mu_G/\mu_L)^{2.144}Pr_L^{-0.1}]/(1-E)^{0.08}$$

where

$$E = 0.015 + 0.44\,\log[(\rho_{gc}/\rho_L)(\,\mu_L j_G/\sigma)^2 10^4] \quad \text{and} \quad \rho_{gc} = \rho_G\,(1 + (1-x)\,E/x)$$

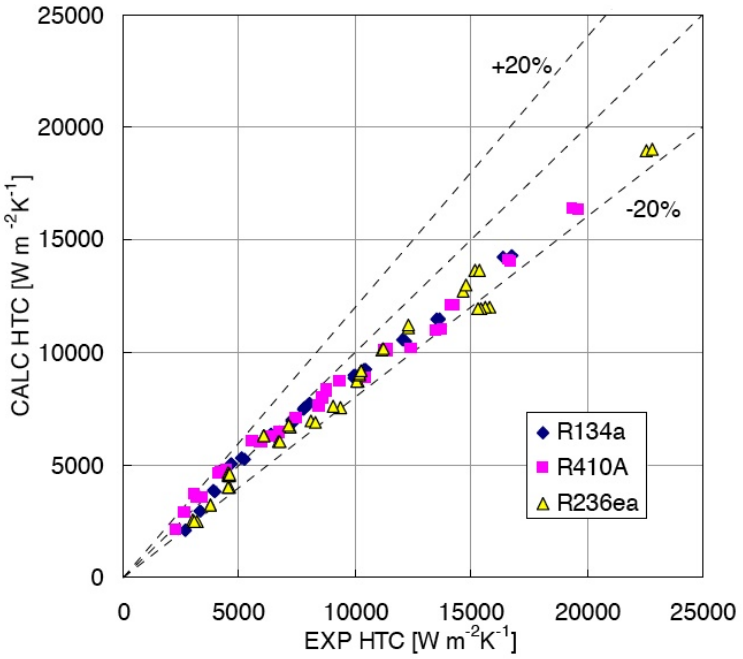

Figure. 6 – Prediction of experimental data for R134a, R410A and R236ea inside l.4 mm inner diameter minichannel, Cavallini et al. (2005a)

Chowdhury et al. (2006) experimentally evaluated pressure drop and heat transfer during condensation of R134a in 7:1 aspect ratio rectangular duct of 0.7 mm hydraulic diameter. They used a unique fabrication technique milling and electroplating to make this channel. They covered the following range of parameters: inlet vapor quality 20-80% and mass flux 130-200 kg/m^{2}s. Outlet conditions were

maintained close to thermodynamic saturated liquid state through a careful experimental technique. The trends of results are similar to those found in recent literature in such microchannels.
Cheng et al. (2007) summarized their findings as follows for condensation in microchannels: At low mass fluxes ($G < 200$ kg/m^{2}s), measured Nusselt numbers are higher than those from macrochannel correlations. At high mass fluxes ($G > 200$ kg/m^{2}s), measured Nusselt numbers can be predicted well with the macrochannel correlations.
Wang and Rose (2006) studied film condensation analytically to determine the effect of tube inclination from +90° (upflow) to -90° (downflow) in square channels with the side 0.5, 1.0 and 3.0 mm. As expected, they found that the effect of inclination was negligible due to surface dominated region and corroborated with the findings of Coleman and Garimella (2003).

Concluding Remarks

Heat transfer information for small diameter tubes are summarized with reference to phenomena and design information for single-phase flow, boiling and condensation.
Micropipes and microchannels as emerging geometries for heat and mass transfer, controlled fluid transport and thermal control are analyzed with reference to manufacturing technologies and possible classification criteria. In this frame the most widely used is the one based on the confinement of bubbles as the tube diameter reduces.
Single-phase fluid flow is examined comparing macro and microscale evidencing the general similarity of behavior provided scaling effects are properly accounted for (entrance length, viscous dissipation). Similarly, single-phase heat transfer does not show any significant change when passing from macro- to microscale, always provided scaling effects are taken into account (thermal entrance length, viscous dissipation, conjugate heat transfer). In single-phase flow there is a common agreement to identify the threshold between micro and macroscale on the basis of scaling effects occurring (depending on fluid properties, velocity and geometry).
Heat transfer with phase change, i.e., boiling and condensation, exhibits large differences between macro- and microscale, the main reason being due to the bubble confinement, which is also the most widely used criterion to identify the transition between micro and macroscale. Although many researches are now available in boiling and condensation, still much has to be studied to accomplish a significant understanding of the microscale heat transfer with phase change.

NOMENCLATURE

D_h	hydraulic diameter, m
G	mass flux, kg/m^{2}s
g	gravitational acceleration, m/s^2
j	superficial velocity, m/s
Nu	Nusselt number, hD_h/k, dimensionless
Pr	Fluid Prandtl number, dimensionless
q	heat flux, kW/m^2
x	vapor mass quality, dimensionless
μ	dynamic viscosity, Ns/m^2
σ	surface tension, N/m
ρ	density, kg/m^3

Subscripts

DEVELOPMENT OF MICRO PLASMA ACTUATOR FOR ACTIVE FLOW CONTROL

S. Okochi*, N. Kasagi, Y. Suzuki, S. Ito
Department of Mechanical Engineering, The University of Tokyo, Tokyo 113-8656, Japan

ABSTRACT. We establish the design and fabrication of mm-size plasma actuators through MEMS process. The flow induced by three differently sized actuators fabricated is measured by laser Doppler velocimetry (LDV) in order to clarify these actuators' characteristics. The present experiment first confirms the same dependency of the induced velocity on the imposed voltage as reported in previous work. Then, it is clarified that there exists the optimal frequency to drive a flow unlike previous studies. In the measurement of the flow field, strong suction as well as blowing near the actuator is found in accordance with conventional large plasma actuators. Moreover, distinct suction and blowing in the lateral direction is also identified when reducing the length of actuator. The efficiency of plasma actuator is not changed significantly through miniaturization. These results show that the micro plasma actuator is applicable to various flow controls, particularly, to turbulent flows where small scale structures should be directly manipulated.

Keywords: plasma actuator, miniaturization, MEMS, flow control, turbulence control

INTRODUCTION

Active and flexible flow control has recently attracted much attention due to economical and ecological interests in various industrial applications. For example, efficient flow control systems could modify the laminar-turbulent flow transition in a boundary layer, prevent or induce separation, reduce drag, stabilize or mix air flow in order to avoid undesirable vibration, noise and energy losses [1]. To achieve such flow controls, many actuators have been developed, e.g., mechanical flaps and wall synthetic jets [2, 3]. These actuators have been successfully applied to mixing control in jet, separation control, and so forth. However, they have some drawbacks; generally, they have complicated structures and generate noise, vibration and secondary flow.

In the middle of the 1990s, Roth *et al.* [4] developed a plasma actuator using atmospheric pressure dielectric barrier discharge. Figure 1 shows the configuration of a typical plasma actuator. A plasma actuator (PA, hereafter) consists of two metallic electrodes asymmetrically mounted on both sides of a dielectric plate and lower electrode is covered with dielectric. They demonstrated that a PA drives gas in the area within a few millimeters away from the actuator surface. So far, PAs have been successfully applied to flow separation control or noise reduction. For example, Roth *et al.* [4] have shown the ability of this actuator to modify the properties of a boundary layer over a flat plate, and Göeksel *et al.* [5] have shown lift improvement in stall configuration.

Considering possible advantages such as no moving parts, simple structure and high frequency response, PA is considered promising also for turbulence drag or mixing control. Suppose we consider friction drag reduction in wall turbulence, the momentum transfer is governed by

microscopic coherent structures, whose length and time scales are 10 μm ~ 1 mm and 0.01 ~ 10 ms in practical applications. Therefore, to achieve active and flexible control in such flows, a small PA (1 mm or less) is strongly needed. The most of the PAs reported so far are one with a width of 20 mm and a length of 300 mm. Since the typical length scale of plasma is about a few millimeters, further miniaturization of a PA bellow this length should affect the dynamics of plasma and the resultant performance. We refer to a PA whose electrode width is less than plasma volume (4 mm) as micro PA. Moreover, for the miniaturization of the plasma actuator, to fabricate micro PAs tolerant to high voltage and plasma is a major issue. Therefore, the aim of this paper is: (1) to establish the fabrication process of micro plasma actuator; (2) to clarify the size characteristics of micro and macroscopic plasma actuators; (3) to explore the induced flow velocity and efficiency of micro plasma actuator.

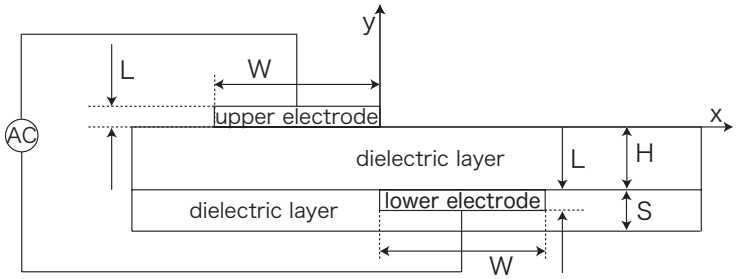

Figure 1. Structure and geometrical parameters of DBD plasma actuator

FABRICATION OF PLASMA ACTUATOR AND EXPERIMENTAL SETUP

Design and fabrication of micro plasma actuator by MEMS

The electrical and mechanical characteristics of a PA depend on various parameters such as electrode width, electrode thickness and dielectric layer thickness. According to Roth *et al.* [4], Forte *et al.* [6] and Hoskinson *et al*. [7], the induced flow is enhanced with decreasing the thicknesses of electrodes and dielectric layer. Based on the knowledge, we designed test actuators are as follows. The electrode width *W* is changed as 1, 4 and 10 mm to investigate the effects of the actuator size on the plasma volume and the induced flow. The electrode thickness *L* is 300 nm, which is the minimum durable thickness through the microelectromechanical system (MEMS) fabrication process we employ. The thickness of a dielectric layer *H* is chosen as 0.525mm, whish is the minimum thickness to avoid dielectric breakdown. The insulate layer thickness *S* is 30 μm to avoid discharge by the lower electrode.

The MEMS fabrication process of micro PA is shown in Fig. 2. The process starts with a 525 μm-thick Pyrex glass wafer. Upper and lower Cr/Au/Cr electrodes are vapour-deposited with a standard lithography process. Then, the lower electrode is covered with Parylene C. Micro PA fabricated by this MEMS process is shown in Fig. 3.

Electric power supply

Figure 4 shows a power supply system used in this experiment. In order to achieve dielectric discharge, the upper electrode is connected to a high voltage amplifier (HEOPT-5B20-L1, ± 5kV) driven by a function generator delivering a sinusoidal waveform. The lower electrode is grounded. A sinusoidal wave voltage with the maximum amplitude up to 5 kV is applied between the electrodes at different frequencies of 0-20 kHz. The voltage and current are monitored by a fast digitizer. The voltage is measured with an internal probe of amplifier, while the current is measured with a Rogowski coil (1kHz-1GHz, 0.1mA-10A).

Velocity measurement

The micro PA is placed flush on the bottom wall surface of the two-dimensional channel, which is about 5 m long and has a test section of 10 × 50 cm^2. A smoke injector is placed at the intake of the channel in order to supply the flow with small oil particles of 1 μm in diameter. The experiment is carried out at low air velocities (Reynolds number based on the channel height and the centerline velocity ~ 1000) in order to easily discriminate the base flow and the flow induced by the micro PA. Although this wind tunnel is designed long enough to reproduce a fully developed turbulence channel flow at the point of measurement, the root-mean-square streamwise velocity fluctuation remains at about 10% of the local mean velocity near the wall region under such a low velocity condition. However, this magnitude of velocity fluctuation is much smaller than the velocity induced by the actuator.

Figure 5 shows the measurement arrangement with a Laser Doppler Velocimeter (LDV) and the coordinate system with its origin being located on the surface just downstream of the center of the upper electrode. The *x*-, *y*- and *z*-axes are defined in the streamwise, wall-normal and spanwise directions, respectively.

EXPERIMENTAL RESULTS

Electric discharge and induction of fluid flow

The driving principle of PA is based on the Townsend mechanism, or electron avalanche, which corresponds to the multiplication of some primary electrons in cascade ionization. When a high voltage is applied between two planes, electrons are accelerated towards the anode by the electric field and they ionize the gas by collisions. An avalanche develops because the multiplication of electrons proceeds along their drift from the cathode to the anode. A discharge current is then created.

Figure 6 shows a typical example of the measured voltage and current (W = 1 mm, V_a = 5 kV and F = 10 kHz). It can be seen that the current has two components. One is a sinusoidal wave in

quadrature phase with the voltage. The other is the impulse current due to the dielectric barrier discharge during the positive and negative half-cycles of the voltage waveform. Note that the discharge is asymmetric during the positive and negative cycle. This demonstrated that the discharge is different during the positive and negative cycles as shown in Fig. 6.

Figure 7 presents the instantaneous velocity induced at x = 5 mm, y = 0.5 mm and z = 0 mm by a plasma actuator (V_a = 5 kV, F = 10 kHz, W = 1 mm). The induced flow is fluctuating because the discharge does not behave similarly during the positive and negative cycles. As the barrier discharge is periodic, it seems to generate a pulsating flow. In fact, Forte *et al*. [6] demonstrated that the induced velocity follows the high voltage waveform frequency.

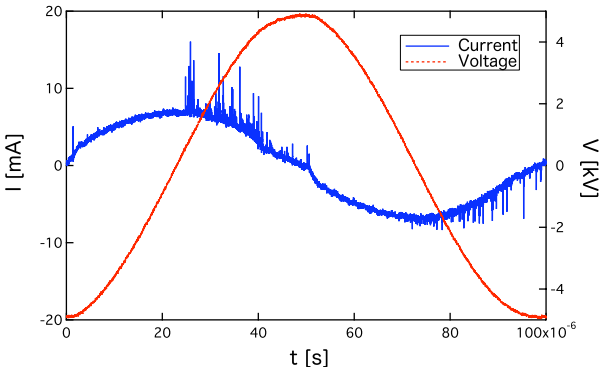

Figure 6. Typical discharge current and voltage waveform

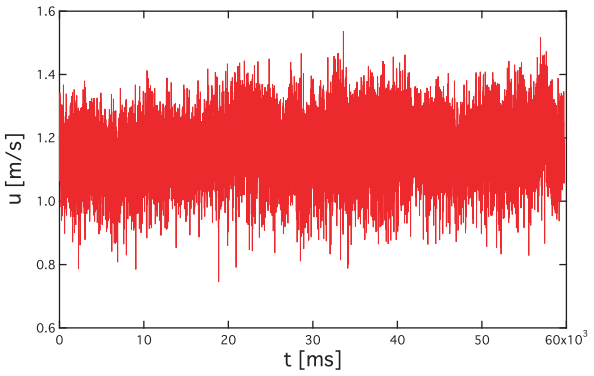

Figure 7. Instantaneous velocity versus time at x = 5 mm and y = 0.5 mm

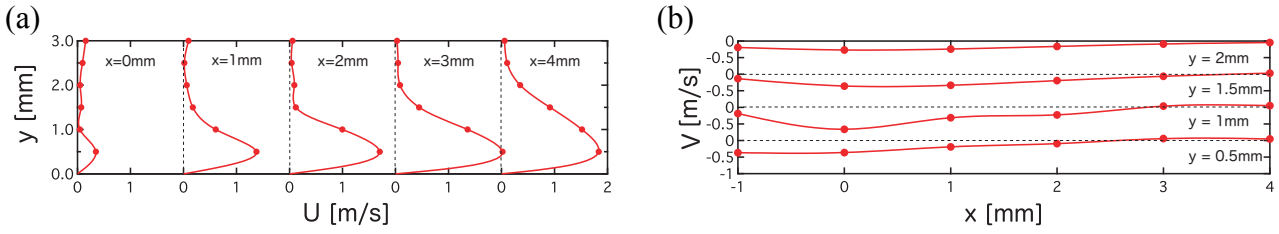
Time-averaged flow distribution

The velocity field induced by the actuator is measured in the x-y plane with the applied voltage of V_a = 5 kV at the frequency of F = 10 kHz. The time-averaged velocity distributions are shown in Fig. 8. Strong suction is observed between the upper and lower electrodes, and a wall-tangential jet is induced in the vicinity of the wall regardless of the size of plasma actuators. These velocity profiles clearly show the momentum transferred from the plasma to the surrounding air. Specifically, the maximum velocity decreases and the controlled area becomes thicker with increasing streamwise distance x. The maximum induced velocity is enhanced with increasing the actuator size. The peak position of induced velocity in the present study is different from that in the previous research. Forte *et al.* [6] demonstrated that the maximum induced velocity was reached at the end of the plasma, and the induced velocity decreased further downstream. In the present work, in the case of electrode width of 4 and 10 mm, the maximum velocity occurs at the end of the plasma and the height is y = 0.5 mm from the wall. In contrast, in the case of actuator of 1mm width, the maximum velocity is measured at x = 3 mm, not at the end of plasma. This fact is in contrast to the previous results.

Figure 9 shows the flow distribution of the actuator of 1mm in width at different z locations. It is clear that the peak location of induced velocity shifts downstream (x = 3 mm at z = 0 mm, x = 10 mm at z = 3 mm and x = 15 mm at z = 6 mm). Associated with shortening the spanwise length of electrode, it is expected that in the x-z plane where $x < 0$, the induced flow is sucked to the actuator, whereas induced away from it where $x > 0$.



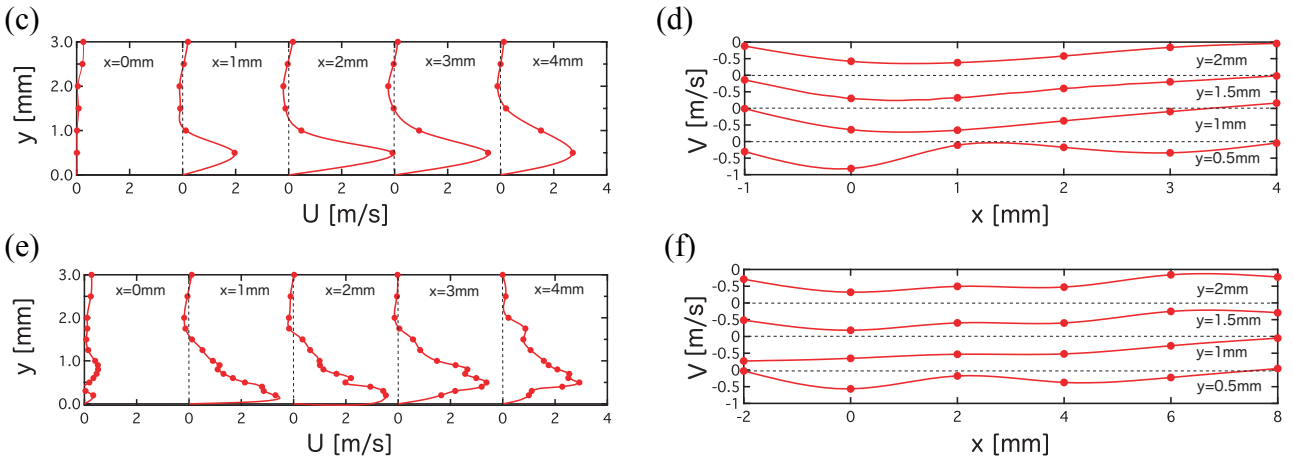


Figure 8. Mean streamwise and wall-normal velocities around the plasma actuator: (a) U with W = 1 mm, (b) V with W = 1mm, (c) U with W = 4 mm, (d) V with W = 4 mm, (e) U with W = 10 mm, (f) V with W = 10 mm

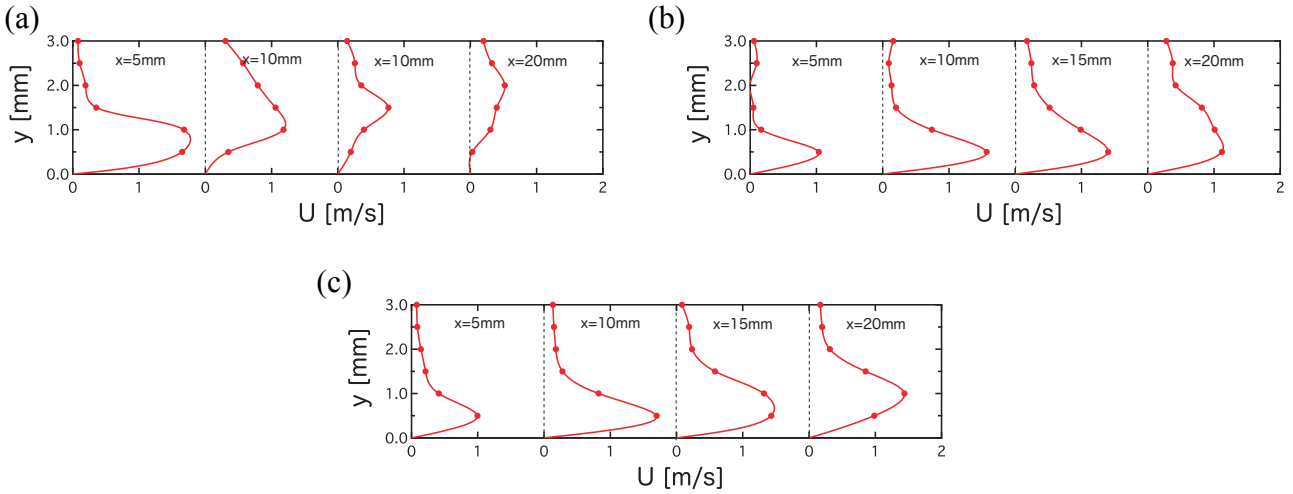

Figure 9. Mean streamwise velocity distributions at different z-planes around the plasma actuator of W = 1 mm: (a) z = 0 mm, (b) z = 3 mm, (c) z = 6 mm

Dependency of induced flow velocity on applied voltage

Figures 10 and 11 respectively show the maximum induced velocity $U_{\max}$, which is measured at the height of y = 0.5 mm, and the electrical power dissipation per unit length P_{elec} at different V_a with F = 5 kHz. The velocity increases monotonously as the applied voltage is increased, because a higher voltage enhances discharge and makes ions undergo stronger Colombian forces. Moreau *et al.* [8] obtained the following empirical equation: $U_{\max} = 0.000166 \times V_a^{3.5}$. In the present work, the relationship between $U_{\max}$ and V_a is approximated as: $U_{max} \propto V_a^{1.8}$, $U_{max} \propto V_a^{1.94}$, and $U_{max} \propto V_a^{2.3}$ for W = 10, 4 and 1 mm, respectively. This difference is due to different discharge modes. It is noted that there is a threshold voltage, at which the discharge mode is changed from glow discharge to filamentary discharge. It is known [6] that the latter filamentary mode of plasma is much less efficient in transferring momentum to neutral gas molecules. However, this threshold voltage is different according to the geometry of PA. Similarly, the electrical power dissipation increases with the applied voltage. The relationship between them is expressed as $P_{elec} \propto V_a^{2.7}$. This result agrees with previous work. For example, Pons [9] and Roth *et al.* [4] demonstrated that $P_{elec} \propto V^n$ with $2 < n < 3$. However, these empirical equations are not based on plasma physics, so that a theoretical approach is needed to establish firm fundamental knowledge.

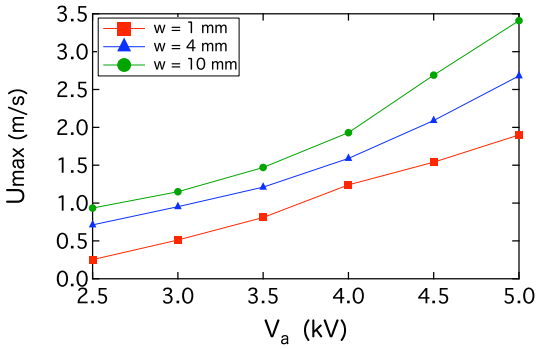

Figure 10. Maximum induced flow velocity versus applied voltage

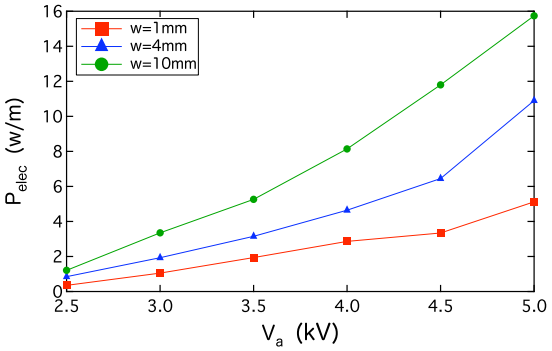

Figure 11. Electrical power dissipation per unit length versus applied voltage

Dependency of induced flow velocity on applied frequency

The maximum induced velocity and the electrical power dissipation per unit length at different frequencies with V_a = 5 kV are shown in Figs. 12 and 13, respectively. It is evident that the optimal frequency to achieve the highest maximum velocity exists and it increases with decreasing the size of the actuator. For example, the optimal frequency is 16 kHz when W = 1 mm, while 12 and 10 kHz for W = 4 and 10 mm, respectively. This fact is in contrast to the previous results, where the induced velocity was monotonically increased with the frequency [6]. The possible reason for this is that, as the frequency is increased, the mean transferred charge increases inducing more collisions between ions and gas and enhancing the induced velocity. However, when the discharge frequency exceeds the ion trapping frequency, the electron avalanche does not grow enough.

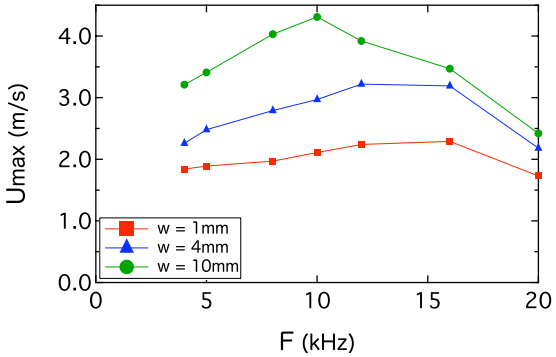

Figure 12. Maximum induced flow velocity versus frequency

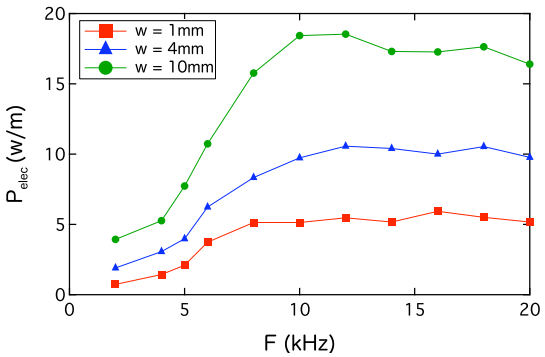

Figure 13. Electrical power dissipation per unit length versus frequency

Efficiency of micro plasma actuator

For a given two-dimensional parallel velocity profile, the corresponding mechanical power delivered to the air can be estimated from the following equation (Moreau [8]):

$$P_{mech} = \int_0^\infty \frac{1}{2}\rho v(y)^3 l dy \ , \tag{1}$$

where ρ is the air density and l is the electrode length. The electrical power dissipation is expressed by the following equation:

$$P_{elec} = \frac{1}{T}\int_0^T V \times I \ dt \tag{2}$$

Then, the mechanical efficiency of a PA is given as:

$$\eta = P_{mech} / P_{elec} \tag{3}$$

The efficiency of micro PA is shown in Fig. 15. It shows that, as the imposed voltage is increased, the electro–mechanical efficiency of a smaller PA reaches its seemingly saturated value faster. Moreover, the efficiency obtained in the present work is much higher than that reported in the previous work. For example, Forte *et al.* [6] demonstrated that the efficiency of PA remains at about 0.03 % as seen in Fig. 15. Figure 16 shows the comparison of maximum induced velocity between conventional and micro PAs. It is clear that the inception voltage of the present micro PA is 2.5 kV and much lower than that reported in previous work. For example, in Forte *et al.* [6], the inception voltage was 8 kV. This is because the employment of a thinner dielectric layer enhances the electric field. Therefore, the efficiency of PA can be even more improved by optimizing design parameters.

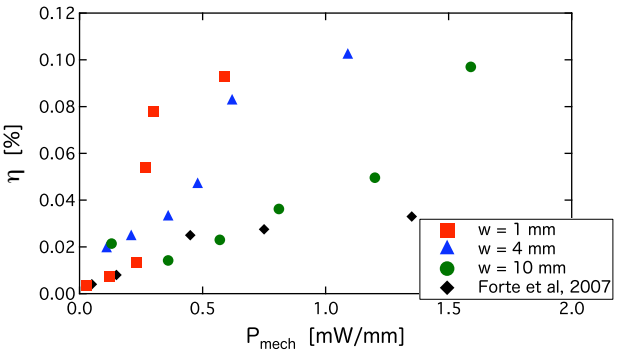

Figure 15. Comparison of the efficiency between conventional and micro plasma actuators

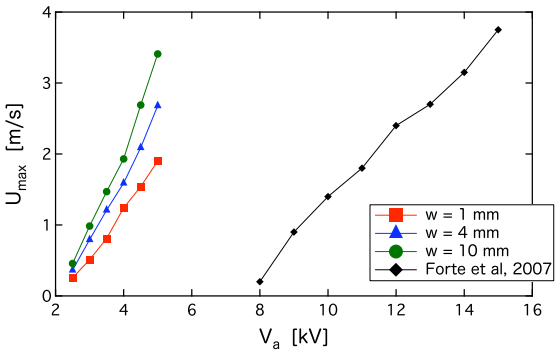

Figure 16. Comparison of the maximum induced velocity between conventional and micro plasma actuators actuator

CONCLUSIONS

In the present work, we proposed and established the MEMS fabrication of micro plasma actuators, of which electrode width is less than the plasma volume size. Then, we experimentally clarified the induced flow characteristics and also the efficiency of the micro plasma actuator. The major findings are summarized as follows:

(1) From the LDV measurement of the flow field, it is confirmed that strong suction and blowing are induced around the plasma actuator regardless of the actuator size tested, i.e., W = 1, 4, and 10 mm. In addition, the induced flow field is essentially three-dimensional because the appreciable spanwise velocity component is also induced, particularly around a smaller plasma actuator.
(2) It is found that the design parameters of plasma actuator affect the discharge and thus the induced velocity considerably. The maximum induced velocity increases with increasing the grounded electrode width and applied voltage, while the optimal driving frequency exists depending upon the size of actuator.
(3) The maximum electro-mechanical efficiency of plasma actuator has weak dependency on the size of the plasma actuator. However, thinning the dielectric layer leads to a higher efficiency.

ACKNOWLEDGEMENTS

We thank Dr. Y. Hasegawa, Messrs. Y. Hamana and D. Ko in the Department of Mechanical Engineering, the University of Tokyo for their discussions and technical supports. The present work was supported through Grant-in-Aid for Scientific Research (A) (No. 20246036) by MEXT, Japan.

ABSTRACT. Recent trends in small-scale (~1 dm^3) satellites motivate the further development of micro-scale propulsion subsystems with thrusts in the μN - mN range. In the present paper, we focus on the importance of wall effects in such small systems, due to the decrease in the characteristic length and the consequent rapid increase of the surface-to-volume ratio. First, a brief overview is presented of the rarefaction effects that can be expected on the basis of the small characteristic dimensions of the system, and that have been studied through Navier-Stokes based continuum simulations and Direct Simulation Monte Carlo (DSMC). Second, the influence of the gas-surface interaction is studied considering different boundary conditions for the flow in both Navier-Stokes and DSMC, with a special attention for the molecular energy exchange at the gas-solid interface. The precise nature of the boundary conditions is found to have a strong influence on the flow in the region of interest, and consequently on the nozzle performance.

INTRODUCTION

Recent trends in small-scale (~1 dm^3) satellites motivate the further development of small-scale, low-mass, low-thrust (μN – mN), microchannel based propulsion systems that allow precise control and manoeuvring of these small spacecrafts. Micro-electromechanical systems (MEMS) technology allows for the fabrication of micronozzles with thrusts suitable for this scale of satellite. In The Netherlands, a large multidisciplinary research program on the development of such propulsion systems is being carried out. An overview of this program is presented in [1], [2].
Micro-propulsion systems differ from large scale propulsion systems: the significant decrease in the characteristic length of such small systems, and the consequent increase of the surface-to-volume ratio, make surface effects strongly influence the flow inside the micro-nozzle. It has been pointed out [3] that while the surface-to-volume ratio is ~1 m^{-1} for a machine with a characteristic length of 1 m, the same ratio for a MEMS device having a size of 1 μm is ~10^6 m^{-1}. As a result, the transport of mass, momentum and energy may be strongly affected by the surface. Some areas of concern, like the inefficiency associated with viscous losses due to the developing boundary layer, and the effect of surface roughness and the way the gas interacts with the solid walls, cannot to be ignored.
Moreover, due to the small characteristic dimensions, comparable to the molecular mean free path, of thrusters in the μN - mN range, rarefaction effects need also to be considered: at these length scales the gas cannot be treated as a continuum, and molecular effects must be taken into account

[4] [5] [6]. The Knudsen number, defined as the ratio between the mean free path of the gas molecules λ and a characteristic length L of the flow:

$$\mathrm{Kn} = \frac{\lambda}{\mathrm{L}} \tag{1}$$

is an important parameter used to predict flow regions where a continuum method cannot accurately solve the flow. Various flow regimes can be distinguished based on the value of Kn [7]. Here we only want to underline that in micro nozzles the criterion for the validity of the Navier-Stokes solution (Kn<0.01) is not met throughout the entire geometry [8].
Micronozzle hydrodynamics have been studied through numerical CFD simulations in e.g. [9], [10]. Rarefaction effects, that start to play a role for very small scale nozzles, have been accounted for through the use of CFD with wall slip conditions [5], [11], [12] and through the use of Direct Simulation Monte Carlo techniques [4], [6], [11], [13]. Some geometrical aspects, such as the dimension of the throat [6], the shape of the divergent [14], and the 3-dimensional shape of the nozzle [13], [15], have been investigated, also observing the influence of viscous effects in relation to the inlet conditions [15]. The gas-wall interactions have been studied for a nozzle configuration with characteristic length of 1 mm and a very low pressure (~130 Pa) in [9]. Comparisons between numerical data and measurements have been provided in [16].
In the present paper we want to focus on the rarefied effects and the gas-surface interactions in 5–25 μN thrusters for a given geometric configuration (see Figure 1). After a brief introduction of the problem and a discussion of the used numerical techniques used (in the next two sections), we will study rarefaction effects and finally investigate at a molecular level how the way gas particles exchange energy at the gas-solid interface can influence the performance of a μN thruster.

STUDIED MICRONOZZLE CONFIGURATION

The studied nozzle is shown in Figure 1. Two different regions can be distinguished: a convergent part, where the flow is accelerated from the initial subsonic velocity to the sonic condition (which is reached at the throat), and a divergent part, where the flow supersonically expands to the outlet. The throat radius is 3.56 μm, while a sharp angle is considered to connect the convergent and the divergent. Both the convergent angle θ_1 and the divergent angle θ_2 are 20°. The inlet area A_i and the outflow area A_e equal 7.27 and 23.23 times the throat area A_t, respectively. In the inlet, nitrogen gas is introduced at a pressure ranging from P_0=0.5 bar to P_0=3.5 bar and temperature of T_0=300 K. A vacuum condition is assumed outside. The walls are modelled as isothermal at T_0=300 K. Under these conditions, the ideal thrust T_{ideal} computed from the 1D isentropic flow theory [17], is approximately 25 μN for P_0=3.5 bar, and approximately 4 μN for P_0=0.5 bar.

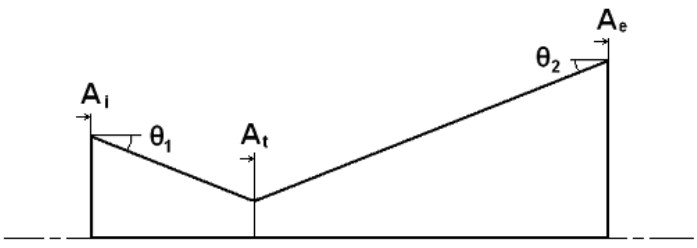

Figure 1. The nozzle geometry configuration considered in the present study, with the geometric parameters of interest.

In order to compare the results obtained through the different numerical models introduced below and to evaluate the performance of different nozzle configurations, two performance parameters will be computed. The first is the efficiency of the nozzle:

$$\eta = \frac{F_{real}}{F_{ideal}} \tag{2}$$

defined as the ratio of the ideal thrust F_{ideal} obtained from 1D isentropic flow theory, and the real thrust F_{real}, computed from

$$F_{real} = \int_{\text{outlet area}} \left[mV_e + (p_e - p_a) \right] dA \tag{3}$$

Where the subscripts e and a refer, respectively, to the conditions at the exit of the nozzle and to the ambient conditions outside the nozzle. The second parameter, the specific impulse, describes the change in momentum of the satellite per unit of propellant weight (on earth)

$$I_{sp} = \frac{F}{mg} \tag{4}$$

NUMERICAL SIMULATION TECHNIQUES

Navier Stokes solver

The Navier Stokes based continuum simulations presented in this paper have been obtained with the general purpose CFD solver Fluent version 6.3 [18]. The studied nozzle has a conical shape and therefore a 2D-axisymmetric flow is considered. The solved equations include the steady state continuity, Navier Stokes and thermal energy equations in compressible form, discretized in space using a second order upwind scheme, and solved using an implicitly coupled pressure based solver. At the nozzle walls, slip flow and temperature jump boundary conditions are imposed according to the formulas derived by Maxwell for the velocity and by Smoluchowski for the temperature [3]:
:

$$V_{gas} - V_{wall} = \frac{2-\sigma_v}{\sigma_v} Kn \left(\frac{\partial V}{\partial n} \right)_{wall} + \frac{3}{4} \frac{\mu}{\rho T} \left(\frac{\partial T}{\partial s} \right)_{wall} \tag{5}$$

$$T_{gas} - T_{wall} = \frac{2-\sigma_T}{\sigma_T} \left[\frac{2\gamma}{\gamma+1} \right] \frac{Kn}{Pr} \left(\frac{\partial T}{\partial n} \right)_{wall} \tag{6}$$

where n and s are the directions normal and the tangential to the wall, respectively, Pr is the Prandtl number and γ is the specific heat ratio. The tangential momentum accommodation coefficient σ_V and the thermal accommodation coefficient σ_T, are defined, respectively, as:

$$\sigma_v = \frac{V_i - V_r}{V_i - V_w} \qquad \sigma_T = \frac{T_i - T_r}{T_i - T_w} \tag{7}$$

where the subscripts i, r and w stand for incident, reflected and solid wall conditions. These parameters are further discussed in the last section. Equations (5) and (6) show that significant slip occurs only if the mean velocity of the molecules varies appreciably over a distance of the mean free path. The slip boundary conditions are approximated by the solver as explained in [18].

DSMC solver

Our 3-dimensional general purpose DSMC code X-Stream [19] has been validated earlier for a wide range of problems [20]. In all simulations presented in this paper, a Variable Soft Sphere (VSS) model has been used, with the corresponding parameter set from the literature [21]. Because of the axi-symmetry, a radial weighting factor [7] has been used such that a computational particle located far from the axis represents more real molecules than one near the axis.
In DSMC, rather than using separate accommodation coefficients for momentum and energy, a single thermal accommodation coefficient α is generally used [7] to account for the fact that incident and the reflected particles have different energies. Several theoretical approaches are available for estimating α [21, 22]. For nitrogen gas and silicon walls, these theories predict $\alpha \approx 0.5\text{-}0.8$. We refer to Section 5 to illustrate how this coefficient is modelled in X-Stream.
Even if DSMC is in principle valid for all Kn numbers, its computational requirements (with respect to the number of particles and time steps) severely increase for decreasing Kn [7]. In order to overcome this problem and to obtain a solution which is accurate both in the low Kn convergent region and in the high Kn divergent region, a hybrid Navier-Stokes/DSMC model has been used, which applies a continuum based CFD approach to model the flow in the low Kn regions where rarefaction effect are unimportant, and the DSMC approach in high Kn regions where rarefaction is important. This approach and a discussion of its results have been discussed in detail in [8]. In particular, it was pointed out how the location of the division between the CFD and DSMC regions may influence the final solution. A vertical division plane located at the throat was used in all the hybrid simulations shown in the present paper.

RAREFACTION EFFECTS

First, a comparison between the solutions obtained from a full CFD simulation (using either no-slip boundary conditions, or slip boundary conditions with $\sigma_V=\sigma_T=0.5$), and the solutions from full DSMC (with $\alpha=0.5$) has been performed for a nozzle with a nominal thrust of ~25 μN.
The DSMC simulation showed the presence of rarefied flow in a large part of the nozzle divergent, leading to a lower pressure and a higher value of the velocity in the exit region, compared to the no-slip CFD solution. In particular, significant differences were observed in the region near the wall, where the presence of a slip velocity strongly influences the thickness of the boundary layer and the mass flow predicted by the model, and, finally, the expansion of the wall. This can be observed from the exit profiles for velocity and pressure, as shown in Figure 2. The CFD simulation with partial slip ($\sigma_V=\sigma_T=0.5$) leads to an outflow velocity profile similar to DSMC, but still leads to a different pressure field. An investigation of the nozzle performance both in terms of thrust and specific impulse (Table 1) showed that the presence of slip velocity allows the flow to reach higher velocities at the outflow with a consequent higher nozzle performance. On the other hand, a full CFD simulation with no-slip wall boundary condition gives an under-prediction of the nozzle thrust compared to full DSMC. It must be stressed however, that the full DSMC solution suffers from the

fact that the DSMC accuracy requirements cannot be met in the low Kn convergent region. More accurate results can be expected from the hybrid CFD/DSMC solution. A comparison between this approach and full DSMC and full CFD solutions with partial slip are shown in Figure 3.

GAS-SURFACE INTERACTION EFFECTS

It has already been pointed out that the large surface-to-volume ratio makes surface effects become prominent in micro-thrusters. One effect is that common micro system manufacturing techniques lead to surface roughness with length scales that are significant compared to both the characteristic dimensions of micro thrusters and the molecular free path. In [2] we performed an extensive study on the influence of such roughness on the performance of a mN thruster.

In the present paper we study gas-surface interactions in μN nozzles at a molecular level. The result of a collision between a gas molecule and the wall depends on the properties of the molecules hitting the surface and of the surface itself. A perfectly smooth wall would be fully specular, such that hitting particles conserve their tangential momentum and exert no shear on the wall. This would result in perfect slip at the wall. An extremely rough wall reflects the impinging particles at random angles, uncorrelated with their entry angle, leading to an averaged zero tangential momentum to be balanced by a finite slip velocity in order to account for the shear stress transmitted to the wall [3]. In the present DSMC simulations, the accommodation coefficient α is set to be the fraction of particles that reflect diffusely, while (1- α) is the fraction that reflects specularly. So, α=1 and α=0 correspond to purely diffuse and purely reflective surfaces, respectively.

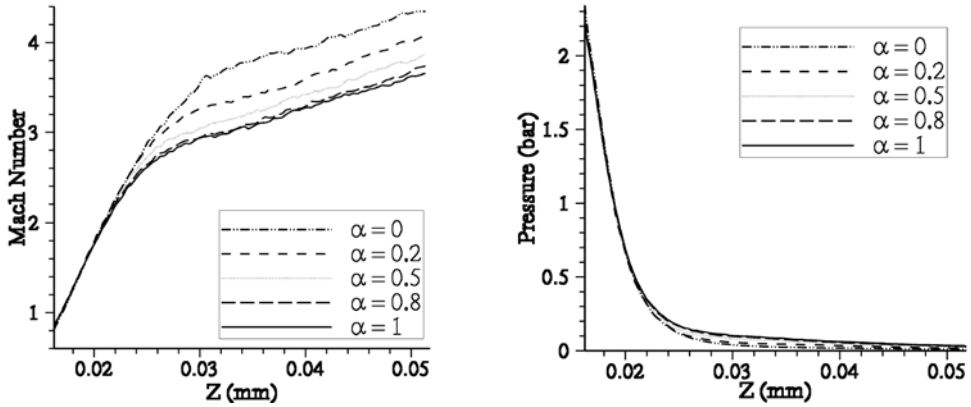

Figure 4. Mach number (left) and Pressure (right) along the nozzle divergent axis, for P_0=3.5 bar

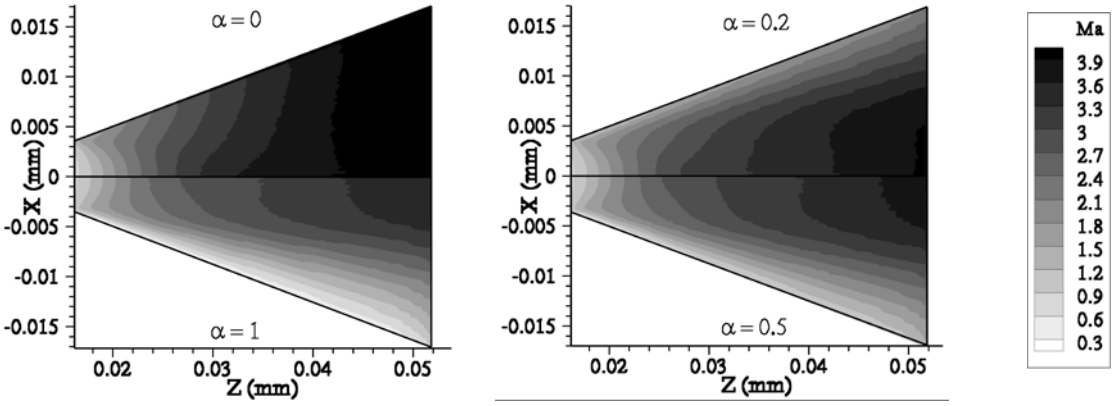

Figure 5. Mach number contours in the nozzle divergent for different values of α, for P_0=3.5 bar

Predictive formulas for thermal accommodation coefficients have been formulated in e.g. [21], [22], but proved to be valid only for a certain range of gas-surface configurations. Experimental data, are provided in [23], [24], [25]. Values between α=0.5 and 0.8 are generally reported for nitrogen molecules interacting with silicon walls. We study the influence of α on the nozzle performance, keeping in mind also that the choice of different gas-surface combinations and the improvement of fabrication techniques may lead to a wide choice in possible values of α.

Figure 4 shows the Mach number and the pressure along the axis of the divergent part of the nozzle, obtained from hybrid CFD/DSMC simulations for P_0=3.5 bar and different values of α. Figure 5 shows Mach number contours, again for P_0=3.5 bar and different values of α. For small values of α, the momentum boundary layers at the walls are thinner and higher velocities and lower pressures are reached at the outflow. This is reflected in the nozzle performance, as reported in Table 2. Thrust, mass flow and specific impulse are significantly higher for low values of α.

Table 2
Nozzle Performance evaluated by the Solutions for Different Values of α, for P_0=3.5 bar

α	T, μN	η	m, g/s	I_{sp}, s
0.0	22.1	95.17	3.19×10^{-5}	70.44
0.2	20.9	90.15	3.10×10^{-5}	68.74
0.5	19.9	86.04	3.04×10^{-5}	66.85
0.8	19.8	85.34	3.02×10^{-5}	66.82
1.0	19.5	84.20	2.98×10^{-5}	66.71

The influence of α was also studied for P_0=0.5 bar. In this case, DSMC was used in the entire nozzle. A fully viscous flow is observed inside the divergent part of the nozzle (Figure 6, left), especially for higher values of α. The flow does not fully expand in the divergent, and the Mach number is not as large as expected. This leads to high losses in terms of thrust and specific impulse, especially for values of α larger than 0.5, as shown in Table 3.

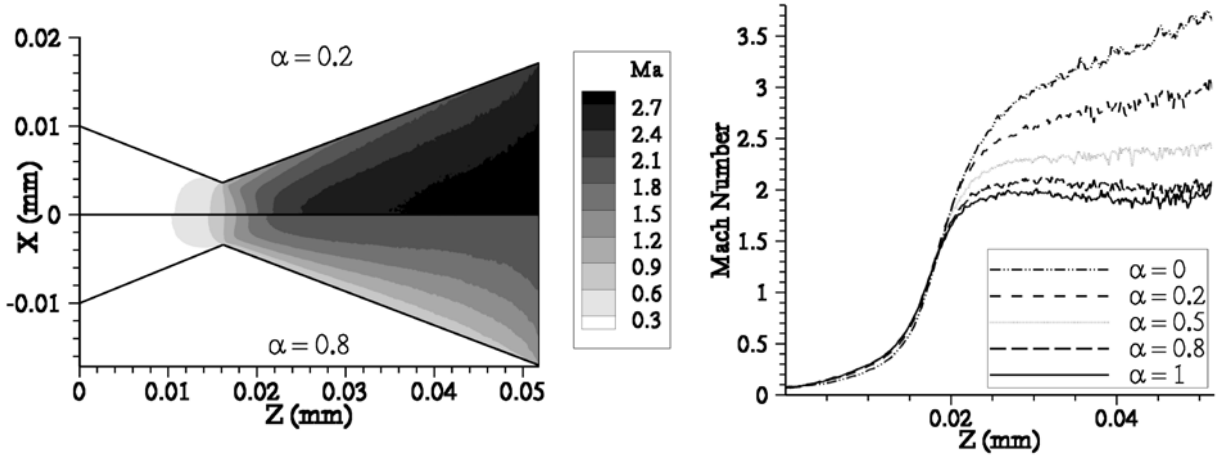

Figure 6. Mach number contours (left) and Mach number profiles along the axis for different values of α, for P_0=0.5 bar

Table 3
Nozzle Performance evaluated by the Solutions for Different Values of α, for P_0=0.5 bar

Configuration	T, μN	η	m, g/s	I_{sp}, s
DSMC – α=0.0	3.16	93.60	4.78×10^{-6}	67.38
DSMC – α=0.2	2.77	82.03	4.43×10^{-6}	63.69
DSMC – α=0.5	2.43	72.08	4.14×10^{-6}	59.87
DSMC – α=0.8	2.26	67.00	3.95×10^{-6}	58.31
DSMC – α=1.0	2.18	64.74	3.84×10^{-6}	57.96

CONCLUSION

CFD with partial slip wall, full DSMC and hybrid CFD/DSMC simulations have been used to study gas flows in ~5-25 μN microthrusters. Due to the small dimensions, the flow was shown to experience strong rarefaction effects in a large part of the divergent. Rarefaction effects lead to increased velocities and decreased pressures in the outflow. This was not correctly predicted by CFD simulations, even when slip flow boundary conditions are used. The thermal accommodation coefficient for gas-surface collisions was found to have a strong influence on the overall nozzle performance, especially for very low thrust nozzles. This suggests that the use of specific coatings or the choice of different gases and wall materials can improve the performance of such devices.

ABSTRACT. We present an experimental study on microjet cooling performance. While microjets are promising for cooling integrated circuits, there have been few detailed studies on understanding both single and two-phase performance. In this work, we fabricated single-jets and multi-jet arrays with diameters ranging from 50 μm to 100 μm and used infrared thermometry to obtain surface temperature distributions and heat transfer coefficients. We found that heat transfer performance with designed devices. This work offers an improved understanding on single-microjet, and multi microjet.

Keywords: *impingement, microjet, multi-jet, electronic cooling, heat transfer*

INTRODUCTION

As electronic devices continue to scale down to smaller sizes, the increasing power densities in microprocessors motivate new cooling techniques. Jet impingement cooling has been traditionally used in industrial applications such as metal manufacturing and high power lasers in macroscale.[1-2] Similarly, there have been studies about electronic device cooling using microchannels and microscale jets. [3-4] Microscale jet impingement offers a potential solution for cooling high power density microscale electronic devices [5-6]. In addition, an increased temperature uniformity can be achieved with multi-jet arrays. In addition to the high heat capacity, two-phase cooling offers improved performance by utilizing the latent heat of vaporization. [7-8] In this work, we performed detailed heat transfer studies using arrays of jets, and obtained heat transfer coefficient for single phase. We designed, fabricated, and tested new microjet structures for these studies to determine optimized designs for future microjet-based cooling systems.

EXPERIMENTAL SET UP

Devices

Fabrication. We fabricated silicon microjets using deep reactive ion etching (DRIE). The inlet, top water reservoir, outlet were DRIE etched from both sides with first substrate. With second substrate, jets and a bottom water reservoir were etched from both sides using DRIE. In order to gain optical access to see the jet impingement process, the bottom water reservoir was covered with a glass substrate after the first and second substrates were fusion bonded together. The final step included dicing the wafer into pieces. On one wafer, we were able to obtain several different designs with various numbers of jets, different diameter jets, and jets at various locations. The fabricated jets were connected to inlet and outlet ports from Upchurch Scientific™. The experimental test rigs that contained the jet devices are shown in Figure 1.

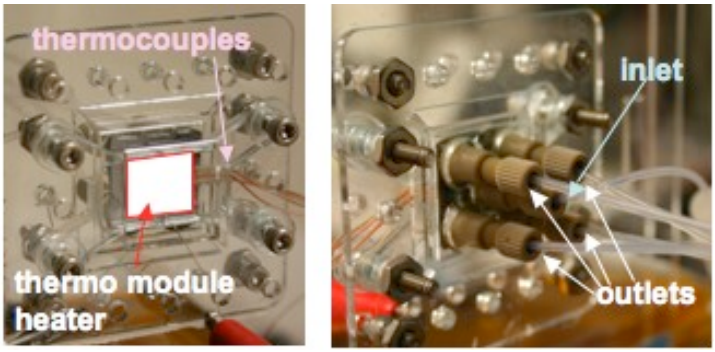

Figure 1. Image of microjet structure in test figure. (a) Front side and (b) back side of microjet device with test fixture.

Design. Figure 2 shows simplified schematics of two different microjet devices used in these studies. The single jet has a 100 µm diameter located at the center, and the 121-jet array has 50 µm diameter jets separated by 150 µm each. There are more design variations, which have 9-jet, 16-jet, 25-jet, 49-jet, we choose two designs to describe jet system in this paper.

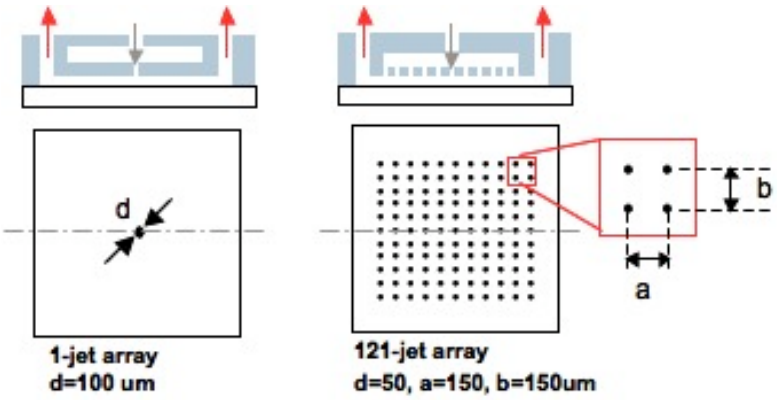

Figure 2. Schematics of example test devices including (a) a single-jet device and (b) 121-jet device.

Experimental work

The jet chip was connected to a syringe pump, which is controlled by the program, to provide fluid with a constant volume rate. De-ionized (DI) water was used as the working fluid. The pressure transducer was also connected to the inlet of the jet chip to see pressure difference between inlet and outlets. Infrared thermometry was used to obtain the surface temperature of the chip. Ti-20 from fluke gives 0.1°C resolution. The images form thermal imager can be used for reading temperatures with different flow rates and power to the heater, and heat transfer coefficients can be calculated. The temperature from thermal imager was calibrated using attached thermocouples and it was compared with the table of emissivities. The emissivity for the chip surface was found to be 0.95.

RESULT AND DISCUSSION

Temperature distribution

We used the data from the thermal imager to extract temperature data with three-dimensional (3-D) surfaces as shown in Figure 3. Figure 3 (a) shows an thermal image with a single-jet device with a flow rate of 0.5ml/min, and 2V bias voltage, which gives 2.4W. The lower temperature region around jet impingement is illustrated in yellow, while the others are red. The 121-jet array with (b) shows almost uniform temperature along the plane, which has mean, minimum, and maximum temperature as 43.2, 42.2, and 45.5 °C, respectively. Each images has x,y axis temperature plots along diagonal lines. These temperature plots explain 1-jet array has a steep region at impingement zone; while 121-jet array has almost const temperature again.

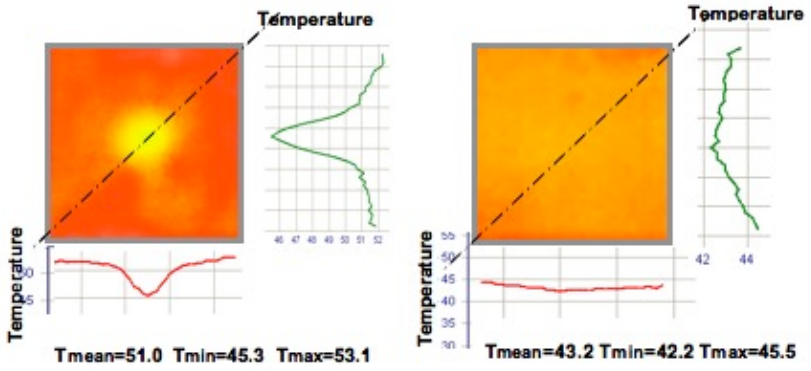

Figure 3. (a) Thermal image with 1-jet array (b) 121-jet array: Thermal image of microjet cooling device with 0.5ml/min, 2V with bias voltage

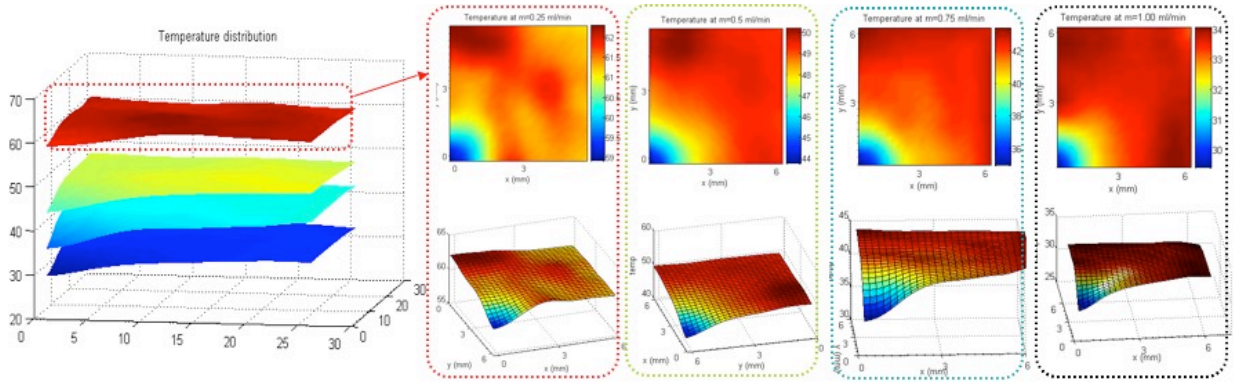

Figure 4. 3-D temperature surface with 1-jet array at m=0.25, 0.5, 0.75, 1 ml/min with voltage 1.8 V.

In figure 4, temperature surface plot has "steep" region at impingement. We can consider steep region as effective region in terms of heat transfer. From the images, there are four plots with different flow rates. At impingement region, which is indicated as origin in figures, each temperature surface plot has minimum temperature, known as the most effective cooling region. Because multi-jet system demonstrates practically uniform temperature, error bars compare the intervals of data for each bias voltage as shown in figure 5. For comparison with different flow rates with different heating power, mean, minimum, maximum temperatures are indicated with bars in figure 5. To make a non-dimensionalized work, real temperatures are divided by the initial temperatures. As shown in graph, higher mass flow rate dissipate with higher removal rates, while plots with lower mass flow rates obtain more effects from higher heating power. The black line is used as a comparison without any liquid cooling impingement. The top black line achieves non-dimensionalized temperature from 1 to 3 with highest heating rates; low mass flow rate experience numbers ranging between 1 to 2.5; while, the highest mass flow rate rises from 1 to 1.2. Therefore more flow flux can lead to more uniformity in terms of large range of heating power. We make comparison work in order to see differences of temperatures with single, multi-jet devices in figure 6. The multi-jet system exhibits much more uniform and lower temperature results.

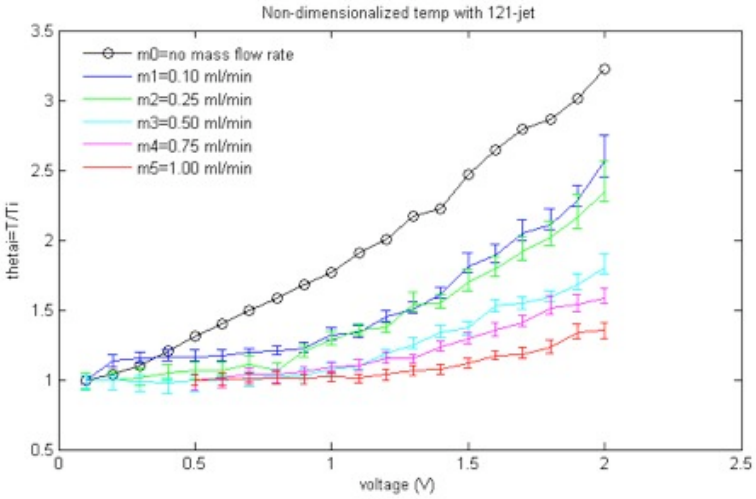

Figure 5. Non-dimensionalized temperature with increasing bias voltage in multi-jet device.

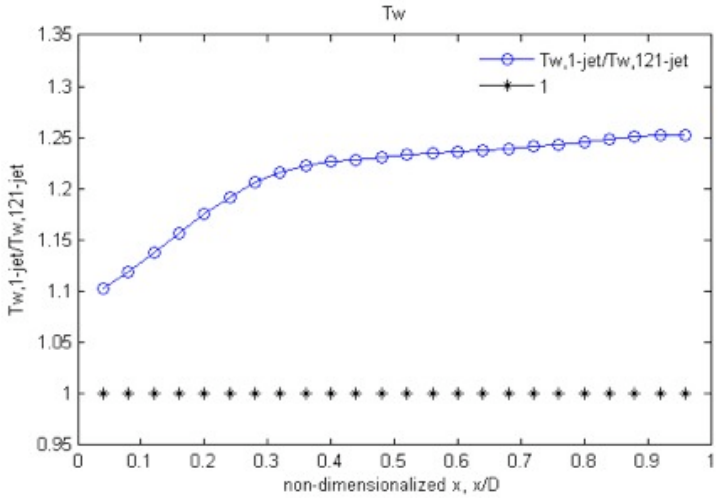

Figure 6. Temperature plots for 1-jet and 121-jet.

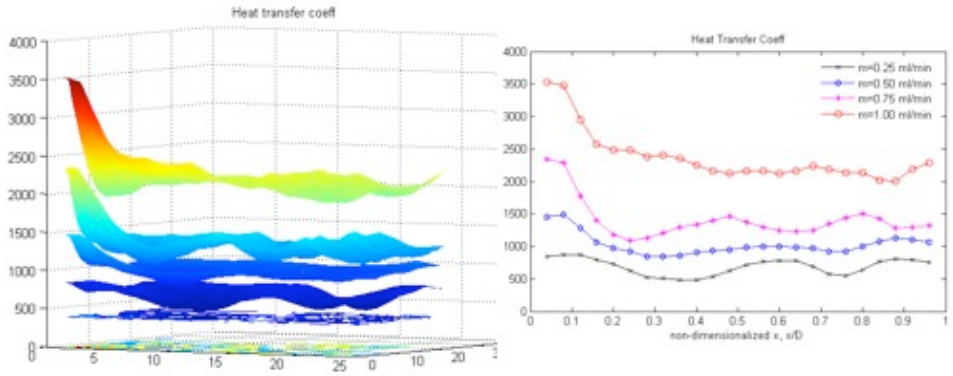

Figure 6. (a) 3-D heat transfer coefficients for m = 0.25, 0.5, 0.75, 1 ml/min with bias voltage 1.8 V. (b) 2-D heat transfer coefficients.

Heat transfer coefficient

From the taken images, we will extract three different temperature sets, which are T_w, taken by imager, T_g as a top glass substrate temperature, T_l as a liquid mean temperature. This simplified jet model shows that convective resistance and conductive resistance exist between different temperautre nods between T_l and T_w as indicated in equation (1). In order to consider additional conductive resistance along x,y axises in 3-D resistances model, we need to consider heat flux from all surrounding points. From equation (2), q (heat flux to the liquid from target point) can be estimated with sum of flux to this point. With known values such as q_{in}, k, material conductivity and geometry numbers (A, cross sectional area, l, length), we can derive a heat flux to the liquid at each point.

$$\frac{T_l - T_w}{q} = R_{conv,z} + R_{cond,z} = \frac{1}{hA} + \frac{l}{kA} \tag{1}$$

$$q = q_{in} + q_{x,i-1} + q_{x,i+1} + q_{y,i-1} + q_{y,i+1} \tag{2}$$

This steep region makes highest heat transfer rate at the origin as shown in figure 6 (a). We achieve higher heat transfer rate with closer to the origin or higher mass flow rates.

Pressure drop

There are two performance goals of microjet design. First, we obtain an enhanced heat transfer coefficient for maximum heat removal from the hot chip surface. Second, we will achieve a small pressure drop to be compatible with micro-pumping technologies. Pressure drop is another important issue in heat sink problems, because engineers have to consider pressure difference to decide a pump capacity.

The total pressure drop is given by [9[

$$\Delta p = n \cdot f\rho \frac{l}{d} v_{jet}^{\ 2} + \rho \frac{v_{out}^{\ 2}}{2} \tag{3}$$

f is the friction factor given by the Blasius correlation for turbulent flow, ρ is the density, d is the diameter of the jet, l is the length of the nozzle, v_{out} is the exit velocity and v_{jet} is the nozzle exit

velocity. The first term on the right hand side of equation (3) gives the losses in the nozzle due to friction, while the second term gives the dynamic pressure loss. While single jet has fewer losses due to friction, compensation with larger dynamic pressure makes comparable value of total pressure drop as shown in figure 8.

CONCLUSION

As a study of micromachined liquid impingement jets, several jet systems with diameters 50 μm-100 μm have been fabricated with silicon substrate. The test structures on single, multi-jet system are used to collect temperature data, extract heat transfer coefficients to make comparison, and analyze optimization of spacing between jet orifices. Images are taken by thermal camera to get plane temperature information. From these images, heat transfer coefficient was calculated. The "effective" region with single jet system only extends to about five times the jet diameter in the 3-D model, while multi-jet array achieves a uniform temperature with plane. The integration of our design will enable high power processors to be run at higher clock frequencies to obtain increased performance, while still ensuring stability and reliability due to sufficient thermal cooling. In addition, liquid impingement cooling has other advantages over traditional air-cooling, such as quieter operation and stable temperature of the processor's operating environment. Future work will aim for an analysis between heat transfer rates and fluid mechanism especially at the impingement region. Optimization of these design parameters will enable an improved design capability for the next generation of jet impingement coolers for electronic circuits.

ACKNOWLEDGMENT

This work is supported by MARCO IFC Program. Work was performed in part at the Stanford Nanofabrication Facility (a member of the National Nanotechnology Infrastructure Network) which is supported by the National Science Foundation under Grant ECS-9731293, its lab members, and the industrial members of the Stanford Center for Integrated Systems.

Abstract. This paper presents a study of forced convection of air flow through porous graphite foams. Three structures, namely stagger, baffle and zigzag were designed to reduce pressure drop while utilizing the thermal properties of Poco graphite foams to enhance the heat transfer. All the structures contain a certain number of thin foam walls perpendicular to the flow direction with empty slots connected throughout the structures. An experimental facility was developed to compare the heat transfer performance of the designed heat sinks with an original block foam under adiabatic condition. The local substrate temperatures, pressure drops and inlet flow velocities were measured. The length-averaged Nusselt numbers of air flow through the samples were calculated. In addition, a numerical simulation was also carried out to explore more details of the fluid flow through the complex structures. It is found that the pressure drops in the designed structures are much lower than that in the block foam. Hence, these heat sinks can remove heat efficiently with relatively low pumping power.

Keywords: *forced convection, porous graphite foam, Nusselt number, pressure drop, pumping power*

INTRODUCTION

The design of electronic packages for modern high-speed computers has led to increased demands for effective cooling methods. The primary concerns in thermal management applications are high thermal conductivity, large specific surface area and low weight. An effective thermal management strategy is to utilize a porous medium to enhance heat transfer by increasing the fluid-solid contact surface area and promoting fluid mixing. As compared to a channel packed with metallic particles or spheres, microcellular materials such as metal and graphite foams are novel porous media with open cell structures. Fluid flow and heat transfer in metal foam have been extensively investigated [1-5]. Recently, the novel porous graphite foam developed at Oak Ridge National Laboratory (ORNL) in USA is a promising heat transfer material because of its high thermal conductivity and low weight-to-volume ratio. The thermal conductivity of the bulk apparent thermal conductivity can be higher than 150 W/m·K, which is almost equivalent to dense aluminum alloys [6].

Motivated by the superior thermophysical properties of graphite compared to its metallic counterpart, several researchers have studied graphite foams for thermal management applications.

Porous carbon foam fins were studied as a replacement for aluminum fins in finned tube radiators by Ott *et al*. [7]. Their interest was driven by the unique properties of the foam which reduce the thermal resistance of a heat exchanger without significantly higher pressure drop. Druma *et al*. [8] performed a finite element analysis to determine the thermal conductivity of graphite foams for the complete range of porosity and presented analytical and semi-empirical solutions. Alam and Maruyama [9] conducted an experimental study to determine the thermal conductivity of various graphite foams. Alam *et al*. [10] numerically studied the thermal conductivity of carbon foams with a finite element model. They concluded that the conductivity of carbon foam is influenced mainly by the ratio of the node and ligament thermal conductivities. Williams and Roux [11] evaluated the cooling effects of graphite foam and microfibrous material in an electronics cooling system and concluded that graphite foams showed a good performance.

It is noted that graphite foams possess low permeability. Figure 1 shows the typical internal structure of graphite foams manufactured by Poco Graphite, Inc. observed under a Scanning Electron Microscope. The complex internal structure of the foam results in high flow resistance although most pores are open and interconnected. In this paper, three foam structures were designed (namely stagger, baffle and zigzag) to reduce pressure drop while utilizing the thermal properties of graphite foam to enhance the heat transfer. An experimental facility was developed to perform heat transfer experiments under adiabatic condition. The local substrate temperature, pressure drop and length-averaged Nusselt numbers of air flow through the samples were measured and calculated to compare their performance. In addition, a numerical simulation was also carried out to study the velocity distribution in the complex structures which would be difficult to obtain experimentally.

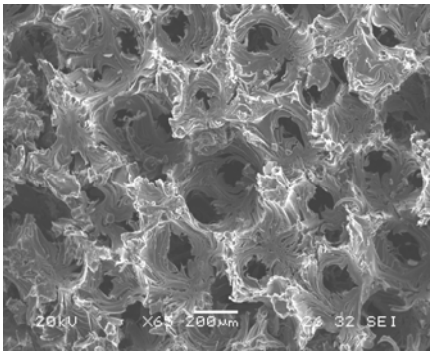

Figure 1 Internal structure of "Poco" graphite foam of 75% porosity

EXPERIMENTAL STUDY

Experimental Setup

Graphite foam configurations. The material used in this study is "Poco" graphite foam of 75% porosity which is licensed by ORNL. It is noted from the literature that the pressure drop for air flow through this graphite foam is rather large. Therefore, the designed structures should be able to reduce the pressure drop significantly while maintaining relatively good heat transfer performance. Three configurations were fabricated into different combinations of thin foam walls and empty slot in a solid block foam (BLK). They are named as baffle (BAF), stagger (STG) and zigzag (ZZG) structures based on their geometric shapes, which are shown in Figure 2.

In these structures, the thickness of the thin foam walls is between 2 to 3 mm and these walls are aligned normally to the flow inlet direction. This arrangement makes the foam dimension comparable to the pore size and therefore part of the inlet fluid can be driven easily through the foam body. Empty slots are connected throughout the structure, which allow the remaining portion of the inlet air to flow through the foam. The wall thickness, length and slot gap are selected based

on the fact that the designed structures should possess approximately the same total wall surface area. Thus, the effect of different surface areas on heat transfer is minimised. Important parameters of the designed configurations are shown in Table 1.

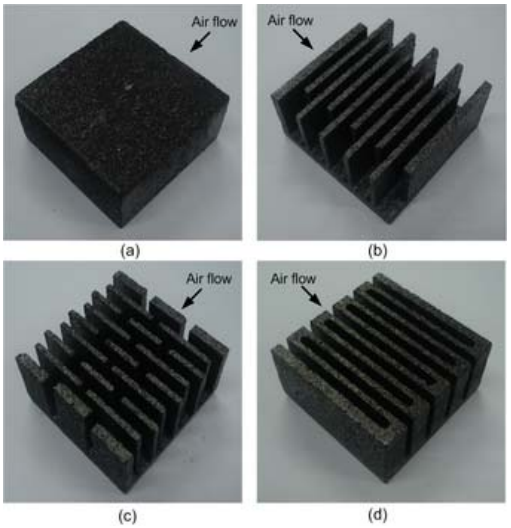

Figure 2 Test structures of (a) block, (b) stagger, (c) baffle and (d) zigzag configurations

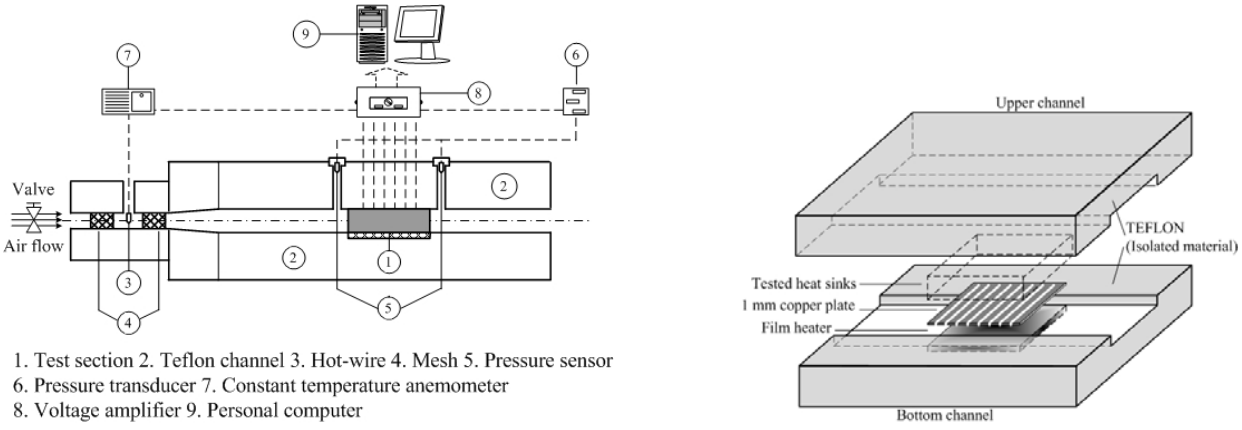
Table 1 Parameters of designed structures

Parameters	Baffle	Stagger	Zigzag
External dimension, W×L×H (mm)	50 × 50 × 25		
Foam wall thickness (mm)	2~3	2~3	2~3
Foam wall number	23	10	19
Foam wall length (mm)	14/22	41.5	46
Slot gap width (mm)	3.625	3	3
Base height (mm)	4	4	4
Total surface area (mm^2)	17976	17913	17955

Test facility. The schematic diagram of the experimental facility is shown in Figure 3(a). The graphite foam is placed in a duct made of Teflon for insulation purpose. Two taps for pressure sensors (VALIDYNE DP15) are placed at the two ends of test section to measure the total pressure drop across the sample. Air flow is provided by an auto-balance compressor (SSR EP15SE) and a hotwire (DANTEC 55P11) sensor is placed in the middle of the inlet section to measure the flow velocity. A three-dimensional close-up view of the test section is shown in Figure 3(b). A film heater is installed at the bottom of channel and a 1-mm thick copper plate with ten uniform narrow slots perpendicular to the flow direction is attached on the surface of film heater. Ten K-type thermocouples are placed in the slots at locations of 0.25, 0.75, 1.25, 1.75, 2.25, 2.75, 3.25, 3.75, 4.25, 4.75 cm from the inlet boundary of the test foam. Highly conductive thermal grease (k = 8.5 W/m·K) is applied as filling material to reduce the contact resistances across the interfaces of the film heater, copper plate and test sample. By clamping the channel tightly, the temperatures of the graphite foam surface and copper plate at the bottom of the channel are assumed to be same in the measurements. During the experiments, the temperatures are monitored for a period of three minutes to ensure that steady state has been reached. After that, the inlet flow velocity is increased to obtain results for different Reynolds numbers.



(a) (b)

Figure 3 (a) Schematic diagram of test facility; (b) three-dimensional view of test section

Uncertainty analysis

The data measured by thermocouples, pressure transducer and hot-wire sensors are monitored and acquired by a data acquisition system. The data acquisition system consists of a signal board (NI CB-68LP), I/O boards (NI PCI-6224) and an operating software (NI DAQmx 4.0) within a workstation. The temperatures, pressures and velocities measured by the sensors were fed into the data acquisition board through the differential connections. Experimental errors were estimated based on the accuracies of individual equipment or sensors. The heat loss in the experiment was estimated to be within 6% based on the calculated air enthalpy rise along the test section. The accuracy of the thermocouples used is within ±0.5 °C according to the calibration and the resolution of the data acquisition system. The corresponding value for the pressure transducer is ± 0.25% of full-scale. The accuracy of the hot-wire anemometer is ±0.01 m/s. Using a time-averaging method, the uncertainties of temperature, velocity and pressure are estimated to be 3.0 percent, 2.0 percent and 2.0 percent, respectively. For the calculated parameters, the uncertainties are determined by the method introduced by Taylor [12]. If α, … β, … γ are measured quantities with uncertainties $\delta\alpha$, … $\delta\beta$, … $\delta\gamma$, and the measured values are used to compute the function $q(\alpha,\ldots, \beta,\ldots, \gamma)$, then the uncertainty in q is

$$\delta q = \sqrt{\left(\frac{\partial q}{\partial \alpha}\delta\alpha\right)^2 + \cdots + \left(\frac{\partial q}{\partial \beta}\delta\beta\right)^2 + \cdots + \left(\frac{\partial q}{\partial \gamma}\delta\gamma\right)^2} \tag{1}$$

In the present experiments, the uncertainties of the measured data were assumed to be independent and random with normal distribution. Using Equation (1), the uncertainties of Reynolds number and Nusselt number were calculated to be 3.9 and 5.7 percent, respectively.

NUMERICAL SIMULATION

Formulation

To achieve better understanding of the transport phenomenon in graphite foams, a FORTRAN-based user program was developed to obtain fluid flow and heat transfer characteristics in the designed structures. The local volume-averaging method is used to derive the governing equations. With the assumptions of laminar flow and constant properties, the mass, momentum and energy equations are

$$\frac{\partial \langle u_i \rangle}{\partial x_i} = 0 \tag{2}$$

$$\frac{\rho_f}{\varepsilon}\left(\frac{\partial \langle u_i \rangle \langle u_j \rangle}{\partial x_j}\right) = -\varepsilon \frac{\partial \langle p \rangle}{\partial x_i} + \mu_f \frac{\partial}{\partial x_j}\left(\frac{\partial \langle u_i \rangle}{\partial x_j}\right) - \frac{\varepsilon \mu_f}{K}\langle u_i \rangle - \frac{\varepsilon \rho_f C_E}{\sqrt{K}}\left|\vec{V}\right|\langle u_i \rangle + \varepsilon \rho_f f_i \tag{3}$$

$$\frac{\partial}{\partial x_j}\left(k_{se}\frac{\partial T_s}{\partial x_j}\right) - h_{sf}\alpha_{sf}\left(T_s - T_f\right) = 0 \tag{4}$$

$$\left(\rho C_p\right)_f u_i \frac{\partial T_f}{\partial x_i} = \frac{\partial}{\partial x_i}\left(k_{fe}\frac{\partial T_f}{\partial x_i}\right) + h_{sf}\alpha_{sf}\left(T_s - T_f\right) \tag{5}$$

where ε, C_E and K are the porosity, inertial coefficient and permeability of the porous material, respectively. f is the body force per unit mass and i, j represent the directional components. In energy equations, k_{se} and k_{fe} are the effective thermal conductivities of the solid and fluid, respectively. h_{sf} is the heat transfer coefficient and α_{sf} is the specific interfacial surface area in the porous medium.

The permeability K and inertial coefficient C_E for graphite foam were obtained by experiments using the Darcy-Forchheimer law for porous media given by

$$-\frac{\Delta p}{\Delta L}\frac{1}{\mu u} = \frac{1}{K} + \rho_f \frac{C_E}{\sqrt{K}}\frac{u}{\mu} \tag{6}$$

where Δp is the pressure drop across the graphite foam and ΔL is the length of the test specimen. By plotting $(-\Delta p/\Delta L)(1/\mu u)$ against $\rho_f u/\mu$ for a range of flow rates, the permeability K was obtained as the intercept and the inertial coefficient C_E determined from the slope. The effective thermal conductivities and interior surface area to volume ratio were calculated by the model given by Tee *et al*. [13]. The interfacial heat transfer coefficient h_{sf} was determined by an empirical equation proposed by Klett *et al*. [14]. The main properties of materials used in the numerical code are given in Table 2.

Table 2 Properties of graphite foam

Parameters	Graphite foam, ε = 0.75
Permeability (10^{-10} m^2)	7.74
Inertial coefficient	0.063
Pore diameter (mm)	0.31
Effective thermal conductivity (W/m·K)	16.2
specific surface area (m^2/m^3)	8216

Numerical scheme

The governing equations (2) to (5) were solved using a finite volume method introduced by Patankar [15]. A staggered grid with scalar and vectorial variables defined respectively at the node and surface of the control volumes was employed. The power law is used to treat the combined convection-diffusion effect. The velocity-pressure coupling is handled within the framework of the SIMPLER algorithm. As the energy equations (for the solid and fluid) are decoupled from the continuity and momentum equations, it can only be solved after the converged velocity field is obtained. Both the solid and fluid energy equations are coupled via the convective terms. Different grids were studied to obtain grid independency results. These equations were solved iteratively until both temperature fields converge.

RESULTS AND DISCUSSION

Temperature and Nusselt Number

Figure 4 presents the temperature distribution of air flow through all the tested foams at heating power of 20 W. It can be seen that the temperature variations on the substrate for all samples are similar. The local temperature T_x increases gradually along the dimensionless location X/D_h and decreases with increasing pore diameter based Reynolds number (ud_p/ν_f). Compared to the designed structures, the temperature in the original block is lower at approximately the same Reynolds number. However, it is noted that the pressure drop in original block foam is very high due to its low permeability as mentioned previously. Figure 5 shows the pressure drop versus inlet flow velocity for all the samples. Comparing the pressure drop in designed structures to that in block foam, the results show clearly that the pressure drop is reduced significantly in all the designed structures. This implies that the designed slots and thin foam walls allow air to be driven through the samples easily.

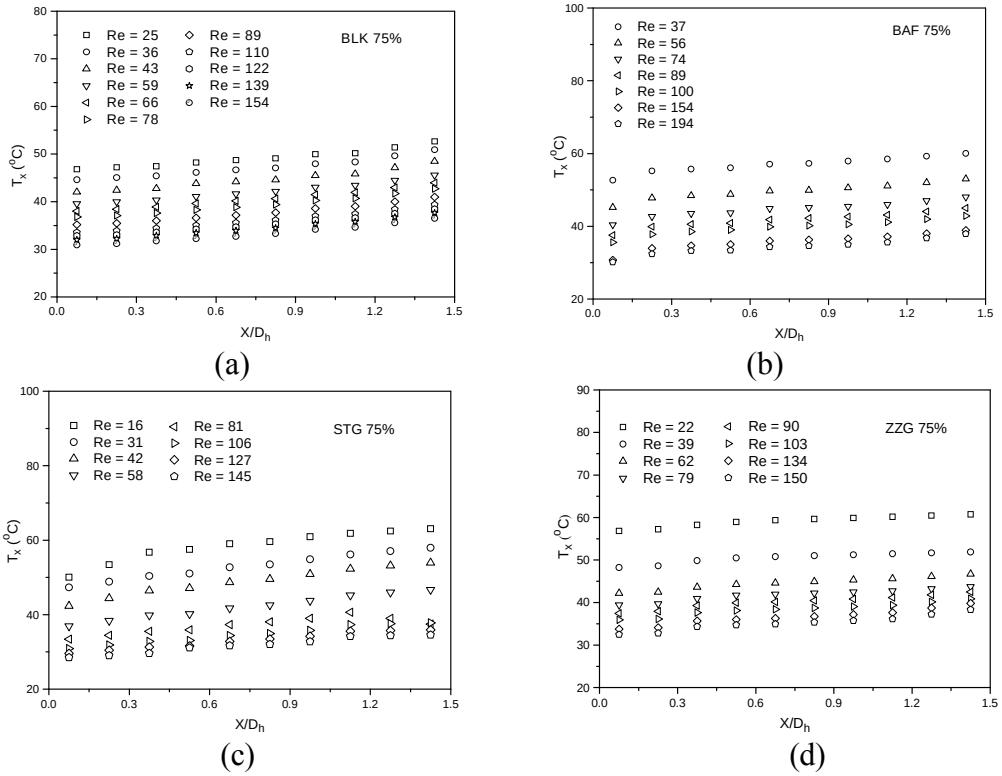


Figure 4 Local substrate temperature variations in (a) block, (b) baffle, (c) stagger and (d) zigzag foams

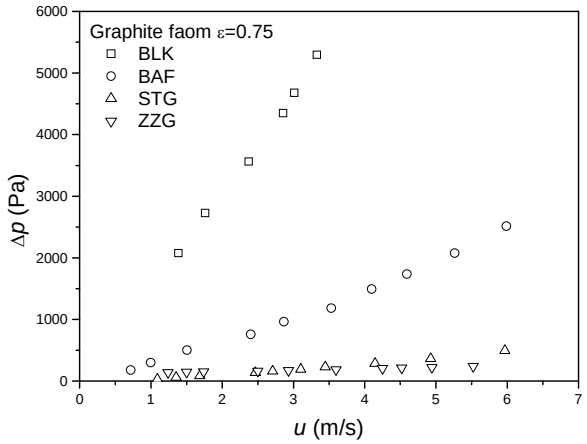

Figure 5 Pressure drop in all the tested samples

To characterize the thermal performance of the samples, we use the length-averaged Nusselt number which is the average of the local Nusselt numbers [Nu=$q''d_p/(T_x-T_{amb})k_f$, where q'' and T_{amb} are the heat flux and ambient temperature respectively] along on the substrate. The experimental and numerical length-averaged Nusselt numbers at various Reynolds numbers are plotted in Figure 6. The simulation results show good agreement with experimental data for all the structures. It can be seen that the block foam has better heat transfer at a given Reynolds number. For Reynolds number from between 10 to 60, the length-averaged Nusselt number in the block foam varies from 4 to 12, while those in the designed structures are between 2 to 7.5. However, the pressure drop is also very high for the block foam for the same Reynolds number.

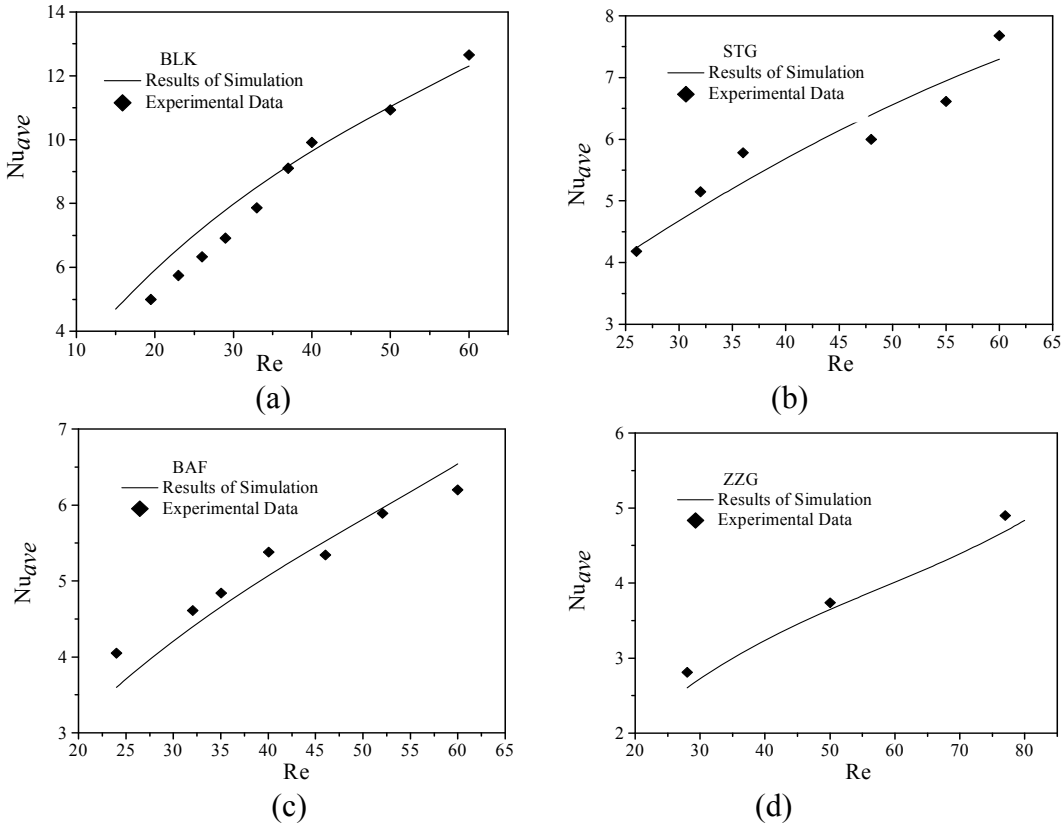

Figure 6 Length-averaged Nusselt number of air flow through (a) block, (b) stagger, (c) baffle and (d) zigzag foams

As analyzed above, the block foam exhibits better enhancement at approximately the same Reynolds number with much higher pressure drop. In practical heat sink design, the driving force for air flow through the structure is a major concern. To quantify the heat transfer of tested samples with consideration of the system driving force, the length-averaged Nusselt numbers are weighted by the pumping power $W_p = \Delta p \dot{V}$ ($\dot{V}$ is the average volumetric flow rate) as plotted in Figure 7. It can be seen that for the same length-averaged Nusselt number, the pumping power for driving air through the block graphite foam is much higher than through the three designed structures for the same heat transfer rate. For instance, to achieve a length-averaged Nusselt number of 10, the pumping powesr for the designed structures are only about 5 to14 W while it is about 70 W for the block foam. This indicates that better heat transfer performance can be obtained from the designed structures as compared to that of block foam at the same pumping power.

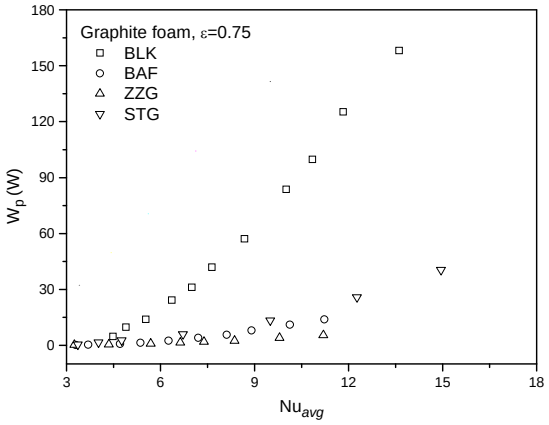

Figure 7 Length-averaged Nusselt number versus pumping power

Velocity Distribution

Figure 8(a) shows the velocity distribution of air flow through block graphite foam. From the simulations, it is observed that the flow characteristics in graphite foams depend mainly on the structure. It is clear that the air flow penetrates the block foam. The velocity profile is uniform throughout the simulated domain. This is expected because the properties of the foam are assumed to be anisotropic in the simulation. Figures 8(b)~8(d) show the velocity distributions in three designed structures. Since the stagger structure is not symmetric, the full size of sample was simulated. It can be seen from these figures that flow in the designed structures is distinctly different from that in the original block graphite foam. Overall, the inlet flow is divided into two streams at the entrance of porous domain. One part of flow penetrates through the foam wall while the rest goes through the foam via the structured empty slots. It is also observed from Figure 8(c) that most of air flows across the zigzag foam through the empty slots and only a small fraction of the air goes through the foam body. This is because the carved slots are parallel to the flow inlet direction and the foam wall area facing the flow is relatively small compared to other structures. Hence, for a given inlet flow velocity, the lowest pressure drop is obtained in the zigzag structure as shown in Figure 5. It can also be observed from the three structures that the magnitude of the velocity vector in the slot area is larger than that in the foam wall due to the low permeability.

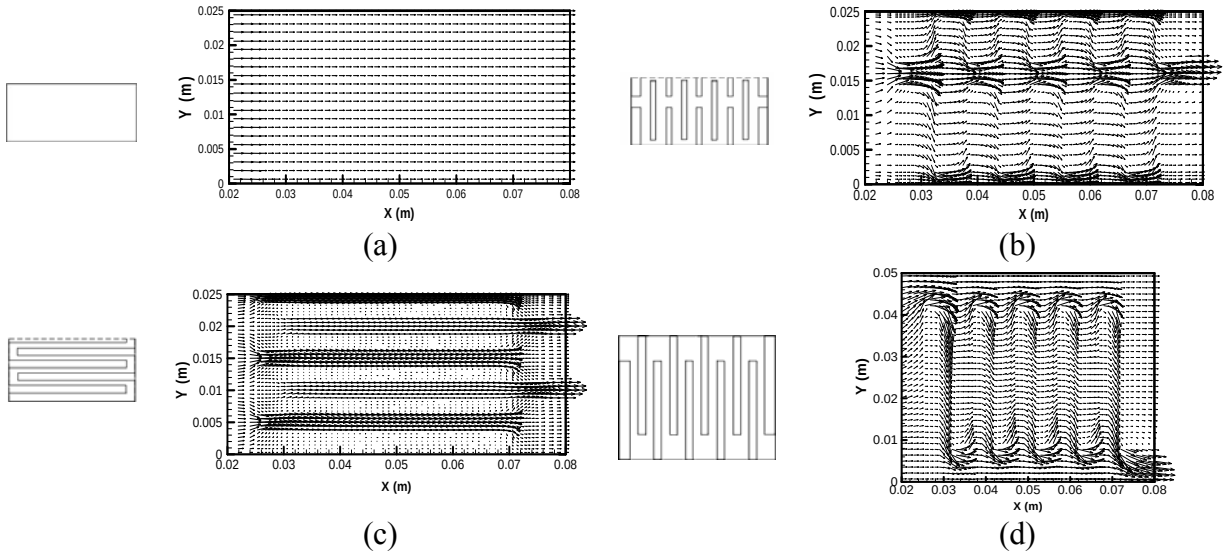

Figure 8 Velocity distributions in (a) block, (b) baffle, (c) zigzag and (d) stagger foams

CONCLUSIONS

In this paper, three configurations of stagger, baffle and zigzag graphite foams were investigated with the aim of reducing pressure drop while utilizing the thermal properties of graphite foam to enhance heat transfer. The experimental results showed that the temperature variations in all the tested samples are similar. It is found that the pressure drops in the designed structures are much lower than that in block foam and that the designed foam heat sinks can achieve relatively good heat removal with lower pumping power. The original block graphite foam requires much more driving force to achieve the same heat transfer rate as compared to the designed structures. The velocity distribution obtained by simulation shows that in the designed structures, one portion of air flow directly penetrates the thin foam wall while the rest goes through the foam via the structured empty slots. This study suggests that high thermal conductivity graphite foams can be appropriately configured for electronics cooling applications with moderate pressure drop.

PHENOMENOLOGICAL MODEL OF TWO-PHASE FLOW INCORPORATING FLOW PATTERN PHENOMENA

Jerry K. Keska
Department of Mechanical Engineering, University of Louisiana
Lafayette, LA 70504, USA

ABSTRACT. This paper presents the developed mathematical model of two-phase flow in a minichannel incorporating flow pattern phenomena. Based on the results of the experimental research conducted on air-water mixture flows in the full range of concentration and flow patterns in a horizontal square minichannel, a mathematical model based on in-situ parameters is developed and presented. The model describes pressure losses in two-phase flow incorporating flow pattern phenomena. The presented model significantly reduces the difference between the experimental and simulated values.

Keywords: *Two-phase flow, flow patterns, mathematical model, flow pattern coefficient.*

INTRODUCTION

Many of today's high-tech electrochemical and electromechanical devices that are employed in aeronautical/aerospace and terrestrial applications implement two-phase flow of heterogeneous mixtures. This also includes micro-electronic packages, compact fission and fusion reactor systems, space power and propulsion systems that are exposed to extremely high temperatures, space suits for extravehicular activity (EVA), backpack fuel cells, and thermoelectric power sources. All of these devices require sophisticated and intense thermal control systems in order to perform properly. Other applications of two-phase flow of heterogeneous mixtures include thermal control systems ranging from those used for cryogenic reactant storage devices to primary structures as well as integrated electronic circuits used for communication, guidance and control, and other functions. Whether these systems are very large (active thermal control systems for the Space Shuttle and the International Space Station, bio- and chemical reactors, oil and gas exploration systems) or very small (micro heat exchangers used for the cooling process in CPUs and ICs), all of these systems have one characteristic in common: their proper functioning is heavily dependent on two-phase flow phenomena.

In two-phase flow attempting to incorporate flow patterns into a mathematical model is a critical and challenging process. The determination of flow pattern phenomena is extremely subjective and ambiguous. It relies primarily on the researcher's visual observation skills and judgment, and it cannot cover the entire range of velocities and concentrations. Before 1990, most of the research focusing on two-phase flow used superficial parameters. Most likely, this was due to difficulties in measuring mixture concentration. More recently, however, more and more research in the field uses in-situ parameters such as in-situ velocity and concentration. These new studies also include models for the pressure gradient and other dynamic phenomena in two-phase flow of a heterogeneous mixture. This reduces the differences partially. Flow patterns, however, which are the most dynamic and subjective phenomena in two-phase flow, have not yet to be satisfactorily incorporated into mathematical models.

One possible solution to this problem involves the incorporation of flow patterns by using the flow pattern coefficient.

The paper presents the results of experimental research on the incorporation of flow pattern phenomena into a mathematical model of pressure losses in the two-phase flow of a heterogeneous mixture of air and water in a horizontal square channel (6.35 mm in size). The generated results allowed the flow pattern coefficient to be obtained, which, when incorporated into the pressure loss model, significantly reduced the differences between experimental and predicted values. Based on the results of the experimental research conducted on air-water mixture flows within the full range of concentration and flow patterns in a horizontal square minichannel, a mathematical model based on in-situ parameters has been developed and presented. The model describes pressure losses in two-phase flow incorporating flow pattern phenomena and significantly reduces the difference between the experimental and simulated values. This model incorporating flow pattern phenomena can be used for applications in two-phase flow of air and water mixtures in minichannels. The model, however, also incorporated parameters such as mixture viscosity and the channel's diameters, which allows it to be potentially useful in other two-phase mixtures and channel sizes.

This work is a continuation of research presented in [2, 6, 7]. Due to space constraints, however, many sections of this paper that would normally be presented have either been omitted or abridged. These sections, including the literature analysis, experimental system, and experimental data, can be found in the above mentioned publications [1, 3, 4, 5, 8].

TWO-PHASE FLOW MODEL WITH FLOW PATTERNS

In order to develop and design a compact heat exchanger with phase transition, it is necessary to develop mathematical models for the two-phase flow and heat transfer processes. Starting from assuming one-dimensional flow and a constant pressure gradient, the pressure drop in a channel/conduit can be expressed by the equation [2, 6, 7]:

$$\Delta P = \frac{dP}{dL}\Delta L. \qquad (1)$$

The total pressure gradient can be formulated as a superposition of three components accounting for mixture acceleration, skin friction and gravity or buoyant forces. This is expressed by the following equation:

$$\frac{dP}{dL} = \left.\frac{dP}{dL}\right|_a + \left.\frac{dP}{dL}\right|_f + \left.\frac{dP}{dL}\right|_g. \qquad (2)$$

For steady-state conditions and for small and moderate pressure differences for a horizontal or short vertical channel/conduit, the total pressure gradient is caused solely by the frictional pressure gradient and is written as:

$$\frac{dP}{dL} = \left.\frac{dP}{dL}\right|_f. \qquad (3)$$

The frictional pressure gradient of a two-phase mixture can be viewed as a superposition of two separate frictional pressure gradients due to the gas component and liquid component as follows:

$$\left.\frac{dP}{dL}\right|_m = \left.\frac{dP}{dL}\right|_l + \left.\frac{dP}{dL}\right|_g, \qquad (4)$$

where for steady-state flow conditions and homogenous spatial and temporal distribution of phases in the mixture with the in situ overall spatial concentration (c_v), the theoretical frictional pressure loss of the mixture is [6, 7]:

$$\Delta P_{theoretical} = \frac{dP}{dL}\Delta L = \frac{\Delta L}{2D}\left[f_g v_g^{\,2} \rho_g \left(1 - c_v\right) + f_l v_l^{\,2} \rho_l c_v \right]. \qquad (5)$$

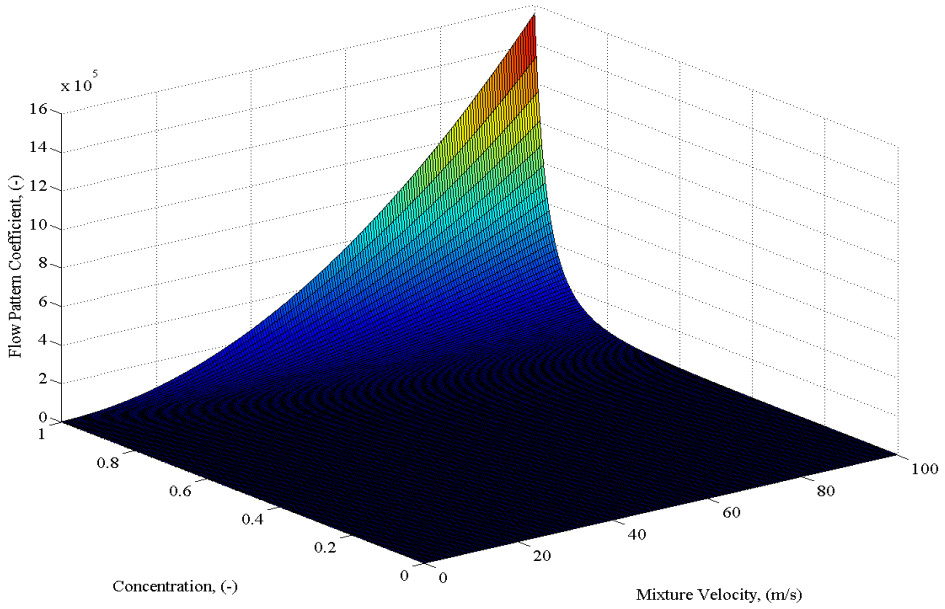

Figure 1. Flow pattern coefficient vs. mixture velocity and in-situ spatial concentration

This represents a surface for an ideal distribution of mixture concentration as a function of mixture velocity and concentration. The friction factors can be determined for the liquid and gas, respectively, in the laminar flow regime by the equation f = 64/Re, and for turbulent flow using either the Colebrook equation or direct numerical values from the Moody diagram for a given Reynolds number and roughness coefficient (ε/D):

$$\frac{1}{f^{1/2}} = -2.0\,\mathrm{Log}_{10}\left(\frac{2.51}{f^{1/2}\mathrm{Re}} + \frac{\varepsilon / D}{3.7} \right) \qquad (6)$$

where Re is the Reynolds number of the mixture, calculated separately for in situ conditions:

$$\mathrm{Re}_m = \frac{v_m D \rho_m}{\mu_m} \qquad (7)$$

Comparing the experimental results for pressure gradient to the theoretical pressure gradients (calculated by Eq. 5), with the flow conditions for given in-situ concentrations and velocities for the various flow patterns, it is not surprising to observe significant differences between the theoretical and experimental pressure gradients caused by the complexity of the flow patterns. These differences are significant, and they are indicative of the need for a significant revision of the model, specifically, through the incorporation of another flow-related independent parameter. A very significant

phenomenon, and one that is not included in Eq. 5, is the flow pattern phenomenon, which includes both the spatial and temporal heterogeneity of the mixture. By the incorporation of the flow pattern phenomenon in the form of a flow pattern coefficient, where the axial pressure gradient becomes a function of in-situ component velocities, friction coefficients, in-situ concentration, and the flow pattern coefficient (Fp), the difference between the theoretical and experimental values should be significantly reduced. This modified correlation can be expressed as:

$$\left(\frac{\Delta \mathrm{P}}{\Delta \mathrm{L}}\right)_{tested} = \frac{1}{2D}\left[f_g v_g{}^2 \rho_g \left(1-\mathrm{c_v}\right) + f_l v_l{}^2 \rho_l \mathrm{c_v} \right] Fp. \quad (8)$$

The application of dimensional and similitude analysis based on Equations 5, 7 and 8 for a steady-state heterogeneous mixture flow of gas and liquid in the horizontal channel results in the following equation for the flow pattern coefficient (Fp):

$$Fp = \frac{1}{E}\left(\frac{\nu_m}{\nu_m}\right)^2 (c_v)^F D^2 \quad (9)$$

where E and F are constants, which could be found experimentally.

The flow pattern coefficient model developed here (Eq. 9) is expressed by the use of in-situ and measurable parameters such as the in-situ mixture concentration and velocity, mixture kinematic viscosity, and channel diameter. In this case, the value of the flow pattern coefficient is independent of the flow pattern visual observations since the flow pattern coefficient is a function of the in-situ measurable parameters. The incorporation of flow patterns occurred through the incorporation of the flow pattern coefficient, which is proportional to the square of in-situ mixture velocity, in-situ concentration to the power of F, the square of channel diameter and reverse proportional to the square of the mixture kinematic viscosity and the constant E (as shown in Eq. 9). The conducted experiments were focused on the collection of data, which allowed for the discovery of the correlation between simulated and measured values of flow pattern coefficients for a two-phase air-water mixture flow in a horizontal minichannel. From Eq. 9, it can be inferred that Fp is a dimensionless number, which varies along with the temporal and spatial distribution of in-situ concentration and the mixture velocity. A graphical image of this is presented in Fig. 1. Thus, two-phase flow of heterogeneous mixtures is extremely dynamic. It is a continuously changing process and any observation of flow patterns is highly observer-dependent. Therefore, in order to obtain accurate experimental results, it is

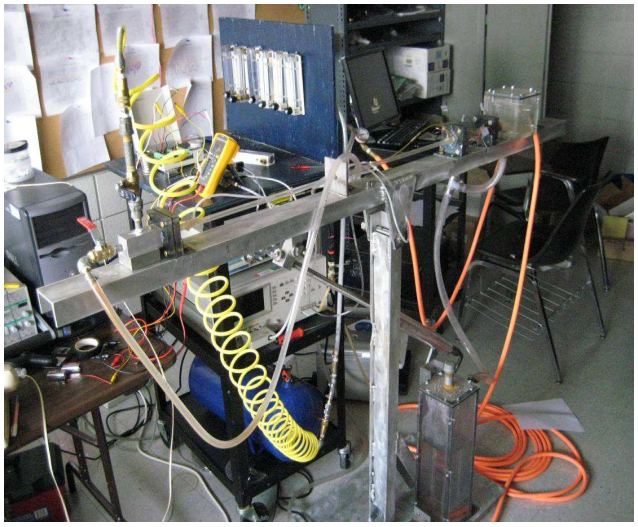

Figure 2. View of the CADAS for two-phase mixture flow in horizontal square channel

critical to use objective, accurate measurement tools for the measurement of the in-situ parameters and for data validation, as well as for the elimination of system-dependent or unique parameters such as flow patterns, superficial parameters, or the quality of the mixture.

EXPERIMENTAL SYSTEM, EXPERIMENTAL DATA AND RESULTS

An experimental system for investigating two-phase flow in minichannels was developed (see Fig. 2), which consisted of a flow set-up with unique measurement systems for concentration using both capacitive and conductive sensors, an optical system, and pressure measurement devices. All of these were interfaced into a computer-aided data acquisition system (CADAS) based on LabVIEW and MatLab software. The experimental apparatus consisted of a horizontal transparent minichannel (cross-section 6.35 mm x 6.35 mm), which was supplied by controlled air and water flow from a mixing chamber. The mixing chamber allows the air and water flows to become fully mixed before entering the test section. The input and output flow rates of air and water are controlled and measured by various instruments, such as cylinders, rotameters, scale, and time and length meters. The system is operated in an closed-loop mode. The controlled, steady-state experiment runs were conducted for all flow pattern types over the full range of concentration (0 – 1.0) and mixture velocity (0 - 20 m/s). These runs were conducted using all five measurement systems (optical, two pressures, conductive, and capacitive) simultaneously in the same space and time for the air-water mixture flow. From this experimental data, the friction factor vs. mixture Reynolds number was calculated using mixture density, velocity and viscosity. Reynolds numbers indicate that the experiments were conducted in laminar and turbulent flow regimes and fit into the classic Moody diagram (Fig. 3). The experimental flow pattern coefficient values change in the range from 0 to 1.7 in function of the Reynolds number values. The Fp values starting from zero for Re = 0, increase to maximum value for Re = 1900 and decrease as the mixture Re continues to increase. It reaches its lowest values at the highest Re, which is 9000.

The conducted experiments were focused on the collection of data, which allowed for the discovery of the correlation between simulated and measured values of flow pattern coefficients for a two-phase air-water mixture flow in a minichannel. Thus, two-phase flow of heterogeneous mixtures is extremely dynamic. It is a continuously changing process and any observation of flow patterns is highly observer-dependent. Therefore, in order to obtain accurate experimental results, it is critical to use objective, accurate measurement tools for the measurement of the in-situ parameters and for data validation, as well as for the elimination of system-dependent or unique parameters such as flow patterns, superficial parameters, or the quality of the mixture. The flow pattern coefficient *Fp* from Equation 9 is defined for the experimental conditions. From obtained experimental data (shown if Fig.4) we could get the values of the constants (E and F) by the application of best fit approach for a steady-state heterogeneous mixture flow of gas and liquid in a horizontal channel, results:

$$Fp = \frac{1}{110000}\left(\frac{\nu_m}{\nu_m}\right)^2 (c_v)^{3.5} D^2 \qquad (10)$$

The presented surface is a graphical representation of the flow pattern coefficient as simulated by Eq. 10 and the points represent experimental values of Fp (Fig.4). The visually observed good fit of experimental points into the calculated surface indicates a high potential for the significant reduction of discrepancies between measured and calculated values of pressure losses. Indeed, the application of the flow pattern coefficient Fp into Eq. 10 reduces the error in the calculated results by very significant values. Using the sum of squares of error values as the measure of error, the value of the error is reduced up to 94% after applying and incorporating the flow pattern coefficient (Fp). The reduction of the error can be visualized by plotting the length pressure gradient, obtained from the theoretical

formula along with the experimental results, with and without considering the Fp, against the in-situ concentration and mixture velocity. This is shown in Fig. 5.

As shown in Fig. 5, the separation of points without the application of Fp from theoretical surface is significantly larger as compared to points with the application of Fp. This indicates that the incorporation of Fp significantly closes the deviation gap between measured and calculated values of the length pressure gradients.

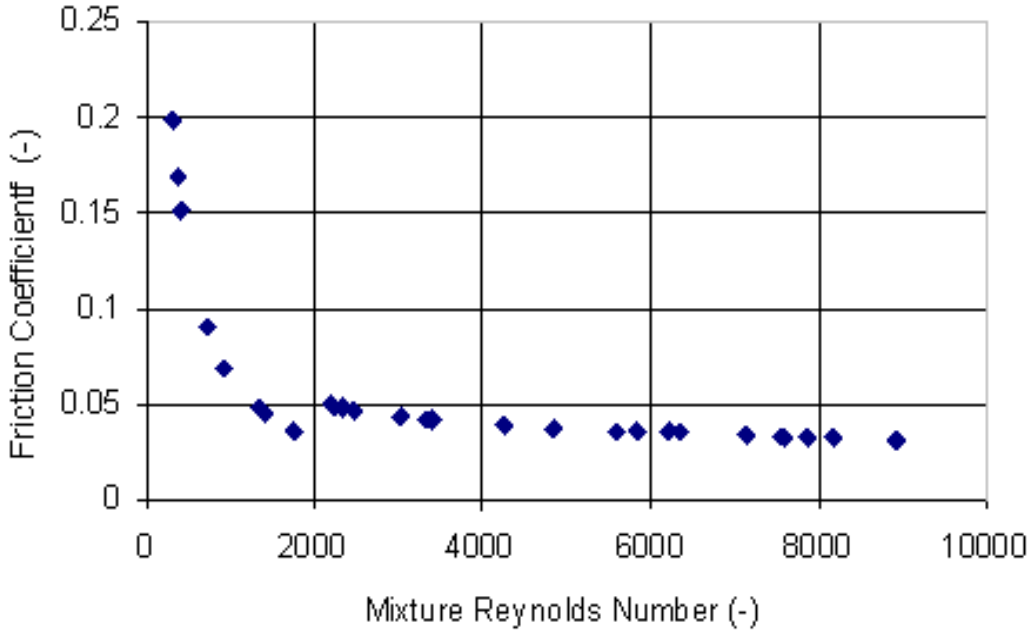

Figure 3. Experimental friction factor vs. Reynolds number for air-water mixture flow.

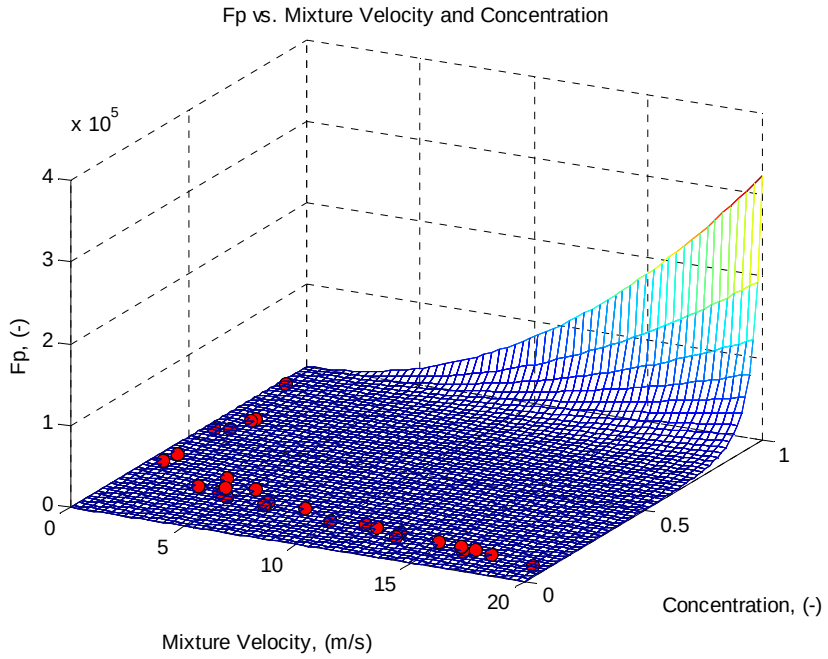

Figure 4. Flow pattern coefficient (surface from simulation and points are experimental values) vs. mixture velocity and in-situ spatial concentration

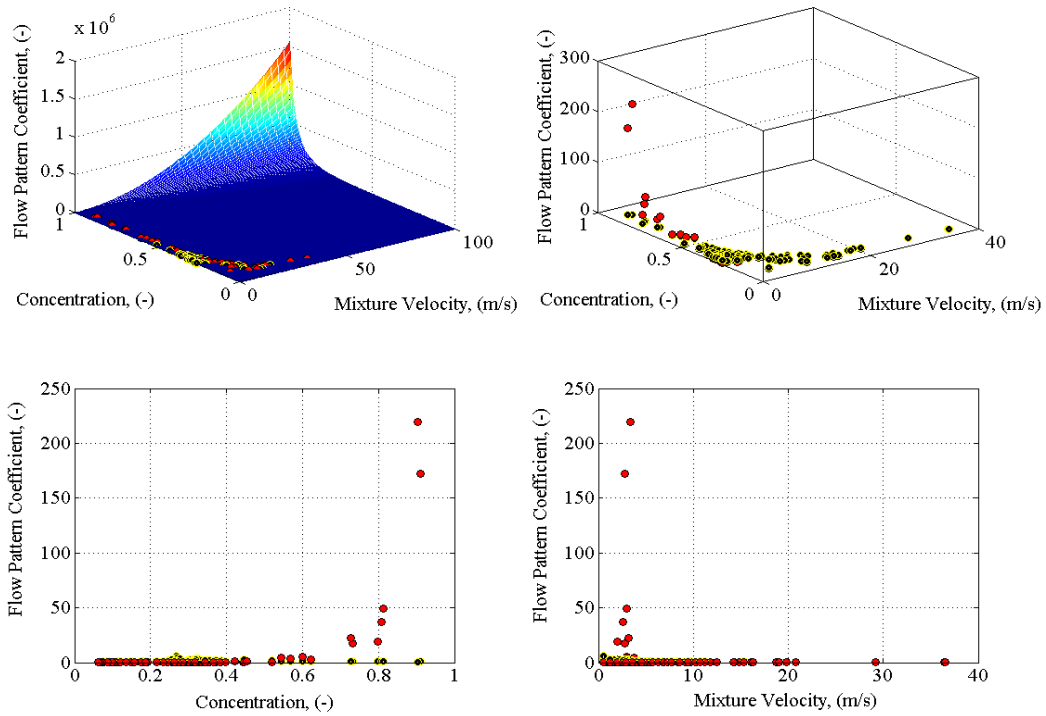

Figure 5. Simulated and experimental values of length pressure gradient losses vs. mixture concentration and velocity.

Figure 5 represents experimental points of the length pressure gradient vs. pair of values of in-situ spatial concentration and mixture velocity, which generated a 3D graph. In analyzing these figures, however, one always needs to keep in mind that those two graphs are reduced from 3D and always have a third parameter, which is depth. From Fig. 5, it is difficult to observe a clear trend for error analysis of the length pressure gradient vs. pair of values of in-situ spatial concentration and mixture velocity for the both cases. The data, however, clearly indicates the importance of considering flow pattern phenomena by using the flow pattern coefficient as defined by Eq. 10.

CONCLUSIONS

This experimental study was performed in an adiabatic minichannel system constructed to generate an air-water steady-state mixture flow over the full range of concentration from 0 (all gas) to 1.0 (all liquid) and with mixture velocities up to 20 m/s. This covered the full range of possible flow patterns and involved the simultaneous measurement of in situ parameters. From this research, the following conclusions can be drawn:

(1) An objective procedure for flow pattern determination and data validation were developed and incorporated into a mathematical model based on in-situ parameters (Eqs. 9 and 10).

(2) The developed mathematical model for the pressure gradient incorporates flow pattern phenomena by integrating a flow pattern coefficient. In this model, the axial pressure gradient is expressed as a function of in-situ mixture concentration and velocity, and the flow pattern coefficient. Although the experiments were limited to mini and microchannels and to water and air mixtures, the proposed model could be expanded for other channel sizes and for other mixtures with different components and mixture properties.

(3) The flow pattern phenomenon significantly affects the process of two-phase flow. This phenomenon is represented by the flow pattern coefficient (Fp) which, when it is incorporated into a mathematical model, reduces significantly the cumulative errors.

INFLUENCE OF THE FLASHING PHENOMENA ON THE BOILING CURVE OF REFRIGERANT R134A IN MINICHANNELS

T. Bohdal, H. Charun, K. Dutkowski *, W. Kuczyński
Koszalin University of Technology, Koszalin, Poland

ABSTRACT. The results of experimental investigations of the heat transfer during the flow of R134a in a minichannel are presented here. The experimental investigations were conducted using a minichannel of a 500 mm total length, and 1.68 mm of the internal diameter. The heated length of the minichannel was 200 mm, the total mass flow rate of the refrigerant (uρ) = 200 ÷ 450 kg/m^{2}s, the inlet subcooling ΔT_s = 5 ÷ 15 K, while the heat flux density q'' = 1.7 ÷ 60.3 kW/m^2. The results of experimental investigations as a curve boiling are presented. The phenomena of the zero boiling crisis, and the influence of the flashing phenomena on the boiling curve show the importance of these elements on a single-phase and a two-phase heat transfer.

Keywords: *experimental investigations, minichannels, boiling curve, zero boiling crisis, flashing*

INTRODUCTION

There are numerous papers dedicated to the general aspects of the heat exchange and flow resistance, especially of two-phase flow in minichannels. However, it is necessary to focus on details, such as the start of the boiling process, the critical heat flux, the flashing, the boiling curve, the phenomena of the zero boiling crisis (boiling hysteresis).
The boiling curve is a curve which represents the influence of the heat flux (q") on the difference of temperatures ($\Delta T = T_w - T_f$), where T_w - the temperature of the heated wall and T_f – the temperature of the fluid. The temperature of the fluid is equal to the temperature of saturation T_s when the process of boiling lasts. Figure 1 presents a fragment of a classical boiling curve. When q" = 0, the temperature of the wall is equal to the temperature of the fluid (ΔT = 0). The increase of heat flux results in an increase of the temperature difference. This means that the temperature of the wall is greater than the temperature of the liquid. The process clearly runs as a straight line and is presented in Figure 1 as section 0-B. In the point B, the temperature of the wall is much higher than the temperature of the liquid, and also the temperature of the wall is higher than the saturation temperature. This is a metastable condition. At a certain moment, the boiling process will occur. Vapour bubbles constitute heat sinks, which results in a reduction of the temperature of the wall. Therefore, with a constant value of q", a sudden drop of ΔT is observed – the line from the point B to the point C. This phenomena is known as a zero boiling crisis. A further increase of heat flux results in an increase of the number of bubble sites. The difference of temperature is slowly increasing. This is so until the Critical Heat

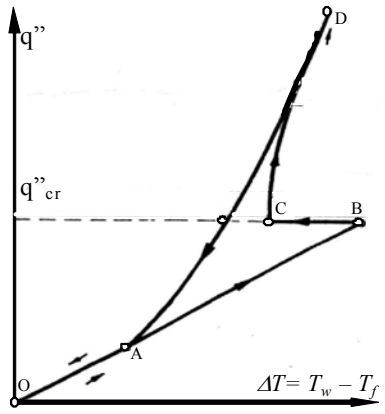

Figure 1. Classical boiling curve

E-mail address: krzysztof.dutkowski@tu.koszalin.pl

Flux (CHF), at which a born-out can occur. During the reduction of the heat flux, the process does not run in the same manner. The ΔT values during the reduction of the heat flux are different from those when the heat flux was being increased. The boiling process lasts until the point A. The abovementioned processes presented in Figure 1 are known as the boiling hysteresis.
The flashing phenomena in minichannels occurs when the pressure at some cross-section of the minichannel drops below the vapor pressure of the fluid being passed, and the whole bulk of the liquid becomes superheated: metastable. The unique characteristic of the flashing processes is a withdrawal of the latent heat of evaporation from the internal energy of the superheated liquid (Hahne E. and Barthau G. [1]). In that cross-section, vapor is suddenly generated in an explosive manner (Elias E. and Chambre P.L. [2]). When flashing occurs, bubbles are formed in the flow stream. These bubbles carry large amounts of energy.
The present paper is focused on the experimental investigation of the influence of the flashing phenomena on the boiling curve. The R134a refrigerant was used as the working fluid considering its widespread application in refrigerating and air conditioning systems. The refrigerant flowed through a stainless steel pipe with the internal diameter of 1.68 mm and 500 mm of the total length. Ten thermocouple sensors were set on a 200 mm electrically heated section in even intervals (18.2 mm). For each location, individual characteristics were prepared. This allowed the determination of the place where flashing started and its influence on the boiling curve. Another issue is to show that the area before the incipience of boiling, considered in all the papers as a single-phase flow area, can be a two-phase flow area (the presence of flashing). Therefore, a proposal is made to introduce the following nomenclature as more correct: first zone - *before incipience of boiling* and the second zone *with boiling*, because as it was further shown in the paper, the flow before the incipience of the boiling process can be both single or two-phase.

LITERATURE REVIEW

Lists of results in the form of boiling curves in minichannels occur more and more frequently in publications. This is so owing to a larger number of experimental data, which as a result of the use of precise measuring equipment and measuring methods have become comparable regardless of the research centre.
Numerous papers include information about the possibility of the occurrence of the flashing phenomena (Schneider et al. [3], Bergles and Kandlikar [4], Revellin et al. [5], Lee and Mudawar [6]). However, there are no publications which would discuss this issue more extensively. One of the few papers is the paper by Warrier et al. [7]. The authors assume that: a two-phase flow starts when a rapid increase of the heat transfer coefficient occurs, and the local vapor quality should also take the flashing phenomena into account.
During the experimental investigations of the liquid nitrogen boiling process conducted by Qi et al. [8] in minipipes with internal diameters of 0.531, 0.834, 1.042 and 1.931 mm the existence of the zero boiling crisis phenomena was noted. The investigations were carried out in the range of mass flow rate ($u\rho$) = 440 – 3000 kg/m^{2}s and heat flux q" = 5.09 – 21.39 W/cm^2. It was noted that a drop of the temperature of the wall at ONB moment reached 5.0 K. Only these authors analyzed the influence of the flashing phenomena on the local vapor quality. An increase of the vapor quality was 18% when flashing phenomena was taken into account.
It is characteristic than in each of the papers above mentioned, the authors speak about the zone of a single and two-phase flow. There are two cases:

- absence of the zero boiling crisis phenomena, then the single-phase flow zone finishes when the trend of the boiling curve changes;
- the zero boiling crisis phenomena occurs - the single-phase flow occurs until the moment of a rapid temperature drop. This moment is considered to be the start of the boiling process and incipience of a two-phase structure. This is also written in those papers where the flashing phenomena is observed.

EXPERIMENTAL APPARATUS AND PROCEDURE

The test loop

A schema of the test loop is presented in Figure 2. The liquid of the R134a refrigerant pumped from tank 12 by pump 2 flowed through filter 3 and precooler 4. Next the Coriolis mass-flowmeter 5 was installed (mass flow rate: 0 - 20 kg/h, accuracy 0.075% of measured value). A liquid with the known flow rate was fed to the set of heat exchangers 6, 7 and 8. There was a possibility to use these exchangers alternatively, which allowed one to obtain the proper conditions of the refrigerant on the test section inlet 1. The parameters of the refrigerant (pressure and temperature) were measured on the inlet (p_1, T_1) and outlet (p_2, T_2) of heat exchangers. The designed set of heat exchangers enabled experimental tests of the heat transfer and pressure drop during a single-phase flow of the refrigerant, subcooled and saturated boiling.

The refrigerant was directed to the test section. The following parameters were measured here: the pressure in the initial cross section of the tested part of minichannel p_{in}, the pressure drop Δp on the tested part of the minichannel, the wall temperature T_1-T_{10} of minichannel, temperature on the inlet T_{in} and outlet T_{out} of the tested part, as well as supplied electric power q_{el}. All the voltage signals of the measured values were connected with data acquisition system 18 which cooperates with computer 17.

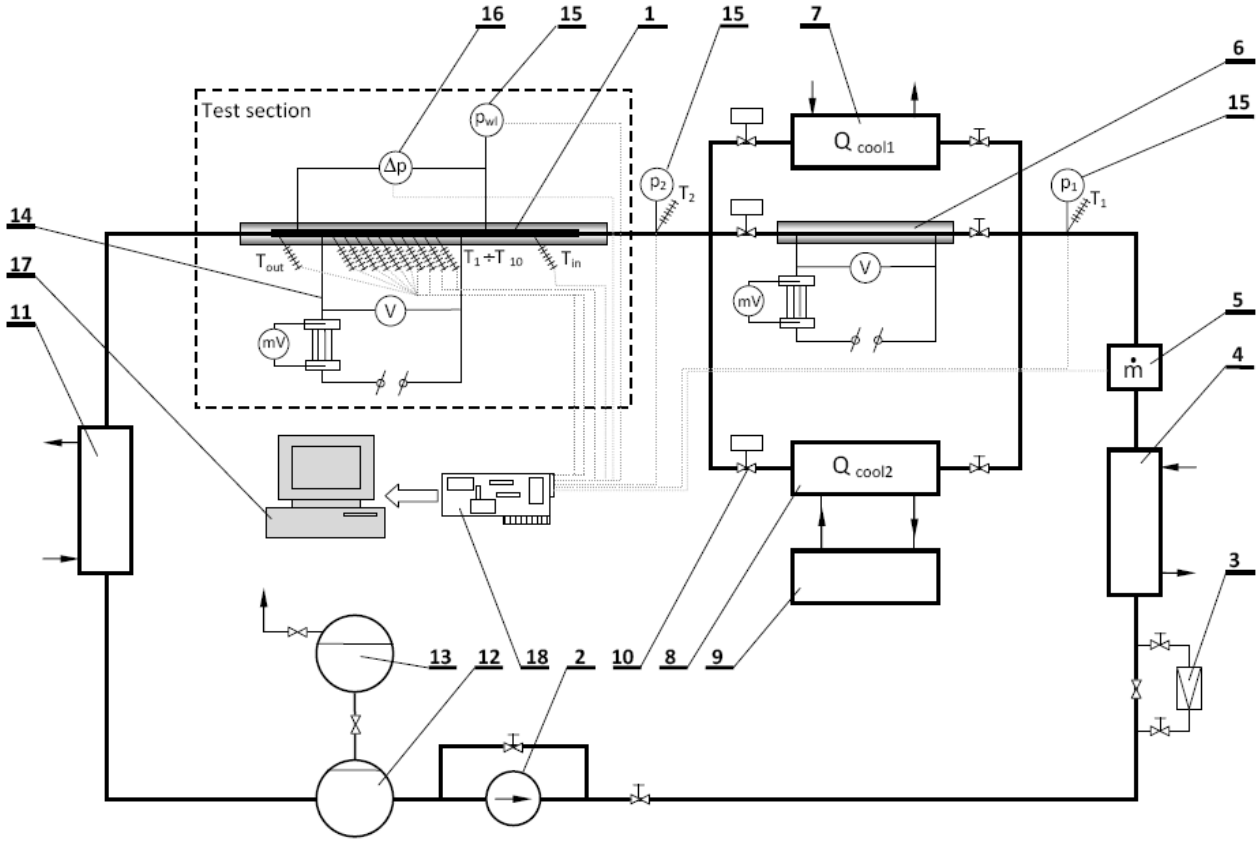

Figure 2. Experimental set-up: 1 – minichannel, 2 – pump (with instrumentation), 3 – filter, 4 – precooler, 5 – flowmeter, 6 – preheater, 7 – cooler no. 1 (cooling with water), 8 – cooler no. 2 (cooling with refrigerant), 9 – additional cooling system, 10 – valves, 11 – condenser (cooled with water), 12 – tank of refrigerant, 13 – spare tank of refrigerant, 14 – system of electric heating of measuring section, 15 – pressure sensors, 16 – differential pressure sensor, 17 – computer, 18 – data acquisition system

The test section

The test section was made from stainless steel pipe 1 with a total length of 500mm and an internal diameter of 1.68mm. The pipe was divided into several sections. The first one, 150 mm long, constituted a hydraulic stabilization area, the further one (300 mm) was the proper test part of minichannel and the third one, 50 mm long, was the outlet section.

The proper test section was electrically heated on the length of 200. Using a high voltage adjustable transformer, a high voltage shunt 150A/60 mV and voltmeters, it was possible to change the heat flux and to measure the parameters required for its determination.

On the measuring section, 10 thermocouples K type and diameter of wire ϕ = 0.2 mm were installed. Using these sensors, the temperature of the external surface of the minichannel wall was measured. Just right before the heated area and after it, the same two thermocouples were additionally fixed to the pipe surface in order to measure the refrigerant's temperature on the inlet and the outlet of the test section. Before the sensors were installed, their individual experimental thermo-electric characteristics were prepared in relation to the precise thermometer with accuracy of 0.1^{o}C.

In the pipe, 50 mm before the heated section and 50 mm after it, holes were made. They made it possible to measure the working fluid pressure and pressure drop on the minichannel's tested part. For the measurement of the pressure, manufactured by Endress+Hauser, a piezoresistant sensor with a transducer was used (Deltabar S PMD75). Measuring range of this device was 0 ÷ 4 MPa and an accuracy of 0.075. The measurement of the pressure drop was conducted with use a differential pressure transducer (Deltabar S PMD75) with a basic measuring range of 0 ÷ 1.6 MPa and an accuracy of 0.075. The uncertainty of the pressure and the pressure drop was ± 3 kPa and ± 1.2 kPa respectively.

The whole test section was insulated in order to have conditions closer to adiabatic ones. The total heat losses to the environment were assessed to be smaller than 5% of the supplied electric power.

The test procedure

All the data was collected once steady state conditions were achieved. The required mass flow rate was set as first. The refrigerant with a required flow rate was directed to one of 3 heat exchangers in the preparation section. The selection of the exchanger depended of the expected value of the refrigerant's temperature on the minichannel inlet. The value of the refrigerant's saturation temperature depended on the working pressure of the refrigerant in the minichannel. This value could be changed with a valve installed behind the test section. When the mass flow rate, pressure, pressure drop and the refrigerant's temperature were constant, data registration began. The averaged values from several measurements were the basis for further calculations. It should be mentioned that in some cases, oscillations of the abovementioned parameters were registered, and then the registration was conducted in a quasi steady state conditions.

The experiments were conducted using R134a refrigerant in the following range of parameters: D = 1.68 mm, $(u\rho)$ = 260 - 2144 kg/m^{2}s, q" = 1.7–60.3 kW/m^2, T_{in} = 13.1 – 23.5 ^{0}C.

Data reduction

The heat transfer rate to the refrigerant in the minichannel is obtained on the basis of the net power input q and the total internal surface area of the minichannel A. The total power input is calculated by subtracting heat loss from electrical power

$$q'' = q/A = (q_{el} - q_{loss})/A. \quad (1)$$

It is accepted that the temperature of the wall on the internal surface of the minichannel is equal to the temperature of the external surface of minichannel. It is assumed that the liquid temperature changes linearly on the length of the channel, and in the single-phase flow it is calculated from the heat balance, while in the two-phase flow region it corresponds to the saturation temperature being the result of the local pressure inside the minichannel:

$$T_f(i) = \begin{cases} T_{in} + q'' \cdot \dfrac{\pi d\ L(i)}{\dot{M} \cdot c_p} - \text{single-phase region} \\ T_s(i) = f(p_s) \quad - \text{two-phase region} \end{cases} . \tag{2}$$

The following was assumed in formula (2): T_{in} – temperature of the liquid measured on the inlet to the heated minichannel section, L(i) - distance measured from the beginning of the heated section, m – refrigerant's flow rate, c_p – specific heat of the liquid, $T_s(i)$ – saturation temperature in cross-section (i) dependent on local saturation pressure - p_s.

RESULTS AND DISCUSSION

Boiling curves without flashing phenomena

Figure 3 presents boiling characteristics of refrigerant R134a determined for the mass flow rate (uρ) = 450 kg/(m^2·s), with the liquid subcooling ΔT_n = 10 K. By the liquid subcooling ΔT_n should understand the difference of saturation temperature T_s and temperature of inflowing liquid T_f. Figure 3a shows the dependence of temperature difference ΔT ($\Delta T = T_w - T_f$) on heat flux density q". T_w denotes the temperature of the wall. Considering the fact that on heated part of minichannel ten thermocouples were placed, it was possible to determine the difference of temperature ΔT= f(L) in ten cross-sections.

In the first phase of heating the difference of temperature in each measuring cross-section on length L had the same value. An increase of the heat flux density resulted in the growth of value ΔT. This corresponds to the conditions of the heating of a liquid during forced convection, which characterizes section O – B in Figure 1. For the parameters of the experiment given in Figure 3, it is observed that a single-phase liquid flow in a minichannel occurs to the value of heat flux q" = 22.4 kW/m^2 (each thermocouple confirms the trend of the process in compliance with section O – B). A further growth of the heat flux caused an increased difference of temperature ΔT, while this process is in a meta stable condition of the system. Any disturbances of the meta-stable equilibrium lead to the initiation of the zero boiling crisis, which was accompanied by an rapid drop of the minichannel wall temperature. For example presented here, this took place when the heat flux was q" = 27 kW/m^2.

The measurement of temperature showed the boiling process occurred initially only on a part of the minichannel length, and covered those cross-sections which were located above 91 mm from the inlet cross-section of the minichannel. It was observed that in this part of the measuring section where five first temperature sensors were installed (18,2 ÷ 91 mm), there was no zero boiling crisis effect (i.e., the states of the refrigerant remained on the part of section O – B of the characteristics from Figure 1). This means that a single-phase liquid flow continued there. An increase of the heat flux to q" = 36.6 kW/m^2 caused the zero boiling crisis to cover also this part of the minichannel, and it was accompanied by a drop of the wall temperature. Only then almost the whole volume of the pipe minichannel was covered by boiling. It should be noted that the temperature recorded by the first sensor, installed in the distance of 18.2 mm from the inlet cross-section to the section heated confirmed a single-phase flow of the R134a liquid in this part of the length of the minichannel. During the zero crisis, the boiling front moved in the direction contrary to the liquid flow in the pipe minichannel. This manner of the movement of the boiling front also occurs in conventional channels [1]. Twice the zero boiling crisis was recorded, and the front of nucleation occurred in range L = 91 ÷ 109.2 mm from the inlet cross-section of the minichannel for q" = 27.0 kW/m^2, and then in range L = 18.2 ÷ 36.4 mm for q" = 36.6 kW/m^2. For the given experiment conditions, this was the maximum value of the heat flux. Then, the heat flux was decreased. With a decreasing heat flux the characteristic points of the boiling curve moved and connected one by one to the straight line of the single-phase liquid flow.

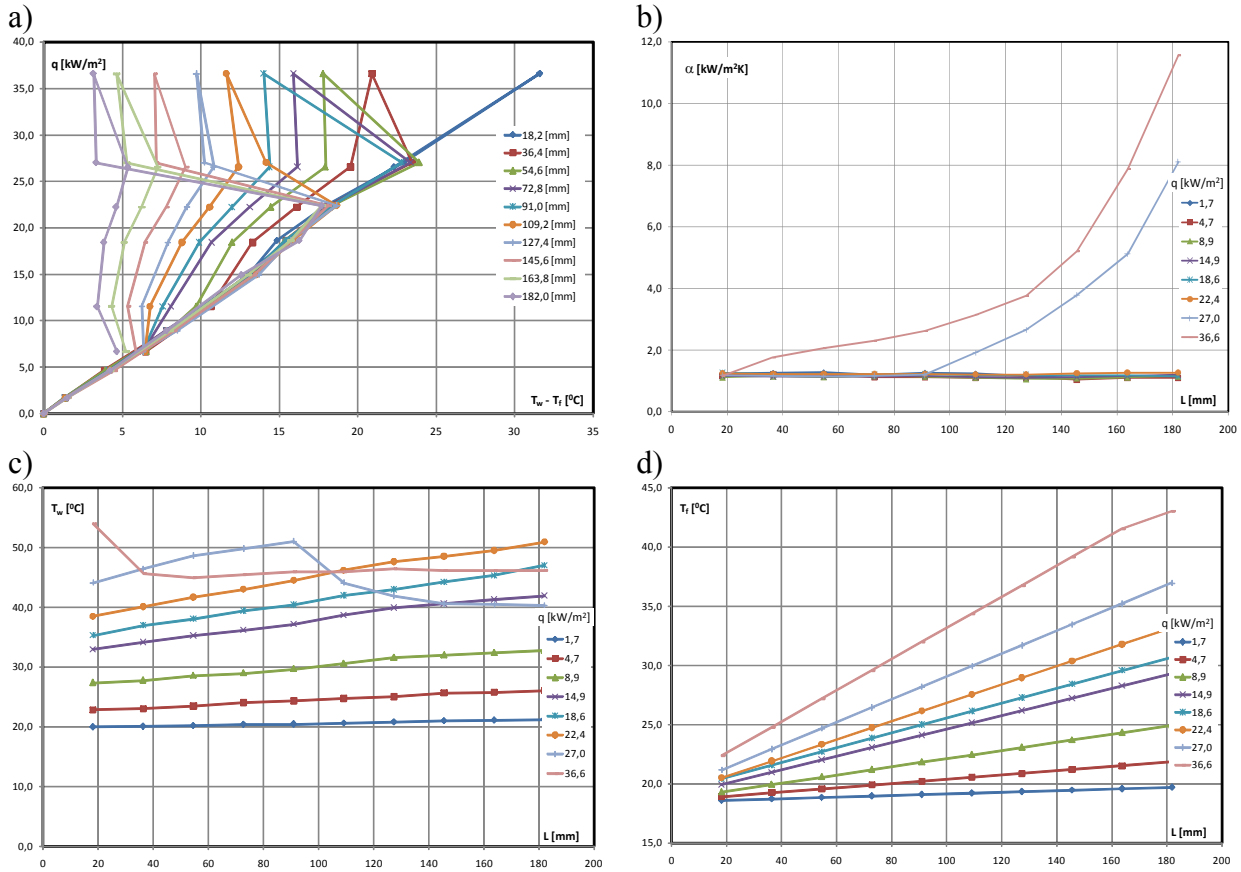

Figure 3. Results of experimental investigation: R134a, D = 1.68 mm, (uρ) = 450 kg/(m^2·s), $\Delta T_n = T_s - T_f = 10$ K; q" = 1.7 - 36.6 kW/m^2
a) heat flux q" versus temperature difference $\Delta T = T_w - T_f$
b) local heat transfer coefficient on the length of the test section
c) temperature of the wall T_w on length of the test section
d) temperature of the refrigerant T_f on length of the test section

The distribution of the local heat transfer coefficient (for selected values q" = const) during a single-phase liquid flow and during boiling is presented in Figure 3b. A clear and significant increase of heat transfer coefficient is observed in the boiling region. The changes of the channel wall temperature during a single-phase liquid flow and after the incipience of boiling (for q" = 27 kW/m^2 and q" = 36.6 kW/m^2) are presented in Figure 3c. Figure 3d presents the distribution of the refrigerant temperature along the minichannel. A linear growth of the refrigerant temperature occurs in the region where it doesn't exceed the level of the saturation temperature.

Boiling curves with flashing phenomena

Figure 4 refer heating of R134a refrigerant in a minichannel with the same internal diameter, but in the conditions of the occurrence of flashing. The results demonstrated that this phenomena has an influence not only on the heat transfer during a single-phase liquid flow but also during flow boiling. Figure 4 presents the results of experimental investigations with following conditions: (uρ) = 280 kg/(m^2·s), $\Delta T_n = 4$ K. During increase of the heat flux, the refrigerant's states should occur in the same manner as for the previously discussed case (in the graphical interpretation along straight line O – B in Figure 1). It appeared that the points which represent the location of these states on the diagram depart clearly from straight line O – B. First of all, this concerned those positions which were placed at the end of the minichannel. For the higher values of the heat flux, the deviation concerned the cross-section situated more and more closely to the inlet cross-section. This can be explained by a drop of the refrigerant temperature on the minichannel length, which causes a

growth of temperature difference $\Delta T = T_w - T_f$. This is clearly visible in Figure 4d, which presents the distribution of the refrigerant temperature on the minichannel length for various values of the heat flux. This undoubtedly is the result of the occurrence of the flashing phenomena, which initially ($q'' = 15.7$ kW/m^2) covered only two last cross-sections of the minichannel located nearest of the outlet cross-section, and moved in the direction opposite to the refrigerant flow. For conventional channels, it is considered that along straight line O - B (Figure 1), heat transfer is realized during a single-phase forced convection. In the case when the flashing phenomena occurs there is in fact a two-phase structure of refrigerant (however, this is not classical flow boiling). In these experimental conditions the value of heat flux $q'' = 54.4$ kW/m^2 can be treated as a maximum one, at which boiling has not yet occurred. Its increase up to 55.1 kW/m^2 resulted in a meta-stable condition. Sufficient overheating of the wall occurred and a boiling process with its zero crisis was initiated. New temperatures of the wall were established as in Figure 4c. As a result a drop of temperature difference ΔT occurred. Also, a rapid growth of the heat transfer (Figure 4b) serves to confirm the fact of flow boiling. It is characterized by a growth of the local heat transfer coefficient. The value of this coefficient significantly exceeds those values which are obtained in forced convection conditions during a single-phase flow and a flow with flashing. The technical potential of the experimental set-up did not allow for tests at the growth of the heat flux above $q'' = 55.1$ kW/m^2.

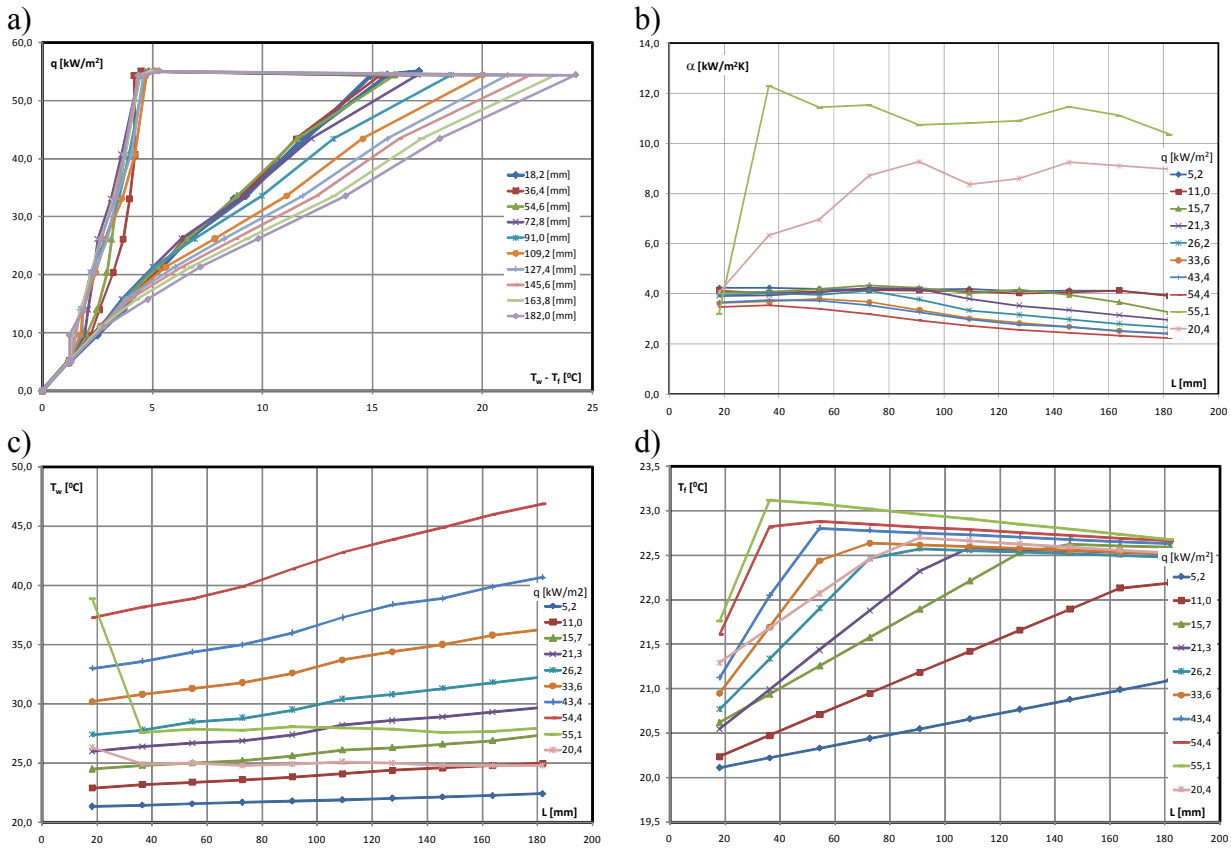

Figure 4. Results of experimental investigations: R134a, D = 1.68 mm, (uρ) = 280 kg/(m^2·s), $\Delta T_n = T_s - T_f = 4$K; $q'' = 5.2 – 55.1$ kW/m^2, flashing
a) heat flux q'' versus temperature difference $\Delta T = T_w - T_f$
b) local heat transfer coefficient on the length of the test section
c) temperature of the wall T_w on length of the test section
d) temperature of the refrigerant T_f on length of the test section

Also, tests were conducted where the heat flux was decreased. A characteristic feature of the boiling process in the flow with the flashing phenomena is overlapping states of the refrigerant in each

cross-section of the minichannel. In practice, this meant that for each value of heat flux density q" which occurred in the conditions of boiling with the flashing phenomena temperature difference $\Delta T = T_w - T_f$ had the same value in all the cross-sections on the whole length of the minichannel. This can be explained by a significant growth of vapour bubbles, which make flow more homogeneous by making it turbulent.

CONCLUSIONS

1. The experimental investigations conducted with the R134a refrigerant during a flow in a heated minichannel with an internal diameter of 1.68 mm, enabled the presentation of boiling curves. A description of boiling curves, known for conventional channels, proved to be insufficient for a minichannel. Instable phenomena have a special significance during heat transfer in minichannels. These are especially the zero boiling crisis and the flashing phenomena.
2. The mechanism of the boiling process in the flow in minichannels is substantially different from the one which has already been well recognized as regards conventional channels. The surface tension and a large drop of the pressure in the flow have a special impact on this mechanism. On the basis of the results of their research, the authors confirmed that boiling in conventional channels and in minichannels cannot be compared directly.
3. The so-called flashing phenomena, which is usually leaved out in an analysis of boiling in conventional channels, which consists in the occurrence of a two-phase structure as a result of the pressure lowering (below the saturation pressure) as a result of large flow resistances in the minichannel, plays a significant role and has an impact on boiling curves.
4. The impact of flashing on the boiling curves in a pipe minichannel constitutes a new look at the description of the boiling mechanism in channels.

EXPERIMANTAL STUDY OF SINGLE-PHASE FLOW HEAT TRANSFER IN A MINICHANNEL

T. Bohdal, H. Charun, K. Dutkowski *, W. Kuczyński
Koszalin University of Technology, Koszalin, Poland

ABSTRACT. In this article the results of experimental investigations are presented. The experiment was conducted with the liquid R134a in a minichannel with an internal diameter of 1.68 mm. The results of the experiment were compared with the calculations of the correlations provided by other authors. Correlations for the calculation of Nusselt number during the heat transfer in a flow known in conventional channels as well as new correlations proposed for the use in minichannels were applied. The usefulness of some correlations used so far in the conventional channels was demonstrated.

Keywords: *experimental investigations, minichannels, single-phase flow, heat transfer*

INTRODUCTION

Widely conducted experiments of two-phase flow in minichannels has demonstrated that both flow resistances and heat transfer coefficients differ significantly from the values obtained from calculations with the dependences used for conventional channels [1, 2, 3]. In order to propose dependences which could be useful for the purpose of a flow in minichannels with a heat transfer analysis, a lot of experimental investigations were conducted. In this research, very accurate measuring devices are used, whose aim is to exclude the influence of the measuring error on the discrepancies occurring. One of the ways to check the correctness of the applied methodology is testing of the set-up during single-phase flow heat transfer [4, 5, 6, 7, 8, 9]. Obtained results of experimental investigations during single-phase flow heat transfer which are compliant with general trends constitutes a guarantee of the correctness of an experiment conducted with boiling. The analysis covered by this paper concerns a comparison of various correlations which describe the heat transfer in a single-phase flow of refrigerants in a minichannel. Those dependences which are recommended for conventional channels and new dependences which are proposed for minichannels were used.

EXPERIMENTAL SET-UP AND DATA REDUCTION

Experimental set-up

The liquid of the R134a refrigerant pumped from tank by pump flowed through filter and precooler. Next, the Coriolis mass flowmeter was installed. A liquid with a known flow rate was fed to heat exchangers. It was able to use these exchangers alternatively, which allowed one to achieve the proper refrigerant conditions on the test section inlet. The refrigerant (with suitable outflow parameters) was directed to the test section. The following parameters were measured: the pressure in the initial cross section of the tested part of the minichannel, the pressure drop on the tested part of the minichannel, the profile of the minichannel wall temperature, temperature on the inlet and outlet of the tested part, and the supplied electric power. All of the voltage signals of the measured values

* Corresponding author: Dr. Eng. K. Dutkowski
Phone: + (48)-94-34 78 378
E-mail address: krzysztof.dutkowski@tu.koszalin.pl

were connected with data acquisition system which cooperates with computer. A detailed description of experimental set-up is presented in paper [10].

Data reduction

The heat flux supplied to the refrigerant on length L(i) of the minichannel (measured from the location of the inlet cross-section) can be described with the following formula:

$$\dot{Q}(i) = \dot{M} \cdot c_p \cdot \left[T_f(i) - T_{in}\right], \tag{1}$$

where $T_f(i)$ is the temperature of the single-phase refrigerant in a cross-section L(i), while c_p is the mean specific heat of the refrigerant determined at the refrigerant's mean temperature on length L(i). From equation (1), the refrigerant's temperature is determined in i^{th} cross-section of the minichannel, from the following equation:

$$T_f(i) = T_{f,in} + \frac{\dot{Q}(i)}{\dot{M} \cdot c_p}, \tag{2}$$

which after a rearrangement takes on the following form:

$$T_f(i) = T_{f,in} + q'' \cdot \frac{\pi \cdot D \cdot L(i)}{\dot{M} \cdot c_p}. \tag{3}$$

Local convective heat transfer coefficient - h(i) was calculated from the below dependence:

$$h(i) = \frac{q''}{\left[T_w(i) - T_f(i)\right]}. \tag{4}$$

Experimental local Nusselt number was determined as:

$$Nu(i) = \frac{h(i) \cdot D}{k_f(i)} \tag{5}$$

where: $k_f(i)$ is the heat conductivity of liquid (calculated for the mean in the cross-section liquid temperature).

METHODOLOGY OF THE CORRELATION SELECTION

It was found on the basis of an analysis of the papers by many authors that two problems need to be addressed in the description of the heat transfer process during a forced convection in a single-phase flow. The first one is the proper determination of the thermal entrance length - L_T, while the other one is the selection of the equation for the calculation of Nusselt number depending of the nature of the refrigerant's flow.

Selection of the thermal entrance length correlation

Selection of thermal entrance length L_T plays a significant role in the calculations of minichannels because in practice (e.g. in compact evaporators) minichannels with small and very small lengths are usually used. Therefore, it is very difficult to guarantee the proper thermal entrance length for all cases. Therefore, it is necessary to consider in which area the measurement is made. This should be taken into account while choosing the suitable correlation.

In the further discussion, the thermal entrance length was according to the formula presented e.g. in articles by Yang and Lin [11] or by Fernando et al. [12, 13]:

$$L_T/D = 0{,}05 \cdot Re \cdot Pr \tag{6}.$$

Selection of the Nusselt number correlation

While selecting comparative correlations for the Nusselt number calculation, the nature of the flow (laminar/turbulent) and zone (thermal entrance length/thermally developed flow) should be taken into account.

Review of the conventional channel Nusselt number dependences

Laminar flow (thermal entrance length)

- For the calculation of local Nusselt number, the authors of paper [11] propose Shah and Bhatti formula:

$$Nu = 1302 \cdot Gz^{1/3}, \text{ for } 1/\text{Gz} \le 0.00005, \tag{7}$$

$$Nu = 1.302 \cdot Gz^{1/3} - 0.5, \quad \text{for} \quad 0.00005 \le 1/\text{Gz} \le 0.0015, \tag{8}$$

$$Nu = 4.364 + 8.68 \cdot 10^{-3} (Gz)^{0,506}, \text{ for } 1/\text{Gz} \ge 0.0015, \tag{9}$$

where: Gz – local Graetz number expressed with the following equation:

$$Gz = \text{Re} \cdot \text{Pr} \cdot D / L(i), \tag{10}$$

while L(i) is the distance between the analyzed cross-section and the inlet cross-section of the heated region.

- Sieder and Tate (1936) provided a dependence which describes the mean Nusselt number in the thermal entrance length for a hydraulically developed flow, with the influence of the fluid properties. The „w" index concerns the liquid properties in the wall temperature, while „f"– in the temperature of the flow core. The formula is recommended for the following range: 0.48 < Pr < 1670 and 0.004 < (μ_f/μ_w) < 9.75 [12, 14, 15]

$$Nu = 1.86 \left(\text{Re} \cdot \text{Pr} \frac{D}{L} \right)^{1/3} \left(\frac{\mu_f}{\mu_w} \right)^{0,14}. \tag{11}$$

- The formula of Shah and London (1978) calculation of the local Nusselt number has the following form [12, 14,16]:

$$Nu = \begin{cases} 1.953 \left(\text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} \right)^{1/3} \\ 4.364 + 0.0722 \left(\text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} \right)^{1/3} \end{cases} \quad \text{for} \quad \begin{cases} \text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} \ge 33.3 \\ \text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} < 33.3 \end{cases}. \tag{12}$$

- According to Hausen (1943) and Kays (1955) [12], the mean Nusselt number can be calculated from the following formula:

$$Nu = 3.66 + \frac{0.0668 \left(\text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} \right)}{1 + 0.04 \left(\text{Re} \cdot \text{Pr} \cdot \dfrac{D}{L} \right)^{1/3}}. \tag{13}$$

Turbulent flow

- According to Dittus – Boelter (1930) for Re ≥ 10 000, 0.7 < Pr < 16 700, $L_H/D > 10$ (smooth channels), for the calculation of the mean Nusselt number, the following formula is proposed [12, 15, 16, 17, 18, 19, 20]:

$$Nu = 0.023 \cdot \text{Re}^{0.8} \, \text{Pr}^{0.4}, \tag{14}$$

- Gnielinski (1976) for 3000 < Re < $5 \cdot 10^6$, 0,7 < Pr < 160 (rough channels), recommends the following dependence [12, 15, 18, 20]:

$$Nu = \frac{(f/8)(\text{Re} - 1000)\text{Pr}}{1 + 12.7 (f/8)^{1/2} \left(\text{Pr}^{2/3} - 1 \right)}, \tag{15}$$

where friction factor f is calculated from the following formula:

$$f = \left[1.82 \cdot \log(\text{Re}) - 1.64 \right]^{-2} \tag{16}$$

or the following dependence which gives very similar results:

$$f = \left[0.79 \cdot \ln(\text{Re}) - 1.64 \right]^{-2}. \tag{17}$$

- According to the proposal put forward by Kakac (1987), for the range of 2 300 < Re < 10 000 [12], the formula has the following form:

$$Nu = 0.116 \cdot \left(\mathrm{Re}^{2/3} - 125\right) \cdot \mathrm{Pr}^{1/3} \left[1 + \left(\frac{D}{L}\right)^{2/3}\right] \left(\frac{\mu_f}{\mu_w}\right)^{0,14} . \tag{18}$$

- Petukhov's correlation [15] for $1000 < \mathrm{Re} < 5 \cdot 10^6$ (rough channels) has the following form:

$$Nu = \frac{(f/8)\mathrm{Re} \cdot \mathrm{Pr}}{K + 12.7(f/8)^{1/2}\left(\mathrm{Pr}^{2/3} - 1\right)}, \tag{19}$$

where K coefficient:

$$K = 1.07 + \frac{900}{\mathrm{Re}} - \frac{0.63}{1 + 10\,\mathrm{Pr}} , \tag{20}$$

while friction factor f is calculated according to the formulae (14 or 15).

- According to Petukhov-Popov, for Re ≥ 10 000 (rough channels) [21], the following correlation is applicable:

$$Nu = \frac{(f/8)\mathrm{Re} \cdot \mathrm{Pr}}{1 + 3.4 \cdot f + \left(11.7 + \frac{1.8}{\mathrm{Pr}^{1/3}}\right)(f/8)^{1/2}\left(\mathrm{Pr}^{2/3} - 1\right)} \tag{21}$$

where f is the friction factor.

Review of the minichannel Nusselt number dependences

Laminar flow (thermally developed flow)

- According to Choi et al. (1991), for Re < 2000 [14] the correlation has the following form:

$$Nu = 0.000972 \cdot \mathrm{Re}^{1.17}\,\mathrm{Pr}^{1/3} . \tag{22}$$

Turbulent flow (thermally developed flow)

- Wu and Little (1983) proposed for 3000 < Re < 20 000 [12, 15, 20] the following dependence:

$$Nu = 0.002222 \cdot \mathrm{Re}^{1.09}\,\mathrm{Pr}^{0.4} . \tag{23}$$

- According to Choi et al. (1991), for 2 500 < Re < 20 000 [12, 15]:

$$Nu = 3.82 \cdot 10^{-6} \cdot \mathrm{Re}^{1.96}\,\mathrm{Pr}^{1/3} . \tag{24}$$

- Yu et al. (1995) proposed for 6 000 < Re < 20 000 correlation [15]:

$$Nu = 0.0007 \cdot \mathrm{Re}^{1.2}\,\mathrm{Pr}^{0.2} . \tag{25}$$

- Adams (1988) modified Gnielinski correlation for 2 300 < Re < 23 000 [15, 20] to the following form:

$$Nu_{Adams} = Nu_{Gnielinski}(1 + F), \tag{26}$$

where:

$$F = 7.6 \cdot 10^{-5}\,\mathrm{Re}\left[1 - \left(\frac{D}{D_o}\right)\right], \tag{27}$$

while D_o=1.164 mm

RESULTS OF EXPERIMENTAL INVESTIGATION

Figure 1 shows a comparison of the experimental local Nusselt number. The mass flow rate was changed in the range (uρ) = 245 ÷ 2150 kg/(m^2·s). The comparison was prepared depending of the Reynolds number. The experiments were conducted during a flow of R134a through a minichannel with an internal diameter of 1.68 mm until boiling occurred. It is noted that with the increase of Reynolds number, Nusselt number increase, as well. In the zone of larger values of Reynolds number, a greater scattering of the measuring results is observed. This is so because of the occurrence of the flashing phenomenon, which decrease the local Nusselt number. The flashing phenomenon consists in the generation of vapor bubbles, which is the result of the decreasing of the saturation temperature of the refrigerant caused by a significant pressure drop on the minichannel length. Then, a two-phase structure is created, however it is not the result of the classical boiling phenomenon.

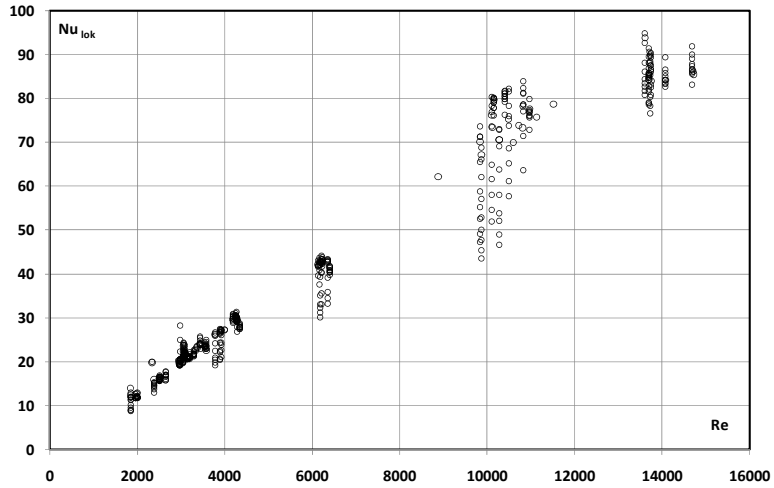

Figure 1. Experimental local Nusselt number versus Reynolds number

COMPARISON OF THE THEORETICAL AND EXPERIMENTAL RESULTS

Results of own experimental investigations as the experimental mean Nusselt number are compared to the theoretical Nusselt numbers obtained from above mentioned correlations.

Laminar thermally developing flow - conventional channel correlations

Figure 2 presents a comparison of the mean Nusselt number obtained from the experiment with the results of calculations made on the basis of dependences applied for conventional channels, as proposed by Sieder and Tate - formula (11), Shah and London – formula (12) and Hausen and Kays - formula (13). It is evident from the comparative analysis placed in Figure 2 that these correlations are useless for calculations for minichannels.

Turbulent thermally developed flow - conventional channel correlations

Figure 3 presents a comparison of the mean Nusselt number obtained from the experiment and from calculations applied for conventional channels, and proposed by Dittus & Boelter – formula (14), Gnielinski – formula (15), Kakac – formula (18), Petukhov – formula (19) and Petukhov & Popov – formula (21).

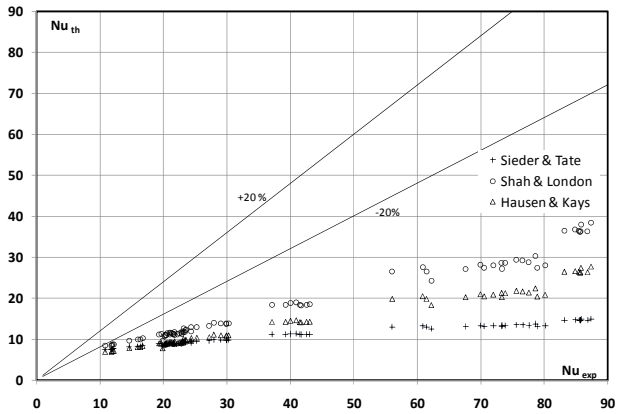

Figure 2. Experimental Nusselt number versus theoretical Nusselt number (Sieder & Tate, Shah & London, Hausen & Kays)

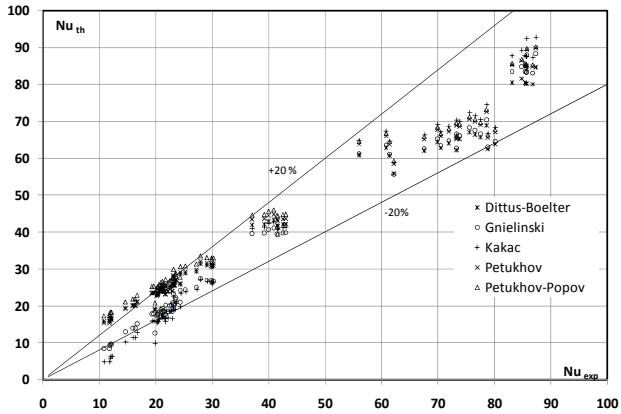

Figure 3. Experimental Nusselt number versus theoretical Nusselt number (Dittus & Boelter, Gnieliński, Kakac, Petukhov, Petukhov & Popov)

The results of calculations made on the basis of the correlations mentioned above, are in the range of ±20% as compared with the experiment. Only in those cases when Nusselt number is smaller than 20, which corresponds to number Re < 3000 (laminar and intermediate flow), the deviations

are larger. This confirms the possibility to use those formulae which have so far been used for conventional channels now in relation to minichannels.

Laminar thermally developed flow – new minichannel correlations

Figure 4 presents a comparison of the mean Nusselt number values obtained from the experiments with the results of the calculations on the basis of the dependences proposed for minichannels by Choi et al. – formula (22). It is interesting to note that the formula recommended by these authors for a thermally developed flow in the area of laminar flow is good for a turbulent flow in the experiment (Re = 1 840 ÷ 14 000). It was found that correlation (22) proposed by Choi is useful for the calculation of the mean Nusselt number also in the thermal entrance length of turbulent flow R134a in minichannels.

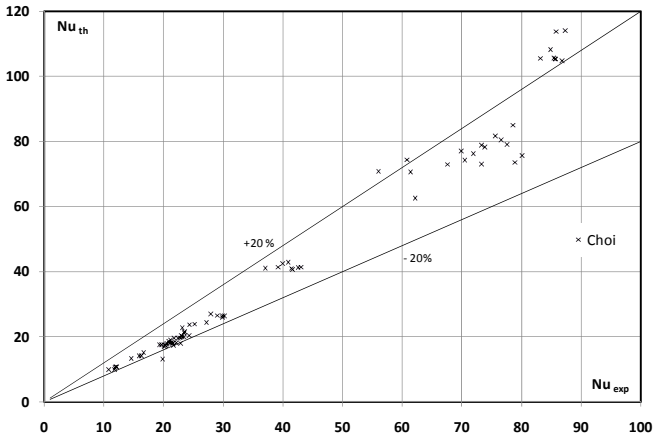

Figure 4. Experimental Nusselt number versus theoretical Nusselt number (Choi et al. – formula 22)

Turbulent thermally developed flow - new minichannel correlations

Figure 5 presents a comparison of the mean Nusselt number obtained from the experiments and from the calculations on the basis of the dependences for minichannels proposed by Wu & Little – formula (23), Choi et al. – formula (24), Yu et al. – formula (25) and Adams – formula (26). The results of the mean Nusselt number obtained from the formulae proposed by Choi et al. – formula (24) and Adams – formula (26), significantly depart from the experimental values. The correlation proposed by Yu et al. (25) gives satisfactory results in the range of ±20%. For Nusselt numbers $Nu_{exp} < 30$, which corresponds to the value of Reynolds number Re < 5 000, the error exceeds 20% (Figure 6). The correlation proposed by Wu & Little overpredicts results of experiment and could be proposed for use after an introduction of a correction factor.

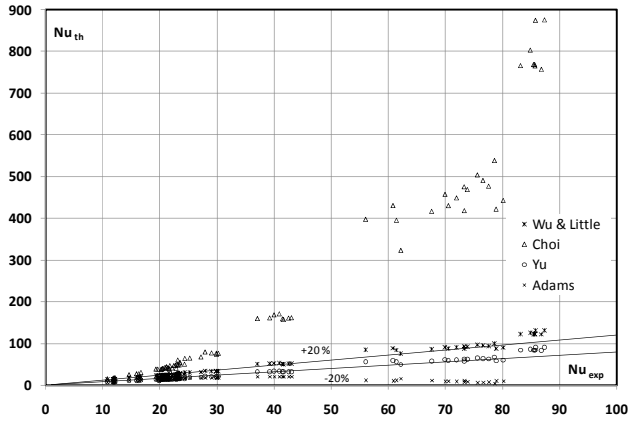

Figure 5. Experimental Nusselt number versus theoretical Nusselt number (Wu & Little, Choi, Yu, Adams)

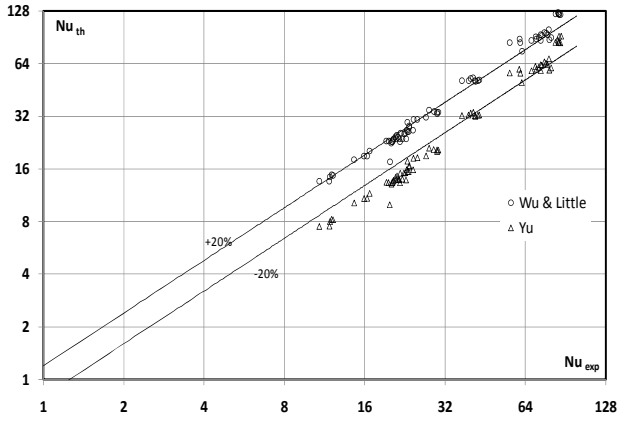

Figure 6. Experimental Nusselt number versus theoretical Nusselt number (Wu & Little, Yu)

For each correlation the value of the mean absolute error (MAE) was calculated. The MAE is described with the following dependence:

$$MAE\ [\%] = \frac{1}{n} \cdot (\sum \frac{\left| Nu_{th} - Nu_{\exp} \right|}{Nu_{\exp}}) \cdot 100\%, \tag{28}$$

where n is the number of measurements. Table 1 includes a list of the results of the calculations of the Nusselt number mean absolute error for each analyzed correlation.

Table 1
List of the Nusselt number mean absolute error (MAE)
R134a liquid flow in a minichannel with internal diameter d=1.68 mm

	Conventional channels								Minichannels				
	Laminar flow			Turbulent flow					Lam. flow	Turbulent flow			
	Sieder & Tate	Shah & London	Hausen & Kays	Dittus-Boelter	Gnielinski	Kakao	Petukhov	Petukhov-Popov	Choi	Wu & Little	Choi	Yu	Adams
MAE [%]	66,4	50,6	61,3	**12,8**	**9,78**	15,3	12,2	17,2	**12,13**	**22,25**	290	**24,3**	56,5

CONCLUSIONS

The following from the investigations of a heat transfer during a single-phase flow of the R134a is evident:

- the value of the mean Nusselt number in a single-phase turbulent flow of the liquid R134a refrigerant in a minichannel can be calculated from the formulae used for conventional channels, especially the Gnielinski or Dittus-Boelter correlations;
- the dependence recommended by Choi et al. (20), which describes Nusselt number during a flow in a minichannel in a laminar flow area, can also be applied in a turbulent flow area;
- from many proposals of the correlations for the calculation Nusselt number during a turbulent flow of refrigerant in a pipe minichannel, satisfactory results are obtained by Yu et al. correlation (applicability as specified by the authors must be preserved).

EXPERIMENTAL INVESTIGATIONS OF THE CONDENSATION PROCESS OF REFRIGERANT R134a IN PIPE MINI-CHANNELS

T. Bohdal, H. Charun, K. Dutkowski, W. Kuczyński

Chair of Thermal Engineering and Refrigerating Engineering
Koszalin University of Technology, Koszalin, Poland

ABSTRACT. In the era of the miniaturization of power equipment, the application of compact systems is a very advantageous solution. Compact heat exchangers which are used in refrigerating systems do not only transfer a large density of the heat flux but also perform environment-friendly functions; a refrigerant occupies a small volume, and when there is no leak tightness, there is little threat to the natural environment. The basic part of the paper is constituted by the presentation of the author's own experimental research into heat exchange in the condensation process of R134a refrigerant in pipe mini-channels with an internal diameter of 0.98 ÷ 3.3 mm. On the basis of a comparative analysis, the usefulness of *Akers* and *Shah's* correlations was stated for the determination of the heat transfer coefficient in this process

Keywords: *heat transfer, condensation, mini-channels, refrigeration, R134a*

INTRODUCTION

In the recent years, a global trend has been observed in the construction of refrigeration heat exchangers, which consists in the miniaturization of their structures. The requirements must be met of transferring a large heat flux density, with thermal-economic criteria being preserved in the scope of the reduction of power and material consumption of heat exchangers. One of the ways of a heat intensification understood in this way in relation to the abovementioned criteria, is the use of the phase changes of a refrigerant, especially of boiling and condensation in the flow in mini- and macro-channels of the exchangers. In this manner, the concept was created of the so-called *compact heat exchangers* (evaporators and condensers), which are included in the refrigerating system [10]. In relation to the small internal volume of mini-channels, additionally the ecological criterion is fulfilled, as in the unfavourable case of unsealing of such a system, the quantity of the refrigerant carried off to the environment will be scanty.

The designers of compact heat exchangers are facing today the same problem concerning the suitable selection of computational procedures as they faced some time ago in relation to conventional exchangers. It needs to be stated, however, that their problems are much more difficult, as the procedures proposed for conventional exchangers have already been tested on numerous occasions, while this is not true of compact exchangers as yet. Two basic problems remain to be solved: the calculation of the required heat exchange surface, and calculations of the resistance of the refrigerant's flow through the exchanger. The first problem consists chiefly in the selections of a dependence for the calculation of the heat transfer coefficient in a two-phase flow with a heat exchange in a mini-channel [11].

It needs to be emphasized that the number of the papers published which present a description of the heat exchange and flow resistances during boiling in mini- and micro-channels is significantly larger that the number of those which deal with condensation in these channels. The state of

knowledge to date covering conventional channels proves that the processes of boiling and condensation in a flow cannot be treated as "symmetric" phenomena in the computational sense. In the boiling process of a refrigerant with heat supplied to the channel, the flow is accelerated, while during condensation with heat being carried off, there is a delay in the direction of the flow, connected with an increase of the condensate created [1]. Apart from that, there are no well-motivated premises so far so that this description of phase changes phenomena could be transferred to mini-channels, as well. However, it was noted that in the scope of the application of computational procedures of flow resistances during boiling and condensation in mini-channels, there exist possibilities to use some of the joint dependences for two-phase mixtures in conventional channels and in mini-channels, while there are relatively large discrepancies in the area of the heat exchange.

The present study covers selected results of an analysis of literature data and the results of the authors' own experimental investigations concerning calculations of heat transfer coefficients and flow resistances during the condensation of the R34a refrigerant in the pipe mini-channels of compact condensers. The analysis was narrowed down to the case of condensation in a single mini-channel. This allows one to indicate those correlations for calculations which have been suitably tested at the present state of knowledge.

RESEARCH ISSUES

The authors reviewed those correlations published in the literature which allow one to calculate heat transfer coefficient α and flow resistances of refrigerants in pipe mini-channels [4, 6, 7]. However, the results of the analysis did not give an explicit answer as regards the selection of the best correlation. It was found for the R134a refrigerant which condensates in pipe mini-channels that the discrepancies of the calculation results of heat transfer coefficient h are at times very large, which is illustrated in Fig. 1. For example, condensation of the R134a refrigerant was taken into account in a pipe mini-channel with an external diameter of 2.75mm in the saturation temperature of +35°C, for heat flux density $\dot{m}$ = 400 kg/(m^2·s). The values of heat transfer coefficient α, depending of dryness level x were calculated with the use of the correlations proposed by the following authors: *Shah* [12], *Cavalli* et al. [5], *Dobson* and *Chato* [8], as well as *Bandhauer* [2]. Relatively large discrepancies were found of the results of calculations, especially in the range of dryness level x = 0.8 ÷ 1.

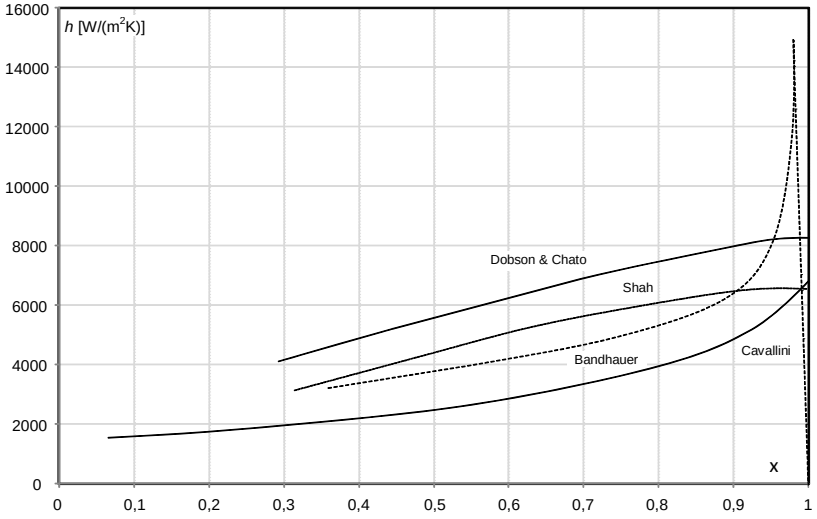

Figure. 1. Dependence of heat transfer coefficient α from dryness level x during condensation of R134a refrigerant in pipe mini-channel with diameter D = 2.75 mm, with heat flux density $\dot{m}$ = 400 kg/(m^2·s) and saturation temperature +35°C according to calculations from correlations of *Shah*, *Cavallini et al*, *Dobson* and *Chato* as well as *Bandhauer*

The results of the calculations of heat transfer coefficient *h* according to the correlations proposed by *Dobson* and *Chato* and the correlations proposed by *Akers* [1] allowed a characteristic to be built which described the dependence of the *h* coefficient from internal diameter *D* of the pipe mini-channel. Figure 2 presents a diagram of dependence *h* = f(*D*) for the R134a refrigerant. A reduction of the internal diameter of a pipe mini-channel leads to an increase of the values of the heat transfer coefficient, while large discrepancies are observed of the results of calculations according to the two correlations given above. These discrepancies increase together with the drop of the measurement of the channel's diameter *D*.

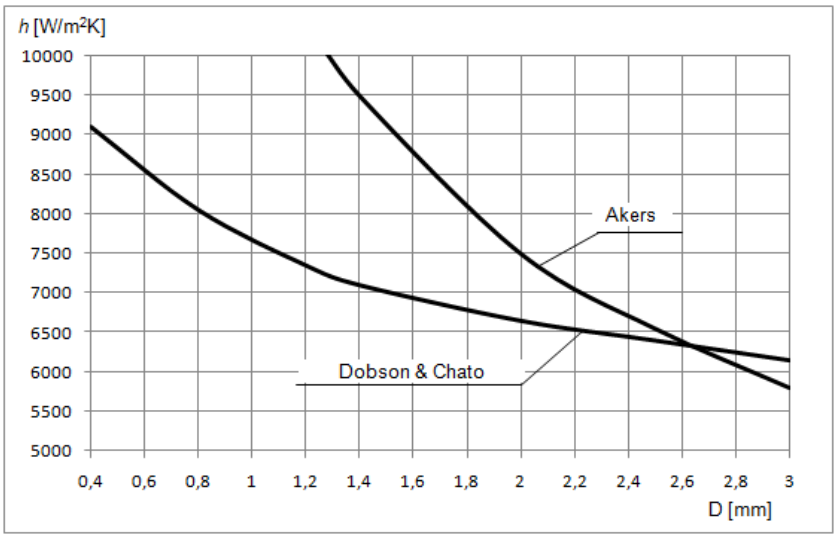

Figure. 2. Influence of diameter *D* of pipe mini-channel on the quantity of heat transfer coefficient *h* during condensation of R134a refrigerant on the basis of calculations according to correlations given by *Akers* and *Dobson* and *Chato*; $\dot{m}$ = 400 kg/(m^2·s), *x* = 0.6

Also, as an example, comparative calculations were conducted with the application of various correlations to calculate the frictional pressure drop for a pipe mini-channel with a diameter of 1.4 mm, in which the R134a refrigerant condenses (Figure 3).

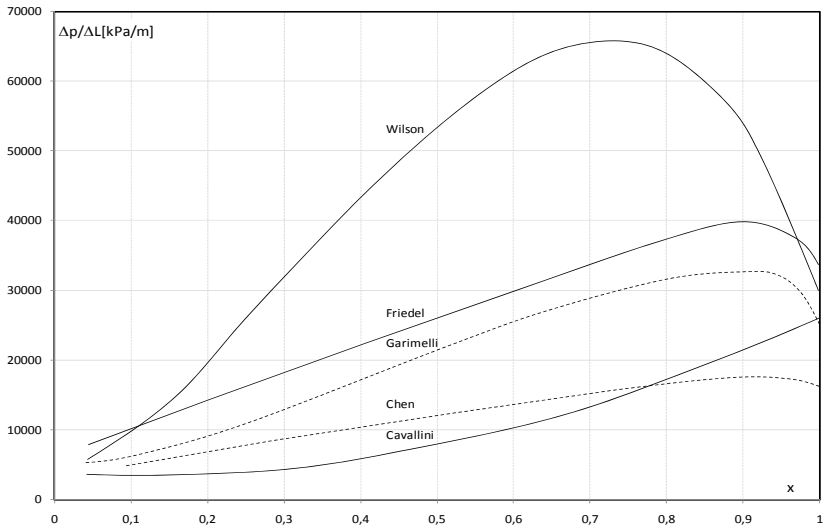

Figure. 3. Comparative listing of the dependence of frictional flow resistance ($\Delta p/\Delta L$) from dryness level *x* during condensation of R134a refrigerant in pipe mini-channel with internal diameter *D* = 1.4 mm, $\dot{m}$ = 400 kg/(m^2·s), T_s = +40^{0}C; for calculations, correlations proposed by *Friedel*, *Chen*, *Wilson, Cavallini* and *Garimell* were used.

Taking into consideration the computational characteristics which describe the heat transfer coefficient during the condensation of the R134a refrigerant and the discrepancies of the calculation

results, the authors decided to conduct their own comparative experimental investigations with this refrigerant in the application for condensation in pipe mini-channels with internal diameter $D = 0.98 \div 3.3$ mm and made of stainless steel [3].

STAND FOR EXPERIMENTAL RESEARCH

An original research stand was designed and built in the Laboratory of the Chair of Thermal Engineering and Refrigerating Engineering, the Koszalin University of Technology. Figure 4 presents the schematic diagram of the stand. On the diagram of the test stand, two refrigeration systems need to be distinguished with the R134a refrigerant, which cooperate in parallel, i.e. a single-stage refrigeration system fed by a compressor and condenser unit, and a refrigeration system which feeds the measuring section of the pipe mini-channel.

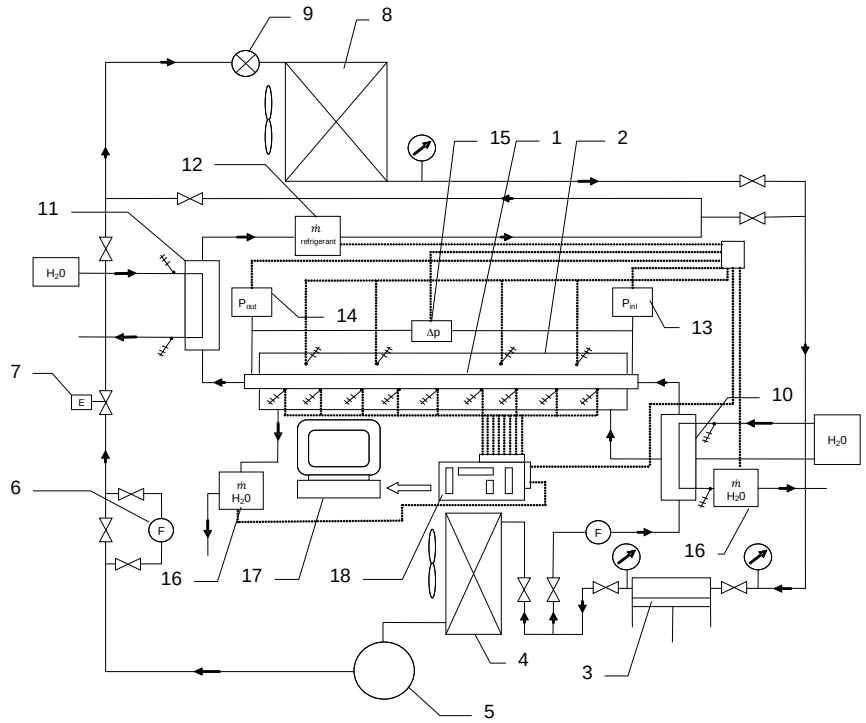

Figure. 4. Schematic diagram of research stand: 1 – measuring section of pipe mini-channel with length $L = 1000$ [mm], 2 – water channel, 3 – refrigeration compressor installation, 4 – condenser cooled with air, 5 – refrigerant liquid tank, 6 – filter and dryer of refrigerant, 7 – electromagnetic valve, 8 – lamelled air cooler, 9 – expansion valve which feeds the cooler, 10 - heat exchanger to collect refrigerant's superheat, 11 – subcooler of refrigerant's liquid, 12 – electronic flowmeter of refrigerant, 13 – sensor of refrigerant's pressure on the inlet to measuring section, 14 - sensor of refrigerant's pressure on the outlet from measuring section, 15 – differential pressure sensor, 16 – electronic water flowmeter, 17 – computer, 18 – data canvassing system

RESULTS OF EXPERIMENTAL RESEARCH

Figures 5 present examples of the experimental investigations of the condensation of the R134a refrigerant in a flow through pipe mini-channels with an internal diameter of 2.3 and 3.3 mm. The diagrams were presented of thermal characteristics in the form of dependence $h = f(x)$, that is the local heat transfer coefficient from dryness level x. A significant influence is to be noted of the heat flux density $\dot{m}$ on the course of the characteristics.

a) b)

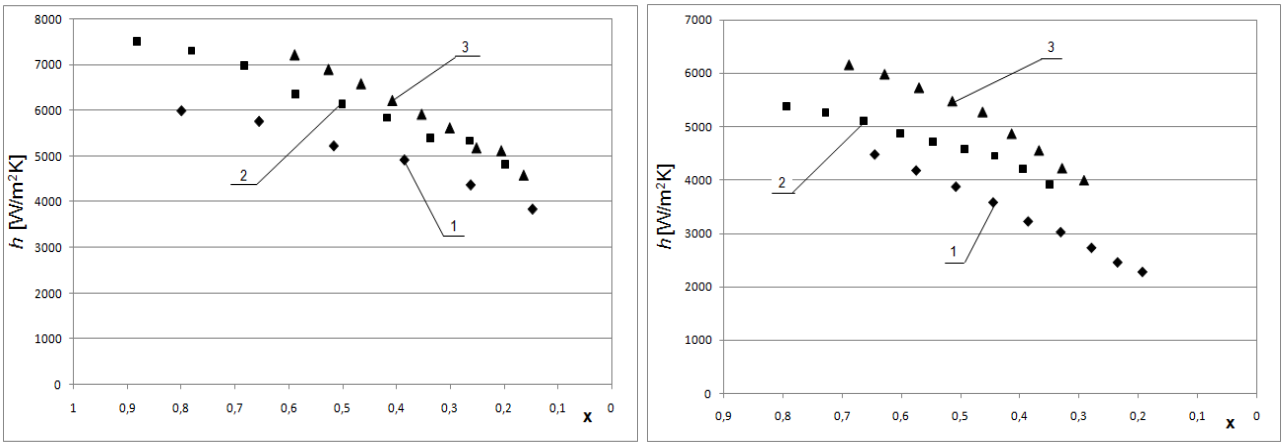

Figure. 5. Results of experimental investigations of characteristics $h = f(x)$ during condensation of R134a refrigerant in pipe mini-channel with internal diameter; a) $D = 2.3$ mm, $\dot{q} \cong 30$ KW/m^2; *1* - $\dot{m} = 337$ kg/(m$^2\cdot$ s), *2* - $\dot{m} = 497$ kg/(m$^2\cdot$ s), *3* - $\dot{m} = 709$ kg/(m$^2\cdot$ s), b) $D = 3.3$ mm, $\dot{q} \cong 30$ KW/m^2; *1* - $\dot{m} = 300$ kg/(m$^2\cdot$ s), *2* - $\dot{m} = 404$ kg/(m$^2\cdot$ s), *3* - $\dot{m} = 543$ kg/(m$^2\cdot$ s)

Also, thermal characteristics were performed of type $h = f(x)$ for other diameters of pipe mini-channels. The results obtained were compared with the results of calculations according to the correlations given by other authors, including *Dobson* and *Chato*, *Cavallini* and *Zecchin*, *Akers*, *Shah* and *Tang* [13]. Figure 6 presents comparative listings of the research results. Their analysis demonstrated that the results of the calculations of the heat transfer coefficients from the correlations proposed by *Akers* and *Shah* correspond best with the results of the experimental investigations (Figure 7). Figure 8 presents examples of the results of investigations of the pressure drop during a complete condensation of the R134a refrigerant (in range $x = 1 \div 0$) in a pipe mini-channel in the form of characteristics $\Delta p = f(\dot{m})$, while Figure 9 presents a comparison of the results of the author's own investigations of flow resistances with the research results of other authors.

CONCLUSIONS

The authors conducted thermal comparative investigations of the condensation of the environment-friendly R134a refrigerant in pipe mini-channels with internal diameters $D = 0.98 \div 3.3$ mm, which confirmed the usefulness of the application of the correlations proposed by *Akers* and *Shah* for the calculations of the heat transfer coefficient (used for the calculations for conventional channels). The discrepancies of the experimental results and the calculations according to the correlation of *Akers* were in the range of ±25%, and for this reason this correlation can be recommended to designers. The experimental tests were conducted in the following range of parameters: saturation temperature $T_s = 35 \div 40^{o}$C, mass flux density $\dot{m} = 200 \div 600$ kg/(m^2·s), and heat flux density $\dot{q} = 5 \div 50$ kW/m^2.

VARIOUS APPROACHES TO THE CALCULATION OF MINICHANNEL FLOW BOILING HEAT TRANSFER

S. Hozejowska[1,*], M.E. Poniewski [2]
[1] Kielce University of Technology, Kielce, Poland
[2] Warsaw University of Technology, Plock Campus, Poland

ABSTRACT. The paper deals with a numerical determination of heat flux and the heat transfer coefficient between boiling liquid flowing through a vertical, rectangular and asymmetrically heated minichannel, and a heating foil. The one-dimensional approach includes the foil temperature change only along the flow direction, whereas the two-dimensional one also in the direction perpendicular to the flow. The two-dimensional approach uses heat polynomials – functions satisfying Laplace's differential equation. The results of exterior foil surface temperature measurements based on the thermosensitive liquid crystal technique are applied. Due to that the only possible method to identify sought local values on the foil interior surface in the two-dimensional approach is to solve the inverse heat conduction problem. Known temperature measurement errors allow employing equalizing calculus and help refine the numerical method in the two-dimensional approach. The equalizing calculus-based criterion for the correctness of numerical method selection is presented.

Keywords: *minichannel, flow boiling, inverse problem, heat polynomials, equalizing calculus*

STATING THE PROBLEM AND OBJECTIVES

The investigated system consists of the flowing boiling liquid (R123) and two walls, a quasi-adiabatic wall on one side and the heating foil with a covering glass on the other, see Figure 1[1,2]. The liquid, whose temperature is lower than its boiling point, flows into a minichannel. Thermo-sensitive liquid crystal technique and design of the experimental stand see Figure 1, only allow measurements of the heating foil temperature on its surface from the side of the glass. We are seeking to identify the local values of temperature, the heat flux and the heat transfer coefficient on the foil interior surface, contacting the boiling liquid. That is an inverse problem in which, on the basis of temperature measurement at the system interior points and the measurement of the electric power supplied to the foil, it is possible to determine the unknown boundary conditions [2,3,4]. We assume a steady state of the entire system but omit the crystal layer thickness and changes in glass, foil and liquid temperature along the minichannel width.

The objectives of the investigations discussed in this paper are as follows: a) to develop one- and two-dimensional approaches for determining local temperature of foil, the heat flux and the heat transfer coefficient at the foil-liquid contact; b) to refine calculation procedures through the use of the known foil exterior surface temperature measurement errors; c) to propose a criterion for verifying the quality of temperature measurement fitting by means of a suitable polynomial.

ONE-DIMENSIONAL APPROACH

The investigations took into account the dimension along the flow direction (x), but the dimension perpendicular to it (y) was related only to the foil or glass thickness, see Figure 1. The glass pane, owing to its very low conductivity ($\lambda_G = 0.71$ Wm^{-1}K^{-1}), quite large thickness ($\delta_G = 5$mm) and a low heat transfer coefficient on its exterior surface, may be treated as a perfect insulator. Consequently, it may be assumed that the entire volumetric heat flux generated inside the foil, is transferred by heat conduction across the foil thickness to the flowing liquid, and the heat flux on the surface contacting the liquid is given by the equations:

$$-\lambda_F \frac{\partial T_F(x,\delta_G+\delta_F)}{\partial y} = q_V\,\delta_F = q_w \quad \text{(a)} \qquad \text{where} \qquad q_V = (U\,I)(\delta_F\,W_F\,L_F)^{-1} \quad \text{(b)} \tag{1}$$

At the boundary surface $y = \delta_F + \delta_G$ heat is dissipated by convection, therefore

$$-\lambda_F \frac{\partial T_F(x,\delta_G+\delta_F)}{\partial y} = \alpha(x)\big(T_F(x,\delta_G+\delta_F) - T_l(x)\big) \tag{2}$$

where $T_l(x)$ changes, for simplicity, linearly from $T_{l,inlet}$ to $T_{l,outlet}$. Since δ_F is very small, it is possible to replace the partial derivative in equation (1a) with a finite difference, and after taking condition (2) into account we get a simple formula for the heat transfer coefficient:

$$\alpha_{1D}(x) = (q_V\lambda_F\delta_F)\,(\lambda_F(T_F(x,\delta_G) - T_l(x)) - q_V\cdot\delta_F^2)^{-1} \tag{3}$$

In equation (3), $T_F(x,\delta_G)$ is obtained from approximation of the liquid crystal measurement results T_k by an n – degree polynomial.

TWO-DIMENSIONAL AAPROACH

The stationary heat transfer process in a two-layer partition is expressed with the equations:

$$\text{• in glass: } \nabla^2 T_G = 0\,\text{(a)} \qquad \text{and} \qquad \text{• in foil: } \nabla^2 T_F = -\frac{q_V}{\lambda_F}\ \text{(b)} \tag{4}$$

At the glass – foil contact the equality of both temperatures and their gradients is found:

$$T_F(x_k,\delta_G) = T_G(x_k,\delta_G) = T_k\ ,\ k = 1,2,...,K \quad \text{(a)} \qquad -\lambda_F\frac{\partial T_F}{\partial y} = -\lambda_G\frac{\partial T_G}{\partial y}\ ,\ \text{y} = \delta_G,\ 0 \le x \le \text{L} \quad \text{(b)} \tag{5}$$

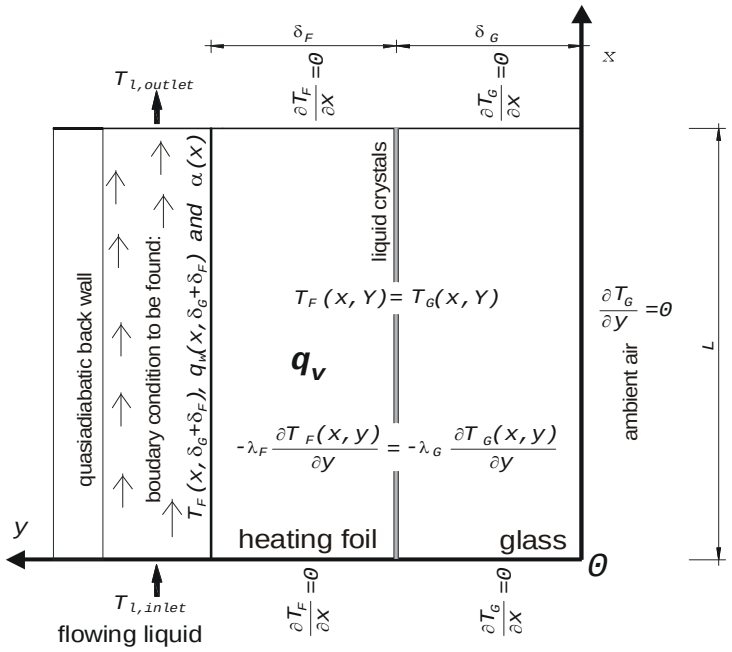

Figure 1. Diagram of flow boiling process in the investigated minichannel and boundary conditions.

It is assumed that the remaining boundaries are isolated, see Figure 1. The unknown $T_G(x,y)$ is approximated with a linear combination of the heat polynomials $u_n(x,y)$, which satisfy equation (4a), whereas the foil temperature $T_F(x,y)$ is given as the sum of the function being a specific solution $\tilde{u}(x,y)$ to equation (4b) and the linear combination of polynomials $u_n(x,y)$ [2,5]:

$$T_G(x,y) \approx \sum_{i=0}^{N} a_i u_i(x,y) \quad \text{(a)} \qquad T_F(x,y) \approx \tilde{u}(x,y) + \sum_{j=0}^{M} b_j u_j(x,y) \quad \text{(b)} \tag{6}$$

Unknown coefficients a_i and b_j are calculated by the least squares method which leads to the minimization of error functionals. Those functionals describe the mean squared errors between approximates and prescribed boundary conditions in Figure 1. This is the heat polynomials method [2,5]. $T_G(x,y)$, which is computed first, and $T_F(x,y)$, determined in this way, satisfy accurately equations (4), and approximately boundary conditions (5). If we know the function $T_F(x,y)$ on the boundary $y = \delta_G+\delta_F$, we can compute the heat flux and the heat transfer coefficient from the condition (3).
The function $T_G(x,y)$ satisfies equation (4a) and the assumed boundary conditions. Thus, in order to determine coefficients a_i, equation (6a), we rely on the error functional J_G defined as follows [2,4]:

$$J_G = \int_0^L \left(\frac{\partial T_G(x,0)}{\partial y} \right)^2 dx + \int_0^\delta \left[\left(\frac{\partial T_G(0,y)}{\partial x} \right)^2 + \left(\frac{\partial T_G(L,y)}{\partial x} \right)^2 \right] dy + \sum_{k=1}^{K} \left(T_G(x_k,\delta_G) - T_k \right)^2 \tag{7}$$

When in (7) $T_G(x,y)$ is substituted with dependence (6a), the minimum of functional J_G is determined from the solution for the system of equations:

$$\frac{\partial J_G}{\partial a_i} = 0, \quad i = 0, 1, ..., \mathrm{N} \tag{8}$$

Coefficients b_j are determined in the same manner as in equation (8). For function $T_F(x,y)$, the minimized functional J_F has a similar form to the functional (7).

TECHNIQUES TO IMPROVE THE ACCURACY OF NUMERICAL CALCULATIONS

Equalizing calculus

In the heat polynomials method measurements T_k can be expressed as a sum of unknown accurate measurements $\tilde{T}_k$ and temperature measurements corrections ε_k, that is,

$$\tilde{T}_k = T_k + \varepsilon_k \tag{9}$$

Corrections ε_k are assumed to have a normal distribution with a mean of zero and finite variance σ_k^2 [6,7], where σ_k are local temperature measurement errors discussed in [1,2,3,4]. They are the errors in estimating values of the foil temperature, based on the hue indicated by liquid crystals.
The normal distribution density function for corrections ε_k is expressed by:

$$\varphi_k = (\sigma_k \sqrt{2\pi})^{-1} \exp(-1/2(\varepsilon_k \sigma_k^{-1})^2) \tag{10}$$

For K independent measurements T_k the density of occurrence probability of given measurement results and corrections ε_k is defined by the product $\Phi = \varphi_1 \varphi_2 ... \varphi_K$ of the density functions φ_k, which is called a reliability function.

The identification of corrected measurements $\tilde{T}_k$ given by equation (9), leads to the determination of the maximum of the reliability function Φ. Corrected measurements $\tilde{T}_k$ are congruent and asymptotically effectual, that is, with the growing number of measurements K the estimation result approaches the real value; the variance of estimator $\tilde{T}_k$ will then be the lowest [6]. The reliability function Φ reaches its maximum when the quadratic form below fulfills the following condition:

$$W = \varepsilon^T V \varepsilon \rightarrow \min \tag{11}$$

where $V = \left[\sigma_k^{-2}\right]$ is the weights matrix [1,3,6,7].

Let T denotes a respective vector hereafter and T_k - the elements of this vector. Additionally, we assume that condition (5a) is fulfilled for corrected measurements $\tilde{T}$

$$\tilde{T}_F - \tilde{T} = 0 \tag{12}$$

where $\tilde{T}_F$ is the corrected temperature of the foil, computed from equation (6b). By solving problem (11) with condition (12), we can find the minimum of the Lagrange function

$$\Omega = \varepsilon^T V \varepsilon + 2\omega^T (\tilde{T}_F - \tilde{T}) \rightarrow \min \tag{13}$$

where: ω is K dimensional vector of Lagrange multipliers [1,6,8]. For the smoothed results - $\tilde{T}$, obtained from conditions (12) and (13), their measurement errors - $\tilde{\sigma}$ - are calculated following the procedure described in [3,8]. As expected, equalizing calculus smoothes the measurement data of temperature, $T \rightarrow \tilde{T}$, and reduces the errors, $\sigma \rightarrow \tilde{\sigma}$. Similar results are obtained when in condition (12) we assume that $\tilde{T}_G - \tilde{T} = 0$, where $\tilde{T}_G$ is corrected glass temperature. If we know the $\tilde{T}$ values, it is possible to calculate new approximations of glass and foil temperatures, and consequently the new heat fluxes and heat transfer coefficients.

Equalizing calculus was used in the same way for the one - dimensional approach [8].

Experimental errors implementation

Originally, when forming error functionals J_G and J_F, equation (7), it was assumed that liquid crystals temperature measurements were error-free [2,3]. The modification is based on the assumption that $T_F(x_k, \delta_G) - T_k$ and $T_G(x_k, \delta_G) - T_k$ have a normal distribution with a zero mean value and variance σ_k^2. In functionals J_G and J_F, the last terms $\sum_{k=1}^{K}\left(T_G(x_k, \delta_G) - T_k\right)^2$, $\sum_{k=1}^{K}\left(T_F(x_k, \delta_G) - T_k\right)^2$ describe how accurately the computed approximations of glass and foil temperatures satisfy the conditions (5). In the modified heat polynomials method, taking into consideration temperature measurement errors σ_k in functionals J_G and J_F will result in reducing the difference between the calculated approximations and measured temperature values [2,3,4]. Modified are only the last components in functionals J_G and J_F, which have the following new forms:

$$\text{a) for glass:} \quad \sum_{k=1}^{K}((T_G(x_k, \delta_G) - T_k)\sigma_k^{-1})^2 \quad \text{b) for foil:} \quad \sum_{k=1}^{K}((T_F(x_k, \delta_G) - T_k)\sigma_k^{-1})^2 \tag{14}$$

In formulas (14), errors σ_k are weights for individual temperature measurements.

The higher the accuracy of the measurement the smaller the error and the greater the weight. The described modification improves conditioning of systems of equations (8) [2,3,4].

For the modified heat polynomials method equalizing calculus was also used [1,3,8].

EVALUATION OF IMPROVEMENTS IN ACCURACY OF HEAT TRANSFER CALCULATIONS

The numerical calculation results presented below are for the experimental data, showed in Figure 2 as hue distributions on the foil external surface obtained through liquid crystal thermography. In the one-dimensional approach the measurements of temperature T_k were approximated using a 5-degree polynomial, i.e. n=5. In the two-dimensional approach it was assumed that $\tilde{u}(x, y) = -0.5 q_v \lambda_F^{-1} y^2$

and $N = M = 5$, which means that six heat polynomials were used to determine glass and foil approximates expressed by equation (6).

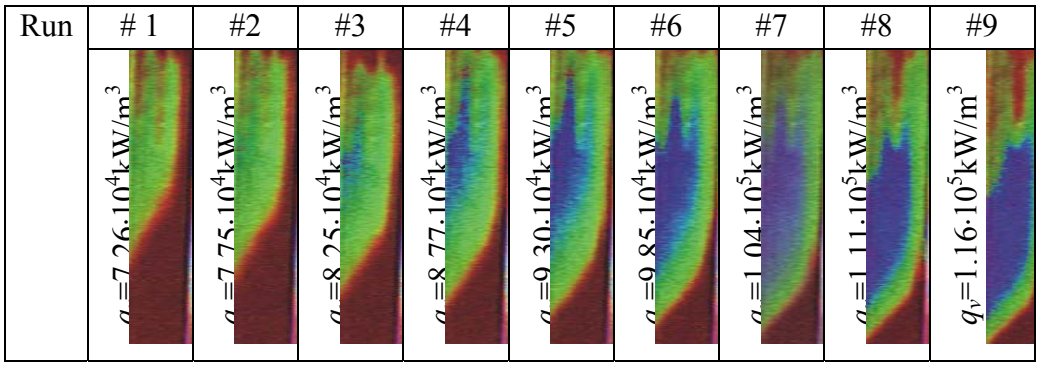

Figure 2. Images of hue distribution on the minichannel external surface while increasing the heat flux supplied to the heating foil; parameters of the runs: mass flow rate = 120 kg m^{-2}s^{-1}; Reynolds number = 543; inlet pressure = 197 kPa; inlet liquid subcooling = 9.6 K.

Further, diagrams for computed heat transfer coefficients α_{1D}, shown in Figure 3(a), and α_{2D}, shown in Figure 3(b), are presented for particular runs. Both coefficients have similar values. The character of coefficient α_{1D}, computed for run #7, is different from diagrams in the remaining runs and different from the character of the diagram for α_{2D}, compare Figure (3a) and Figure 3(b). The differences result from the temperature measurement approximation by a 5-degree polynomial, which causes over fitting. To avoid this effect, in calculations we should either use measurement data instead of approximates, or apply the equalizing calculus in the one-dimensional approach [8].

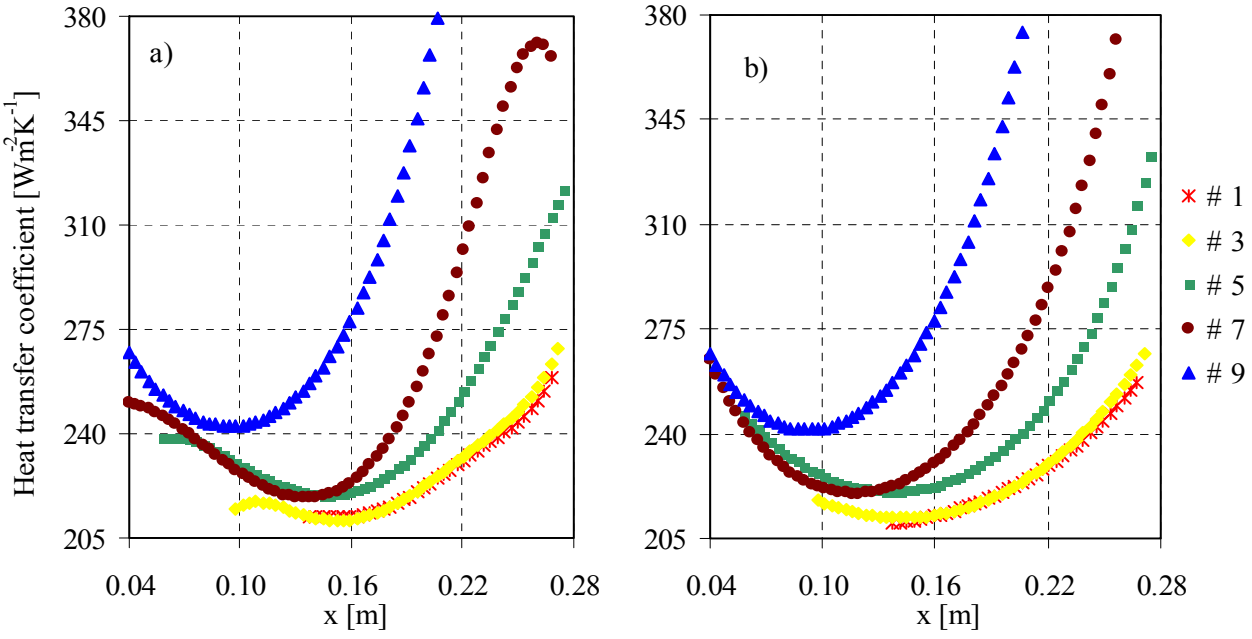

Figure 3. Heat transfer coefficient dependence on the distance along the channel length: (a) α_{1D}, (b) α_{2D}; experimental data as in Figure 2.

The use of the equalizing calculus in the one-dimensional approach and in the heat polynomials method resulted in a smaller standard deviation of the smoothed measurements $\tilde{T}$, when compared with temperature measurements T, see Figure 4b. This means that the equalizing calculus reduces the errors of the smoothed temperature measurements. For instance, for run #5, measurement errors

σ_k change from 0.5K (x=0.06) to 1.63K (x=0.18.), whereas the smoothed measurement errors have values from 0.11K to 0.25K (for one-dimensional approach) and from 0.11K to 0.19K (for heat polynomials method).

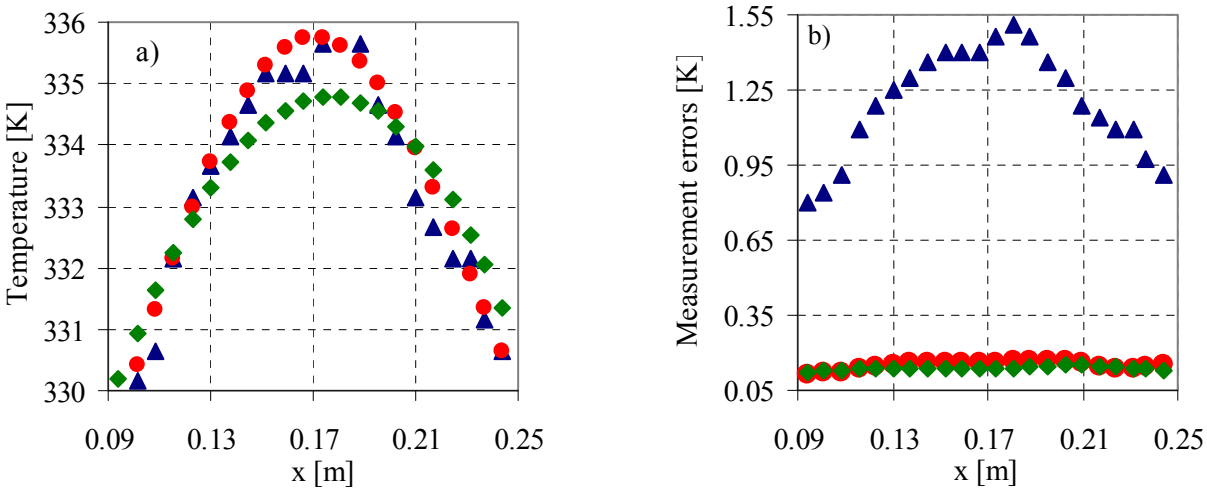

Figure 4. Temperature distribution and measurement errors for run#5:
a) temperature: ▲ – measurements, ● – smoothed measurements (one-dimensional approach), ♦ – smoothed measurements (heat polynomials method); b) ▲ – measurement errors (σ_k), ● – measurement errors for smoothed measurements (one-dimensional approach), ♦ – measurement errors for smoothed measurements (heat polynomials method) .

The corrections ε_k given by equation (17), to temperature measurements T_k are assumed to have the normal distribution with a mean of zero and finite variance σ_k^2, and they should fulfill condition [7]:

$$|\varepsilon_k| < 3\sigma_k \tag{15}$$

For one-dimensional model, 98.4% of corrections meet condition (15); run #7 is an exception. For the heat polynomials method (modified and classical) condition (15) is always fulfilled.

With the assumed corrections ε_k, function W given by equation (11), has a distribution χ^2 with *K-n-1* number of the degrees of freedom in the one-dimensional approach, and *K-N-1* in the heat polynomials method [6]. The calculations confirm that the value of function W in each run is lower than the number of freedom degrees. This makes the calculations reliable (except for run #7, see Table 1). Function W helps test the fitting of measurement data by means of an *n*-degree polynomial (one-dimensional approach) or a combination *N+1* of heat polynomials (for the heat polynomials method). With the use of χ^2 we can verify the correct fitting hypothesis for measurement data T_k using a 5-degree polynomial (one-dimensional approach) or a combination of six heat polynomials (for the heat polynomials method) [6]. The assumed hypothesis is rejected when at the significance level β:

- in the one-dimensional approach: $W > \chi^2_{1-\beta}(K-n-1)$ (a)
- for the least squares method: $W > \chi^2_{1-\beta}(K-N-1)$ (b) (16)

Table 1 presents the values of the functions given by equations (11) determined for one-dimensional approach (W_1), the heat polynomials method (W_2), the modified heat polynomials method (W_3) and the values $\chi^2_{0.99}$ at the significance level of 1% and the suitable number of degrees of freedom. Conditions (16) are fulfilled only in the case of run #7. Thus, there are no grounds for adopting the assumed hypothesis of a correct fitting of measurement data using a 5-degree polynomial (one-dimensional approach) or a linear combination of six heat polynomials (heat polynomials method).

Table 1
Values W_1, W_2, W_3 and $\chi^2_{0.99}$, at the significance level of 1%, and a suitable number of degrees of freedom (*K-n-1* or *K-N-1*, depending on the applied model).

Run	W_1	$\chi^2_{0.99}$	W_2	$\chi^2_{0.99}$	W_3	$\chi^2_{0.99}$
1	38.82	< 182.98	41.59	< 184.12	24.63	< 184.12
3	30.32	< 234.91	44.99	< 236.03	33.69	< 236.03
5	74.69	< 286.14	76.95	< 287.45	84.21	< 287.45
7	**352.89**	**> 304.94**	**414.11**	**> 306.04**	**500.36**	**> 306.04**
9	26.85	< 239.39	25.88	< 240.51	28.56	< 240.51

The application of the equalizing calculus to the heat polynomials method improved the percentage of calculated approximations $T_G(x,y)$ and $T_F(x,y)$ which fulfill conditions (2) and (3). Also, the conditioning of system of equations (8) improved. In order to verify the changes introduced by the equalizing calculus, the mean squared error between randomly chosen functions of two variables *f* and *g* was defined with the formula

$$d(f,g) = (K^{-1}\sum_{k=1}^{K}\left(f\left(x_k,\delta_G\right)-g\left(x_k,\delta_G\right)\right)^2)^{1/2} \tag{17}$$

T_F and T_G denote respectively foil and glass temperature approximates obtained from the classical method; $T_{F,1}$ and $T_{G,1}$ - foil and glass temperature approximates obtained from the classical method after introducing the equalizing calculus; $T_{F,2}$ and $T_{G,2}$ - foil and glass temperature approximates obtained from the modified method; $T_{F,3}$ and $T_{G,3}$ - foil and glass temperature approximates obtained from the modified method after the equalizing calculus application. Table 2 lists mean squared errors calculated from formula (17), between a suitable foil and glass temperature approximate and measurements: T - for the classical method; $\tilde{T}$ - for the classical method after the equalizing calculus application; $\approx{T}$ - for the modified method after the equalizing calculus application. Moreover, for all the runs from #1 to #9 computed foil and glass temperature approximates (T_F and T_G; $T_{F,1}$ and $T_{G,1}$; $T_{F,2}$ and $T_{G,2}$; $T_{F,3}$ and $T_{G,3}$) fulfill condition (5b) with the mean squared error not exceeding 0.012 Wm^{-2}; most often the error is 0.002 Wm^{-2}. The analysis of data presented in Table 2 shows that equalizing calculus reduces mean squared errors in both classical and modified methods. This means that equalizing calculus improves the accuracy with which the calculated approximates fulfill conditions (5). The smallest mean squared errors occur for approximates $T_{F,3}$ and $T_{G,3}$, that is, for functions obtained from the modified heat polynomials method combined with the equalizing calculus. Approximate $T_{F,3}$ is the most accurate when approximating unknown temperature distribution in the foil, thus the heat transfer coefficient based on this approximate corresponds to the actual heat transfer coefficient.

Table 2
Mean squared errors expressed by formula (17) for run #5.

	The method	Mean squared errors $d(f,g)$ [K]		
1	Classical heat polynomials	$d\left(T_G,T_F\right)=0.72$	$d\left(T,T_G\right)=0.97$	$d\left(T,T_F\right)=0.63$
2	Classical combined with equalizing calculus	$d\left(T_{G,1},T_{F,1}\right)=0.67$	$d(\tilde{T},T_{G,1})=0.70$	$d(\tilde{T},T_{F,1})=0.03$
3	Modified heat polynomials	$d\left(T_{G,2},T_{F,2}\right)=0.67$	$d\left(T,T_{G,2}\right)=1.09$	$d\left(T,T_{F,2}\right)=0.67$
4	Modified combined with equalizing calculus	$d\left(T_{G,3},T_{F,3}\right)=0.02$	$d(\approx{T},T_{G,3})=0.02$	$d(\approx{T},T_{F,3})=0$

The smallest mean squared errors occur for approximates $T_{F,3}$ and $T_{G,3}$, that is, for functions obtained from the modified heat polynomials method combined with the equalizing calculus.

Approximate $T_{F,3}$ is the most accurate when approximating unknown temperature distribution in the foil, thus the heat transfer coefficient based on this approximate corresponds to the actual heat transfer coefficient.

CONCLUSIONS

• The calculated heat transfer coefficients α, based on all the presented approaches, have similar values, see Figure 3.The results verify one another, which confirms the correctness of the assumed approaches and the used numerical procedures.
• The application of equalizing calculus in the one-dimensional approach and the heat polynomials method „smoothed" temperature measurements and reduced standard deviations of the „smoothed" measurements considerably, see Figure 4.
• Test χ^2 verifies the hypothesis of measurement data fitting using an *n*-degree heat polynomial (for the one-dimensional approach) or a linear combination *N*+1 of heat polynomials. Measurement data fitting is fulfilled for nearly all the runs, Table 1.
• The modification of the heat polynomials method helped obtain foil and glass temperature approximates which fulfil boundary conditions (5) with a mean squared error smaller than in the classical method. The smallest mean squared error was obtained for the modified method combined with the equalizing calculus, Table 2.

ABSTRACT. Recently, thermal insulation technique having higher thermal resistance is highly required to save energy and space. A superior thermal insulation can be achieved by VIPs (vacuum insulation panels) having designed inner structures. For this purpose, staggered beam structure is designed and tested. Its effective thermal conductivity is investigated theoretically and experimentally. Heat transfer in VIP occurs via solid conduction, gaseous conduction and radiation. Radiation can be reduced to a negligible order when radiation shields are installed. To minimize gaseous conduction, the core structure is evacuated to below 1.33×10^{-1} Pa and sealed in aluminium laminated film envelope after a baking process. The material is selected as polycarbonate thanks to its relatively low thermal conductivity and high strength. The calculated result is compared with experimental one. It shows the effective thermal conductivity as low as 0.89×10^{-3} W/m·K, which means about 30 times higher thermal resistance than the conventional insulators such as polystyrene or polyurethane foams. This proves the practical applicability of the proposed VIP structure and further, there is a room for further improvements.

Keywords: *Vacuum insulation panel*, *Thermal conductivity*, *Staggered beam structure*

INTRODUCTION

About half of the energy in the world is consumed for HVAC (heating, ventilating and air conditioning) of buildings [1]. Thermal insulation of buildings is thus becoming the key element to improve energy utilization efficiency. Although most insulation materials are developed in the early 20th century, their insulation performances are stagnant at the level of 0.03 W/m·K of thermal conductivity for a century. If we can develop an excellent insulator, this is the most promising solution for the energy crisis. The VIPs being developed lately are the very candidates. Thermal resistance of VIPs is by a factor of ten to hundred times greater than the conventional insulation materials such as polystyrene and polyurethane foams at the same thickness. This means that much thinner insulation layer will save the energy and the building space.

VIPs usually have filling materials to withstand the external atmospheric pressure. Filling materials must have maximum thermal path to enhance the insulation performance. Many studies of the VIPs are performed during the last two decades. Early studies include PU (polyurethane) foam and fumed silica [2, 3]. These bulk-type materials have random structure. Most of the core materials are not loaded up to the ultimate compression strength, which means they do not have the maximum possible thermal resistance. Hence, these are not optimized. Accordingly, an optimized design is highly required. The purpose of this study is to develop a super insulator having outstanding insulation performance. As one of such insulators, staggered beam structure is investigated in this

E-mail address: taehosong@kaist.ac.kr

study. It is designed considering strength and deflection. Effective thermal conductivity is obtained by theoretical and experimental methods. The calculated result is compared with experimental one.

DESIGN OF THE STAGGERED BEAM STRUCTURE

To the authors' knowledge, the first practically realized VIP with designed inner structure which is the vacuum glazing of Collins et al. [4]. They install support pillars between two layers of glass. Though simple in its shape, the overall heat transfer coefficient is lowered to about 1/5 of that of a single glass plate [5]. This demonstrates the potential possibility of designed inner structure of VIPs. In this study, a staggered beam structure is proposed to enable multi-layered structure (see Figures 1 and 2). As can be seen from the figures, a layer of beam is placed at a right angle on another layer. A third layer, then is placed half pitch staggered from the first layer. Heat conduction thus occurs along the beam in a spiral manner.This design is similar to that of G. Kawaguchi and K. Nagai [6].

Consider a staggered beam under compression load. The beam cross-section should be minimal to decrease the thermal conduction. Two design conditions are thus derived considering the maximum stress constraint [7]. First, bending strength constraint is expressed as

$$\frac{3}{4}\frac{P_{atm}}{\sigma_t} \le \frac{bh^2}{w^3} \tag{1}$$

where P_{atm} is the atmospheric pressure, σ_t is the tensile strength of core material, w is span between beams, b is width and h is height of the beam. Second, the deflection of staggered beam should not be greater than $h/2$ to avoid beam-to-beam contact (for example, beams of layers 1 and 4 may contact each other). Therefore, stiffness constraint by deflection of beam is expressed as

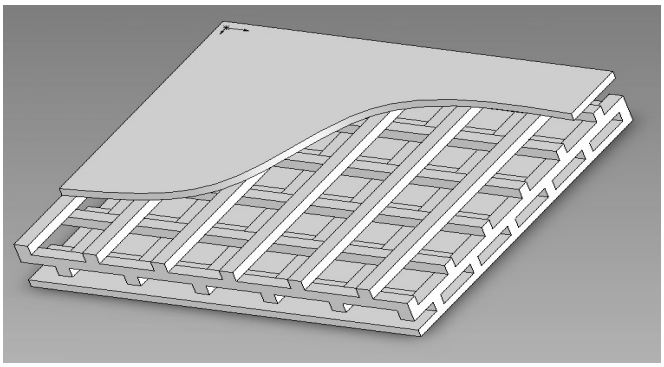

Figure 1. Super insulator with staggered beam structure

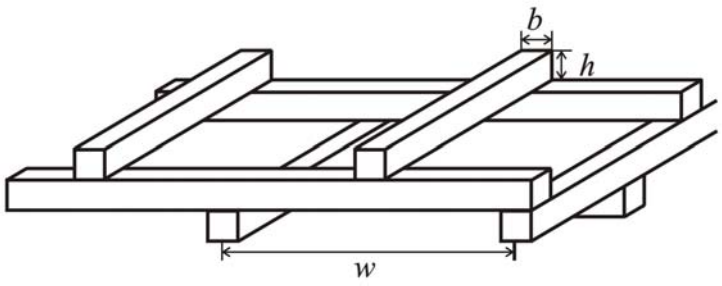

Figure 2. Schematic diagram of the super insulator with staggered beam structure

Table 1
Mechanical and Thermal Properties of Polycarbonate

Thermal conductivity	Tensile Strength	Compressive strength	Young's modulus
0.192 W/m·K	65.5 MPa	74.5 MPa	2,380.0 MPa

$$\frac{\delta}{w} \le \frac{P_{atm} w^4}{16 E b h^3} \tag{2}$$

where δ is the maximum deflection and E is Young's modulus. Staggered beam structure having a pair of layers is fabricated based on these design conditions by injection molding. The pairs can be stacked in series in a staggering manner to any total height. Its parameters are determined as b = 1mm, h = 1mm and w = 7.6mm. The material of staggered beam is selected as PC (polycarbonate) for its relatively high tensile strength and low thermal conductivity. Its mechanical and thermal properties are shown in Table 1 [8].

ANALYSIS OF THE THERMAL TRANSPORT MECHANISM OF THE VIP

Thermal transport in VIPs occurs via solid conduction, gaseous conduction and radiation. The solid conduction depends on the structure and material properties of the core. The gaseous conduction depends on the gas pressure which increases with time by permeation of atmospheric gases and outgassing of the inner material. Thermal radiation depends on the structure and optical properties of the core. The total effective conductivity k_{eff} of VIPs can be determined by summation of the solid conductivity k_s, the gaseous conductivity k_g and the radiative conductivity k_r as

$$k_{eff} = k_s + k_g + k_r \tag{3}$$

Separate study of each contribution is required to improve the thermal insulation performance of the VIP. In the meanwhile, experimental separate measurement of these contributions is not easy because any of them cannot be fully eliminated.

Solid conductivity

Consider staggered beam structure having $N \times N$ beams and M layers. The total resistance is given as

$$R_{total} = k_{eff}^{-1} \frac{hM}{w^2 N^2} \tag{4}$$

There exists contact resistance because contact region is not perfectly flat. Total resistance is determined by summation of total beam and contact resistances. So, the effective solid conductivity k_s neglecting beam deflection is given as

$$k_s = \frac{k_{s0}}{\frac{w^2}{8 r_c h} + \frac{w^3}{4 b h^2}} \tag{5}$$

where k_{s0} is thermal conductivity of core material and r_c is contact radius. In a denominator of this equation, first term is related to contact resistance and second one is related to beam resistance. It is

assumed that plastic deformation occurs in the contact region, which has the minimum contact area and thus maximum contact resistance. The contact radius is given as

$$r_c = \frac{w}{\sqrt{\pi}}\left(\frac{P_{atm}}{\sigma_c}\right)^{\frac{1}{2}} \tag{6}$$

where σ_c is the compressive strength of the core material. If equation (1) determines w for given b and h with a safety factor S, equation (1) is rewritten as

$$\frac{w^3}{4bh^2} = \frac{1}{3S}\left(\frac{\sigma_t}{P_{atm}}\right) \tag{7}$$

This equation determines the ratio w/h as

$$\frac{w}{h} = \left(\frac{b}{h}\frac{4\sigma_t}{3SP_{atm}}\right)^{\frac{1}{3}} \tag{8}$$

The contact radius and this equation are substituted in equation (5). Then, the solid conductivity can be expressed as

$$k_s = \frac{k_{s0}}{\frac{\sqrt{\pi}}{8}\left(\frac{b}{h}\frac{4\sigma_t}{3SP_{atm}}\right)^{\frac{1}{3}}\left(\frac{\sigma_c}{P_{atm}}\right)^{\frac{1}{2}} + \frac{1}{3S}\frac{\sigma_t}{P_{atm}}} \tag{9}$$

The parameters and properties of fabricated VIP are substituted in equitation (9). In the denominator, the value of first term becomes 45.4 and second one becomes 107.8. Thus, it is found that the effect of beam resistance is more dominant than the contact resistance for this case. It is also found that the contact resistance can be increased by increasing b/h. Also, it is important to choose core material having great FOM (figure of merit), which is given as

$$FOM = \frac{\sigma_t}{k} \tag{10}$$

Gaseous conductivity

Thermal conductivity of gas is independent of pressure as far as the gaseous conduction may be treated as continuum because the pressure is inversely proportional to the mean free path [9]. However, it is considerably reduced when the mean free path is almost same as or longer than the gap or pore size. The mean free path λ (m) for air in room temperature is given as [9]

$$\lambda = \frac{6.65\times10^{-3}}{P} \tag{11}$$

where P is the pressure in Pa (N/m^2). If the pore size of the VIP's core material is known, the pressure level which gaseous conduction is significantly lowered is determined by this equation. The fabricated VIP must be evacuated to below 3Pa by this equation because the pore size of staggered beam structure is 2mm. However, it is evacuated to below 1.33×10^{-1} Pa in this experiment to have a long durability.

Next, the gaseous conduction is expressed. A theory of gaseous conduction in rarefied gas is developed by Smoluchowski [10]. It is based on the concept of temperature jump and discontinuity. For two surfaces separated by distance d, the heat flux q is given as

$$\dot{q} = \frac{k_{g0}}{d + 2\beta}(T_1 - T_2) \tag{12}$$

where k_{g0} is the thermal conductivity of free gas. Here, β is given as [11]

$$\beta = \left(\frac{9\gamma - 5}{2\gamma + 1}\right)\left(\frac{2 - \alpha}{\alpha}\right)\lambda \tag{13}$$

where γ is specific heat ratio of gas and α is the accommodation coefficient. Common gases have α between 0.7 and 1.0 at room temperature [12]. Equation (11) and γ=1.4, α=0.8 for air in room temperature are substituted in equation (13). Equation (13) is then rewritten as β=0.016/P. Thus, the gaseous thermal conductivity is derived by Fourier's heat conduction equation and equation (12) as

$$k_g = \frac{k_{g0}}{1 + \dfrac{0.032}{Pd}} \tag{14}$$

Radiative conductivity

Generally, radiative heat transfer is important when the system is at an elevated temperature. However, it can not be ignored even in VIPs because its effective thermal conductivity has very small order of magnitude. If reflective surfaces are installed in the gap of VIPs, radiative heat transfer is considerably lowered, for they function as radiation shields. An advantage of staggered beam structure is that many radiation shields can be installed between the beam layers. There may exist evanescent wave in the gap if the gaps are as small as micro-meter. It, then, is very complicated to analyze the heat transfer rate. Yoon and Song [13], after performing the analysis, conclude that radiative transfer can be treated using simple ray theory if the gap size between the shields is more than 5 μm at room temperature. Here, it is assumed that radiation by staggered beam itself is ignored. Then, the radiative thermal conductivity having N gaps is given as

$$k_r = \frac{t_{core}\sigma T_m^3}{N\left(\dfrac{2}{\varepsilon} - 1\right)} \tag{15}$$

where t_{core} is the thickness of the VIP, T_m is the average temperature in the VIP, σ is Stefan-Boltzmann coefficient and ε is emissivity of the radiation shield surface. This is as small as 6.25×10^{-5} W/m·K for the real system to be explained later in detail.

Table 2
The Patameters of Fabricated Staggered Beam

w	h	b
7.6mm	1mm	1mm

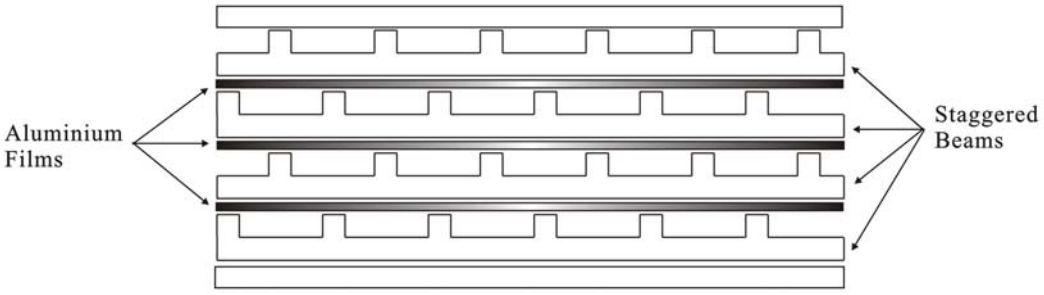

Figure 3. Fabricated staggered beams with aluminium films.

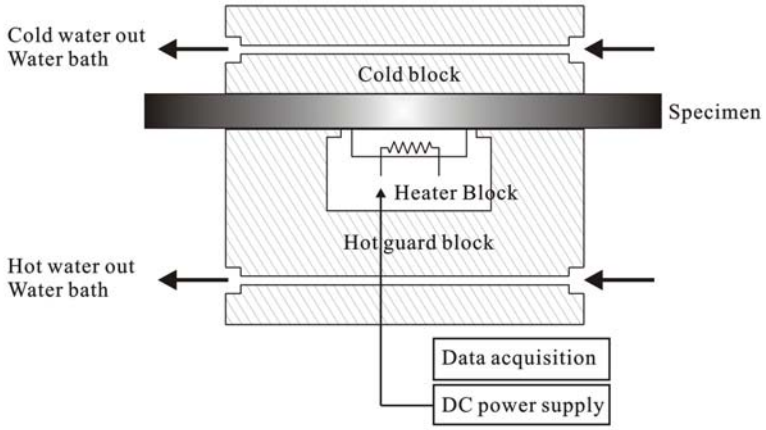

Figure 4. Guarded hot-plate apparatus

EXPERIMENT

The fore mentioned staggered beam structure is fabricated. Strength constraint is determined by equation (7) with negligible deflection given by equation (2). Staggered beam pair having 2 layers is made by injection molding. VIP having 8 layers is made for the experiments (see Figure 3). As mentioned above, the material of staggered beam is selected as PC (polycarbonate) for its large FOM (= 340 $\frac{MPa}{W/m\cdot K}$). See Table 2 for the detailed dimensions, *w*, *h*, and *b*. Aluminium films of 7 μm thickness are installed between the beam pairs to reduce the radiative heat transfer. A getter, product from SAES Getters®, is inserted in the VIP for maintenance of the vacuum level. Laminated core structure is evacuated to below 1.33×10^{-1} Pa. Also, it is baked at 80℃ for 24 hours to avoid the outgassing from PC itself. Envelope material to minimize permeation and leak from the atmosphere is a laminated film consisting of PET (polyethylene terephthalate), LDPE (low density polyethylene), aluminium and L-LDPE (linear low density polyethylene).

The total effective thermal conductivity k_{eff} is measured using a guarded hot-plate apparatus [14]. The principle of this apparatus is shown in Figure 4. Two copper blocks are in good contacts with the VIP surfaces. One block is located in the guard side which is maintained as high temperature T_h, while the other is at low temperature T_c. High temperature T_h and low temperature T_c are maintained using constant temperature water bath. Heater block temperature T_m is precisely controlled to be equal to T_h. Then heat transfer does not occur between the heater block and the hot guard. All electrical energy supplied to heater block flows as heat to the cold guard in a one-

dimensional manner. Using the electric power Q, overall heat transfer coefficient U of VIP can be calculated as

$$U = \frac{Q}{A_c(T_h - T_c)} \tag{16}$$

where A_c is the effective area of heater block. The thermal conductivity of a reference insulation material (SRM 1450C) is measured to check the accuracy of this apparatus [15]. The relative errors between the standard conductivity (0.0333 W/m·K) and measured one (0.0350 W/m·K) are found to be 5.1%, which proves the reliability of the proposed apparatus. Thermal conductivity of fabricated VIP is measured by this apparatus. Note, however, that the apparatus basically measures the overall heat transfer, rather than the thermal conductivity itself. The error 5.1% is that of the overall heat transfer coefficient when it is about 1 W/m^2·K. For super insulators of about 1cm thickness, the overall heat transfer coefficient is as low as 0.1 W/m^2·K. If the absolute error of the overall heat transfer coefficient remains the same, it may result in a significant relative error for the super insulators. More investigations are necessary in this problem.

RESULTS AND DISCUSSIONS

Before presenting the experimental results, the theoretical thermal conductivity of VIP is calculated as based on the fabricated one. The parameters, properties and safety factor S = 2 (see Tables 1 and 2) are substituted in equation (9). Then, the solid conductivity k_s is determined as 1.25×10^{-3} W/m·K. The fabricated VIP is evacuated to below 1.33×10^{-1} Pa. Its gap size is 2mm with the installed radiation shields. The gaseous conductivity k_g is calculated by equation (14) as 2.14×10^{-4} W/m·K. The fabricated VIP has 4 gaps over its total thickness of 8mm. The average temperature T_m is taken as 300K. The emissivity of the aluminium radiation shield is 0.04. Then, the radiative conductivity k_r becomes 6.25×10^{-5} W/m·K from equation (15). It is found that the solid conduction mostly contributes to the overall heat transfer of VIP.

The thermal conductivity of fabricated VIP is measured by guarded hot-plate apparatus. It is 0.89×10^{-3} W/m·K as contrasted to the calculated one in Table 3. The analytical results are slightly overpredicting k_{eff}. The discrepancy is considered to be primarily due to the measurement error of the guarded hot-plate as mentioned before. Secondly, the predictions may be containing some errors, especially the error in k_s, with additional uncertainty in k_g. It is impressive that k_{eff} is as small as 1/30 of those of conventional insulation materials. This strongly proves the usefulness of the current super insulator. Remember, also, that there is a significant room to improve the insulation performance by adjusting the safety factor and/or allowing beam deflection.

Table 3
Theoritical and Experimental Thermal Conductivity of VIP

Thermal conductivity	Analytical result (W/m·K)	Experimental result (W/m·K)
k_s (solid conductivity)	1.25×10^{-3}	-
k_g (gaseous conductivity)	2.14×10^{-4} @ 1.33×10^{-1} Pa	-
k_r (radiative conductivity)	6.25×10^{-5}	-
k_{eff} (total conductivity)	1.53×10^{-3} @ 1.33×10^{-1} Pa	0.89×10^{-3} @ 1.33×10^{-1} Pa

CONCLUSIONS

A staggered beam VIP (vacuum insulation panel) is proposed and fabricated using PC (polycarbonate) by injection molding. Its effective thermal conductivity is experimentally and theoretically investigated. Thermal conductivity of VIP via solid conduction, gaseous conduction and radiation is theoretically calculated. The effective thermal conductivity is measured by guarded hot-plate apparatus. The performance of the fabricated VIP in this study is proved through experimental and theoretical investigations. It has about 30 times higher thermal resistance than the conventional insulators such as polystyrene or polyurethane foams. Also, further improvements are possible through parameter adjustments. The proposed experimental and theoretical methods are useful for further VIP developments.

OSCILLATORY THRERMOCAPILLARY FLOW IN ANNULAR POOL OF SILICON MELT

WY Shi[1], M. K. Ermakov [2], YR. Li[1], L. Peng[1], N. Imaishi*[3]
[1] College of Power Engineering, Chongqing University, Chongqing, China
[2] Institute for Problems in Mechanics of the R.A.S., Moscow, Russia
[3] Institute for Materials Chemistry and Engineering, Kyushu University, Japan

ABSTRACT . The influence of buoyancy force on the thermocapillary convection instability in the annular pools (R_i = 20 mm, R_o = 40 mm, and depth d ranging from 1 mm to 10 mm) of silicon melt (Pr = 0.011), differentially heated at the outer wall and cooled at the inner wall, is investigated numerically. The critical Marangoni numbers (Ma_c) for the incipience of oscillatory flow are determined by linear stability analysis (LSA) under both microgravity and normal gravity conditions. The results indicate that the buoyancy force destabilizes the thermocapillary convection under different liquid layer depths from 3mm to 10mm. With increasing the layer depth, the critical Ma number, critical azimuthal wave number and critical phase velocity decrease. Some of 3-D simulation results are compared with those of LSA. 3-D results are found consistent with the LSA results.

Keyword: Thermocapillary flow, Buoyancy, Hydrothermal wave, Silicon melt, Annular pool

INTRODUCTION

It is well known that the thermocapillary force may cause unstable fluid flow in single-crystal growth processes such as the Czochralski (Cz) methods [1-3]. Spatiotemporal changes of flow and temperature distributions in the melt may cause inhomogeneous distributions of impurities and point defects in the grown crystals. Related to the flow instability in the melt pool of Cz crystal growth furnaces, many research works have been reported for thermocapillary flow and the hydrothermal wave [4] (HTW) type instability in annular pools. So far, many reports are available on HTW in annular pools of silicone oils [5-16]. Schwabe et al. [5-7] revealed, through their on-ground and microgravity experiments, that buoyancy force tends to suppress the incipience of HTW in annular pool of silicone oil (0.65 cSt). Schwabe [7] experimentally determined the critical temperature difference for the incipience of oscillatory flow for different liquid depths. Wakitani [8] observed surface temperature patterns on annular pools of silicone oil (Pr=18). 3-D numerical simulations have been also applied for the thermocapillary flow instabitlities in annular pool of silicone oils [9-12]. Recently, Shi and Imaishi [11] performed a series of numerical simulations of HTW in an annular pool of silicone oil (Pr = 6.7) with the same Ri and Ro as those of Ref. 7 but the depth 1 mm. They compared their results for microgravity (0G) and normal gravity (1G) conditions and concluded that gravity tends to stabilize the basic steady thermo-capillary flow. Linear stability analysis (LSA) is also a powerful tool for determining the critical conditions for the incipience of flow instabilities. Hoyas et al. [13-15] performed linear stability analysis and obtained a stability diagram for the incipience of stationary or oscillatory secondary flow in annular pools of

silicone oil heated at the inner wall. In our previous work [16], both LSA and 3-D numerical simulations were applied to determine the critical conditions for the incipience of HTW in annular pool of silicone oil (Pr=6.7) with a depth d=1mm under 0G.

On the other hand, little is known for thermocapillary flow instabilities in annular pool of low Pr fluids. Azami et al. [17] speculated that hydrothermal wave (HTW) type instability may play an important role in the formation of such unstable melt flow in Cz crucible, based on their experiment of silicon melt flow in shallow annular pool (R_i = 15 mm, R_o = 63.5 mm). So far, numerical analysis related to their experiments in annular pool of silicon melt is quite sparse [18, 19]. In this study, a series of LSA is conducted to determine the critical conditions for the incipience of oscillatory flow of silicon melt (Pr=0.011) in differentially heated annular pools with the same geometry with those used for silicone oil problems [5-7, 9,12,16] and with various liquid depths (from 1mm to 10mm) under both 0G and 1G conditions so as to evaluate the effect of the buoyancy on the stability of steady axisymmetric basic flow and the results are qualitatively compared with the critical conditions determined by 3-D numerical simulations [18].

MODELS AND METHODS

Physical and mathematical models

Figure 1 shows the model system of an annular pool, with an open top free surface, a solid bottom, an inner solid wall (radius R_i = 20 mm), an outer solid wall (radius R_o = 40 mm), and depth d varied from 1 to 10 mm. This geometry is the same as that of Ref. 7 and Ref. 11. The fluid is silicon melt, and its physical properties are listed in Table 1.

The outer wall is maintained at a constant temperature T_h while the inner wall at a lower temperature T_c ($T_h > T_c$ and $\Delta T = T_h - T_c$). The top and bottom surfaces are assumed to be adiabatic. The silicon melt is considered to be an incompressible Newtonian fluid with constant properties except for the temperature dependence of surface tension. Thermocapillary force acts on the free surface. The flow is considered to be laminar and the liquid top surface is assumed to be flat and non-deformable.

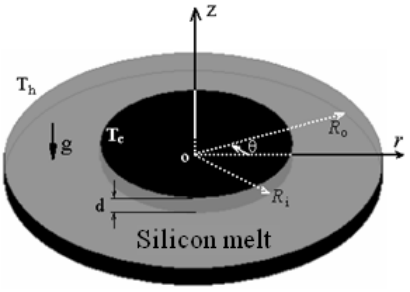

Figure 1 Configuration of the model system.

Table 1
Physical properties of silicon melt

Prandtl number:	$Pr = 0.011$
Density:	$\rho = 2530$ kg/m^3
Thermal diffusivity:	$\alpha = 2.53 \times 10^{-5}$ m^2/s
Dynamic viscosity:	$\mu = 7.0 \times 10^{-4}$ m^2/s

Under the above assumptions, the mathematical model is expressed by the following non-dimensional equations. In the cases of axisymmetric steady simulations, we assume that all gradients in the azimuthal direction are zero.

$$\nabla \cdot \boldsymbol{V} = 0 \tag{1}$$

$$\frac{\partial \boldsymbol{V}}{\partial \tau} + \boldsymbol{V} \cdot \nabla \boldsymbol{V} = -\nabla \boldsymbol{P} + \nabla^2 \boldsymbol{V} + Gr\Theta \boldsymbol{e}_z \tag{2}$$

$$\frac{\partial \Theta}{\partial \tau} + \boldsymbol{V} \cdot \nabla \Theta = \frac{1}{Pr} \nabla^2 \Theta \tag{3}$$

Here, $\boldsymbol{e}_z$ is the axial unit vector. The boundary conditions are obtained as follows:
at the top surface ($z = D$, $r_i < r < r_o$, $0 \le \theta \le 2\pi$, $\tau > 0$):

$$\frac{\partial u}{\partial z} = -\frac{Ma}{Pr}\frac{\partial \Theta}{\partial r}, \quad \frac{\partial v}{\partial z} = -\frac{Ma}{Pr}\frac{\partial \Theta}{r\partial \theta}, \; w=0, \; \frac{\partial \Theta}{\partial z} = 0 \tag{4a, b, c, d}$$

at the bottom ($z = 0$, $r_i < r < r_o$, $0 \le \theta < 2\pi$, $\tau > 0$): $u = v = w = 0$, $\dfrac{\partial \Theta}{\partial z} = 0$ (5a, b, c, d)

at the inner wall ($r = r_i$, $0 \le z \le D$, $0 \le \theta < 2\pi$, $\tau > 0$): $u = v = w = 0$, $\Theta = 0$ (6a, b, c, d)

at the outer wall ($r = r_o$, $0 \le z \le D$, $0 \le \theta < 2\pi$, $\tau > 0$): $u = v = w = 0$, $\Theta = 1$. (7a, b, c, d)

where u, v and w are non-dimensional velocities in the r, θ, and z directions, respectively. The length, time τ, pressure P and velocity are scaled by $(R_o–R_i)$, $(R_o–R_i)^2/\nu$, $\nu\mu/(R_o–R_i)^2$ and $\nu/(R_o–R_i)$, respectively. The non-dimensional temperature is defined as $\Theta = (T - T_c)/\Delta T$, where, $\Delta T = T_h - T_c$. The Marangoni number, Prandtl number and Grashof number are defined as $Ma = \gamma_T(R_o–R_i)\Delta T/\mu\alpha$, $Pr = \nu/\alpha$, $Gr = g\rho_T\Delta T(R_o–R_i)^3/\nu^2$, respectively. Here, μ is the viscosity; γ_T, the temperature coefficient of surface tension ($\gamma_T = -\partial\gamma/\partial T$, where γ is the surface tension); ν, the kinematic viscosity; and α, the thermal diffusivity of silicon melt. g is the gravitational acceleration; the case with g =0 (microgravity case) is indicated by 0G, while g =9.8m/s^2 (normal gravity case) by 1G in the following. The non-dimensional stream function ψ is defined as follows:

$$u = -\frac{1}{r}\frac{\partial \psi}{\partial z} \text{ and } w = \frac{1}{r}\frac{\partial \psi}{\partial r} \tag{8}$$

The numerical method for 3-D simulations based on this mathematical model is described in [18].

Linear stability analysis

2-D axisymmetric steady flow and temperature fields, a basic flow, are obtained by solving Eqs. 1-7 numerically [11]. Stability of the basic flow against small 3-D perturbations is investigated by means of LSA.

The fully unsteady 3-D equations, equations(1)-(7), are linearized for perturbations $(u',v',w',p',\phi)^T$ in the vicinity of the basic solution $(u_0,v_0,w_0,p_0,\Theta_0)^T$ and the perturbations are approximated by the superposition of integer-valued azimuthal normal modes.

$$\begin{pmatrix} u \\ v \\ w \\ p \\ \Theta \end{pmatrix}(r,\theta,z,\tau) = \begin{pmatrix} u_0 \\ v_0 \\ w_0 \\ p_0 \\ \Theta_0 \end{pmatrix}(r,z) + \begin{pmatrix} u' \\ v' \\ w' \\ p' \\ \phi \end{pmatrix}(r,z)e^{\lambda\tau + im\theta} \tag{9}$$

The resulting non-dimensional linearized equations and boundary conditions will be found in our previous paper [16]. These are discretized at the same staggered grid as that used for the basic flow calculation. Therefore, the problem is reduces to a generalized eigenvalue problem

$$\boldsymbol{A}\boldsymbol{x} = \lambda \boldsymbol{B}\boldsymbol{x}, \qquad \boldsymbol{x} \in \mathbf{C}^n \tag{10}$$

where $\boldsymbol{A}$ and $\boldsymbol{B}$ are sparse square matrices with 5n×5n elements; n is the total grid number in the r-z plane. The vector $\boldsymbol{x}$ indicates the unknown perturbation variables $(u',v',w',p',\phi)^T$ in the discretized equations. **C** represents a complex matrix set. Further, $\boldsymbol{A}$ is the coefficient complex matrix of all

terms except those involving λ, while $\boldsymbol{B}$ is the coefficient matrix of terms involving λ, which is a diagonal singular sparse matrix. The singularity arises due to the continuity equation and the boundary conditions included in the problem formulation. In contrast to reference [20], the azimuthal velocity is not excluded from the formulation due to the continuity equation; moreover, this equation is not transformed into the equation for pressure. Based on reference [20], the inverse iteration [21] is applied to the solution of the generalized eigenvalue problem. Since the linear stability of the system is defined by the eigenvalue of the maximum real part, the minimum value of *Ma* at which the system attains the eigenvalue with a nonnegative real part is the critical Marangoni number (Ma_c) and the corresponding *m* value is the critical azimuthal wave number (m_c). The grid-independence has been carefully checked [16].

RESULTS AND DISCUSSIONS

Basic flow

It is well known that thermocapillary flow in shallow pools is not so much influenced by the buoyancy force. This is also true for the present annular pool of silicon melt for D<0.15. However, the buoyancy force tends to enhance the thermocapillary flow in deep pools. Figure 2 compares the basic flow fields for D=0.5 (d=10mm) at Ma=79.05 (ΔT=1K) under 0G and 1G conditions. Figures 2(a) and 2(b) indicate that the temperature and radial velocity on the surface under 1G are larger than those under 0G condition. These are caused by the change of induced vortexes near the hot wall. Under 0G, a large positive valued vortex appears near the hot wall as well as the small corner vortex near the cold wall, both are driven by the main vortex driven by the Marangoni effect. There is another very weak negative valued corner vortex near the hot wall but is too weak to be plotted in the figure The buoyancy force acting near the hot wall takes significant role to suppress the positive vortex near the hot wall. Thus the main vortex becomes stronger.

Critical conditions for the incipience of oscillatory flow

Linear stability analysis provides us with the critical condition for the onset of flow instability in annular pool of silicon melt with different depth as summarised in Table 2. The critical Marangoni number Ma_c, the critical azimuthal wave number m_c and the critical phase velocity ω_c decrease steeply with increase in the pool depth, D in a range from 0.05 to 0.1 and their changes become less significant at $D \geq 0.1$. Comparison of those critical conditions indicates that the buoyancy force gives small effects on the critical conditions for shallow pools ($D \leq 0.1$). However, for deeper pools (D>0.1), the buoyancy force slightly destabilizes the basic 2-D steady flow fields and decreases m_c and ω_c.

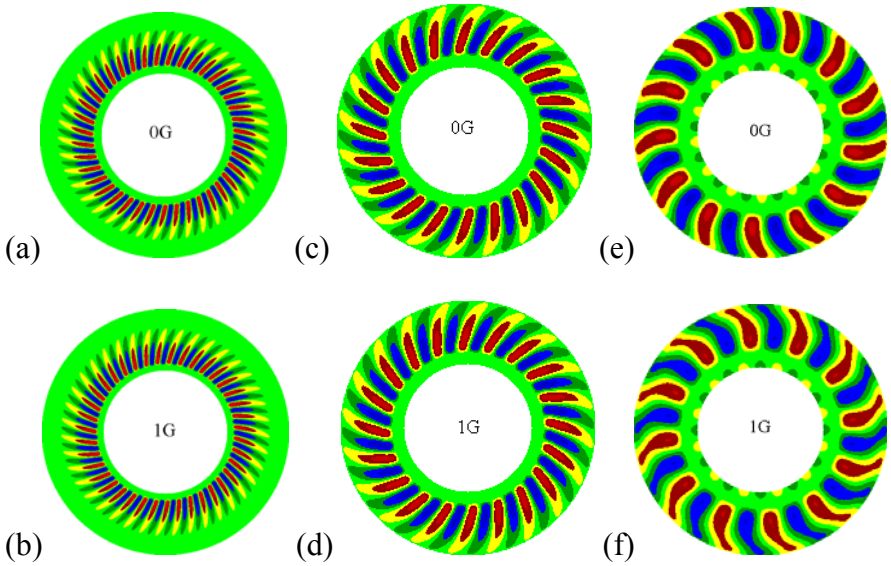

Figure 3 Distribution of temperature eigenfunction on the surface at the critical conditions.
(a) D=0.05, 0G, m_c=39. (b) D=0.05, 1G, m_c=39.
(c) D=0.10, 0G, m_c=20. (d) D=0.10, 1G, m_c=20.
(e) D=0.50, 0G, m_c=13. (f) D=0.50, 1G, m_c=12.

However, ω_c shows an increase at D=0.5. Figure 3 compares the temperature eigenfunctions on the surface for D=0.05, 0.10 and 0.5 under both 0G and 1G at each critical state. For the cases of D=0.05 and 0.10, patterns of the temperature eigenfunction under both gravity levels are quite similar, while they are slightly different for D=0.5.
It should be noted here that the influence of the buoyancy force on the critical Marangoni number Ma_c for the silicon melt is quite different from that for silicone oil (Pr=6.7) via experiments [7] and non-linear numerical simulations [11] (i.e. the buoyancy force stabilizes the basic steady 2-D flow field in annular pools of silicone oil). The difference in the effect of the buoyancy force on the critical Marangoni number for low and high Pr fluids is related to the difference in the physical mechanism of HTW, i.e., waves derive their energy from the imposed horizontal temperature gradient through horizontal convection when the Prandtl number is small and from the vertical temperature gradient through vertical convection when it is large [4,23].

HTW by 3-D numerical simulation

Several 3-D numerical simulations are conducted under slightly super critical condition. Some of the surface temperature distributions obtained by the numerical simulation are shown in Figure 4 in which the $\delta\Theta$ (temperature deviation from the average temperature (averaged in the azimuthal direction) is adopted, i.e.,

$$\delta\Theta(r,\theta,z,\tau) = \Theta(r,\theta,z,\tau) - \frac{1}{2\pi}\int_0^{2\pi}\Theta(r,\theta,z,\tau)\,\mathrm{d}\theta \tag{11}$$

Figure 4(a) is a result for D=0.1 (d=2mm) at Ma= 1.19×10^3 (ΔT=15K and ε=(Ma–Ma_c)/Ma_c=0.15) under 0G, and Figure 4(b) is a spatiotemporal diagram (STD) (a plot of $\delta\Theta$ at r=1.25 during 10 seconds). (For this simulation, a grid (n_r, n_θ, n_z=202, 303, 41) was used.) These figures indicate that the basic flow in the melt pool is unstable and an oscillatory flow with a wave number m=20 is induced at this condition. The STD indicates the oscillation of surface temperature is a pulsating type with ω=26.7, although the LSA predicts a HTW with a temperature distribution shown in Figure 3(a) traveling in the azimuthal direction (m_c=20 and ω_c=22.15) at ε=0. Movie of surface temperature pattern shows that the black and white fringes shown in figure 4(a) move outward and then the phase is changed. This time history of the pattern is explained as an interference of two HTWs of m=20 (similar to that shown in figure 3(c)) propagating in the opposite azimuthal directions to each other.

Figure 4(c) is a snapshot of surface temperature deviation at Ma=118.6 (ΔT=1.5K, ε=0.43) in a deep melt pool (D=0.50) under 1G. The STD (Figure 4(d)) shows 8 bend spokes which propagate in the azimuthal direction with ω= −7.07 (f=0.039Hz). The shape of the spoke is similar to that of the temperature eigenfunction shown in Figure 3(f) but number of spokes and the oscillation frequency are different from the critical values (m_c=12, ω_c=8.71). These differences can be attributed to the large super criticality for this simulation. It should be noted here that a 3-D simulation run at Ma=118.6 under 0G end up with a steady 2-D flow. This is quite reasonable because the Marangoni number is smaller than Ma_c (=151.79) for 0G condition. These confirm the result of present LSA for deep pools, i.e., the buoyancy force destabilizes the basic thermocapillary flow in deep annular pool of silicon melt. (For this simulation, a grid (n_r, n_θ, n_z= 82, 123, 51) was used.)

YR. Li *et al*. [18] determined critical conditions for the incipience of oscillatory flow in annular pool of silicon melt with adiabatic free surface under 0G by means of 3-D numerical simulations.

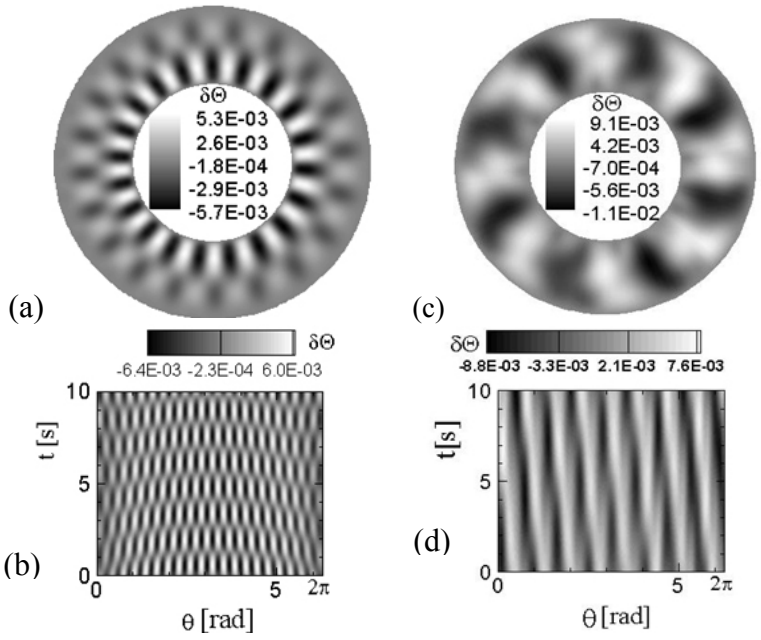

Figure 4 Snapshots and STD of surface temperature deviation, obtained by 3-D numerical simulations.

(a) Snapshot at Ma=1190, D=0.10, 0G. (b) STD on a circle at radius r=1.25: m=20, ω=26.7.

(c) Snapshot at Ma=118.6, D=0.50, 1G. (d) STD on a circle at radius r=1.25: m=8, ω=–7.07.

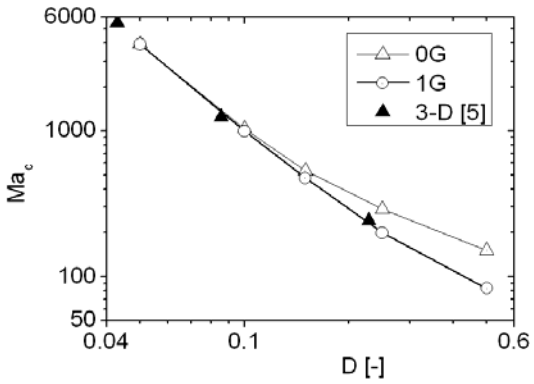

Figure 5 Comparison of the Ma_c determined by 3-D simulations [18] with the present LSA results (Table 2) for annular pools of silicon melt.

Although the radiuses of their pool are slightly different from those of the present ones, i.e., R_i=15mm and R_o=50 mm, it is worth to compare their results with the present LSA results. They obtained critical Marangoni numbers for the incipience of oscillatory flow in three different pool depths, Ma_c =5504 for D=0.0429 (d=1.5mm), Ma_c=1244 for D=0.0857 (d=3.0mm) and Ma_c=242 for D=0.229 (d=8mm). They used relatively coarser grids in Ref. 5, i.e., (n_r, n_θ, n_z= 80, 120, 20), (n_r, n_θ, n_z= 80, 92, 20) and (n_r, n_θ, n_z= 80, 60, 30), for layers of d=1.5 mm, 3 mm and 8 mm, respectively. Figure 5 indicates that their critical conditions are also closely correlated together with those of LSA if these critical conditions are plotted as a function of the non-dimensional depth D ($=d/(R_o-R_i)$: i.e., reciprocal of the aspect ratio of the pool). However, for the case of d=8mm, their Ma_c value falls much lower than the present LSA's prediction for 0G and closer to that for 1G. It should also be noted that they reported a different type of pulsating oscillatory flow for a pool of d=8mm. These may be partly attributed to the coarser grid they used for d=8mm.

CONCLUSIONS

The critical Marangoni numbers for the incipience of oscillatory flow in small annular pools of silicon melt are determined by means of LSA under both microgravity and normal gravity conditions. The results indicate that the buoyancy force destabilizes the thermocapillary convection in the annular pools with depth ranging from 3mm to 10mm. With an increase in layer depth, the critical Ma number, critical azimuthal wave number and critical phase velocity decrease. Most of the 3-D numerical simulations are found consistent with those obtained by LSA.

STUDY OF DRYING BEHAVIOR REMAINING LIQUID FILM / DROPLET ON MARANGONI DRYING

Y. Miyamoto*, J. Kamoshida and J. Yamada
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT. To clarify the drying mechanisms of droplets remaining on a silicon wafer in the Marangoni drying process, the dry-up time of droplets during organic gas dissolution has been investigated using a CCD camera. The concentration of the organic component in the droplets has also been measured using a micro-optical concentration sensor. In addition, numerical calculations of dry-up time and the organic component concentration based on phase equilibrium methods were performed. The numerical results were found to be in good qualitative agreement with the experimental data. Finally, optimal concentrations of the organic component and water vapor were determined to reduce the formation of watermarks on the silicon wafer.

Keywords: *Marangoni drying, Watermark, Mass transfer*

INTRODUCTION

In semiconductor manufacturing, cleansing and drying technologies are of paramount importance for achieving ultra-clean surfaces and improving production efficiency. Marangoni drying is a process that has become widely used for silicon wafers due to its superior drying effects [1-2]. However, even with this method, residual water traces (watermarks) and particles are sometimes present after drying, leading to a decrease in the yield ratio. Normally, such residues have been prevented by optimizing various operating conditions used during the cleansing/drying process [3]. However, in recent years, as wafer sizes become larger, the occurrence of residues has become an increasing problem, and improvements are needed in the drying method itself. To achieve this, it is necessary to understand the mechanism for remnant formation in order to develop preventive measures.

In the Marangoni drying process, following cleaning, a silicon wafer is drawn from the rinse bath in an atmosphere containing an organic gas, typically isopropyl alcohol (IPA). As shown in figure 1, this gives rise to a higher concentration of the organic component in the thin top part of the meniscus than in the thicker bottom root. Since the organic component causes a reduction in the surface tension of the liquid, a surface tension gradient is formed in the meniscus, which increases from the top to the bottom. As a result, the Marangoni force is produced, which causes the meniscus to be pulled back to its root, enhancing the drainage.

Previously, the mechanisms of Marangoni drying were clarified by measuring the IPA concentrations in the meniscus and the liquid surface far from the meniscus and visualizing with ammonia gas [4].

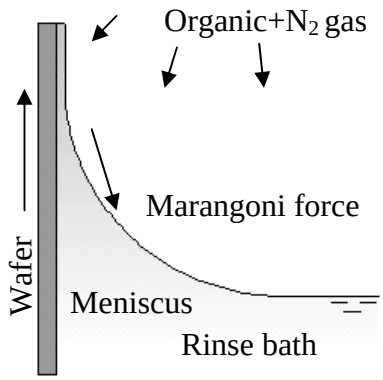

Figure 1. A tentative mechanism of Marangoni drying.

In addition, in the same study, the formation mechanism for residual liquid films or droplets that are thought to be the origin of residual particles and watermarks was examined. The results revealed that the leftover films/droplets are produced when a wave occurs on the liquid surface in the rinse bath.

Residue particles in the cleaning liquid are difficult to avoid if the drainage failed and liquid films/droplets remain on the wafer and dry up. To prevent this, it is necessary that the drainage is performed with no remaining liquid present, or that higher purity cleaning liquid is used. Watanabe et al. studied the mechanism of watermark formation and concluded that it was caused by the elution of Si from the silicon wafer into the rinse liquid and subsequent oxidation due to the presence of dissolved oxygen [5]. If this mechanism is correct, then the formation of watermarks may be suppressed if residual liquid films/droplets can be made to evaporate faster, since the time available for Si elution would be reduced. Furthermore, Koo et al. showed that if the concentration of the organic component is high, watermark formation can be suppressed even for longer dry-up times [6]. It is believed that the amount of Si elution is reduced when the wafer is in contact with an organic solution instead of pure water.

These results imply that control of the IPA concentration in the droplets and the dry-up time are effective methods for suppressing the formation of watermarks. However, Marangoni drying is a complicated process in which the remaining liquid films/droplets are drying concurrently with IPA gas dissolution. Therefore, it is difficult to predict which parameters would have a dominant effect on IPA concentration and dry-up time.

It is likely that even if the influence of temperature is ignored, since the drying process is generally performed at room temperature, the concentrations of IPA and water vapor (relative humidity) in the atmosphere will affect both the dry-up time and the IPA concentration in the liquid. In this study, the effects of the organic component and water vapor concentration in the drying atmosphere on the dry-up time of the droplets have been investigated using a CCD camera, and the concentration of organic gas in the droplets has been measured using an unique optical fiber probe concentration sensor. In addition, numerical methods based on phase equilibria have been used to evaluate the dry-up time and organic component concentration for the liquid, and to determine the optimum concentrations of water vapor and organic gas for suppressing the formation of watermarks.

EXPERIMENTAL EXAMINATION

Experimental equipment and method

Figure 2 shows a schematic diagram of the experimental apparatus. In this set-up, a single liquid droplet is placed on a horizontal silicon wafer. The test cell is almost airtight and has a volume of 1×10^{-3} m^3. Water is stored in a container at the cell bottom to obtain water vapor. To produce IPA

gas, N_2 gas is flowed through a container of liquid IPA at a rate of 4×10^{-3} m^3/min. The concentration probe sensor used to measure the IPA concentration of the droplet consists of an optical fiber that can measure the refractive index of the droplet. Details of the design of the sensor are given in [7]. The probe is set at a position 0.15 mm distant from the wafer surface in the vertical direction, and a LED is used as a light source. The test sample was a specular silicon wafer (width: 25 mm, height: 40 mm, thickness: 0.72 mm), with a hydrophilic surface. The method used to obtain a hydrophilic surface is described in [8]. The contact angle between the droplet and the wafer surface was 10 deg as a result of the sessile droplet method. Droplets with volumes of 0.5 and 2×10^{-9} m^3 were used in this study. It is difficult to perform this type of experiment on droplets produced during practical wafer cleaning because of the very small sizes involved. Therefore, extrapolations were performed from the droplet volumes used in this work to predict the tendencies as the volume is reduced. The initial IPA concentration (x_{IPA}) of the droplets was 0.016 mole fraction as a result of IPA gas dissolution while the droplet was on the silicon wafer. The atmospheric IPA concentration (Rh_{IPA}) was varied from 40% to 90%, and the relative humidity (Rh_{water}) was varied from 0% to 50%. The humidity values are based on an assumed temperature of 25 ^{o}C. Rh_{IPA} is controlled by changing the IPA liquid surface height and Rh_{water} by changing the surface area of the water in the container.

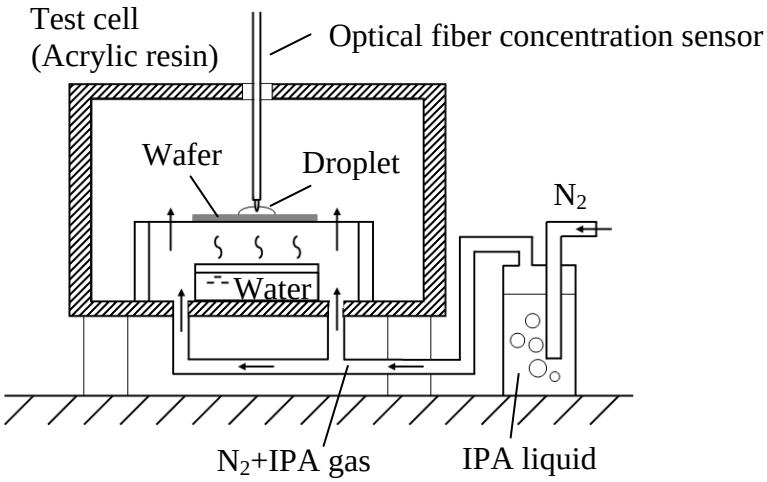

Figure 2. Schematic diagram of experimental apparatus

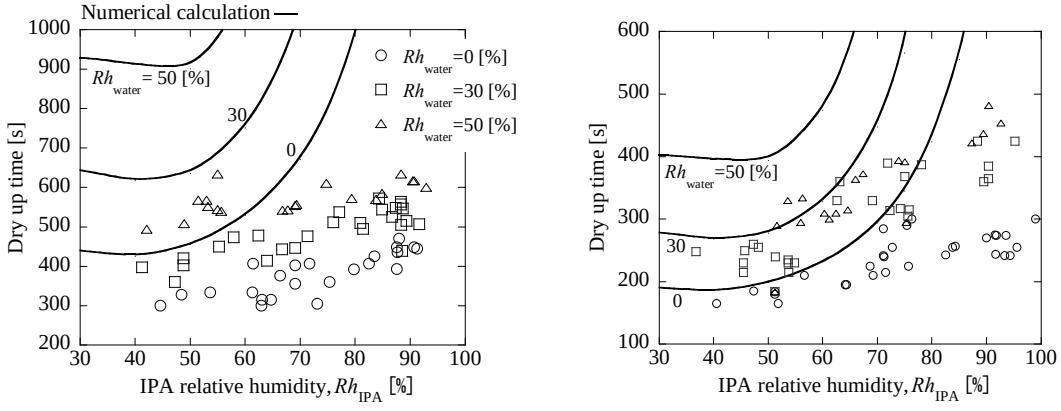
Dry-up time measurements

Figure 3 shows the dry-up time of the droplets on the silicon wafer during the IPA gas dissolution. In this experiment, the concentration probe was not used. Solid lines in the figures are the results of



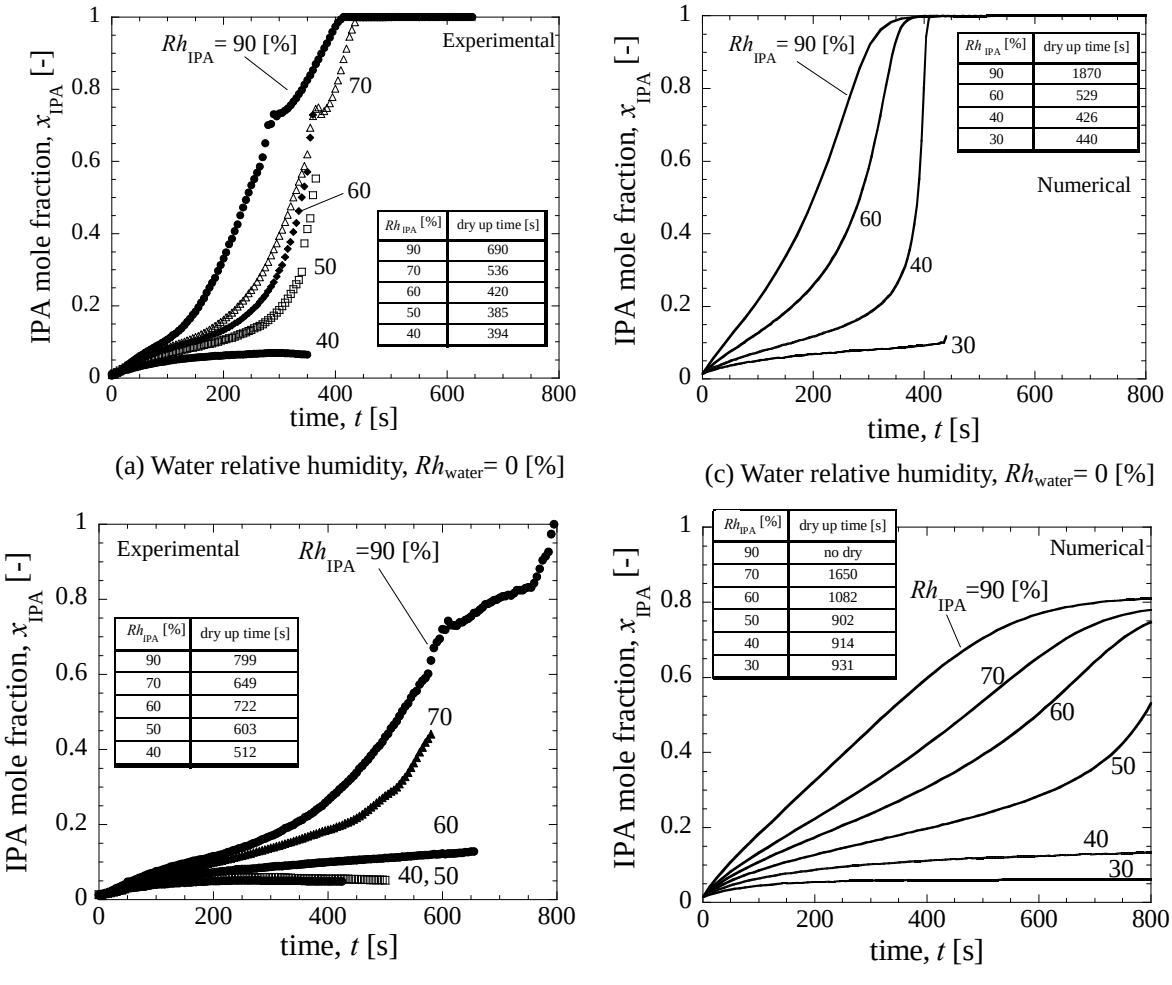
(a) 2×10^{-9} m^3 (b) 0.5×10^{-9} m^3

Figure 3. Influences of water and IPA relative humidities on the liquid droplet dry-up time.

a numerical calculation that will be described later. Figure 3 (a) is for a droplet volume of 2×10^{-9} m^3. As seen in this figure, the dry-up time increases as Rh_{IPA} and Rh_{water} increase. A similar tendency is found for the droplet with a volume of 0.5×10^{-9} m^3 (figure 3 (b)). Practical drying processes usually take between about 180 and 300 seconds, and thus figure 3 (b) is close to the practical situation. Therefore, it is considered that a similar tendency would be found for very small droplets.

IPA concentration measurements

Figure 4 (a), (b) shows the time variation of x_{IPA} in the droplet during the IPA gas dissolution, whereas figure 4 (c), (d) shows the results of a numerical calculation that will be described later. The final values of x_{IPA} could not be measured since the droplet height decreased to less than 0.15 mm due to evaporation, which is the distance of the probe from the wafer surface. Therefore the dry-up times are also shown as tables in these figures. x_{IPA} was measured only for the droplet with a volume of 2×10^{-9} m^3. As seen in figure 4 (a), x_{IPA} is found to increase with Rh_{IPA}, since the IPA gas readily dissolves in the droplet. Furthermore, it appears that the droplet changes completely to liquid IPA for very high values of Rh_{IPA}. The reason for the very long dry-up times (as shown in the table in figure 4 (a)) when Rh_{IPA} is very high is due to the fact that these IPA droplets cannot evaporate into the IPA-saturated atmosphere. A similar tendency is found for the case where Rh_{water} is high (50%), although the increase in x_{IPA} is much slower. Again, this is due to the fact that evaporation of the water component of the droplet is inhibited by the large amount of water vapor in



(a) Water relative humidity, Rh_{water}= 0 [%]

(c) Water relative humidity, Rh_{water}= 0 [%]

(b) Water relative humidity, Rh_{water}= 50 [%]

(d) Water relative humidity, Rh_{water}= 50 [%]

Figure 4. Time variation of IPA concentration in a liquid droplet during IPA gas dissolution.

the atmosphere. The discontinuities in the plots for x_{IPA} = 0.7-0.75 are due to a limitation of the concentration sensor, in that a reversal occurs in the relationship between the concentration and the refractive index of IPA-water. Next, numerical analysis based on phase equilibrium diagrams was carried out to investigate the drying process in more detail.

NUMERICAL CALCULATION

Calculation model

Figure 5 shows the phase equilibrium diagram for the IPA-water system [9]. The horizontal axis is the liquid or gas phase concentration and the vertical axis is vapor pressure. This figure represents the equilibrium diagram, but the system in this study is in a non-equilibrium condition. The evaporation of the droplet is investigated by first assuming that the droplet comes close to an equilibrium point, which is the atmosphere gas situation. The outline of the calculation is then as follows. If x_{IPA} of the droplet is given by the dotted line in the diagram, the vapor pressure at the surface will be described by the symbol □. This vapor pressure is the sum of the IPA and water vapor pressure, as indicated by the symbols ▲ and ■. If the IPA and water vapor pressure of the atmosphere are given at △ and □, the amount of evaporation or dissolution per unit time will be determined by the difference between each vapor pressure, which represents the driving force. For the example shown in figure 5, the IPA gas dissolves and the water vapor evaporates. If these vapour pressure differences are decided, to calculate the droplet volumes and x_{IPA} momentarily are easy. The details of the calculation model to determine the amount of evaporation and dissolution per unit time will now be presented.

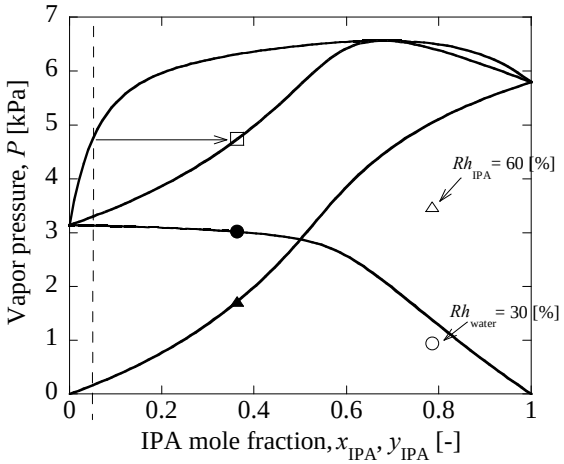


Figure 5. Phase equilibrium diagram for the system IPA-water

This calculation assumes that droplet evaporation is enhanced by the airflow that carries the IPA gas. In addition, the following assumptions are made:

[1] The droplet on the silicon wafer is a hemisphere and the system is isothermal.

[2] The droplet volume is very small, and there is enough IPA gas in the atmosphere to dissolve uniformly in the droplet. Therefore, the concentration distribution of each phase is uniform without the need to consider the diffusion resistance of each phase.

The amount of evaporation or dissolution per unit time is determined by the following equation:

$$\sum_{i=1}^{2} W_i = \frac{1}{2}\pi d^2 h_i(\rho_{is} - \rho_{i\infty}) \tag{1}$$

W_i is the amount of evaporation or dissolution for component i, d is the droplet diameter, h_i is the mass transfer coefficient for component i, and ρ_i is the vapor density for component i. Since there is no mass transfer coefficient suitable for the experimental system, a formula related to droplet evaporation proposed by Ranz-Marshall, shown in equation 2, is used instead [10].

$$\frac{h_i d}{D_i} = 2 + 0.60\,\mathrm{Re}_i^{1/2}\, Sc_i^{1/3} \tag{2}$$

The value of ρ_{is} is given by the following equation of state for an ideal gas.

$$\rho_{is} = \frac{P_{is} M_i}{RT} \tag{3}$$

P_{is} is the surface vapor pressure, and M_i the molecular weight of component i. R is the gas constant and T is the temperature. P_{is} can be written as

$$P_{is} = y_{is} \sum_{i=1}^{2} \gamma_i P_{i,sat} x_i \;,\; y_{is} = \frac{\gamma_i P_{i,sat} x_i}{\sum_{i=1}^{2} \gamma_i P_{i,sat} x_i} \tag{4}$$

Moreover, $\rho_{i\infty}$ is given by the equation.

$$\rho_{i\infty} = \frac{Rh_i P_{i,sat} M_i}{100RT} \tag{5}$$

For each component i, γ_i is the activity coefficient, x_i is the mole fraction of the liquid phase, y_{is} is the mole fraction of the gas phase, and Rh_i is the relative humidity. Each diffusion coefficient D_i is obtained from the data of Thurener et al. [11]. The kinematic viscosity of air is also taken into account in these calculations. The value of $P_{i,sat}$, which is the saturated vapor pressure of component i, is estimated from the Antoine equation for water and the Wagner equation for IPA. The activity coefficient γ_i is obtained from the Wilson equation based on the phase equilibrium data of Sazonov [9]. A gas velocity of 0.1 m/s in the test cell is used in these calculations. This value is close to that measured by an anemometer, although the accuracy of the measurement is not very high. Since equation 2 does not perfectly describe the current system, the mass transfer coefficients obtained in this study are approximate values.

Dry-up time

The numerical results together with the experimental data are shown in figure 3 (a), (b). The solid lines in these figures are the numerical results. In each figure, both the numerical and experimental results show a similar behavior in that the dry-up time increases with increasing Rh_{i}. However, the magnitude of the effect is different. In particular, the dry-up time in the numerical data increases much faster than that for the experimental data. This is probably due to the fact that the actual Rh_{IPA} value in the test cell is less than the theoretical value, since some of the IPA gas is swept away by the N_2 gas before it has a chance to fully diffuse. The differences in the dry-up times between the numerical and experimental data as the value of Rh_{water} is increased are likely due to a similar effect.

Time variation of IPA concentration

The numerical results for IPA concentration are shown in figure 4 (c),(d). Figure 4 (c) shows the case for low Rh_{water} (0%). The curves are qualitatively in good agreement with the experimental data. Specifically, the tendency of x_{IPA} to increase rapidly at certain times, and the influence of Rh_{IPA} on this rapid increase, are reflected in both the experimental and numerical data. Similar agreement is found for the high Rh_{water} (50%) case (figure 4 (d)). However, the calculated x_{IPA} curves never reach a value of 1.0, whereas this does occur in the experimental data. This is again most likely due to the fact that Rh_{water} does not reach its theoretical value due to being removed by the gas flow. Slight differences between the numerical and experimental results are expected since the proposed model is not a rigorous representation of the experimental system and certain parameters (surrounding environment, gas velocity etc.) related to the mass transfer coefficient are based on assumptions and predictions. However, the level of agreement that is observed indicates that this model has potential for predicting the dynamics of the drying process.

GUIDELINES FOR SUPPRESSING WATERMARK FORMATION

As mentioned previously, to decrease watermarking, dry-up times should be as short as possible, or the x_{IPA} value in the droplet should be increased as rapidly as possible. In this section, the optimum values of Rh_{IPA} and Rh_{water} are discussed. A droplet volume of 0.5×10^{-9} m^3 is used, since this is thought to be more representative of practical drying processes. Figure 6 shows a contour map of dry-up time, where the horizontal axis is Rh_{IPA}, the vertical axis is Rh_{water}, and the dry-up time is indicated by shade and numerical values. The scale is logarithmic and darker regions represent longer dry-up times. When Rh_{IPA} is comparatively low (0-50%), the dry-up times are dependent on Rh_{water} and independent of Rh_{IPA}. On the other hand, when Rh_{IPA} is high, the contour map takes on a longitudinal striped appearance. In this case, the dry-up times are dependent on Rh_{IPA} and independent of Rh_{water}. Therefore, to achieve short dry-up times, the value of Rh_{water} should be low, and Rh_{IPA} should be maintained at moderate levels. As mentioned previously, a rapid increase in x_{IPA} is also effective in reducing watermarking. According to Koo at al., Si elution ceases at a x_{IPA} value of 0.26 (corresponding to a volume fraction of 0.6) [6]. Figure 7 shows the time required to increase the mole fraction of IPA to 0.26 for different values of Rh_{IPA} and Rh_{water} referred to as the

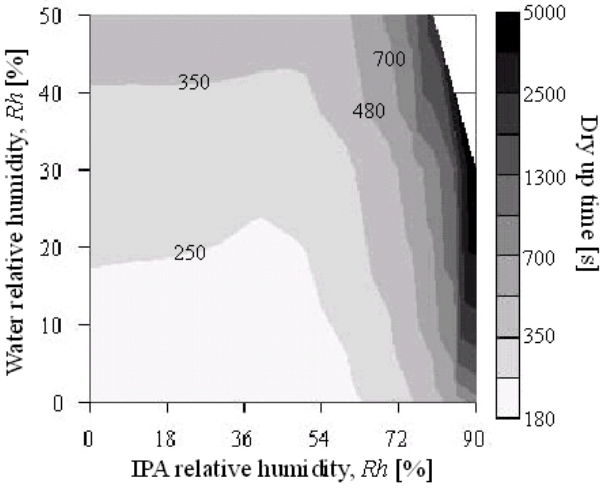

Figure 6. Contour map for dry-up time.

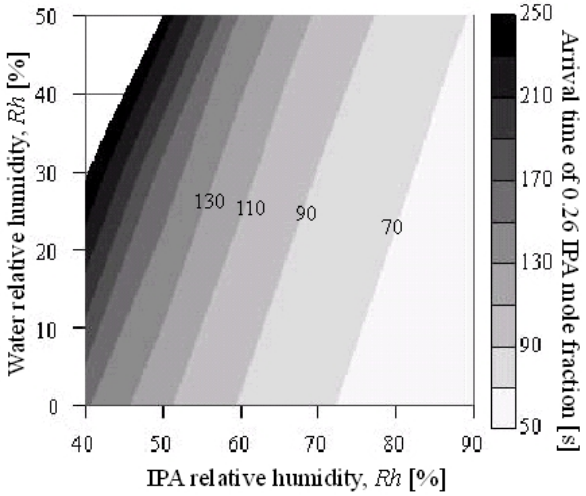

Figure 7. Contour map for IPA exchange.

"arrival time". The horizontal axis is Rh_{IPA}, and the vertical axis is Rh_{water}, similar to figure 6. However, the scale of the arrival time is linear in this case. As seen in this figure, the contour map has a longitudinal striped appearance, which indicates that the arrival time is strongly dependent on Rh_{IPA}. It is seen that high values of Rh_{IPA} lead to short arrival times. In addition, it is also confirmed that the similar tendencies were found for very small droplets, e.g. 0.3×10^{-9} m^3.

CONCLUSIONS

To clarify the drying mechanisms of droplets remaining on a silicon wafer in the Marangoni drying process, the dry-up time of droplets during organic gas dissolution has been investigated using a CCD camera. The concentration of the organic component in the droplets has also been measured using a micro-optical concentration sensor. In addition, numerical calculations of dry-up time and the organic component concentration based on phase equilibrium methods were performed. The numerical results were found to be in good qualitative agreement with the experimental data. Finally, optimal concentrations of the organic component and water vapor were determined to reduce the formation of watermarks on the silicon wafer.

A STUDY OF LASER ENGINEERED NET SHAPING PROTOTYPING TECHNOLOGY

R.S. Amano[1*], Z.Xu[1], P.K. Rohatgi[1]
[1]University of Wisconsin, Milwaukee, USA

ABSTRACT. The objectives of this work are to study Laser Engineered Net Shaping (LENS^{TM}) produced materials and identify the microstructures. Numerical method was used to examine the influence of materials' type and LENS^{TM} process parameters on the forming of the specific microstructures from thermodynamics and fluid dynamics point of view. Samples of 316L stainless steel were examined, microstructures of samples were used to estimate the corresponding cooling rate, and the cooling rate was compared with the results of three different level of simplified models..

INTRODUCTION

LENS^{TM} is a type of Rapid Prototyping (RP) technology, which is unique in fabricating fully dense metal parts directly from Computer Aided Design (CAD) solid models by layer additive methods[1-9]. The LENS^{TM} process can be thermodynamically described as the following four steps:

* Corresponding author: Prof. R.S. Amano

1. The Laser hits on the substrate and creates a melting pool with a size of 1-2 mm[1].
2. The micro or nano powders of desired material are injected into the melting pool; the powders are melted and deposited.
3. As the substrate traverses forward, the laser heat moves away relatively, the temperature of the melting pool begin to fall, And at the same time, the melting pool with deposited powders experience a solidification process.
4. The substrate keeps traverse back and forth, and the powders are added on layer by layer.

The thermo history plays an important role in this process, particularly; the heating and cooling history are the critical factors to determine the microstructure of the produced part.

In this paper, the microstructures of LENS^{TM} produced 316L stainless steel were examined and corresponding cooling rates were calculated using the experimental relations [2]. At the same time, numerical method was enrolled and the results were compared with experiment data.

.

NUMERICAL METHOD

When the substrate traverses under the laser, metals are melted for the closing up of laser spot and solidified for the parting away of laser spot. Simultaneously, powders are injected into the melting pool, there are following several phenomena involved: convection, conduction and radiation heat transfer; metal's melting and solidification, heat and mass exchange between discreet particle powders and continuum melting pool.

Navier-Stokes (N-S) equations are the governing equation for simulating the flow field and thermal field in and around the melting pool. In addition, Lagrange-Eulerian method is used to track the motion of powders and heat transfer between powders and melting pool. The Volume of Fluid (VOF) method was used to track the interface between liquid metal and environment gas, Argon. Mushy zone melting / solidification model is used to mark the interface of liquid metal and solidified metal.

RESULTS

This paper simplifies the real LENS system as shown in Figure. 1. The upper stationary part represents the laser & powder nozzles assemble and the surrounding environmental gas, while the under moving part represents the moving metal substrate. The dimension of upper part is $0.18m \times 0.06m \times 0.03m$ and the dimension of under part is $0.10m \times 0.06m \times 0.03m$.

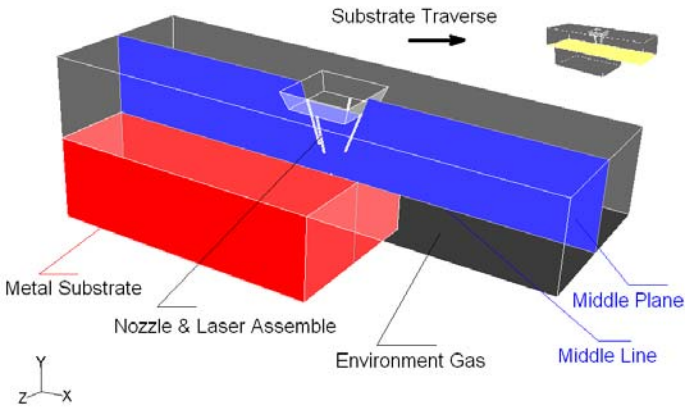

Figure 1. Real and Simplified LENS^{TM} System

As shown in Fig. 2, the mesh size of the whole model is 480,000. There are heat flux boundary condition exerted on position of laser spot and the value is coming from the calculation of laser

power used and laser spot diameter; Powder injections are set on each nozzle and the powder size, flow rate and injection speed is directly from the sample making parameters. The surrounding boundary is to be constant temperature wall, this is reasonable with high precision, because the heat infected zone is small, around 5-10mm [3], this will be verified when the temperature distribution is calculated out.

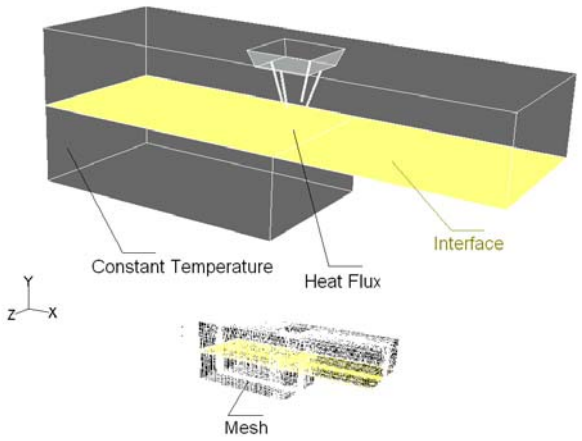

Figure 2. Boundary Conditions & Mesh

In this paper, three real samples are studied; correspondingly, three simulations were carried out. The parameters are collected in Table 1.

Table 1

Simulation Parameters

Density (kg/m^3)	7730
Specific Heat Cp (J/kg/K)	450
Thermal Conductivity (W/m/K)	21.5
Viscosity (kg/m/s)	0.0055
Solidus Temperature (K)	1390
Liquidus Temperature (K)	1440
Laser Power (W)	220
Beam Diameter (m)	0.0005
Traverse Velocity (m/s)	0.0148
Powder Feeding Rate (kg/s)	3.34E-5*4
Powder Injection Velocity (m/s)	6.37
Powder Diameter (m)	1.00E-07
Heat Flux (W/m^2)	1.12E+09
Environment Temperature (K)	320
Environment Pressure (Pa)	101325

In case 1, the powder injection model, VOF model, and Melting/Solidification model were used. In case 2, the powder injection model was taken off form case1, so case 2 didn’t take the effect of

powder's absorption of energy in to count. While in the metal was only treated as a solid, so the whole effect of melting pool was get rid of. The cases descriptions are as table 2 shown.

Table 2
Cases Description

	Case 1	Case 2	Case 3
VOF Model	√		
Melting/Solidiffication Model	√	√	
Powder Injection Model	√		

Figure 3 shows the temperature distribution of three cases along the middle line at time t=1s separately. the temperature remains unchanged as the environment temperature; only in the small area around laser spot (x=0m) the temperature shoots up suddenly.

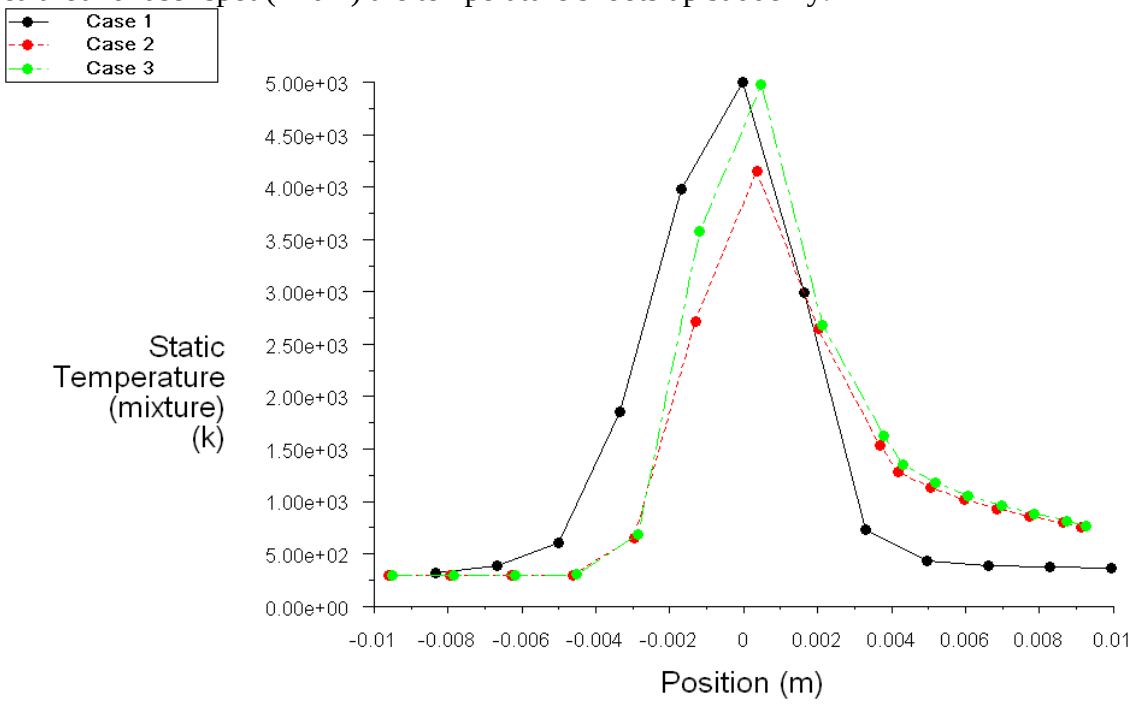

Figure 3. Temperature Distribution along the middle line at different time: t=1s

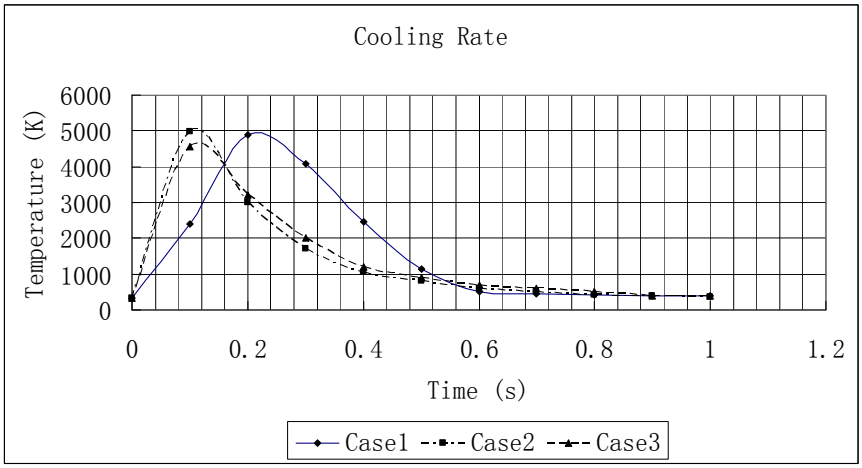

Figure 4 Temperature Changing with time

Figure 4 shows the temperature changing with time of three cases; from this figure, the heating rate and cooling rate is easy to find. The numerical results and experimental sample results on cooling rate is listed in Table 3.

Table 3
Cooling Rate (K/s)

	Experimental Data	Numerical Data
Case 1	11000	9163
Case 2	11000	7954
Case 3	11000	6163

Further work can be done to refine to dig out more precise mass transfer between powder and melting pool, so that more precise cooling rate can be measured.

CONCLUSION

Compared with previous work [4], the case 2 yield more accurate results by compared with experimental data for the refined mesh. While in case 2, because the powder injection model was ignored, so as the energy transfer between the powder and continuum metal was ignored, so the final average cooling rate is smaller than the experimental data. In case 3, the melting pool effects was also get rid of, so the results between case 2 and case 3 differ from each other. From the comparison of three cases, the cooling rate largely depends on the metal's solid metal' material properties, at the same time, the powder's injection also contribute much to the final cooling rate.

VALIDATION AND VERIFICATION PROCEDURE OF THE FREE SURFACE MAPPING IN AN ELECTRICAL TRANSFORMERS MOULDING PROCESSES

Z. P. Buliński*, A. J. Nowak
Institute of Thermal Technology, Silesian University of Technology, Gliwice, Poland

ABSTRACT. Paper presents a numerical simulation, verification and experimental validation of an electrical transformer moulding process. For this purpose an experimental stand, which would allow us to carry out and monitor such a process, was designed and built. Two types of experiments were preformed. First was an isothermal experiment in ambient conditions, in which an analog liquid was used. As an analog liquid substance with highly non-Newtonian properties was used. The second experiment was done in non-isothermal conditions with an epoxy resin as a working fluid. In this experiment epoxy resin was used and the internal transformer parts were heated up to the process temperature before filling the mould with epoxy resin. The course of transformer casting process highly depends on the rheological and surface properties of the epoxy resin and their dependency on temperature and degree of polymerisation. This properties were carefully measured. In case of non-isothermal simultaneously to moulding process, polymerization reaction of the epoxy resin take place. This effect was also considered in the mathematical model of the process, for this purpose DSC measurements of the epoxy resin was carried out to estimate curing kinetics. Geometrical and numerical models of both experiments were created with the use of the commercial Computational Fluid Dynamics code *Fluent*. Mathematical model of the moulding process considered free surface flow with Volume Of Fluid method, in this model also surface tension and wall adhesion were include with Continuum Surface Model. In the non-isothermal case transport properties of epoxy resin were assumed to be a function of temperature and curing degree. Calculations were preformed on several numerical grids with different mesh densities based on which the spatial discretisation error was estimated using Richardson extrapolation rule. Finally obtained results for both cases were compared with experimental measurements showing satisfactory agreement.

INTRODUCTION

During the last thirty years or so, an incredible development and a dramatic cost decrease in computers has caused them to become one of the most important tools in the work of a modern engineer in the field of modelling fluid and heat flows. Computational Fluid Dynamic (CFD) techniques are efficiently used in conceptual studies of new designs, detailed product development, troubleshooting or redesign, optimisation and control of many industrial processes, etc. Broad use of CFD in industrial applications has resulted in more complicated problems being solved. However, each CFD code and simulation needs to be inspected if the obtained results are reliable. This objective is accomplished by means of a credibility analysis (or Validation & Verification - V&V analysis) of the numerical model [1].

Dry-type resin-impregnated electrical transformers are very important parts of many industrial power supply systems. In those devices all electrical circuits are enclosed in tight casings made of epoxy resin, whose main function is the electrical insulation of the device. It must ensure that it carries away heat produced inside the transformer. To assure the proper fulfilment of these tasks, the transformer epoxy casing must be free of any internal failures, such as air voids or material discontinuities. This type of electrical transformers are produced in so called Vacuum Casting Technology. In this technology the internal elements of the transformer are placed in a mould which is then filled with an epoxy resin composition. After the introductory curing in the mould, the casting is further cured outside the mould by heating it in a tunnel furnace. One of the types of transformers produced in this technology are instrument electrical transformers, which are commonly used in measuring and controlling systems of power plants. They separate measuring instruments from primary circuits, and prevent any damage due to short-circuit currents. They can also extend the measuring range of standard devices.

EXPERIMENTAL RIG

Based on the dimensions of the common voltage transformer UMZ-24 produced in ABB's plant in Poland, the experimental stand for the casting of such a transformer is designed and built. On this experimental stand two experiments were carried out, the first isothermal one with analog liquid and the second non-isothermal one with epoxy resin [2]. The experimental stand was the same in both experiments (see Figure 1) and consists of: glass tank (casting mould), inner transformer elements and resin feeding system. The mould in the experiment has been made of glass to allow us the tracing and filming the position and shape of the liquid free surface. The main internal parts of the voltage transformer are: core made of steel sheets, primary and secondary coils wounded concentrically around one arm of the core, connectors which establishes connections between windings and phase terminals (Figure 2).

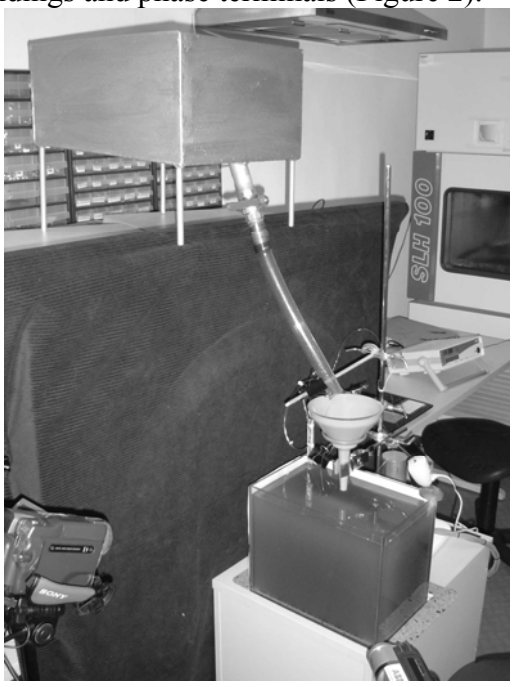

Figure 1. Casting experimental rig.

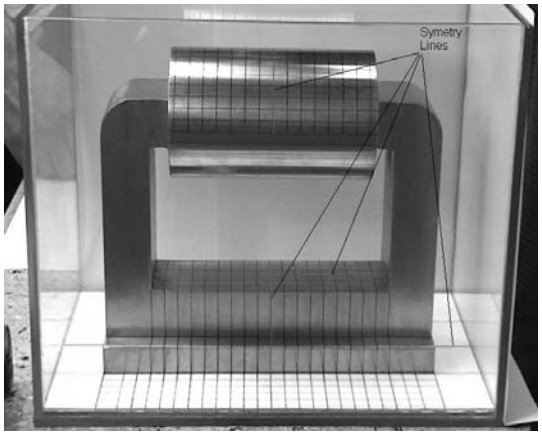

Figure 2. Mould made of glass and Internal parts of the transformer.

Original geometry of internal transformer parts has been simplified. Moreover the core and the coil have been made of one solid piece of steel whose properties are well defined. The feeding system was designed as a gravitational one (Figure 1) where the driving force is the difference between the free surface of the liquid in the main tank and the level of the inlet to the mould. On the surfaces of

the selected internal elements, grids have been plotted which would allow us to validate the free surface mapping. Three digital cameras were used to film both experiments. Their location assured the best capture of the shape of the flowing free surface. Two experiments were carried out on the experimental stand [3]. The first one was isothermal experiment with analog liquid with highly nonlinear viscosity. In the second one, performed in non-isothermal conditions, epoxy resin was used. In the non-isothermal experiment temperature of the epoxy composition during the experiment was measured with a coat thermocouples placed in the funnel and inside the mould.

MATHEMATICAL MODEL OF THE CASTING PROCESS

Numerical model in case of isothermal experiment encompassed mould inner and a part of the feeding pipe. In case of the non-isothermal experiment, computational domain was extended to include also mould walls. Geometrical model and numerical grid was created with use of commercial code *Gambit*. Since two symmetry planes can be spotted in the mould, numerical models were restricted to its quarter. Calculations for isothermal experiment were preformed on three different grids with 145753, 255278 and 509420 hexahedral cells. Therefore the numerical model consists of the mould interior, internal transformer elements and the walls of the mould. For these calculations only one grid is used with 314374 hexahedral cells [3]. Mathematical model and CFD calculations were carried out with commercial code *Fluent*.

Governing equations

The Volume of Fluid (VOF) formulation was chosen to describe multiphase flow [5] in casting process. In this approach, for each phase the volume fraction α_i of that specific phase in a computational cell of the domain is defined. In analysed problem two phases were considered: liquid phase *l* and gas phase *g*. Liquid phase volume fraction α_l is governed by the following transport equation:

$$\frac{\partial \alpha_l}{\partial \tau} + \nabla \cdot (\alpha_l \mathbf{w}) = 0 \tag{1}$$

where **w** is the fluid velocity vector. The volume fraction of the gas phase is calculated using following formula:

$$\alpha_g = 1 - \alpha_l \tag{2}$$

Transport equation for polymerization reaction progress β (degree of cure):

$$\frac{\partial \beta}{\partial \tau} + \nabla \cdot (\beta \mathbf{w}) = R_\beta \tag{3}$$

where R_β is the reaction rate.
A single momentum equation is solved throughout whole domain:

$$\frac{\partial \rho \mathbf{w}}{\partial t} + \nabla \cdot (\rho \mathbf{w}\mathbf{w}) = \rho \mathbf{g} - \nabla p + \nabla \cdot \left(\mu \left(\nabla \mathbf{w} + \nabla \mathbf{w}^T\right)\right) + \mathbf{F}_\sigma \tag{4}$$

where ρ is the density, p pressure, μ dynamic coefficient of viscosity and $\mathbf{F}_\sigma$ is the body force due to surface tension:

$$\mathbf{F}_\sigma = 2\sigma \frac{\rho \kappa_l \nabla \alpha_l}{\rho_g + \rho_l} \tag{5}$$

where σ is the surface tension between liquid and gas phase and κ_l is curvatures of phases interface. The energy equation is shared by both phases:

$$\frac{\partial \rho h}{\partial t} + \nabla \cdot \left[\mathbf{w}(\rho h + p) \right] = \nabla(\lambda \nabla T) + R_\beta \Delta H \tag{6}$$

last term on the right hand of equation is a heat source due to polymerization reaction, h is enthalpy of the two-phase mixture and ΔH is the heat of reaction. The properties which appear in the governing equations are calculated as a volume-weighted average.

Physical properties

Most important properties which influence a real-life process and numerical computation as well are viscosity, surface tension and in case of epoxy resin polymerization reaction kinetics. Since both fluids used in experiments were not described in available literature, their properties were measured. Surface tension was determined with du Nouy ring tensiometer Krüss K-800. Rheological properties were measured with AR2000ex rheometer from TA Instruments. Epoxy resin reaction kinetics were established with use of Netzsch STA409 differential scanning calorimeter. Obtained rheological and kinetics models where implemented in mathematical model through user defined functions capability.

Analog liquid rheological model. Analog liquid used in isothermal experiment revealed highly non-Newtonian rheological properties, which successfully can be described by Cross model:

$$\frac{\mu - \mu_\infty}{\mu_0 - \mu_\infty} = \frac{1}{1 + (k\dot{\gamma})^n} \tag{7}$$

where μ_0, μ_∞, k, n are the model parameters and $\dot{\gamma}$ is shear rate. Figure 3 presents measured flow curve fitted with Cross model.

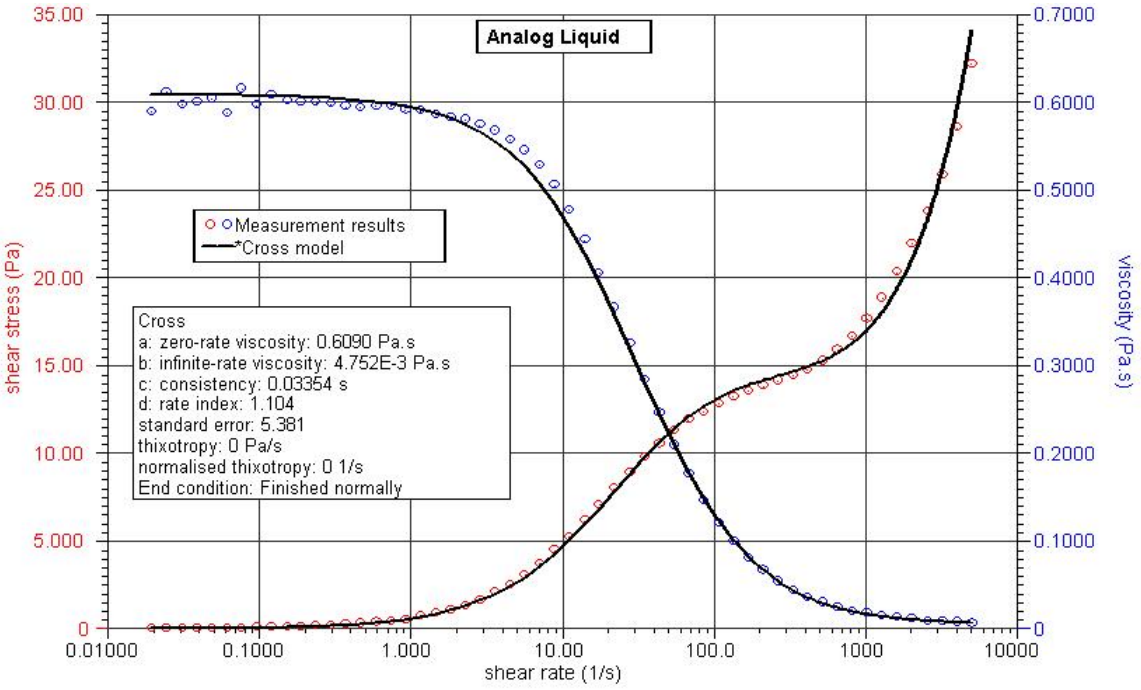

Figure 3. Flow curve of analog liquid.

Epoxy resin rheo-kinetic model. In non-isothermal experiment commercial epoxy composition EPR04820+EPH860 from Bakelite AG was used. To resolve coupling between rheological properties, temperature and reaction progress, simultaneous rheological and calorimetric measurements were done. First calorimetric data were elaborated and reaction kinetics model determined [6]:

$$R_\beta = \frac{\partial \beta}{\partial \tau} = \exp\left(-\frac{E_\beta}{RT} \right) \left[k_1 \beta^{m_1} (1-\beta)^{n_1} + \left(k_2 + k_3 \beta^{m_2} \right) (1-\beta)^{n_2} \right] \tag{8}$$

where E_β, k_1, k_2, k_3, m_1, m_2, n_1, n_2 are model parameters, R is the universal gas constant and T is temperature. Obtained reaction rate model as a function of reaction progress (degree of cure β) for a few different temperatures is presented in figure 4. Having reaction rate kinetics, parameters of Macosko-Cross rheological model were calculated [4]:

$$\mu = \mu_0 \exp\left(\frac{E}{RT}\right)\left(\frac{\beta_g}{\beta_g - \beta}\right)^{c_1 + c_2\beta} \tag{8}$$

where μ_0, E, c_1, c_2 are the model parameters, β_g is resin gelation point. Figures shows resin viscosity measurement results compared with Macosko-Cross model.

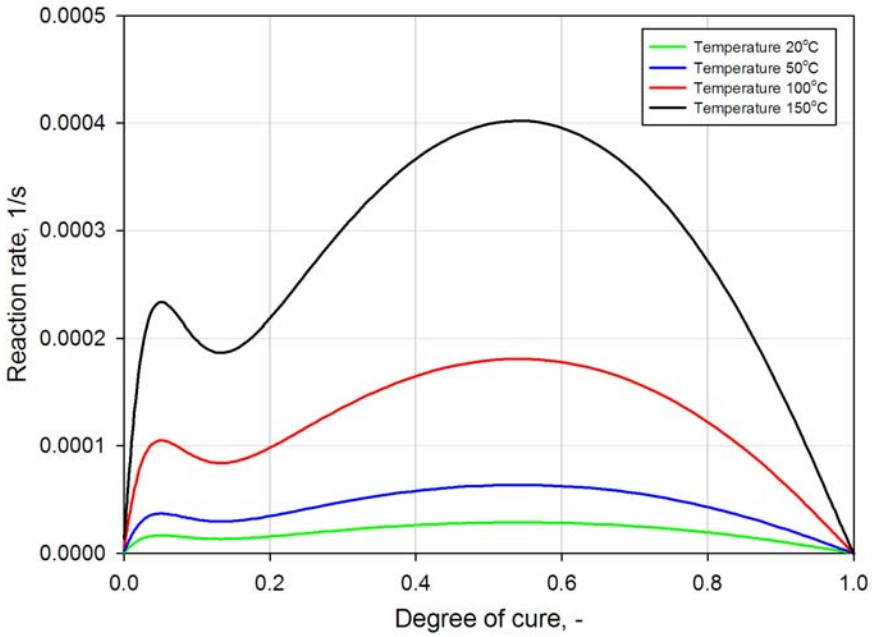

Figure 4. Plot of reaction rate kinetics model against degree of cure for a few different temperatures.

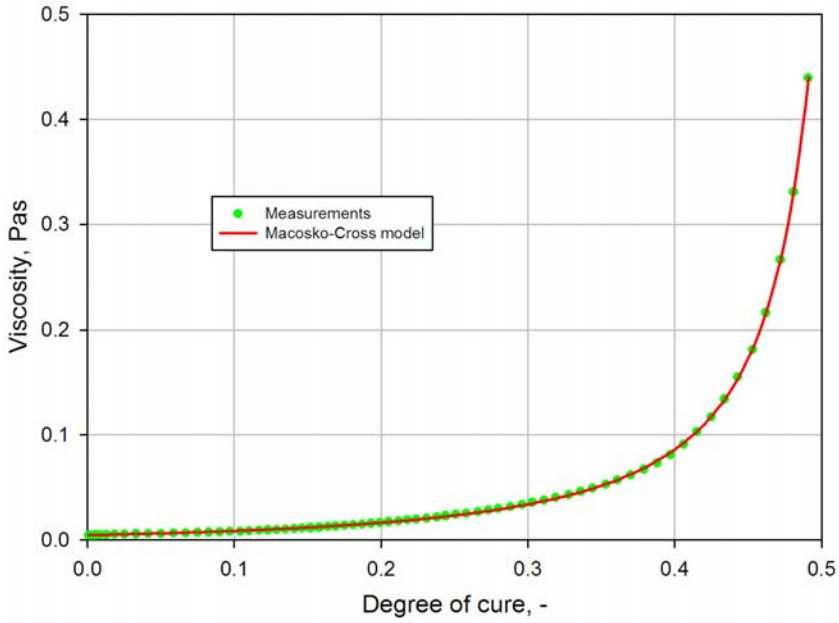

Figure 5. Comparison of measured resin viscosity fitted with Macosko-Cross model at temperature 150°C and shear rate 143 1/s.

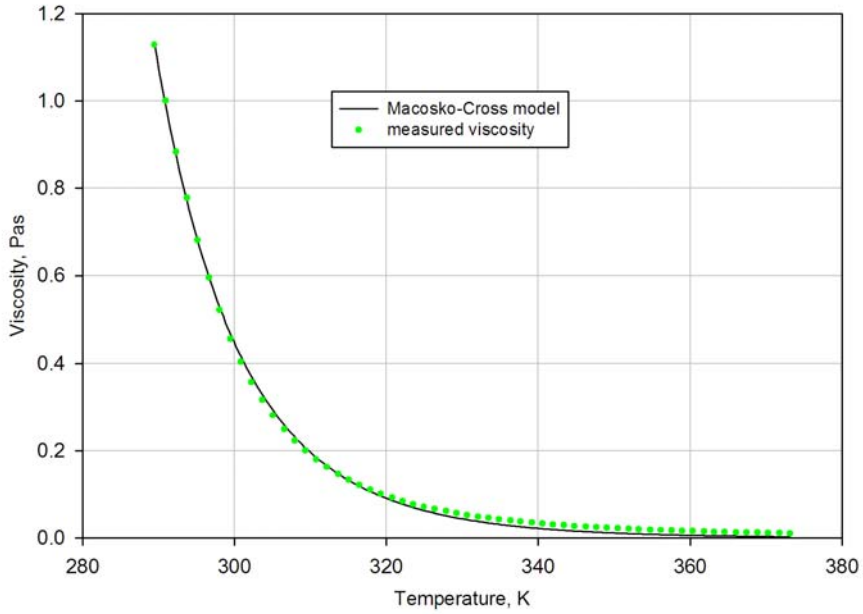

Figure 6. Comparison of measured resin viscosity fitted with Macosko-Cross model in temperature range from 15 ^{o}C to 100^{o}C at shear rate 143 1/s.

RESULTS AND CONCLUSIONS

Main objective of this work was to developed validation procedure for casting process. To be able to quantitatively compare experimental results with simulations on some of surfaces inside the mould measuring grid was plotted. This allowed us to measure some of the two phase flows features, giving the means for simulation validation. One of measured quantity was the liquid film width formed at the transformer coil. In tables 1 and 2 results for isothermal and non-isothermal experiments are compared with computations results. Since for isothermal experiment calculations were done on a few numerical grids it allowed us to calculate extrapolated solution with Richardson extrapolation rule (see Table 1).

In case of non-isothermal experiment thermocouple were placed inside the mould to compare with simulation results. In figure 7 exemplary temperature reading from one of thermocouples is compared with simulation result.

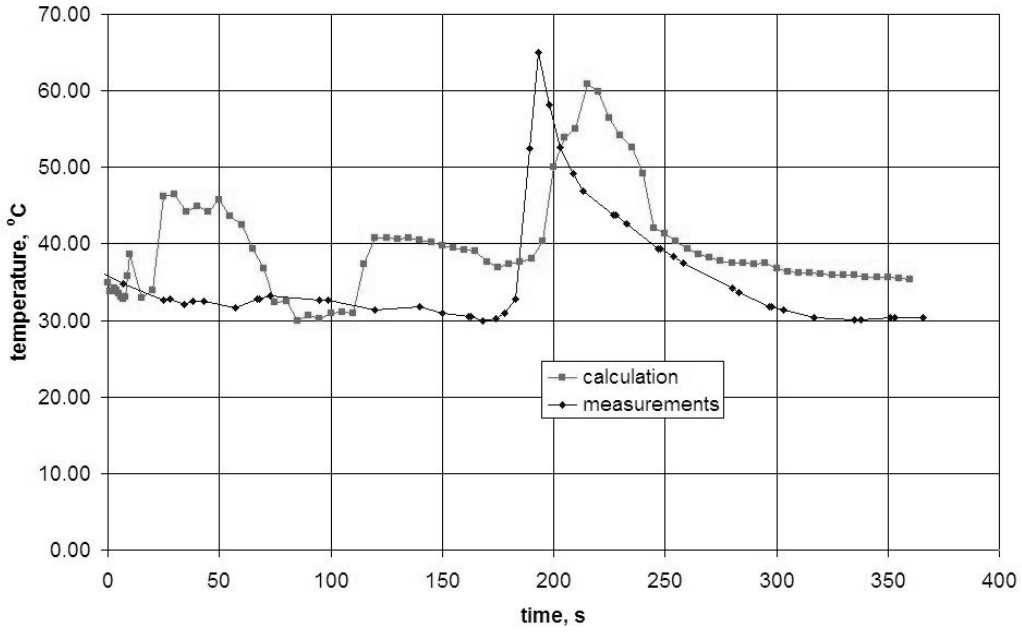

Figure 7. Comparison of temperature reading from thermocouple placed inside the mould with calculation results.

Summarizing, simulation results show good agreement with the experimental data. Solutions found with the use of the Richardson extrapolation method corresponded very well with the measured value of width of liquid stream at the transformer's top. Although the Richardson extrapolation procedure is restricted to smooth solution which is in asymptotic grid convergence region and to grids with uniform spacing, it was successfully applied in this complex case with a nonuniform grid present and solution discontinuities.
The results obtained for the second case are not as good and discrepancy between the calculated and measured results were significant. However, still some of the effects observed during the experiment were successfully captured by the numerical simulations e.g. the liquid stratification.

ACKNOWLEDGEMENTS

Research has been financed by the Polish Ministry of Science and Higher Education within the grant N512 022 31/2577 and by the BK funds. This help is gratefully acknowledged herewith.

EXPERIMENTAL INVESTIGATION OF THE SWIRL OF THE LIQUID METAL FLOW PRODUCED BY THE NON-UNIFORM ELECTRIC CURRENT

V. Zhilin, Yu. Ivochkin, A. Oksman, I.Teplyakov*
Joint Institute for High Temperatures RAS, Moscow, Russia

ABSTRACT. The results of the experimental and numerical investigation of the electrovortex flow formed at non-uniform electric current passing through the liquid metal volume are presented. The experiments were carried out on the working section which was the copper hollow hemispherical container filled with eutectic alloy In–Ga–Sn. The electric current value was up to 400 A. Experimental data on the velocity fields are presented. Measurements of different velocity components were carried out by the unique fiber-optical transducers. A swirl of the flow in azimutal plane was revealed and it was shown that the cause of this swirl is the external magnetic field. A numerical calculation of the electrovortex flow subject to the external magnetic field was carried out and satisfactory correspondence between calculation results and experimental data was received.

Keywords: *liquid metal, electric current, magnetic field, velocity, swirl*

INTRODUCTION

Among the different types of magnethydrodynamic flows with liquid-metal heat-transfer medium, the so-called electrovortex flows (EVF) formed as a result of the interaction between of the electric current passing through the electroconductive liquid and the electric current's own magnetic field are of special interest for investigators [1]. Investigation of the electrovortex flows has not only fundamental orientation but also is of great importance for different branches of machine-building, energetics and metallurgy. For example, EVF affects the quality of the weld at submerged arc welding and the presence of EVF changes the evolution dynamics of electroslag remelting.

Usually electroslag technological processes of welding and remelting are investigated by physical modeling method by the apparatus where electric current spreads into the volume of electroconductive liquid from the point source (electrode) located on the surface of the liquid metal [2]. It is assumed that under this condition EVF formed as the result of the electric force action $\mathbf{F_{el}}=\mathbf{j}\times\mathbf{B}$ is the toroidal curl with a jet directed down under the electrode. Such 2D axisymmetric approximation is convenient for the numerical and theoretical investigation of EVF and demonstrates value in practice of application of the velocity stream structure reconstruction method in the volume of liquid metal by the shape of surface flows. However, observation results both in model experiments and in industrial apparatus are evidence of conditions under which the azimutal swirl appears and the stream becomes 3D. Evidently, the effect of swirl can raise due to the increase of instability in convergence flow or can be connected with the influence of magnetic field of the

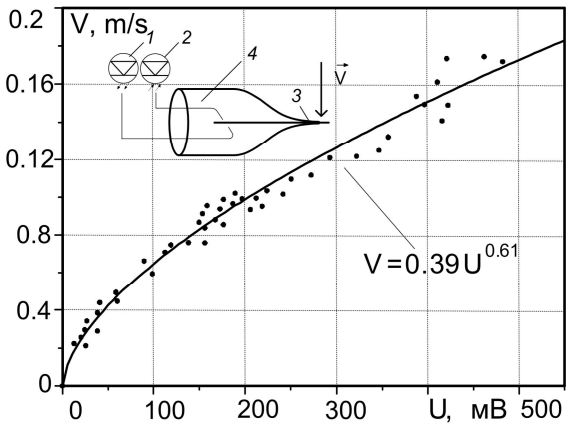
Earth and power wires, and Coriolis effect. In our opinion the second factor out of the listed above is the most important one. The aim of the presented investigation was to verify this suggestion.

EXPERIMENTAL APPARATUS AND MEASUREMENT METHOD

The experiments were carried out on the apparatus the scheme of which is shown on fig.1. An eutectic alloy In-Ga-Sn with content by weight Ga – 67%, In – 20.55, Sn – 12.5% (melting temperature +10.5 ^{0}C) was used as a working liquid. The hollow copper hemispherical container with 188 mm diameter serving as a big electrode was filled with the alloy. The small electrode was made of copper, too, in the form of a convex hemisphere and its diameter could be varied from 3 up to 6 mm. The source developed on the basis of three-phase rectifier of alternating current was used for power supply of experimental installation. The electric current value was varied in the range 50 – 400 A. The power wire containing both vertical and horizontal sections was located in 0.15 – 1 m from the apparatus axis. To measure velocity in the volume of current-carrying liquid the fiber-optical transducer (fig.2) was used. Its construction and working principle are described in [3].

The probe of the fiber-optical transducer (as well as the temperature sensor) was L-shaped and attached to the traverse gear which allowed moving the probe in three perpendicular directions. The output signal form measuring sensors (of temperature and velocity) was amplified and filtered by the signal forming units and then applied to analog-to-digital converter and then was processed on the computer.

Experimental apparatus. 1 – copper container; 2 – eutectic alloy; 3- sensor of fiber-optical transducer; 4 – probe; 5 – small electrode; 6 – power wire; 7 – thermocouples; 8 – thermocouple probe; 9 – amplifier; 10 – analog-to-digit converter; 11 – computer; 12 – water-cooling system; 13 - power source.



Figire 2. Scheme of fiber-optical transducer and calibration curve. 1 – photodiode; 2 – light-diode; 3 – sensor;4 – fibre.

The calibration of the fiber-optical transducer was carried out in the air jet and then was calculated for eutectic alloy stream. The form of the gauge dependence typical for fiber-optical probes (for range of velocity 0 – 0.2 m/s) is shown on fig. 2. The thermocouple probe made of two copper and constantan wires with 0.075 mm diameter was used to measure temperature.

The analog-to-digital converter La2M3 by *Rudnev-Shilyaev* with 16 channels and 12 digits allowing to make a numbering with a maximum frequency of 500 kHz was used as secondary equipment as well as the set of measuring devices by *National Instruments.* An original precision amplifier with 8 channels of our own production was used to coordinate the electric signal level of the fiber-optical transducer and thermocouple with this ADC. The visualization of the surface flow with the help well observed hydrogen bubbles produced at the contact of 3% HCl and the liquid metal surface was carried out.

MATHEMATICAL DESCRIPTION OF PROCESSES AND CALCULATION METHOD

As mentioned above EVF is formed as the result of the interaction of the non-uniform electric current with density **j** with its own magnetic field **B** (fig.4). Navier-Stokes's equation describing hydrodynamics of the electrovortex flows looks like:

$$\rho\left(\frac{\partial V}{\partial t}+(V\nabla)V\right)=-\nabla p+\rho\nu\nabla^2 V+\rho g+F_{el} \qquad (1)$$

Where $\mathbf{F}_{el}=\mathbf{j}\times\mathbf{B}$ – electromagnetic force producing the movement of electroconductive liquid.

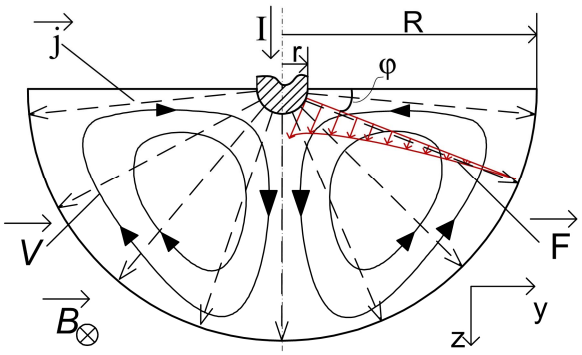


Figure 3. Scheme of EVF forming

For hemispherical geometry where current density depends on radius R as $j=\frac{I}{2\pi R^2}$, the expressions for magnetic field and electromagnetic force in liquid metal have the following form:

$$B_{evf}=\frac{\mu_0 I(1-\cos\varphi)}{2\pi R\sin\varphi} \text{ and } F=\frac{1}{4}\frac{\mu_0 I^2(\cos\varphi-1)}{\pi^2 R^3\sin\varphi}$$

Taking into account the external magnetic field produced by power wire the summary magnetic field in container has the form:

$\mathbf{B}_\Sigma=\mathbf{B}_{evf}+\mathbf{B}_\parallel$ for vertical power wire and $\mathbf{B}_\Sigma=\mathbf{B}_{evf}+\mathbf{B}_\perp$ for horizontal power wire.

The configuration of the magnetic fields produced by EVF proper and two current wires variously arranged in relation to the experimental installation axis is shown on fig.4.

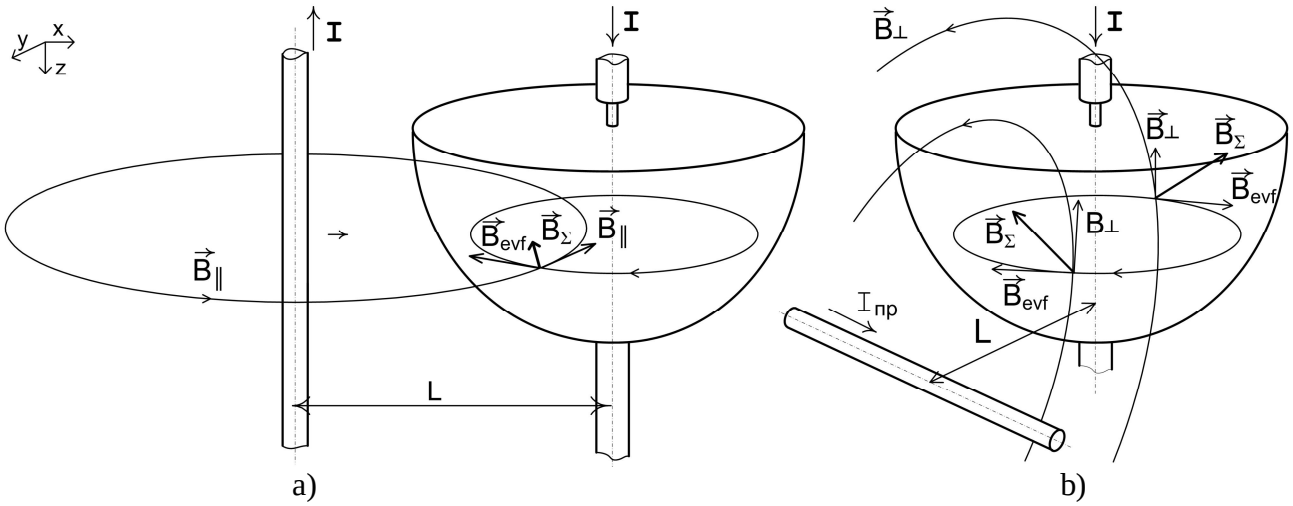

Figure 4. Configuration of the magnetics fields (a) verical wire, (b) horizontal wire.

The calculation area was the concentric hemisphere with radiuses corresponding to the small and big electrodes. Computation mesh consisted of the ~80000 tetrahedral elements. 3D steady and unsteady Navier-Stokes's equation with specified electric force was solved with the control volume method in Cartesian coordinate. K–ε turbulent model with standard parameter was used. As the motionless oxide film is formed on the free surface of liquid metal, the condition of the solid stationary wall was specified on the surface. The cases of absence of the external magnetic field and the presence of the field of vertical and horizontal power wire were considered.

RESULTS OF THE INVESTIGATION

At the same time the result of visual observation showed that there is flow swirl in horizontal plane (photo on fig. 6) accompanied by the formation of the funnel near the small electrode at the current over 400A. This funnel deepens as the electric current increases up to the electric arc forming and break of a circuit.

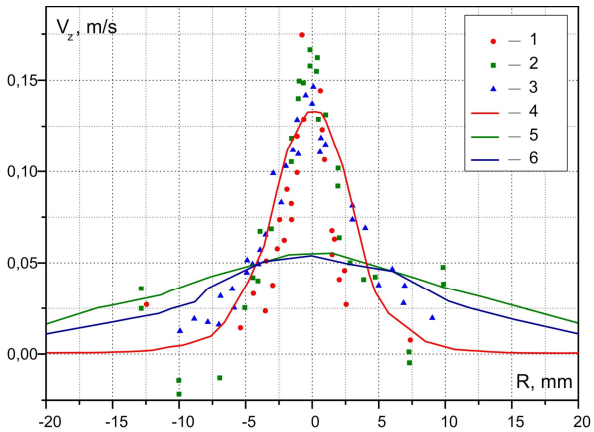

Figure 5. Velocity profile at different depth. Experiment: 1 – 2.5 mm; 2 – 20 mm; 3 – 30 mm; calculation 4 – 2.5 mm; 5 – 20 mm; 6 – 30 mm; I=250A.

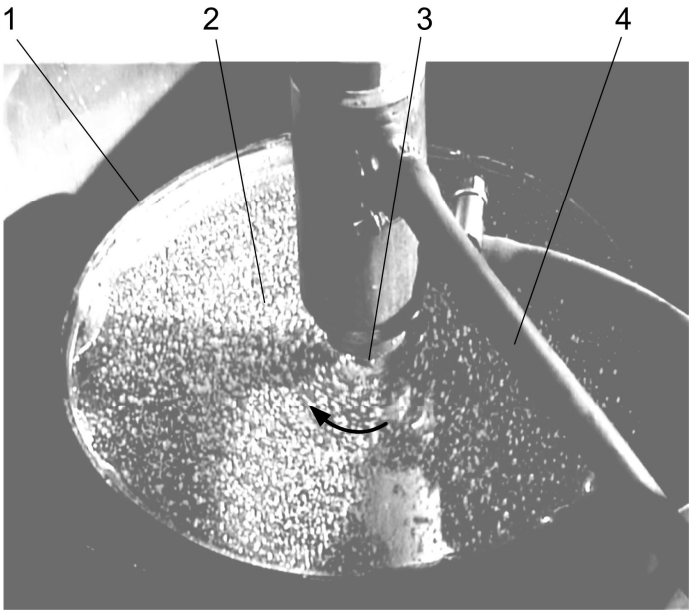

Figure 6. Visualizaton of rotation. 1 – Big electrode; 2 – surface of liquid metal with bubbles of hydrogen; 3 – small electrode; 4 –water-cooling system.

Theoretical estimates confirmed by calculation results show that the magnetic field of the vertical power wire (parallel to experimental installation axis) does not lead to the swirl of the stream and do not distort flow on the whole. On the contrary force interaction of the magnetic field of the horizontal power wire and electrovortex flows leads to the swirl of the liquid metal in the horizontal plane. This process is accompanied by the formation of the axis upward flow suppressing EVF
The latter effect is registered by fiber-optical transducer of velocity. (Fig. 7).

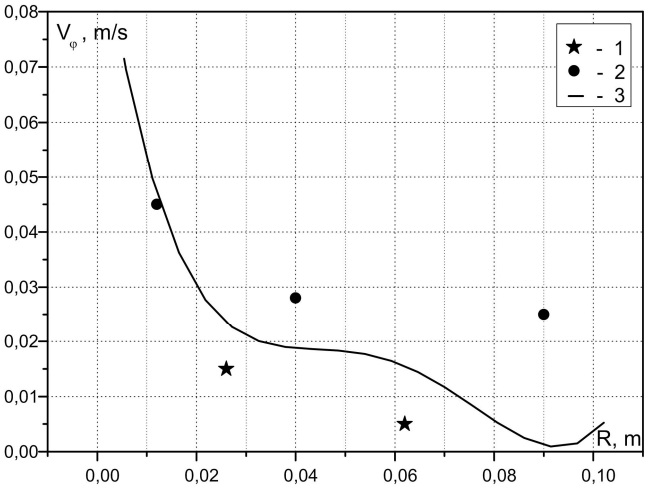

Figure 7. Dependence of azimutal velocity on radius. 1 – Experiment with fiber-optical transducer (z=5 mm); 2 – visualization; 2 – calculation (z=5 mm). I=400A.

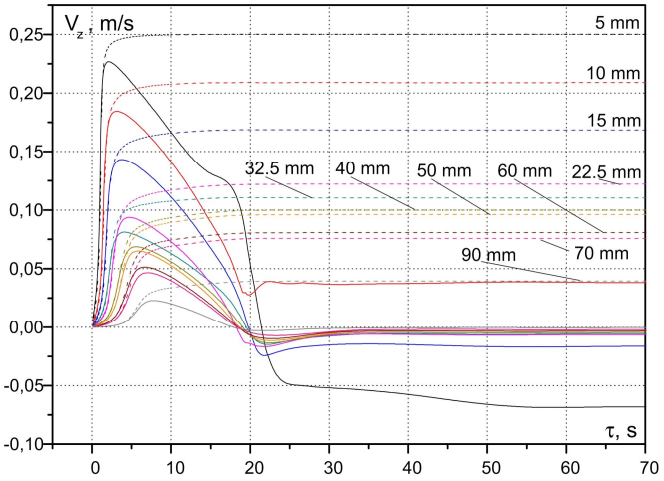

Figure 8. Dependence of vertical velocity on time with external magnetic field (—) and without (---) at different depth. I=400A.

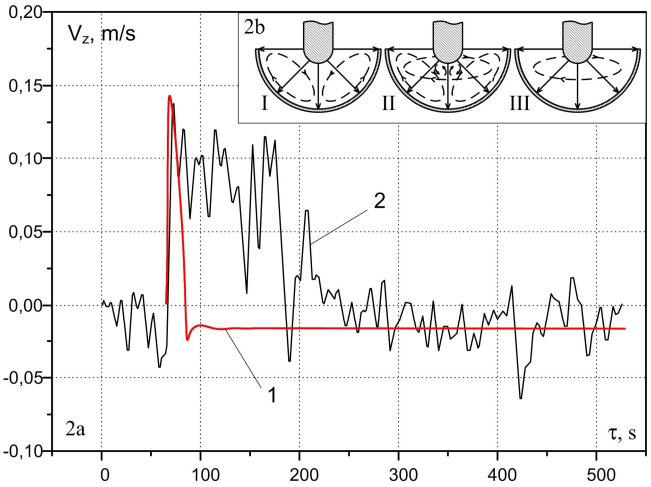

Figure 9. Comparison of the results of the unsteady calculation of the axis velocity under electrode and measurement results. 1 – calculation; 2 – experiments. I=400A, z=11.5 mm.

On the ground of the received data we can suggest the following scheme of the evolution of the electrovortex flow with presence of the external magnetic filed of the horizontal power wire. At first the toroidal curl with the central part in the shape of the jet directed to the bottom of the container is formed. (Fig. 9-I). Then the azimutal rotation appears and the upward flow is developed. (Fig. 9-II). And at last the upward flow is superimposed on EVF and suppresses it forming the stagnant zone. (Fig. 9-III).

CONCLUSIONS

The received experimental data supported the results of the calculations demonstrates the complicated 3D structure of electrovortex flow. The received experimental data supported the results of the calculations demonstrates the complicated 3D structure of electrovortex flow. This structure substantially differs from simplified two-curl flow model on the free surface of current-carrying liquid which is usually used as EVF [1].

Three-dimensionality of the flows in question is produced by azimutal swirl of stream stipulated by the strong dependence of EVF stability from external magnetic field which always present in model and industrial experiments.

The authors express gratitude to Belov K.I and Lozina E.Y. for the help in carrying out the experiments and the calculations.

ABSTRACT. The solidification and cooling of Al alloys elaborated under helium have been thoroughly investigated. Al alloys cast under helium in steel mould have solidified and cooled faster than the ones made under air. The solidification time has been reduced by up to 25% and the overall cooling time has been decreased by up to 45% in steel mould. A second set of experiments were carried out in order to estimate the improvement of the heat transfer coefficient under Helium. Thermal inverse analysis was employed in order to estimate the heat flux at the interface chill/aluminium. Then heat transfer coefficient was deduced from the estimated heat flux and calculated temperatures on both sides of the interface chill/aluminium. Heat transfer coefficient values of 3300 $W.m^{-2}.K$ have been calculated under helium against 1800 $W.m^{-2}.K$ under air.

Keywords: *Aluminium alloys, casting under Helium, inverse heat flux problem.*

INTRODUCTION

Aluminium (Al) alloys are attractive due to its high mechanical properties to weight ratio. The use of Al alloys in the transport industry allows reducing the weight of the vehicles and, consequently, leads to low petrol consumption. Mechanical properties of Al alloys rely heavily on the cooling rate during casting. Greater is the cooling rate, smaller will be the grain size and the secondary dendrite arm spacing what leads to better tensile strength and ductility [1].

In casting process, the heat is transferred from the core (casting) to the mould (sand, steel, copper…) and, finally dissipated by either radiation, convection or a cooling system. In die casting, the interface mould/casting represents a barrier to heat transfer because of the air gap. Furthermore, during the solidification the casting shrinks what leads to larger air gap and low heat transfer at the interface. In the aim to improve the heat transfer at the interface mould/casting, air was replaced with helium. Helium thermal conductivity (0.275 $W.m^{-1}.K$) is 4 times greater than Air (0.058 $W.m^{-1}.K$) at same temperature. Argyropoulos et al. investigated the addition of Helium at the interface mould/casting [2]. They showed an increase of 30% of the heat transfer coefficient. The Helium was mainly applied to one surface of the casting. In this work, the mould and the casting are totally surrounded with Helium what allows a thorough investigation of the Helium effect from a thermal, metallurgical and mechanical points of view. The thermal point of view is proposed in this communication. A first experiment has been carried out to evaluate the helium effect on the solidification and the overall cooling of the casting.

The knowledge of the heat transfer coefficient at the mould/casting interface is necessary in order to perform accurate modelling of Al casting solidification. Better understanding of casting processes is made by simulation tools. The process is optimised by avoiding solidification defects such as shrinkage or better design of the feeding system, etc. A good solidification model requires

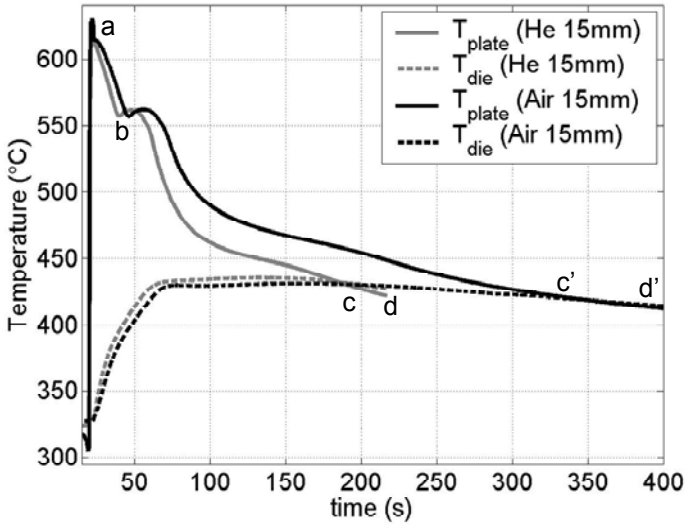
an accurate thermal modelling, good thermophysical properties of the material studied, a good knowledge of initial temperatures and thermal boundary conditions (namely heat transfer coefficient). A second experiment has been dedicated to the estimation of the heat transfer coefficient under helium. Temperature measurements in a steel chill and in Al casting have been done. Thermal inverse analysis was used in the aim to estimate the heat flux at the interface chill/casting. Then heat transfer coefficient (HTC) has been deduced from the estimated heat flux. HTC could have been evaluate by taking into account all the thermal resistance at the mould/casting interface (gaseous gap size, areas of contact, coating thickness, etc.) as did Hallam et al. [3]. HTC has been calculated for both cases: helium and air. Inverse thermal analysis allowed knowing the HTC at each time of the experiment.

In this communication, the first section deals with the effect of helium versus air on the cooling of the Al casting. Secondly, the experiment dedicated to the estimation of the HTC is described as well as its thermal modelling and its inverse thermal problem. Then the inverse analysis results are presented and discussed.

HELIUM EFFECT

Helium effect on the improvement of the heat transfer has been investigated in Argyropoulos et al[1]. Unfortunately their experiment could not show the overall effect of the helium on casting microstructure and mechanical properties. The developed experimental procedure answers to these points: the casting procedure is carried out entirely under helium. Thus, the effect of helium on the microstructure and the mechanical properties of the Al casting can be analysed in addition of the measured temperatures in the casting. In this communication, only the helium effect on the heat transfers is discussed.

In order to evaluate correctly the effect of the helium, an airtight chamber has been built connected to a vacuum pump and helium gas cylinder. Inside the chamber, a 12 kg furnace is used to melt the aluminium bars. Then the molten aluminium is poured in the cast iron mould. The cast iron mould has been used to make aluminium plates of several thicknesses (5 mm, 15 mm and 25 mm). Cooling curves for the 15 mm thickness aluminium plates are presented in figure 1. 15 mm thickness plates have been cast in air and in helium.



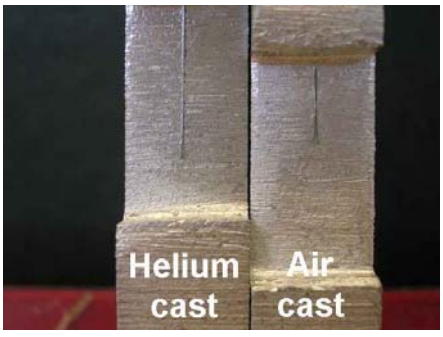


Figure 1. Cooling curves in the cast iron mould (dashed lines) and in the aluminium plate (full lines). Two cases are exhibited: one aluminium plate has been cast in air (black curves) and the second one in helium (grey curves). Picture on the left: position of the thermocouple head in the aluminium plates.

The operating conditions were:

- Melt the aluminium and keep the temperature of the molten aluminium around 770-780ºC (the chamber is set under partial vacuum to avoid any hydrogen absorption by the molten aluminium);
- Warm the cast iron mould to 360-370ºC;
- Fill the chamber with helium until its concentration is equal or upper to 95%.

The temperatures of the molten aluminium and the cast iron mould were almost the same for each experiment undertaken under air and under helium (within ±5ºC).

The cooling temperatures for each Al castings are presented in figure 1. The black curves denote the experiment carried out under air while the grey ones symbolise helium experiment. Similar thermal behaviours have been observed with plates of 5 mm and 25 mm thickness plates. The start of the solidification process is noticed with the first dentritic formation (point a, figure 1) around 615ºC followed with the eutectic plateau (point b, figure 1) around 555ºC. The solidification of the aluminium under helium started earlier than under air.

The reduction of the solidification time was about 25% under helium. Moreover the temperature of the aluminium under helium has reached the mould temperature in less than 3 min (c) while it was about 5 min and a half under air (c'). That means a decrease of 43%-45% of the cooling time of the plate. Then the cooling curve of the casting-mould set beyond point (d) under helium seems to decrease faster than the one at point (d'). Helium affects both the solidification and the global cooling of the casting. Its effect is not linear with the time: firstly the solidification time has decreased about 25%, secondly the global cooling of the casting is superior to 40%.

The position of the type K thermocouples located into the Al castings have been checked, figure 1 left. The thermocouples were both well positioned in the middle of the plates.

The modelling of the casting process is an approach to better understand the different casting mechanisms. One of the most important parameters is heat transfer coefficient at the metal-mould interface. The effect of helium atmosphere on the casting process is significant but the heat transfer coefficient at interface is not known so far. An experiment has been designed in order to evaluate it.

ESTIMATION OF THE HEAT TRANSFER COEFFICIENT

Experimental setup

The experiment consists in casting an aluminium bar in a refractory tube inserted on a H13 steel chill as depicted in figure 2. The steel chill is water cooled as it is commonly done industrially.

The operating conditions were the following:

- Firstly, the still chill is heated until the temperature of the steel at the interface steel / aluminium is about 250ºC.
- Then, the molten aluminium (A356), average temperature of 820ºC, is poured in the refractory tube.
- The water cooling system is switched on.

Three 0.5 mm diameter mineral-insulated type-K thermocouples were inserted into the chill, at distances of 5, 37.5, and 75 mm from the top of the chill. Other 0.2 mm homemade type K thermocouples were inserted in the casting and in the refractory tube. The thermocouple outputs were connected to a data-logger itself connected to a laptop, which recorded the thermal histories at these points in the chill, in the casting and in the refractory tube every 0.025 seconds, for approximately 10-15 minutes.

Measured temperatures inside H13 steel chill were used to estimate the heat flux at the interface steel / aluminium. An inverse heat flux problem has been developed for. Heat transfer coefficient

was deduced from this heat flux and the measured temperatures in the aluminium and in the steel chill. First of all, an accurate thermal modelling of the steel chill is required.

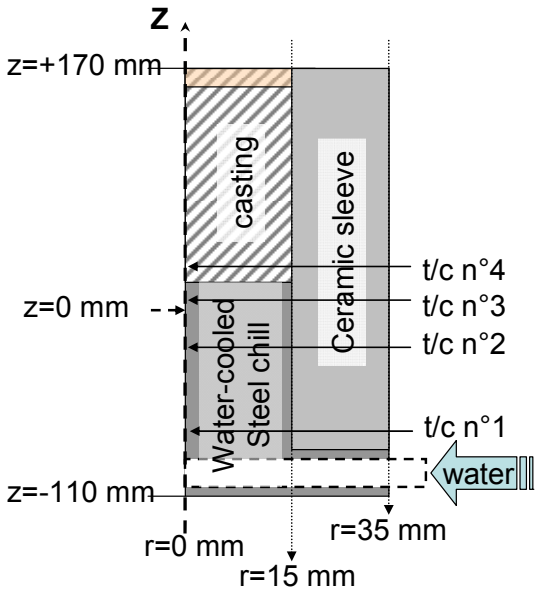

Figure 2. Experimental H13 steel chill used for the estimation of the heat transfer coefficient at the interface steel / aluminium. The steel chill is water cooled at the bottom and the molten aluminium is poured in a refractory tube (thermal insulator) put on the steel chill.

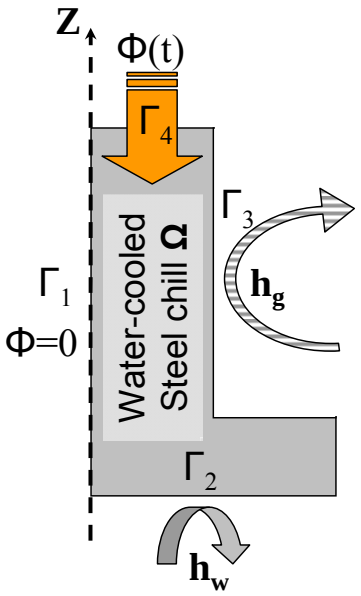

Figure 3. thermal modelling of the H13 steel chill. A global convective coefficient (h_g) is considered on the lateral frontier of the steel chill to take into account the refractory tube. The interface steel/aluminium is subjected to a heat flux. The water cooling is modelled as a convective exchange.

Thermal modelling

A sketch of the thermal modelling of the steel chill is presented in figure 3. Problem geometry is two dimensional axi-symmetric. Lower part of the steel chill is cooled with water, figure 3. Heat loss on the lateral frontier of the steel chill is modelled with convective exchange (the inverse of the refractory thermal resistance: R_g with $h_g = 1/R_g$). The heat transfer at the steel/aluminium interface is modelled with a time dependent heat flux $\phi(t)$.

The stated thermal modelling is described with the following equations:

- the heat conduction equation in the H13 steel chill (domain Ω) during the studied time interval I :

$$\rho(T)C_p(T)\frac{\partial T}{\partial t} - \nabla(\lambda(T)\nabla T) = 0 \quad in\ \Omega \times I \tag{1}$$

- the boundary conditions:

$$-\lambda(T)\frac{\partial T}{\partial n_1} = 0 \quad on\ \Gamma_1 \times I \tag{2}$$

$$-\lambda(T)\frac{\partial T}{\partial n_2} = h_W(T - T_W) \quad on\ \Gamma_2 \times I \tag{3}$$

$$-\lambda(T)\frac{\partial T}{\partial n_3} = h_g(T - T_{room}) \quad on\ \Gamma_3 \times I \tag{4}$$

$$-\lambda(T)\frac{\partial T}{\partial n_4} = \varphi(t) \quad on\ \Gamma_4 \times I \tag{5}$$

- the initial condition:

$$T(r,z;t=0) = T_{room} \quad in\ \Omega \tag{6}$$

where $\rho(T)$, $C_p(T)$ and $\lambda(T)$ are respectively the density, the specific heat and the thermal conductivity of the H13 steel. h_W, T_W, h_g and T_{room} are respectively the water convective exchange coefficient, the water temperature, the inverse of the refractory tube thermal resistance and the ambient temperature. $\phi(t)$ is the heat flux exchanged between the steel chill and the aluminium.

The heat transfer coefficient HTC can be defined as follows:

$$\phi(t) = HTC.(T_{chill} - T_{casting}) \quad \text{on } \Gamma_4 \times I \tag{7}$$

Therefore HTC can be deduced from the heat flux when steel and aluminium temperatures are known at the interface. The statement of the inverse heat flux problem is briefly described in the next section.

Inverse Heat Flux Problem

The inverse heat flux problem can be stated as follows:

Let's find $\phi(t)$, the unknown heat flux, such as $T(r,z,t;\phi) = \hat{T}_m(t;\phi)$ where $T(r,z,t;\phi)$ are the calculated temperatures from the thermal modelling, $\hat{T}_m(t;\phi)$ are the measured temperatures at the thermocouples and $m = 1, n_{th}$ is the number of thermocouples.

This expression can be formulated to least square sense, so the problem consists in minimizing the following cost function $J(T,\varphi)$:

$$J(T,\varphi) = \int_{t_0}^{t_f}\int_{\Omega}\sum_{m=1}^{n_{th}}\left(T(r,z,t;\varphi) - \hat{T}_m(t)\right)^2 \delta(\vec{x} - \vec{x}_m)dtd\Omega \tag{8}$$

Due to the high non-linearity of the thermal problem (temperature dependent parameters, high temperature variations) and the high number of heat flux parameter to estimate (one for each time step of the simulation), a regularization technique is necessary in order to solve and stabilize the formulated inverse problem. The conjugate gradient method developed by O.M. Alifanov [4] has been employed to solve this inverse heat flux problem.

The overall principle of the inverse heat flux problem regularized with the conjugate gradient method is the following (details of the method are given in Alifanov [4]):

Load experimental data

[1] Inverse heat flux loop starts:

Solve **Direct problem** (thermal problem),

Export calculated temperatures $T(x,t)$ at each sensor positions,

Compute cost function $J^n = \sum\left(\theta(x_i,t) - \hat{\theta}_{meas}(t)\right)$, test if $J^n < J_{stop}$ else go to [2],

Solve **Adjoin problem** (derivated from the thermal problem in the order to compute the cost function gradient $J'(T,\phi)$),

Compute the descent direction $d^n = J'(T,\phi) + \beta_n d^{n-1}$,

Solve **Variational problem** (in order to compute the descent depth γ_n),

Compute the descent depth γ_n,

Compute the new estimated heat flux $\bar{\phi}^{n+1} = \bar{\phi}^n + \gamma_n \bar{d}^n$ go back to [1]

End loop

[2] Display estimation results.

EXPERIMENTAL RESULTS

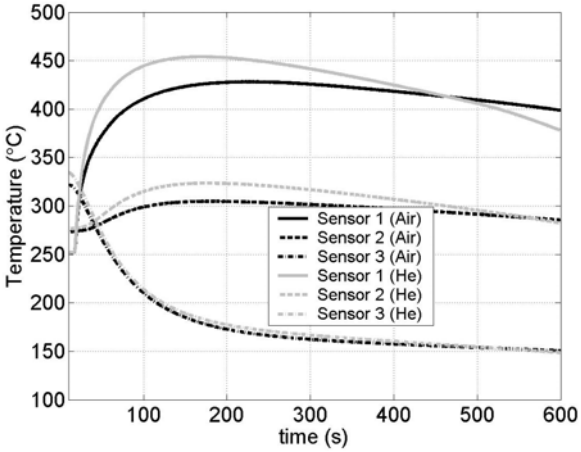

Figure 4. measured temperatures through the depth of the steel chill under air (black curves) and under helium (grey curves).

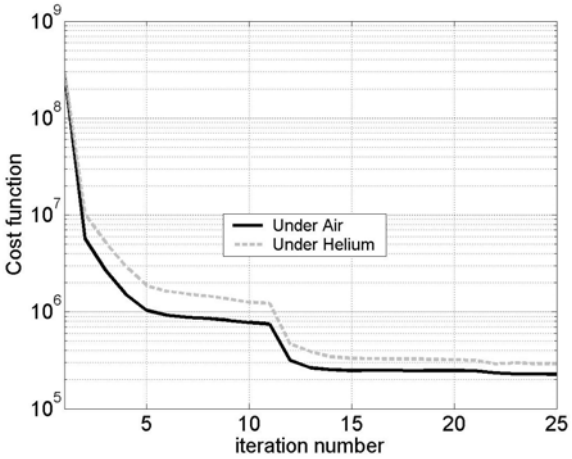

Figure 5. Cost function evolutions for each investigated inverse heat flux problems.

Let's compare the measured temperatures in the steel chill for both conditions: under air and under helium. These experimental data are plotted in figure 4: black curves denote air experiment while the grey curves are for helium. The steel chill heated higher and faster under helium than under air. The thermocouple located to the closest to the interface has risen slightly over 450ºC while it was only 425ºC under air. Steel chill started cooling faster under helium than in air after it has reached his maximum temperature.

These experimental data were used in the inverse heat flux problem in order to estimate the heat flux at the interface mould/casting under helium and under air. Evolutions of the two cost functions are presented in figure 5. The two cost functions have the similar trend. An important decrease is observed in the first 5 iterations as the inverse heat flux problem converges towards the solution. The two cost functions stabilized around a value of 2.10^5 what corresponded to an average standard deviation about $\pm 8°C$ between measured and calculated temperatures as it can be seen in figure 6.

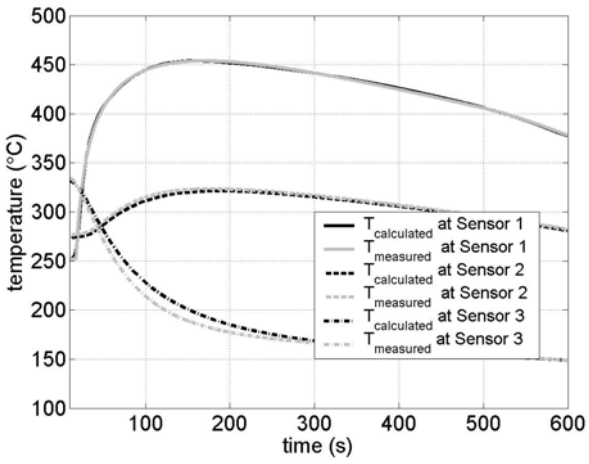

Figure 6. Comparison between measured and calculated temperatures once the inverse heat flux problem was solved (helium experiment).

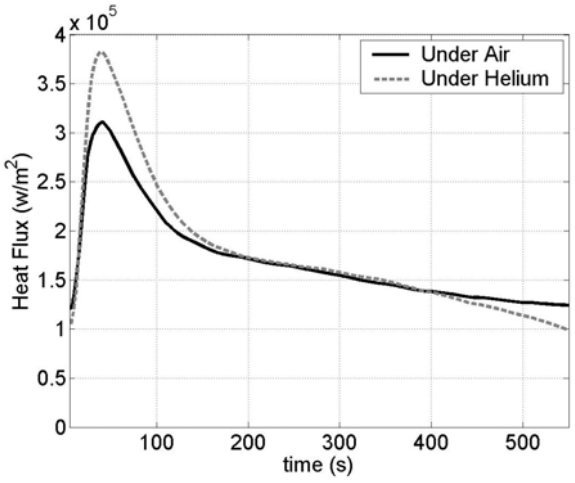

Figure 7. Estimated heat fluxes at the interface mould / casting. Air experiment: black curves; Helium experiment: grey curves.

Calculated and measured temperatures fit quite well except for the thermal sensor which is the closest to the water cooling boundary. The convective exchange coefficient was underestimated on this boundary.

The two heat flux solutions of their respective inverse problem are reported in figure 7. Maximum heat flux values can be of few $kW.m^{-2}$ with sand moulds to few $MW.m^{-2}$ with copper moulds [5]. Maximum heat flux values under helium are about 23% higher than the one under air. The heat flux values under helium are greater than the one under air in the first 180 seconds of the experiments. Then these values remains quite similar between $180\ s$ and $400\ s$. Heat flux values under helium dropped beyond $t \geq 400\ s$. The decrease of both estimated heat fluxes can be decomposed in two parts: the first one starts from the maximum reached value to time $t \sim 110\ s$ and the second one beyond $t \geq 110\ s$. This special time corresponds to a temperature about $555°C$ in the aluminium at the interface mould/casting, figure 9 (temperature of the eutectic plateau). Heat flux rate slowed as the aluminium is solid at the interface mould/aluminium and shrinks, generating a gaseous gap at the interface mould/aluminium what slows the heat transferred through the interface.

Estimated heat fluxes have been used in a second thermal simulation (including the refractory tube and the solidifying aluminium). This thermal simulation allowed calculating the temperature of the aluminium at the interface chill/casting. Then heat transfer coefficients (HTCs) were deduced from previous heat fluxes according to the formula (7). HTCs are presented in figure 8. The HTC calculated under air reached a maximum value of $1700\ W.m^{-2}.K^{-1}$, in the first $50\ s$. Then this value stabilized around $1600\ W.m^{-2}.K^{-1}$ over the remaining time. These HTC values are typical as regards to the literature [1,2].

HTC estimated under helium reached maximum values of $3200\ W.m^{-2}.K^{-1}$ in the first $50\ s$. HTC values stabilized around $2500\ W.m^{-2}.K^{-1}$ until $t \leq 400\ s$ and started decreasing beyond this point to reach $1800\ W.m^{-2}.K^{-1}$ at the end of the time interval. HTC values stabilized over the eutectic transformation and dropped once the casting was totally solidified, see figure 9, probably due to the end of heat release by latent heat of solidification.

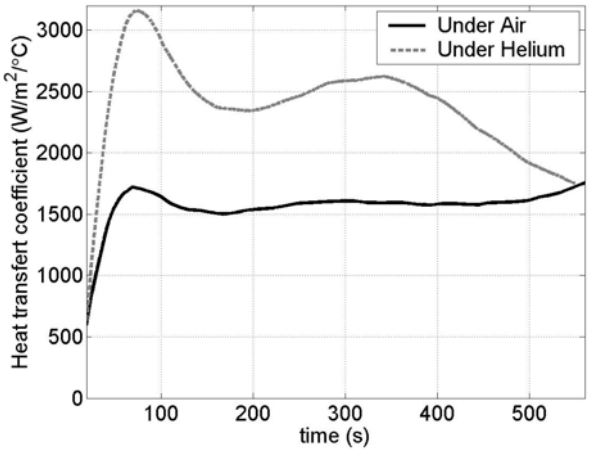

Figure 8. Deduced heat transfer coefficients at the interface mould / casting (Air: black curves and helium: grey curves).

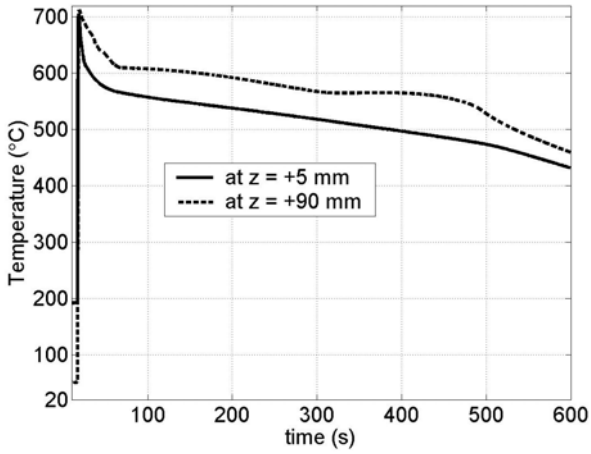

Figure 9. Measured temperatures in the Al casting at different distance from the interface, see figure 3. Helium experiment.

Several phases have been distinguished:

- During the solidification, the HTC values under helium are twice larger than the one under air.
- During the eutectic transformation, the HTC values under helium keep a stabilized value. This one is 1.5 times greater than under air.
- HTC values dropped off once the aluminium is totally solidified. This behaviour has not been observed under air as the temperature measurements were stopped after 10 minutes.

CONCLUSIONS

1. The influence of the helium on the aluminium solidification duration is important. This duration has been shortened by up to 25% in comparison with Al casting under air. Improvement of the heat transfer at the interface mould/casting is due to helium's high thermal conductivity. This reduction of the solidification times should lead to a refinement of grain size [1] and hopefully to an improvement of aluminium mechanical properties.
2. The influence of the helium on the overall cooling of the aluminium casting and steel mould is also significant: the aluminium casting reaches the steel mould temperature 45% faster in comparison with air experiment. Heat losses at exterior mould surfaces are enhanced due to the helium atmosphere as well as the heat transfer at the casting/mould interface. Productivity is almost divided by two according to our results.
3. Heat transfer coefficient values under helium atmosphere are 2 times greater than under air during the solidification of the aluminium. The ratio drops to 1.5 times during the eutectic transformation.

The use of helium in casting industry sounds promising. At least, it should improve the productivity. At this productivity time, the time used to evacuate the air out of the chamber and the time used to refill in the chamber with helium have to be added. In order to decrease the preparation time (air vacuum and helium refilling), it should be interesting to investigate the percentage of helium required to get a good preparation/casting productivity time. The presented experiments have been made with at least 95% of helium. What would have happened with 50% of helium in the chamber?

The effect of the helium on the micrography and mechanical is not known yet but it is currently investigated on the aluminium alloys cast in this work. A last remark: it should be interesting to add some special elements such as sodium, at low concentration, which has the property to help refining the grain size. A study made by Kumar et al [5] showed a grain size refinement and an improvement of the heat flux at the interface. How fast would be the cooling?

ABSTRACT. A thermal model of friction stir welding is presented that proposes an energy-based formulation of the Johnson-Cook plasticity model in order to account for heat generation due to plastic deformation. The proposed formulation is derived from an empirical relationship between the ratio of the maximum welding temperature to the solidus temperature of the alloy and the welding energy. The thermal model is applied to Sc-modified Al-Zn-Mg-Cu alloy extrusions joined by friction stir welding at 225, 250, 300 and 400 RPM (all other weld parameters held constant). With the incorporation of heat generation due to plastic deformation, the thermal model accurately predicts the maximum weld temperatures and temperature profiles at the higher energy weld conditions. At the lower energy welds where plastic deformation contributes a larger portion to the total heat generation, the model under predicts the maximum weld temperatures under the tool shoulder but shows good agreement with the remaining experimental temperature data.

Keywords: *friction stir welding, thermal model, slip factor, heat flux, aluminum alloys*

INTRODUCTION

Friction stir welding (FSW) is a novel solid-state joining process that is gaining popularity in the manufacturing sector and, in particular, the aerospace industry [1, 2]. The plastic deformation and temperature profile during FSW produce a microstructure characterized by a central weld nugget surrounded by a thermo-mechanically affected zone (TMAZ) and heat-affected zone (HAZ). The welded joint is fundamentally defect-free and displays excellent mechanical properties when compared to conventional fusion welds [3]. Since its introduction, numerous researchers have sought to characterize the principles of FSW and to model the microstructural evolution and temperature behavior. The current status of FSW research has been well summarized by Mishra and Mahoney [4].

Researchers have found success in modeling the heat transfer characteristics of FSW. Frigaard et al. [5] developed a finite difference thermal model for a moving heat source and correlated the predicted temperature profile with the measured temperature profile for friction stir welded AA6082-T6 and AA7108-T79 extrusions. Khandkar et al. [6] introduced a model of heat input based on tool torque and successfully modeled the temperature history of friction stir welded AA6061-T651 plate. Early thermal models, such as those of Colegrove and Shercliff [7], however, did not account for the slip that occurs when the tool/workpiece interface softens as the welding temperature approaches the solidus temperature of the alloy. As a result, these models significantly over predicted the maximum temperature for “hot” welding conditions.

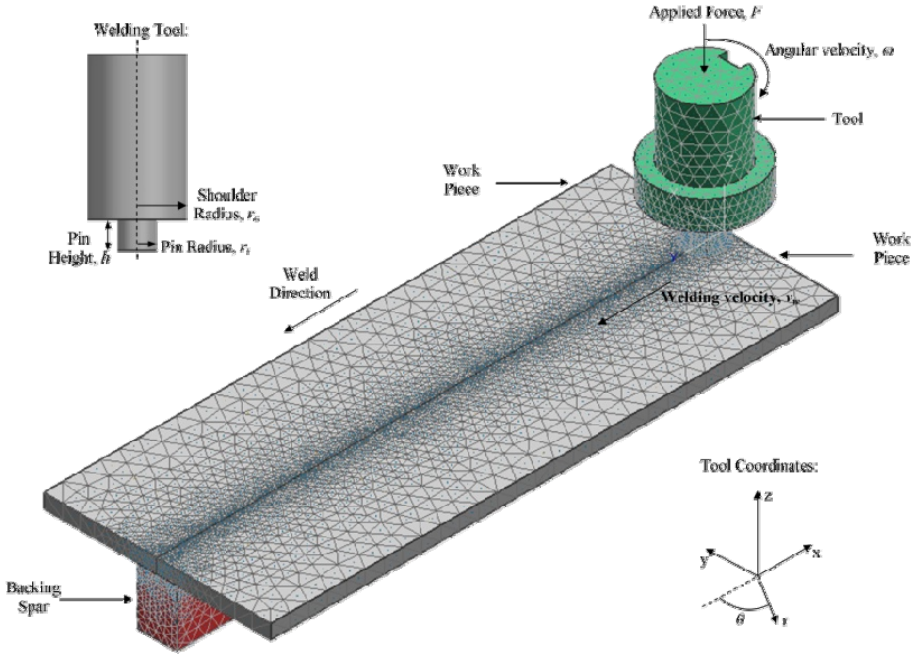

Figure 1. Finite element model of FSW, tool coordinate system and tool geometry

Utilizing Khandkar's torque model, Hamilton et al. [8] proposed an energy-dependent expression for the slip factor for aluminum alloys based on a relationship between the ratio of the maximum weld temperature to the solidus temperature of the alloy and the energy per unit length of weld. The model, however, did not take into account heat generation due to plastic deformation. As a result, the predicted maximum temperatures for low energy welds deviated from experimental data. The current investigation incorporates heat generation due to plastic deformation into this thermal model and demonstrates better agreement between the predicted temperature distributions and the experimental data. A new formulation of the Johnson-Cook plasticity model is also proposed that, like the slip factor, is based upon the weld energy.

EXPERIMENTAL PROCEDURE

Sc-modified Al-Zn-Mg-Cu billets (SSA038 [9]) were extruded as 50.4 mm x 6.35 mm bars and heat treated to a –T6 temper. The extrusions were then sectioned into eight 305 mm sections and sent to the Edison Welding Institute (Columbus, OH) to produce four friction stir welded samples with the configuration shown in Figure 1.The diameter of the FSW tool shoulder was 17.8 mm, the pin diameter tapered linearly from 10.3 mm at the tool shoulder to 7.7 mm at the tip, and the pin depth was 6.1 mm. More specific details of the tool design are proprietary to EWI, but Mishra and Mahoney [4] have reviewed many FSW tool designs that are similar to those utilized in this investigation. With a weld velocity of 2.1 mm/s and an applied force of 22 kN, welds were produced at the following tool rotational speeds: 225, 250, 300 and 400 RPM. Since the force oscillated during welding, the average load values were determined to be 21.4, 20.1, 22.8 and 20.1 kN for 225, 250, 300 and 400 RPM, respectively. The recorded data verified that the weld velocity remained constant at 2.1 mm/s for all welding trials. The temperature profile across the weld was experimentally recorded using a Mikron M7815 Infrared Thermal Imaging Camera. These data were used to verify the efficacy of the numerical model developed during this investigation. The uncertainty in these measurements was ± 2% (or approximately ± 9°C). The thermal emissivity for the infrared data was calibrated by imaging an extrusion length heated to 460°C and adjusting the emissivity value until the recorded temperature of the camera matched the reference temperature. The appropriate thermal emissivity value was determined to be 0.285 which is typical of a lightly oxidized surface.

RESULTS AND DISCUSSION

Energy Contribution due to Plastic Deformation

During friction stir welding, the total energy imparted by the tool to the workpieces, E_{total}, is partitioned between the energy required for plastic deformation and material flow, $E_{plastic}$, and the energy due to friction between the tool and workpieces, $E_{friction}$. The total energy per unit length of weld may be derived from Khandkar's [6] torque-based model for which the total torque, T_{total}, is expressed as the sum of torque contributions from the tool shoulder against the workpiece, the bottom of the tool pin against thickness material and the pin surface against thickness material. If the taper of the welding pin is ignored for simplification, then for the FSW representation in Figure 1, the total torque then becomes:

$$T_{total} = 2\mu F\left(\frac{r_o}{3} + \frac{r_i^3}{r_o^2}h\right) \tag{1}$$

where r_o is the radius of the tool shoulder, r_i is the radius of the pin, h is the pin height, τ is the shear stress during welding, F is the applied force and μ is the coefficient of friction between the tool and the workpieces. The coefficient of sliding friction between aluminum and steel depends on the temperatures produced by the welding conditions. Frigaard et al. [5] reasoned that the coefficient of friction between aluminum and mild steel should be set as the average value between 0.5 for sticky friction and 0.25 for dry sliding. For this investigation, a coefficient of friction 0.5 was used in all calculations. The total energy per unit length of weld, E_{total}, is found by dividing the average power, P_{avg}, by the weld velocity to yield the expression in equation (2):

$$E_{total} = \frac{P_{avg}}{v_w} = T_{total}\frac{\omega}{v_w} \tag{2}$$

where v_w is the welding velocity and ω is the tool angular velocity.

The energy leading to plastic deformation, $E_{plastic}$, may be estimated by considering the stress-strain behavior of metallic materials. The energy required to deform a volume of material to a desired strain is given by the area under the stress-strain curve, and for the idealized case of an elastic, perfectly plastic material:

$$E_{plastic} = V\left(\frac{1}{2}\sigma_y\varepsilon_y + \sigma_y(\varepsilon_f - \varepsilon_y)\right) \tag{3}$$

where V is the volume of material deformed, σ_y is the yield strength of the material, ε_y is the strain value at yield and ε_f is the final strain level of deformation. Hamilton et al. [10] hypothesized that the tool shoulder extrudes a volume of material from an interaction layer into the workpieces to form the weld. The volume of material is contained within a ring centered on the tool at the extrusion distance, r_e (the calculation of which is found in [10]). Thus, the volume of material extruded into the weld center per unit length, V_l, is given by the following expression:

$$V_l = 2\pi r_e w t\frac{\omega}{v_w} \tag{4}$$

where t is the thickness of the interaction layer, w is the width of the extruded column and all other terms have their previous meaning. Based on experimental observations in [10], w was estimated as the tool advance per revolution, $2\pi v_w/\omega$, and t was found to be 0.1 mm. Substituting V_l from equation (4) into equation (3) for V and evaluating at the onset of plastic deformation to simplify the analysis (i.e. $\varepsilon_f = \varepsilon_y$), the energy due to plastic deformation during FSW becomes:

$$E_{plastic} = 2\pi^2 r_e t\sigma_y\varepsilon_y = 2\pi^2 r_e t\frac{\sigma_y^3}{E} \tag{5}$$

where E is the modulus of elasticity.

The yield strength, σ_y, which is dependent on the temperature and the strain rate, is typically modeled using the Johnson-Cook material law that is of the form [11]:

$$\sigma_y = (A + B[\bar{\varepsilon}^{pl}]^n)\left(1 + C\ln\frac{\dot{\bar{\varepsilon}}^{pl}}{\dot{\varepsilon}_0}\right)\left(1 - \left(\frac{T - T_{ref}}{T_{melt} - T_{ref}}\right)^m\right) \quad (6)$$

where $\bar{\varepsilon}^{pl}$ is the effective plastic strain, $\dot{\bar{\varepsilon}}^{pl}$ is the effective plastic strain rate, $\dot{\varepsilon}_0$ is the normalizing strain rate and *A, B, C, n, T_{melt}, T_{ref}* and *m* are material/test constants for a particular alloy. As the welding energy of FSW increases, the welding temperature also increases, thereby decreasing the yield strength of the material. Hamilton et al. [8] proposed that during FSW a characteristic relationship exists for aluminum alloys between the ratio of the maximum weld temperature to the solidus temperature of the alloy, T_{max}/T_s, and the total energy per unit length of weld, E_{total}. From that relationship, the following energy-dependent expression for the slip factor was offered:

$$\delta_E = \exp\left(-\frac{E_{total}}{(E_{total})_{max}}\right) \quad (7)$$

where $(E_{total})_{max}$, the maximum effective total energy, is defined as the energy level for which the maximum welding temperature is equal to the solidus temperature of the alloy (i.e. $T_{max}/T_s = 1$). Thus, one possible energy based expression for the temperature dependence of the yield strength during FSW is then:

$$(\sigma_y)_T = (\sigma_y)_o \exp\left(-\alpha\frac{E_{total}}{(E_{total})_{max}}\right) \quad (8)$$

where $(\sigma_y)_T$ is the yield strength at the welding temperature corresponding to an energy level of E_{total}, $(\sigma_y)_o$ is the room temperature yield strength, α is a scaling factor and all other terms have their previous meaning.

Figure 2 plots the Johnson-Cook model for the temperature-dependent yield strength of AA6061-T6 and the energy-dependent relationship given by equation (8) applied to the AA6061-T6 FSW-data taken from [6] and [8]. The $\bar{\varepsilon}^{pl}$ and $\dot{\bar{\varepsilon}}^{pl}$ inputs for the Johnson-Cook model were selected such that the predicted yield strength at room temperature equaled the value of the *A* coefficient. These inputs and coefficients are summarized in Table 1 [11]. Figure 2 demonstrates that with the scaling factor, α, in equation (8) set to 1.4, the two models show excellent agreement with one another over a temperature range from 100°C to 500°C, typical FSW temperatures. The perturbation in the energy-dependent model beyond 400°C results from a change in the coefficient of friction value for higher weld energies, as discussed in [8]. Therefore, by substituting equation (8) into equation (5), the plastic energy per unit length of weld during friction stir welding becomes:

$$E_{plastic} = \frac{2\pi^2 r_p^2}{E}(\sigma_y)_o^2 \exp\left(-2\alpha\frac{(E_{total})_{eff}}{(E_{total})_{max}}\right) \quad (9)$$

Table 1
Johnson-Cook plasticity model coefficients and input parameters

Coefficients		Input Parameters	
A	324 MPa	$\bar{\varepsilon}^{pl}$	0.0001
B	114 MPa	$\dot{\bar{\varepsilon}}^{pl}$	0.001 s^{-1}
C	0.002		
n	0.42		
m	1.34		
$\dot{\varepsilon}_o$	1.0 s^{-1}		
T_{melt}	925 K		
T_{ref}	294 K		

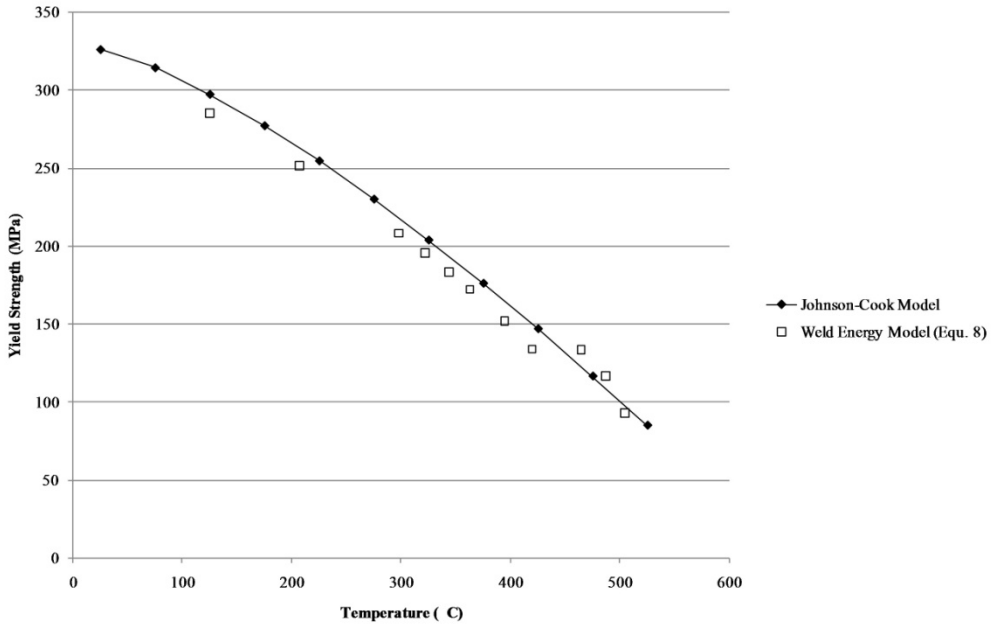

Figure 2. Comparison of the Johnson-Cook material model for AA6061-T6 with the proposed welding energy model presented in equation (9)

The energy expression in equation (9) approximates the plastic energy during FSW, but underestimates the actual plastic energy due to three assumptions that were employed in its derivation. First, although the yield strength and tensile strength for certain alloys can be similar in magnitude (for example, the tensile strength of SSA038-T6 is 663 MPa, and the yield strength is 605 MPa), some strain-hardening is expected to occur and increase the amount of plastic energy over the elastic, perfectly plastic condition assumed in this analysis. Second, during FSW, the strain level will exceed the strain at yield resulting in higher plastic energies than predicted by this model. Finally, the volume of material calculated using equation (4) is conservative and represents only a portion of the total volume that is actually plasticized during FSW. Despite these assumptions, this method of accounting for the heat generation due to plastic deformation improves the correlation between the experimental temperature data and the temperature distributions predicted by the thermal model.

Heat Equation and Heat Flux

For the FSW representation and tool coordinate system shown in Figure 1, the heat flux, q, is typically presented in the following form [12]:

$$q = \left[(1-\delta)\eta\tau_y + \delta\mu P_N\right](\omega r - v_x sin\theta) \tag{10}$$

where v_x is the welding velocity in the x-direction, δ is Nandan's slip factor from [12], η is the mechanical efficiency (the amount of mechanical energy converted to heat energy), τ_y is the maximum shear stress at yielding, P_N is the normal pressure relative to a tool face and θ is the radial angle measured about the tool axis. For typical welding velocities, the $v_x sin\theta$ term in equation (10) is small relative to the ωr term; therefore, the ($\omega r - v_x sin\theta$) expression can effectively be replaced by ωr.

The first term in equation (10) represents heat generation due to plastic deformation, and the second term represents heat generation due to friction between the tool and workpiece. Thus, as presented in the equation, δ represents the partition of heat generated from plastic deformation to heat generated from friction. The slip factor proposed by Hamilton et al. [8], δ_E, however represents the efficiency of frictional heat transfer rather than the partition of heat between plastic deformation and friction. Therefore, if one defines the energy partitioning factor, γ, as the ratio of the plastic

energy to the total energy (i.e. $\gamma = E_{plastic}/E_{total}$) and introduces δ_E as the slip factor, an alternate representation for equation (10) becomes:

$$q = \gamma\eta\tau_y\omega r + (1-\gamma)\delta_E\mu P_N\omega r \tag{11}$$

The value of γ decreases with increasing welding energy, reflecting the decreasing contribution of plastic deformation to heat generation and the increasing contribution of friction. The maximum shear stress in the first term of equation (11) can be estimated from the von Mises yield criterion, such that $\tau_y = (\sigma_y)_T/\sqrt{3}$, where $(\sigma_y)_T$ is the welding temperature dependent yield strength defined in equation (8).

For the tool shoulder and pin bottom, the normal pressure, P_N, is the applied pressure on the workpiece during welding. For the interface between the side of the pin and the workpiece, however, the heat flux is assumed to be zero since the normal pressure here is significantly less than the applied pressure on the workpiece under typical welding conditions. Therefore, the thermal model developed in the following sections utilizes the average heat flux on the pin bottom, $q_{pinbottom}$, and tool shoulder, $q_{shoulder}$, to calculate the welding temperatures. Assuming axisymmetric heat generation, these heat flux equations given in equations (12) and (13) are:

$$q_{pinbottom} = \frac{\int_0^{r_i}\gamma\eta\tau\omega r+(1-\gamma)\delta_E\mu P_N\omega r dr}{r_i} = \frac{\gamma\eta\tau\omega r_i+(1-\gamma)\delta_E\mu P_N\omega r_i}{2} \tag{12}$$

and

$$q_{shoulder} = \frac{\int_{r_i}^{r_o}\gamma\eta\tau\omega r+(1-\gamma)\delta_E\mu P_N\omega r dr}{r_o-r_i} = \frac{\gamma\eta\tau\omega(r_o^2-r_i^2)+(1-\gamma)\delta_E\mu P_N\omega(r_o^2-r_i^2)}{2(r_o-r_i)} \tag{13}$$

where all terms have their previous meaning. Based on other FSW research, the value of the mechanical efficiency factor, η, is taken as 0.5 [12].

Thermal Model: Material Properties and Boundary Conditions

Using NX 5.0, a thermal model of friction stir welding was developed that included tool articulation. Figure 1 shows the finite element model of the FSW process that utilizes a backing spar. Due to the applied pressure during FSW, most heat flows from the workpiece to the backing plate at the interface under the tool resulting in high localized heat transfer in this region. Some thermal models introduce a variable gap conductance to simulate the workpiece/backing plate interface, but in this treatment, the thermal model uses a spar, reducing the number of equations to be solved while still capturing the flow of heat between the workpiece and backing plate. The width of the backing spar is equal to the tool diameter with a height of 25.4 mm, consistent with the spar dimensions used by other researchers [6, 7].

Since the chemistry of SSA038 is similar to that of AA7050, the thermal model utilizes the thermal conductivity and specific heat capacity for AA7050 [9]. For the tool material, the thermal model uses 410 stainless steel. The model assumes perfect contact between the workpieces along the weld line and assumes perfect contact between the tool shoulder and the workpieces. A gap thermal conductivity of 157 W/m·K, the average thermal conductivity of AA7050 between 300 K and 700 K, was applied between the pin bottom and the bottom of the workpieces. For the boundaries exposed to ambient conditions, the convective heat transfer coefficient was set to 15 W/m^2·K to approximate free convection on these surfaces. For the tool top and spar bottom, a convection coefficient of 200 W/m^2·K was applied, and for the area outside of but adjacent to the backing spar (and therefore removed from tool articulation), a convective coefficient of 100 W/m^2·K was used. Heat dissipation due to radiation was ignored.

Table 2
Total energies and maximum weld temperatures for each weld condition

RPM	E_{total} (J/mm)	Maximum Welding Temperature (°C)		
		Experimental	Plastic Def.	No Plastic Def.
225	938	346	313	294
250	977	350	320	301
300	1331	372	365	356
400	1567	390	391	385

Thermal Model: Execution and Results

The thermal model was then used to determine the maximum welding temperatures and temperature profiles of SSA038-T6 for the four, unique total energy levels (see Table 2), and these predicted results were then compared with the experimental temperature data. The model was executed for each weld condition with heat fluxes calculated from equations (12) and (13) to include the effect of heat generation due to plastic deformation. For comparison, the model was also run without heat generation due to plastic deformation (i.e. the partitioning factor, γ, was set equal to zero). The maximum welding temperature stabilized after approximately 26 simulated seconds of friction stir welding. (Note: The model did not utilize a dwell time prior to tool advance.) Table 2 summarizes the predicted maximum welding temperatures and the experimental temperatures for each weld trial.

As seen in the table, inclusion of plastic deformation brings the predicted temperatures of the thermal model into better agreement with the actual welding temperatures. At 225 RPM, without plastic deformation, the thermal model predicts a maximum temperature of 294°C, a 15% error with respect to the experimental value. Introducing plastic deformation into the model raises the predicted temperature to 313°C and reduces the error to 9.5%. At 400 RPM, without plastic deformation, the predicted welding temperature is 385°C, a 1.3% error. But with plastic deformation taken into account, the predicted temperature rises to 391°C and shows good agreement with the experimental value (< 1.0% error). The efficacy of the model with plastic deformation, however, is primarily observed in the lower energy welds. Since the flow stress is greater at the lower weld energies, the contribution to heat generation from plastic deformation represents a greater portion of the total heat generation at lower weld energies (225 and 250 RPM), than at higher weld energies (300 and 400 RPM). This behavior is captured in the partitioning factor, γ, introduced in equation (11).

Figure 3 plots the experimental temperature data for each weld trial with the profiles predicted by the thermal model for the same location. The profiles extend from the weld centerline into the workpiece along the top surface of the FSW configuration. As seen in each figure, inclusion of plastic deformation shifts the predicted temperature profiles toward the experimental profiles. For the lower weld energies, the thermal model under predicts the maximum weld temperature but shows relatively good agreement with respect to the magnitude and shape of the experimental temperature profile beyond 9 mm, the approximate radius of the tool shoulder. The conservative approach utilized to calculate the plastic energy may explain the observed discrepancy between the maximum weld temperatures that were experimentally observed and numerically predicted. For the higher weld energies, the predicted maximum weld temperatures show good agreement with the experimental values, but the temperature profiles beyond 9 mm generally under predict the temperature as compared to the experimental data.

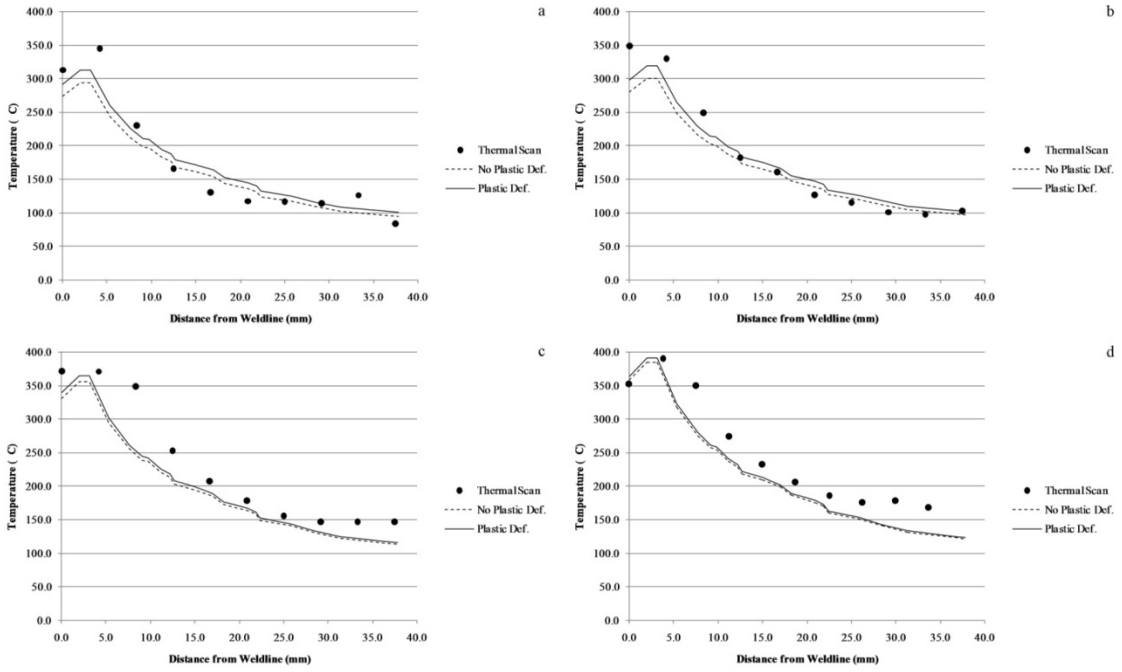

Figure 3. Experimental temperature and predicted temperature profiles: a) 225 RPM, b) 250 RPM, c) 300 RPM and d) 400 RPM

CONCLUSIONS

A thermal model of the friction stir welding of aluminum alloys is presented that incorporates heat generation due to plastic deformation and partitions the heat generation between friction and plastic deformation based on the ratio of the plastic energy to the total effective energy. To calculate the plastic energy and to account for the change in the yield strength with welding temperature, a formulation of the Johnson-Cook material model based on welding energy is utilized. This energy-based formulation shows good agreement with experimental yield strength/temperature data found in the literature for AA6061-T6; however, its application to other aluminum alloys has not yet been verified due to a paucity of published experimental data.

For the Sc-modified Al-Zn-Mg-Cu alloy examined in this work, the thermal model successfully predicts the maximum welding temperatures and temperature distributions over the energy range investigated. The model, however, shows its greatest potential at higher energy welds (i.e E_{total} > 1000 J/mm) where heat generation due to friction dominates. At lower energy levels (i.e. E_{total} < 1000 J/mm), the predicted temperature profile shows good agreement with experimental temperature data in terms of magnitude and shape away from the tool shoulder, but the model under predicts the maximum welding temperatures due to the assumptions/simplifications that were used in the calculation of the plastic energy.

ABSTRACT. Hot stamping is a novel process that comes out as a combination of hot forming and simultaneous quenching of the blank. In this paper, an original experimental procedure developed to estimate the thermal conductance at the Part-Tools interfaces during a hot stamping process, is presented. The tools set (punch and die) has been designed to form samples with an omega shape. Reproducibility tests carried out under a pressure contact of 10MPa demonstrated the good reliability of the device. In order to describe correctly the thermal boundary conditions at Part-Tools interfaces, the adopted procedure consists in estimating accurately the thermal contact resistance *TCR* at different contact points. We noticed a good repeatability of thermal conductance time evolution and particularly, of the final reached value $R_c = 2.88*10^{-4}\ m^2.K/W$. The analysis of experimental results showed that the heat transfer intensity is maximum at the bottom of the die.

INTRODUCTION

Safety improvement and weight reduction has become the major objectives of automotive manufacturers in the design of new BIW components. Therefore, it is essential to realize parts presenting not only a high mechanical properties but also significant thinner sheet thickness [1]. Hot stamping of a quenchable steel comes out as a quite novel process which allow reaching strength levels which are far above those of best-in-class cold stamping steels. Moreover, the traditional balance between high strength and low formability is overcome by hot stamping: as the forming is done at high temperature, the austenitic material exhibits a very good ductility and complex shapes can be realized in a single step [2].

A specific steel grade, called Usibor 1500P, dedicated to the hot stamping process has been developed by ArcelorMittal [3]. Usibor1500P is a coated Aluminium-Silicon boron steel designed to reach an ultimate tensile strength above 1500MPa after hot stamping. This forming technique consists, first, in heating blanks until complete austenitization (900°C to 950°C) during 4 to 10 minutes. Afterwards the hot sheet is transferred, as fast as possible, to the press and immediately stamped in order to take advantage of the excellent formability at high temperature (600°C to 800°C). The tool is held closed for 20 seconds for quenching the sheet below the martensite finish temperature M_f (figure 1).

To determine the feasibility of Usibor1500P components and help the hot stampers in the fast evolution of this innovative technology, the numerical simulation of this thermo-mechanical process is paramount. It requires a good knowledge of thermal and mechanical material characteristics that are needed as input data in any finite element code.

In this objective, thermal study is of a fundamental importance for the hot stamping process modelling. It requires a proper control of the temperatures and thus, the heat transfer coefficient at the part-tools interfaces during the different process steps, from the blank positioning in the die until the blank quenching in the closed tools.

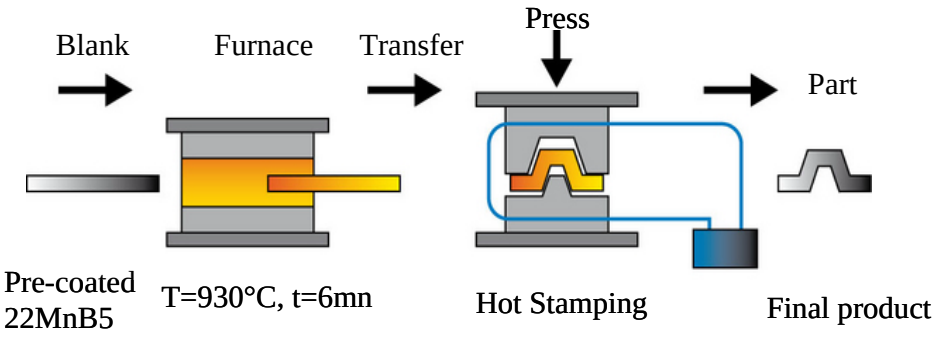

Figure 1. Schematic sketch of the hot stamping process of Usibor1500P.

In this paper, we present a brief description of the experimental procedure developed in order to determine the thermal contact resistance *TCR* at the part-tool contact interface. In the second section of this work, the experimental results of tests carried out at a contact pressure of 10 MPa are described. The last section details the analysis of the experimental results at different contact pressures.

THE EXPERIMENTAL PROCEDURE

After blanking, the first step of the hot stamping process is austenization. The blank is heated in a continuous furnace above material's specific AC_3-temperature for a defined duration in order to guarantee a homogeneous micro-structural phase transformation from ferrite-pearlite to austenitic. The aluminium-silicon coating is transformed to Al-Si-Fe alloyed layer which avoids corrosion and decarburization of the base material. Then, the blank is transferred very quickly to the press where it stays a short time on the die during punch approach (Approach step ~2sec). Afterwards, the hot blank is stamped between the moving punch and the static die to get a final Omega shape when the tool is completely closed (Forming step ~2sec). Finally, the formed part is quenched between the die and the punch (Quenching step ~20sec). Figure 2 summarizes the different steps of hot stamping procedure.

As the objective of this study is the heat transfer estimation at the part-tools contact, one or more flux sensors made of at least two thermocouples are placed in the close vicinity of the tools surface. Four thermocouples are also inserted in the half thickness of the blank sample at various positions judiciously chosen.

The measurement principle and the experimental device, particularly the thermal instrumentation, are fully described in [4]. So, a brief description is presented in this paper.

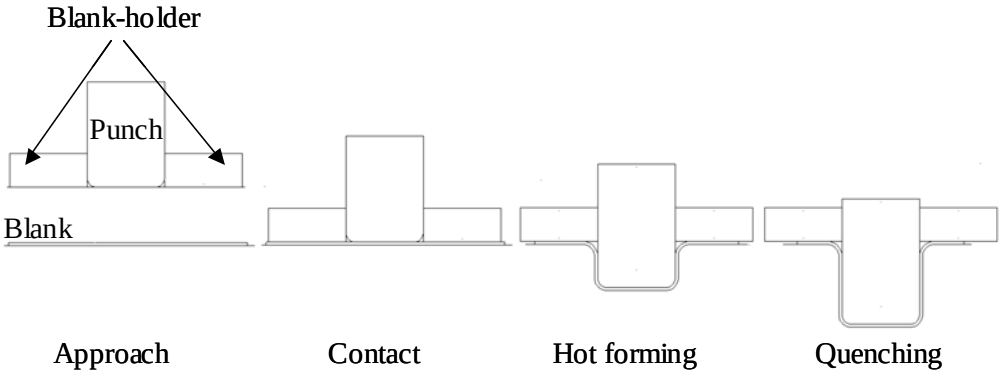

Figure 2. Sketch of different phases in hot stamping process (the die is not shown).

The measurement principle

The principle of the method is based on the transitory analysis of the temperature fields recorded on both sides of the interface. An example of the *TCR* estimation at a specific position is presented in figure 3:

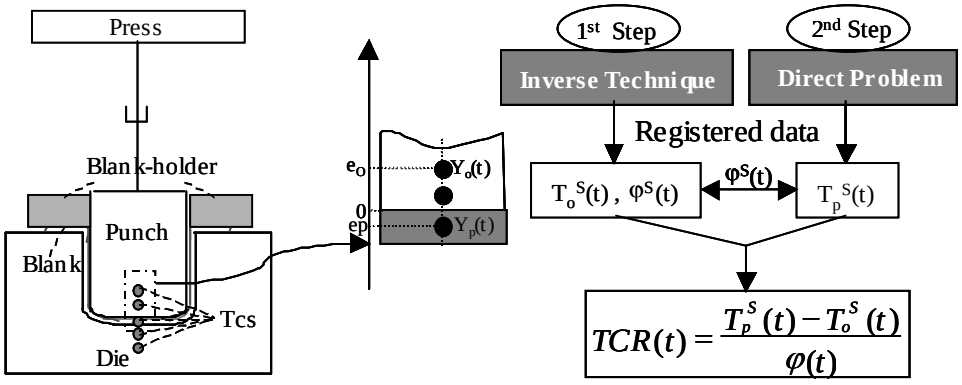

Figure 3. The measurement principle.

The formulation of the direct problem in the part is as follows:

$$(\rho.C_p)_p \frac{\partial T_p(x,t)}{\partial t} + P_p(T) = \frac{\partial}{\partial x}[\lambda_p . \frac{\partial T_p(x,t)}{\partial x}] \qquad 0 \le x \le e_p \ , \qquad t > 0 \tag{1.1}$$

$$-\lambda_p \left.\frac{\partial T_p}{\partial x}\right|_{x=0} = \varphi(t) \qquad t > 0 \tag{1.2}$$

$$T_p(e_p,t) = Y_p(t) \qquad t > 0 \tag{1.3}$$

$$T_p(x,0) = Y_p(0) \qquad 0 \le x \le e_p \ , \qquad t > 0 \tag{1.4}$$

P_p is the internal source due to the metallurgical transformation from austenite to martensite. It is obtained from the literature. The formulation of the direct problem in the tools is similar by replacing the index p (work-piece) by O (tool). The heat conduction equation in this case becomes homogeneous ($P_O = 0$). To summarize, the estimation procedure is as follows:

a- Considering the data recorded by the two thermocouples and the direct problem in the tool, we estimate the flux density $\varphi(t)$ and the temperature at the surface on the tool side $T_O(0,t)$ by the inverse technique based on the sequential method of Beck.

b- Then, knowing the heat flux density at the contact interface and the temperature measured by the thermocouple placed on the blank, we can calculate the surface temperature on the blank $T_p(0,t)$ by resolution of the heat conduction problem.

c- Finally, knowing the two surface temperatures on the blank and the tool sides as well as the flux density at the contact interface, we estimate *TCR(t)*:

$$TCR(t) = \frac{T_P(0,t) - T_O(0,t)}{\varphi(t)} \tag{2}$$

The experimental device

The *TCR* measurement at the Blank-Tool interface suggests us to develop an experimental device made up of five elements as represented in Figure 4: the forming press, the furnace, instrumented blanks and tools and the acquisition system.

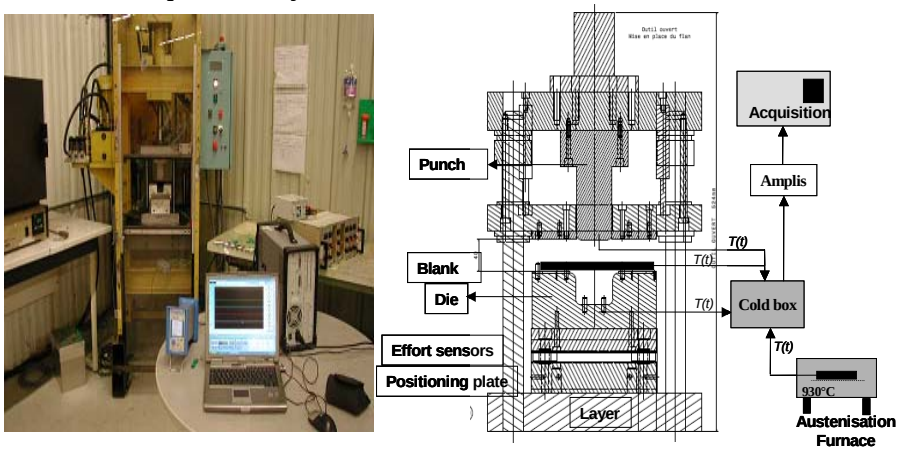

Figure 4. The experimental device.

The sample is designed as a 165x50x1.5 mm^3 plane blank and made in Usibor 1500P. The hot stamping tool designed for the study is made up of a die and a punch made in Z160CDV12 steel material. One or more flux sensors made of at least two thermocouples are placed in the immediate vicinity of the tool surface. The positions of the measurement points are selected based on the sensibility and the precision of the *TCR* estimation. Thus, certain rules that govern parietal instrumentation by thermocouple have to be considered [5].

The tool dimensions (die and punch) and the technological choices for the implementation of the measurement system described above, were specified in a way to respect the ability and the capacity of the press (speed, maximal stamping force,…). Therefore, we choose the thermocouple type K ($d = 100\,\mu m$) sheathed with silky glass in order to avoid the saturation phenomenon of thermocouples at high temperature. The blank and the tools dimensions and the positions of different flux meters are presented on figure 5:

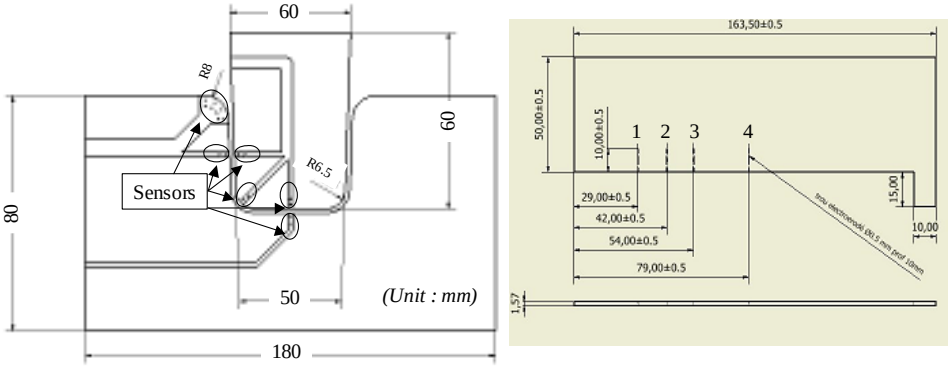

Figure 5. Part and tools dimensions and thermocouples positions.

EXPERIMENTAL RESULTS

In order to ensure the repeatability of the results, six instrumented samples made in Usibor 1500P are successively hot stamped. Each sample is first homogenously heated in a furnace up to 930°C until its complete austenization. It is, then, transferred from furnace to press and put on the die. The hot sample is rapidly formed and finally quenched by direct contact with the tools.
The post processing of recorded data is conducted according to the measurement principle. In this section, we will focus on the *TCR* estimation during the quenching phase where the part-tools contact is static. A typical temperature variation registered by the thermocouples inserted in the blank and in front of the bottom of the die at the end of forming is presented in figure 6:

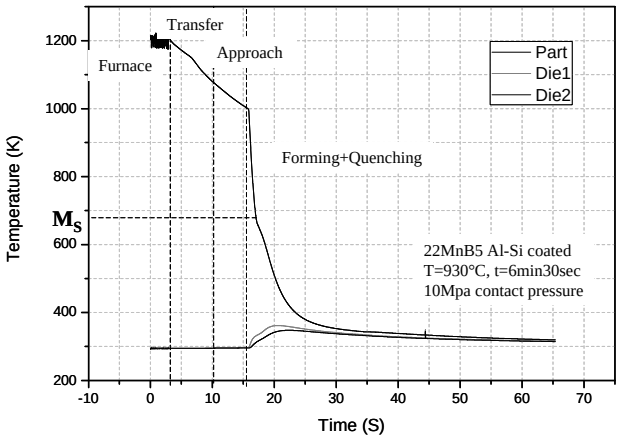

Figure 6. Typical cooling rate under a contact pressure of 10MPa.

This figure shows the temperature variation given by the thermocouples implanted in the sample and the die (the thermocouples are aligned on the symmetric vertical plane of the tool). We notice that the cooling rate during the transfer phase is roughly identical to the approach phase (~15 K/S). The blank temperature decreases from 930°C to 730°C which is considered as acceptable as the blank keeps its high formability at this temperature. Thus, the forming phase begins still at the austenitic phase ($T > M_S$).

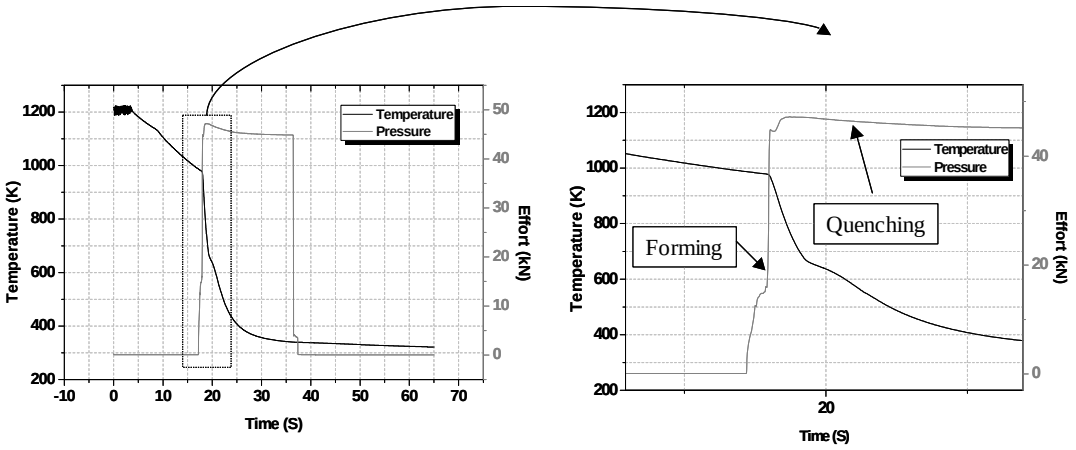

Figure 7. The part temperature and the pressure evolution.

Figure 7 shows the blank temperature given by the thermocouple #4 and the stamping force evolution. We observe that the blank temperature at this very point is not influenced by the forming. In fact, in this zone, the punch is not in contact with the blank during the forming phase, as illustrated on Figure 8.

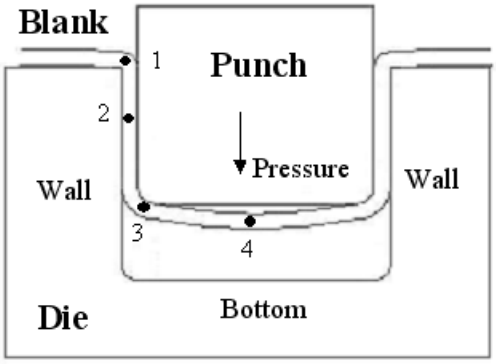

Figure 8. Position of the thermocouples in the blank during the forming phase.

First, reproducibility tests were carried out at a contact pressure of 10MPa. We estimate the *TCR* evolution as function of time at different contact positions during the quenching phase. Figure 9 illustrates the good repeatability of the *TCR* results. In this figure, a singularity is also observed on the *TCR* curves that appears systematically at the thermal level corresponding to the metallurgical transformation from austenite to martensite.

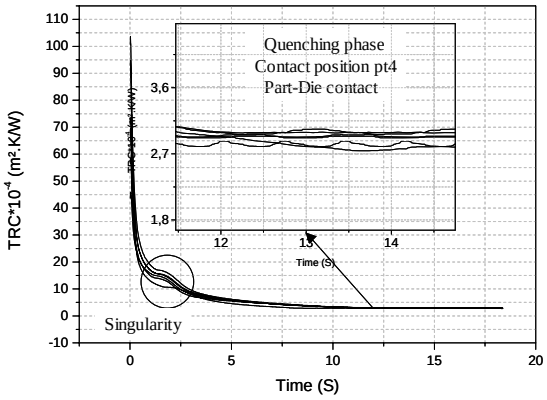

Figure 9. The *TCR* evolution as function of time under a contact pressure of 10MPa.

The *TCR* decreases to reach a constant value around $\mathrm{TCR} = 3.0\mathrm{x}10^{-4}\ \mathrm{m^2.K/W}$. A mean value of $\overline{\mathrm{R_C}} = 2.88\mathrm{x}10^{-4}\ \mathrm{m^2.K/W}$ is obtained with a dispersion that doesn't exceed $1.9\mathrm{x}10^{-5}$. All results have a dispersion of about 5 % which is considered as acceptable, considering the high influence of surface parameters of each samples and the difficulty of the temperature measurement. The singularity observed on the *TCR* curves is due to microstructure transformation in the sample. Indeed, the rapid cooling by tool quenching induces a transformation of the austenite into martensite. The martensitic transformation takes place through a process of nucleation and growth. Literature shows that this microstructure transformation causes the release of an elastic energy (volume change due to the difference in structure of austenite and martensite) and dissipative energy (latent heat release). The volume change of the sample caused by the martensitic transformation leads to a normal stress that tends to antagonize the punch force:

$$\sigma_{A-M} = \varepsilon * E = \alpha * \Delta T * E \tag{3}$$

In a second step, we compared the heat transfer at the blank-tool interface at two different contact positions during the quenching phase (with a contact pressure of 10MPa). The sample-bottom of the die (position #4) and the sample-vertical wall of the die (position #2) contact areas were analyzed (Figure 8).

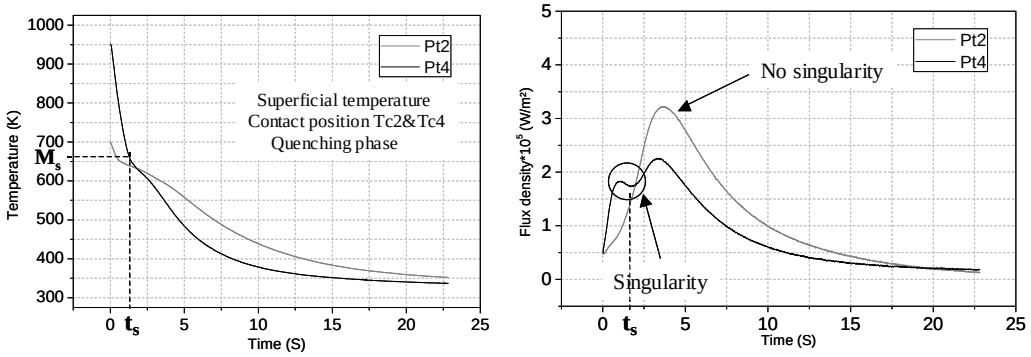

Figure 10. Superficial temperature and flux density evolutions at position #2 & #4.

The surface temperature of the blank and the flux density absorbed by the die at position #2 & #4 are presented in figure 10. It can be noticed that the cooling velocity at position #4 is significantly higher than in position #2. This is due to the reduction of heat transfer between the blank and the die wall. In fact, during the forming step, the blank slides along the die wall leading to an increase of the die surface temperature. Thus, the temperature difference between the blank and the die at this contact point becomes lower than the one observed at point #4, where the die has not been in contact with the hot blank. On the flux density curves shown in Figure 10, we notice also the presence of the singularity at contact position #4 while the superficial heat flux density at position #2 remains unchanged. It is due to the influence of the normal stress induced by the martensitic transformation on the punch force. This normal stress at position #2 is not captured by the force sensors placed under the die.

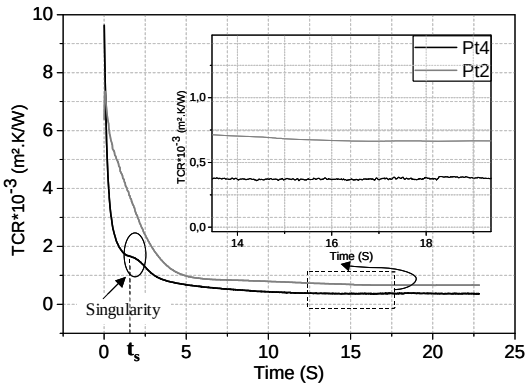

Figure 11. The *TCR* curves as function of time at position #2 & #4 during the quenching.

Figure 11 gives the *TCR* evolution as function of time at position#2 and #4 during quenching. Here also it is noticed that the singularity linked to the phase transformation is only observed at position #4.

Finally, tests under different contact pressure values were carried out in order to determine the law governing heat transfer between the blank and the die during the quenching phase. Figure 12 shows the comparison of the *TCR* curve as function of the contact pressure at both contact positions (#2 & #4) during the quenching phase. TCR values are lower at position #4 than at position #2. As mentioned earlier, it is due to the sliding of the hot blank against the die wall during the forming phase which warms up the die surface.

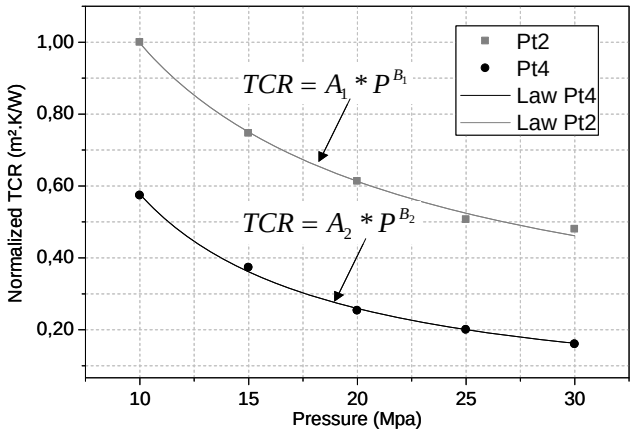

Figure 12. The *TCR* curve as function of contact pressure at position#2 & #4 during quenching.

CONCLUSION

In this paper, an experimental device which has been designed and developed to measure the Thermal Contact Resistance under hot stamping conditions was presented. Reproducibility tests were carried out and showed repeatable and accurate values of TCR at blank-tool interface. Hot stamping trials were conducted with various contact pressures to determine the TCR law as function of pressure. A comparison of thermal conductance values measured in two different contact areas (respectively sample-bottom of the die and sample-die wall) during the quenching phase, was presented. It appears that the heat transfer of the sample with the bottom of the die is higher than with the die walls due to different contact conditions.

ABSTRACT. A model experiment is carried out for the Czochralski crystal growth configuration under the horizontal rotational magnetic field. The transient temperatures at various locations in the melt are measured by thermo-couples. A pair of permanent magnets is placed at the outside of crucible sidewalls and the magnet is rotated by a motor. Asymmetric temperature distributions occur in the melt and rotate in the crystal rotating direction without or in a static magnetic field. Under the rotational magnetic field, the temperature distributions rotate in a rotating direction of the magnetic field under the strong and/or the large rotating rates of magnetic field even against to the rotating direction of the crystal rod. The periodic temperature oscillation is caused due to the rotation of the asymmetric temperature distribution in the melt. The oscillation period strongly depends on the rotational magnetic field.

INTRODUCTION

The silicon single crystal for the semiconductor has been mainly manufactured by the Czochralski (Cz) method and the fluid flow of melt affects the quality of grown crystal [1]. Therefore, the fluid flow in the crucible has been controlled by the crystal and the crucible rotation under the traditional system. However, recently horizontal or vertical static magnetic field has been applied to the Cz melt to control the melt convection [2, 3]. Lorentz force works for electrically conductive fluid under the magnetic field and the fluid flow can be suppressed in a static magnetic field. However, the non-homogenous oxygen concentration and the other various positive and/or negative characteristics occur in the melt under the static magnetic field [4]. Previously, we reported [5] the oxygen concentration in the melt under the horizontal and the rotational magnetic field numerically. The oxygen concentration at the crystal-melt interface was decreased under the rotational magnetic field compared to the horizontal static magnetic field for the same magnetic induction. The 3-dimensional numerical computation of Cz melt convection was also reported [6] under the rotational magnetic field, and the temperature distribution and the concentration of oxygen transfer changed from the spoke to the 2-folded one with increasing the magnetic flux density and the rotational rates of magnetic field.
In this study, the temperature distribution in the Cz melt is measured under the horizontal and the rotational magnetic field. A pair of permanent magnets is used to generate the magnetic field and

the magnets are rotated with the motor. This system is simple and the low frequency (0.05 - 1.5 Hz) rotational magnetic field can be applied to the melt. The magnetic flux density and the rotational rates of magnetic field are changed and the temperature oscillation period and the temperature distribution in the melt are measured.

EXPERIMENTAL CONDITIONS

Experimental apparatus is described in detail in the accompanying paper in this meeting and is not repeated herein. Experimental conditions are summarized in Table 1. Four different strengths of magnetic field are employed. They are case A at 0 mT, case B at 1.8 mT, case C at 2.7 mT and case D at 4.5 mT. The rotating rates of magnetic field are changed for each case from +10 rpm to -30 rpm.

The gallium melt is selected as the experimental fluid. The physical properties of gallium melt [7, 8] are shown in Table 2 at the average temperature ($T_{ave.}$= 319.69 K) of this experiment. The melting point of gallium is 302.93 K and the electrical conductivity is high.

Table 1

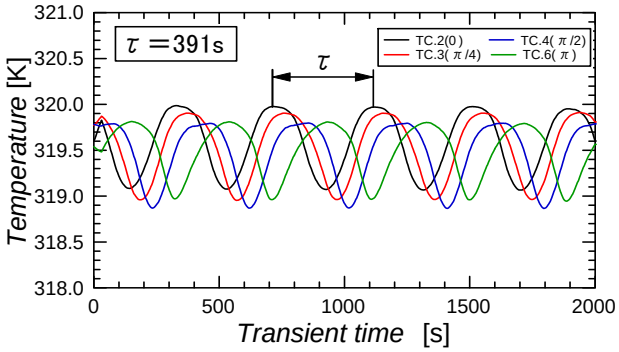
EXPERIMENTAL RESULTS

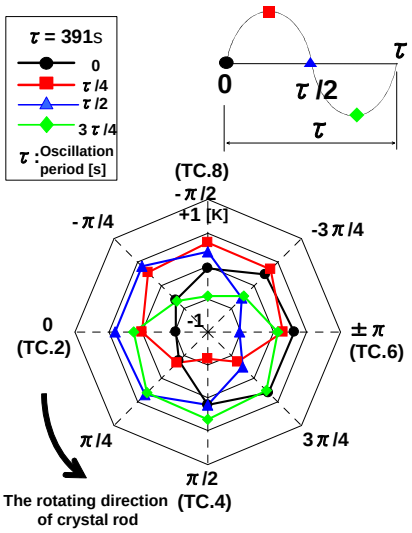
No magnetic field.

At first, temperature measurement is carried out without a magnetic field for Case A. Figure 1 shows the measured temperatures at four locations in a circumferential direction. Figure 1 (c) shows these locations in the melt. They are located at $\pi/4$ shifted in a horizontal plane and are named as TC2, TC3, TC4 and TC6. As shown in Figure 1(a), the temperature in the melt is periodically oscillating at all measuring positions in this experimental condition. The temperature oscillation period is found to be τ = 391s. Temperatures at four locations are shifted due to the shifted locations in the circumferential direction.

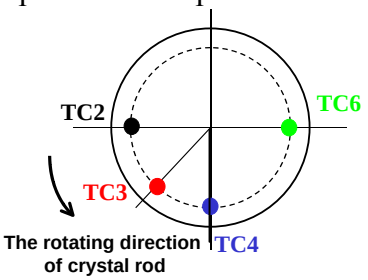
Figure 1(b) shows the instantaneous temperature distribution is defined as the temperature difference from the average of oscillating temperature to the measuring temperature at each angular location. Radial locations are indicator of temperature difference from its average temperature. At the center it corresponds to - 1 [K] and at the outer most locations it corresponds to + 1 [K]. This is possible since the temperature oscillation amplitude is less than 1 [K] as seen in Figure 1(a). Four different timings in one oscillating period τ are shown in a sine function as shown schematically in the top right of Figure 1(b). The top views of these temperature distributions show different peak values depending on the timings in one cyclic oscillation period. The peak locations rotate in the same circumferential direction as the crystal rod rotation which is indicated with a bold arrow in the left lower side of this picture.



(a) Transient temperature



(b) The top view of temperature distribution



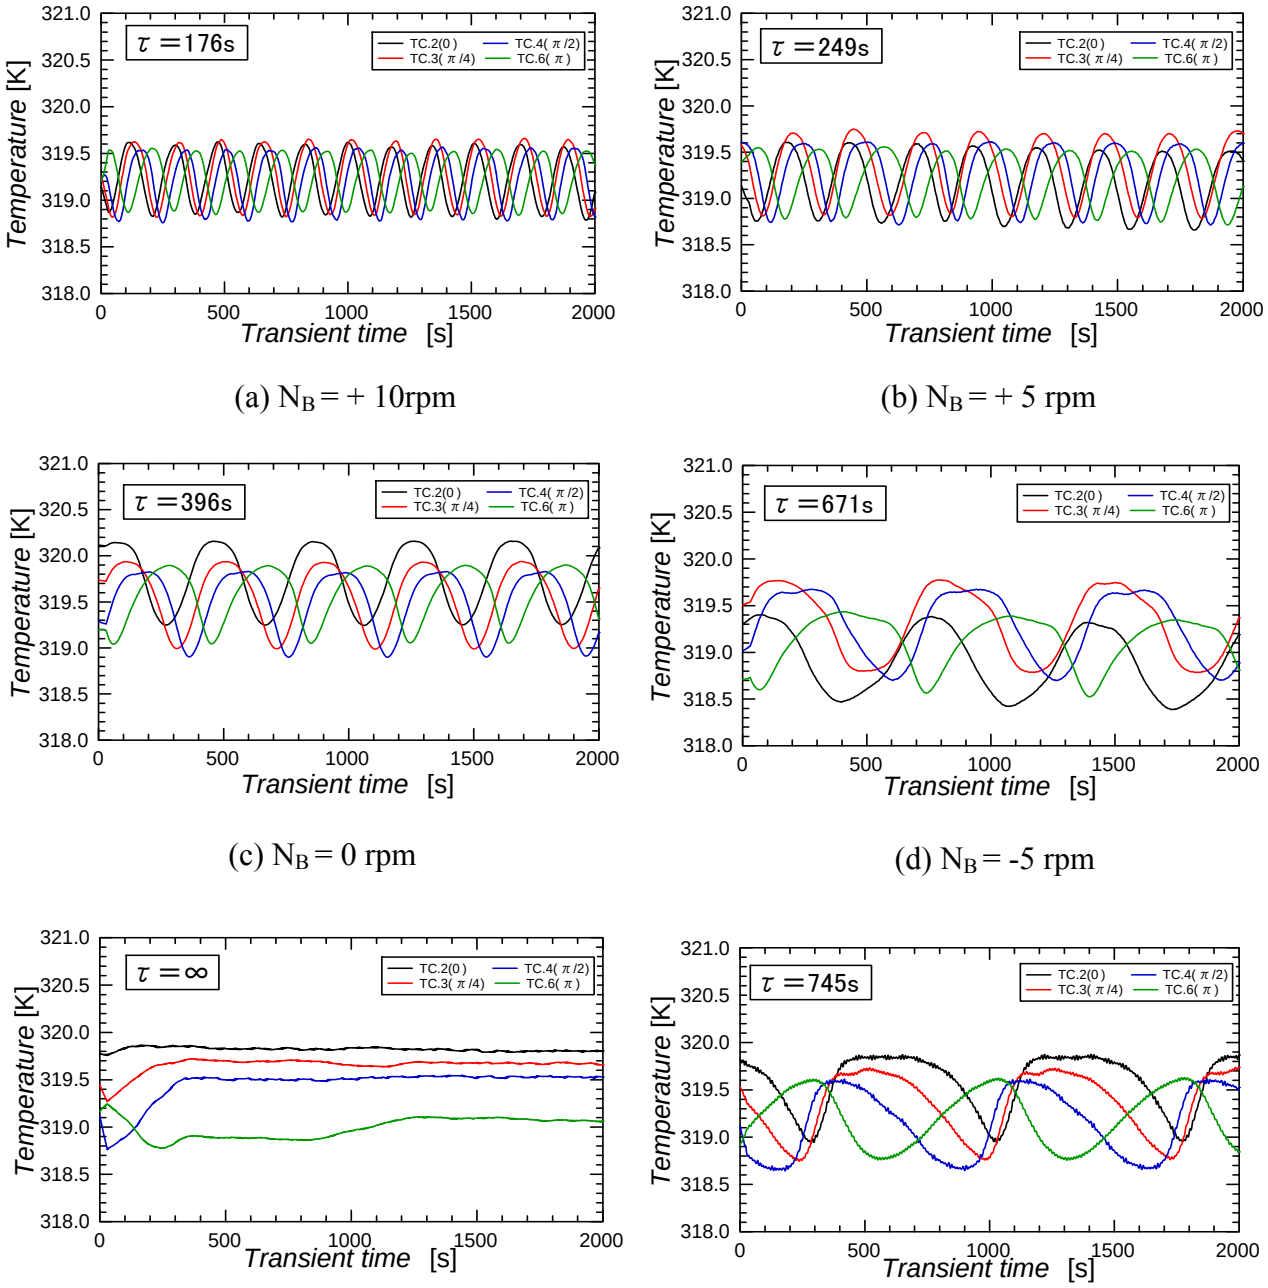
(c) Measuring position

Figure 1. Transient temperature and the top view of temperature distribution in the melt for B = 0 mT (Case A).

Horizontal rotational magnetic field

The horizontal rotational magnetic field is applied to the melt. The magnetic flux density and the rotational rates of magnetic field are varied. Figure 2 shows the transient temperature at B = 1.8 mT (Case B) and the rotating rates of magnetic field are from N_B = + 10 to - 25rpm. The positive symbol of rotating rates of magnetic field N_B shows the same rotating direction as that of crystal rod and the negative symbol shows the opposite direction. The oscillation period for each case are varied with the rotating rates of magnetic field and the rotating direction. Under the positive rotating direction, the oscillation period is shorter than that of the negative rotating direction and the oscillation period at N_B = + 10 rpm is shorter than that at N_B = + 5 rpm. For the cases of negative rotating direction of Figures 2(d)-(f), the oscillation period at N_B = - 5 rpm is longer than that of the static horizontal magnetic field (N_B = 0 rpm) in Figure 2(c). The transient temperatures at N_B = - 15 rpm are almost constant and the

temperature oscillations occur at N_B = - 25 rpm again. However, the temperature oscillation turns from black to green, blue and red at N_B = - 25rpm. This transition is reverse to those at $N_B \geq -5rpm$.



(a) N_B = + 10rpm

(b) N_B = + 5 rpm

(c) N_B = 0 rpm

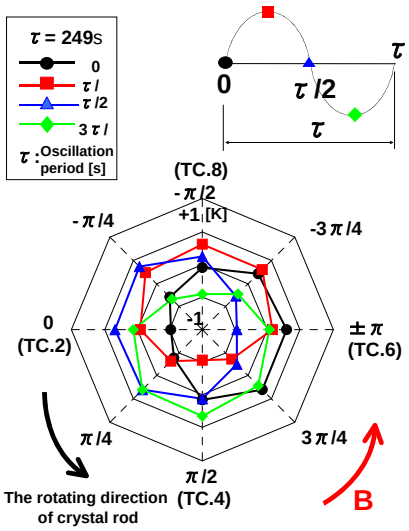
(d) N_B = -5 rpm

(e) N_B = - 15 rpm

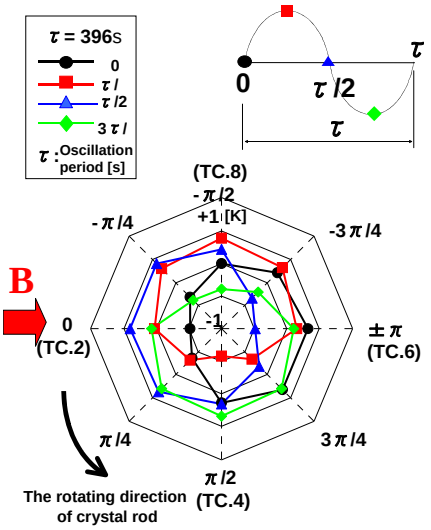
(f) N_B = - 25 rpm

Figure 2. Transient temperature in the melt for B = 1.8 mT (Case B).

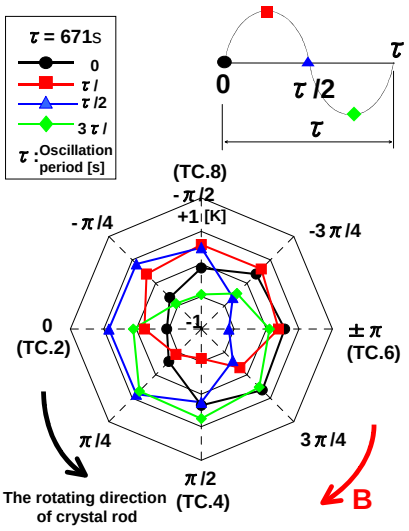
Figure 3 shows the top view of temperature distribution in the melt at B = 1.8 mT (Case B). The red arrow with symbol B indicates the rotating direction of magnetic field. The temperature distributions are asymmetry and rotate in the crystal rotating direction (counter clockwise) at N_B = + 5, 0 and - 5 rpm. However, the temperature distribution at N_B = - 25 rpm rotate clockwise in the same rotating direction as that of a magnetic field. The rotating direction is switched under the large rotating rates of magnetic field. At N_B = - 25 rpm, the Lorentz force appears to overcome the strength of the crystal rod rotation.



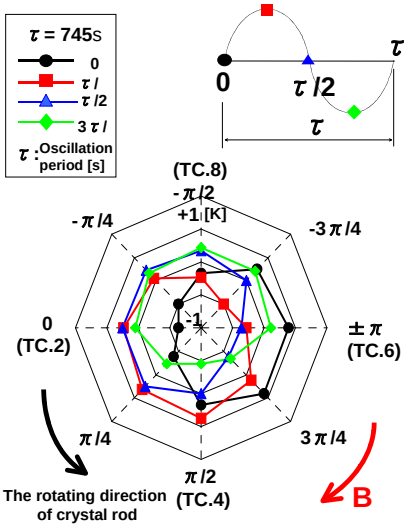
(a) N_B = + 5 rpm



(b) N_B = 0 rpm



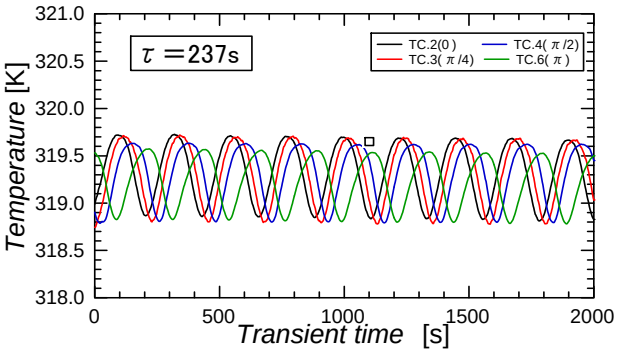
(c) N_B = - 5 rpm



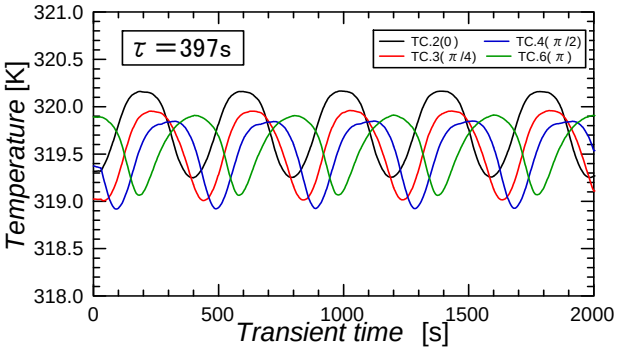
(d) N_B = - 25 rpm

Figure 3. The top view of temperature distribution in the melt for B= 1.8 mT (Case B).

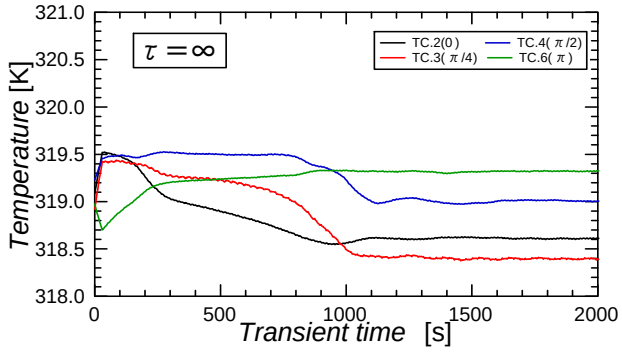
Figures 4 and 5 show the transient temperature at B = 2.7 mT (Case C) and B = 4.5 mT (Case D). For the positive rotating direction of N_B = + 5rpm in Figures 4 (a) and 5(a), the oscillation period of temperature is shorter than that of the static horizontal magnetic field at N_B = 0 rpm for each case. The oscillation period at B=4.5mT is shorter than that at B = 2.7 mT at N_B = + 5 rpm. For the static horizontal magnetic field at N_B = 0 rpm, the oscillation period slightly increases with the increase in the magnetic flux density. At N_B= - 5 rpm and B = 2.7 mT in Figure 4(c), the temperature is almost constant which appears to be similar to Figure 2(e) (B = 1.8 mT, N_B = - 15 rpm). At N_B = - 5 rpm and B = 4.5 mT in Figure 5(c), the temperature distribution turns from black to green, blue and red. This transition is reverse to those at N_B = + 5 and 0 rpm.



(a) N_B = + 5 rpm

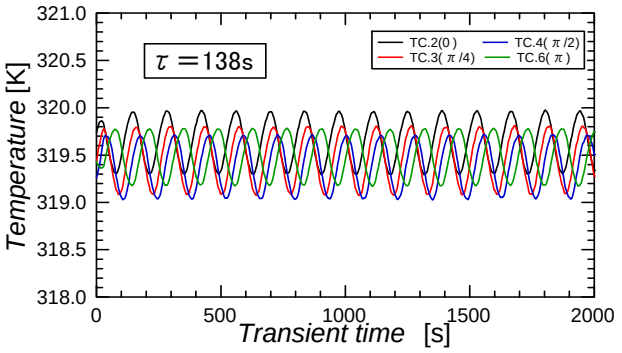


(b) N_B = 0 rpm

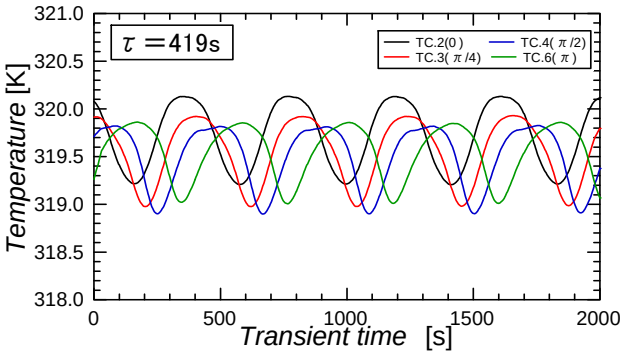


(c) N_B = - 5 rpm

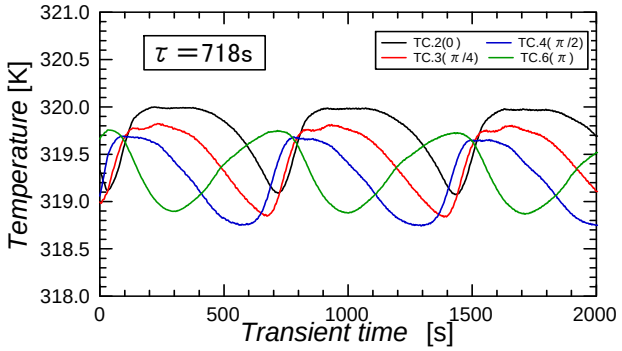
Figure 4. Transient temperature in the melt for B = 2.7 mT (Case C).



(a) N_B = + 5 rpm



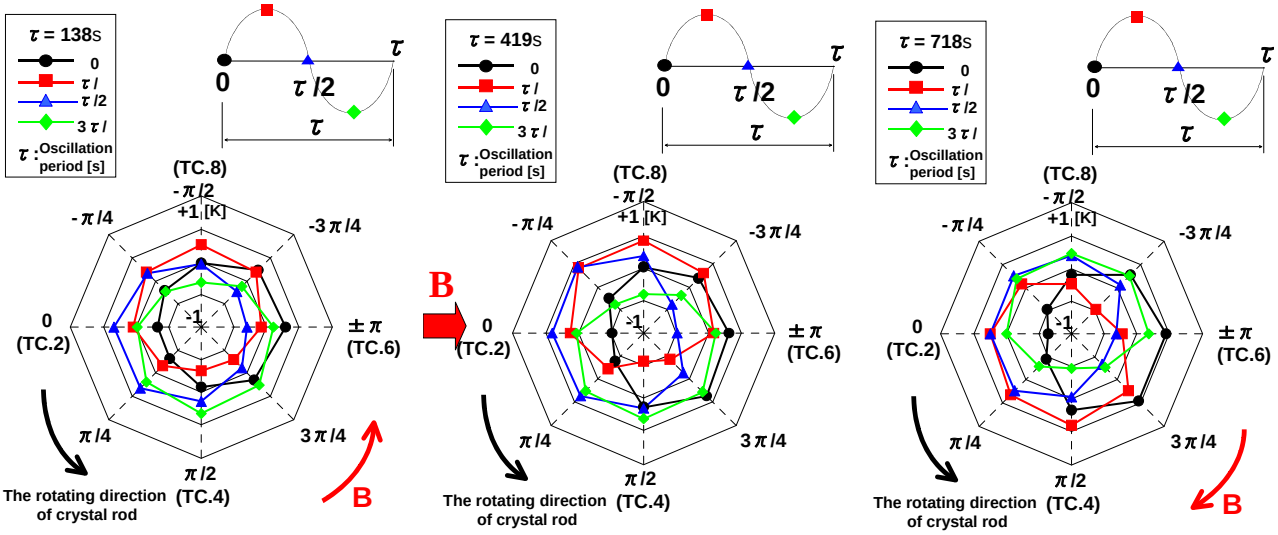
(b) N_B = 0 rpm



(c) N_B = - 5 rpm

Figure 5. Transient temperature in the melt for B = 4.5 mT (Case D).

Figure 6 shows the top view of temperature distribution in the melt at B = 4.5 mT (Case D). The temperature distribution at N_B = + 5 and 0 rpm rotates in the crystal rotating direction. At N_B = - 5 rpm, the temperature distribution rotates in the opposite rotating direction of crystal rod. The rotating direction of temperature distribution is switched with the increase of magnetic flux density at the same rotating rates of magnetic field in comparison to that at B = 1.8mT in Figure 3(c).
Figure 7 shows the inverse of oscillation period of temperature $1/\tau$ versus the rotating rates of magnetic field N_B. N_B = 0 rpm corresponds to the static horizontal magnetic field. Each symbol corresponds to the strength of the magnetic flux density B. All data show the similar characteristic that $1/\tau$ takes the minimum value of zero ($\tau \to \infty$) somewhere between 0 and - 20 rpm depending on the strengths of the magnetic field. As shown above in detail, disappearance of temperature oscillation is due to the reverse rotation of the horizontal magnetic field against to that of a crystal rod at N_{rod} = 35 rpm in this experiment. Therefore, this characteristics should depend on the magnitude of the rotating rate of the crystal rod N_{rod} as well as the rotating rate of crucible, though N_{cru}=0 in this study.



(a) N_B = + 5 rpm (b) N_B = 0 rpm (c) N_B = - 5 rpm

Figure 6 The top view of temperature distribution in the melt at B = 4.5 mT (Case D).

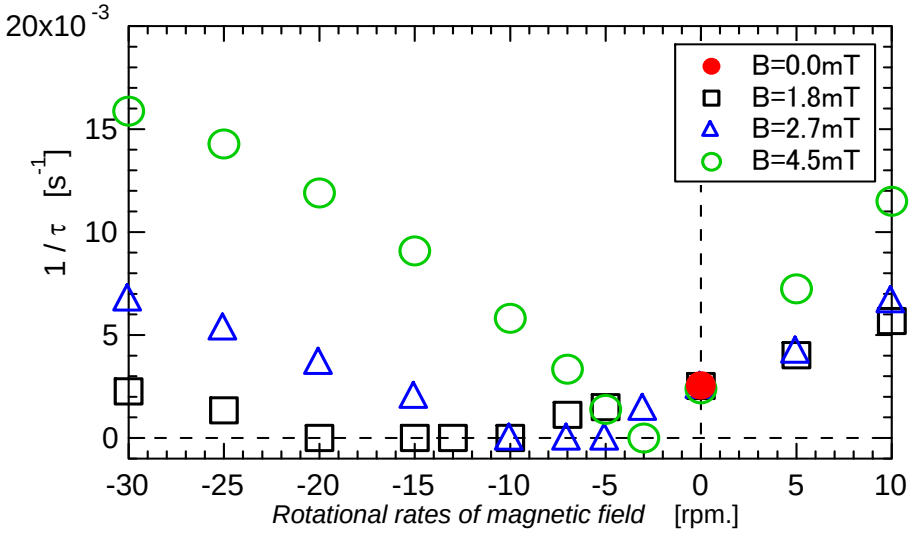


Figure 7. The inverse of the oscillation period of temperature in the melt versus the rotating rates of magnetic field at N_{rod} = 35 rpm and N_{cru} = 0 rpm.

CONCLUSION

The temperature distribution and the transient temperature in the Czochralski melt are measured under the rotational magnetic field. The periodic temperature oscillation is observed in this experimental condition and the temperature distribution rotates in a crystal rotating direction under the non-magnetic field. The oscillation period slightly increases with the increase in the magnetic flux density in a static horizontal magnetic field, though the rotating direction of temperature distribution is the same as that of the crystal rotating direction. Under the rotational magnetic field, the oscillation period decreases with the increase in the rotating rates of magnetic field in the same rotation direction as that of a crystal rod. For the counter rotation of the magnetic field against to that of the crystal rod, the oscillation period becomes longer for faster rotation rates of a magnetic field. Finally, the melt becomes almost stagnant and starts to be rotated in the same direction as that of a magnetic field at larger strength or at faster rotation rates of a magnetic field.

ABSTRACT**.** The experimental preparation of the rotational magnetic field is studied for the configuration of Czochralski crystal growing system. A pair of permanent magnet is used for generating the magnetic field and the magnet is rotated by the motor. This system enables to vary low rotational frequency (0.05 Hz -1.5 Hz) of magnetic field in contrast to the previous one with using 3-phase electromagnet and inverter power supply. The test experiments for confirming this system are carried out and the temperature distribution and the transient temperature in the melt are measured under the variation of the magnetic flux density and the rotational rates of magnetic field. The horizontal rotational magnetic field is found to affect the melt convection more than the static horizontal magnetic field with relatively weak magnetic strength.

Keywords: *Liquid Metal, Czochralski Method, Rotational Magnetic Field, Permanent Magnets*

INTRODUCTION

The Czochrakski crystal growing method was invented by a Polish chemist, Czochralski [1] and has been widely employed to manufacture the single crystal rods of silicon to be used for semi-conductor integrated circuits. Recent development and economic requirement force to enlarge the crystal rod diameter from current 300 mm to a larger size. This inevitably requires the larger depth and diameter for a crucible for silicon melt and makes the melt convection faster and more chaotic. It is important to calm the convection of melt for the successful seeding and/or stable growing with a constant diameter single crystal rod, etc. To calm the melt convection, various magnetic fields have been proposed and employed such as vertical, horizontal or cusp-shaped field (Figure 1(a)-(c)). However, these have various positive and/or negative characteristics [2-4]. On the other hand, a rotational magnetic field could rotate the melt with relatively weak magnetic strength, although there are many unknown characteristics..
The Czochralski crystal growing apparatus includes various complicated scheme such as rotation of a crystal rod, rotation of a crucible, heating system for a crucible, cooling system for growing a

crystal rod as well as a lifting system of a grown crystal rod. The application of additional rotational magnetic field makes the system more complicated even for the simple laboratory experimental system like the present study. The detailed description of this complicated experimental system is the motivation of the present report. Figure 1(d) shows the scheme of the rotational magnetic field. A transverse magnetic field passes through the melt and rotates with time. Some experimental studies were carried out for the rotational magnetic field under the Czochralski system [5,6]. The 3-phase electromagnet and inverter power supply were used to generate the rotational magnetic field. In their system, they had a difficulty to apply the low rotating frequencies of magnetic field at less than 20 Hz due to the limitation in the inverter power supply. Previously, we [7] carried out the model experiment of Czochralski system under the rotational magnetic field for which magnetic field was applied with using 3-phase and 2-pole electromagnet with the inverter power supply. In that system, the inverter power supply was limited up to 10Hz and the output voltage varied with the frequency of output power. It was difficult to fix the magnetic flux density for the general inverter power supply, for which the magnetic flux density of electromagnet was controlled by three phase transformer and the gauss meter. On the other hand, our present experimental apparatus can supply the low frequency transverse rotating magnetic fields with a simple magnetic system for the Czochralski configuration. The experimental results will be reported in an accompanied paper in this same meeting.

EXPERIMENTAL APPARATUS

Figure 2 shows total scheme of the experimental system in which each apparatus is numbered and named. Followings are the system configuration.

Scheme of the system

The apparatus in Figure 2 is a model for a Czochralski crystal growing system. No.1 is a model for a crucible which is made of a Plexiglas cylindrical enclosure. Its inner diameter is 46 mm, height 90 mm and the bottom wall 3 mm thick. Outside of this cylinder is a water jacket (No.3) through which hot water is circulated from a constant temperature bath (No.5) kept at 60 degree Celsius. The model for a crystal rod (No.2) is a cylindrical copper plate whose bottom surface is in contact with a melt surface. This copper plate is connected to a bottom of a cooling water jacket (No.4) in which water is filled and this water is cooled at a lower temperature with an annular cylindrical jacket. In this jacket, cooling water is run from another constant temperature bath (No.5) kept at 0 degree Celsius. This cylindrical model for a crystal rod is rotated by a motor (No.7) which is controlled on its rotational rate by a motor control unit (No.8). The experimental fluid is molten gallium which is filled in a model of a crucible. The free surface of gallium is easily oxidized and solidified in air. Furthermore, low temperature at 0 degree Celsius produces the water droplets over

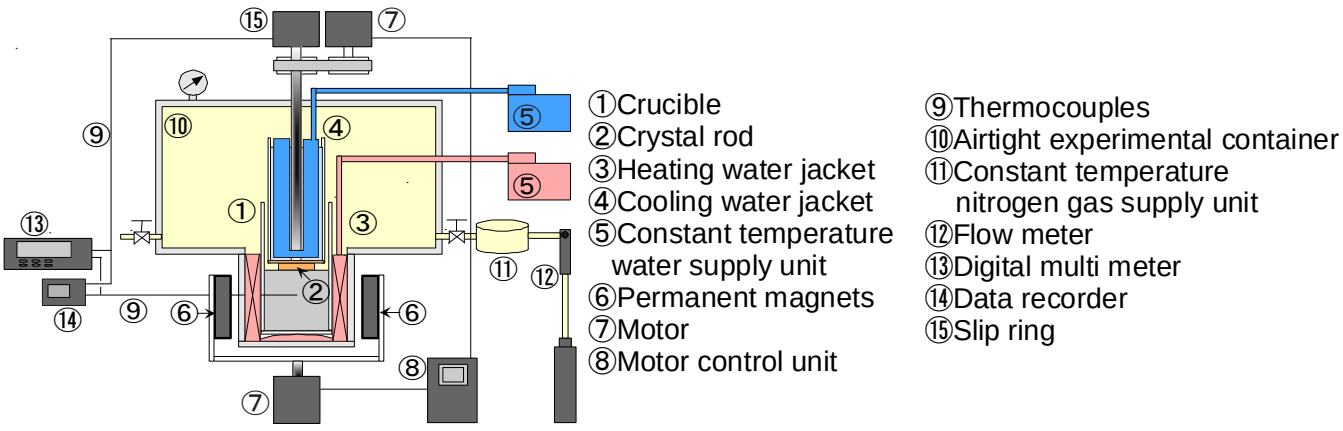

Figure 2. Schematic drawing of an experimental apparatus.

the surface of the model of a crystal rod. To avoid these anomalies, the whole experimental system is kept in an air-tight nitrogen gas chamber (No.10). Nitrogen gas is circulated in this chamber. The nitrogen gas is supplied through a constant temperature supply unit (No.11) and through a constant flow rate controller (No.12). Horizontal magnetic field is applied with a pair of permanent magnet (No.6). This pair of magnet is rectangular shaped and connected to a U-shaped steel plate which is rotated by another motor (No.7). This motor is controlled by a unit (No.8). This magnet provides an almost horizontal magnetic field through a crucible cylinder and is rotated to provide a rotational magnetic field. Rotational direction of this motor is taken as positive for an anti-clockwise one seen from top. This rotational direction is the same as that of a crystal rod. The clockwise rotation is taken as negative.

K-type (Alumeru-Chromeru) thermo-couples (No.9) of 0.1 mm diameter are placed at various locations in a melt, inside and outside of a crucible, crystal rod surface and inside an air-tight nitrogen gas room. These outputs are processed in a digital multi-meter (No.13) and a data logger (No.14).

The gallium melt is selected as the experimental fluid. The physical properties of gallium melt are reported in an accompanied paper in this same meeting.

Magnetic system

Figure 3 shows the sets up of magnets. Two permanent magnet plates of neodymium are fixed on the U-shape steel plate which is 19 mm wide and the distance of magnets (Symbol L) can be varied. The magnets are set at the outside of crucible and the magnetic field passes through the melt in a horizontal direction. The size and the distance of magnets are changed for varying the magnetic intensity. Four kinds of magnets are used for this experiment. The size of magnets and the magnetic flux density on the surface of magnets are listed in Table 1. Various magnetic intensities are tested in this operation. These magnets are rotated by the speed controlled motor with the reduction gear (ratio 1:18) and their rotating rates are controlled from 3 rpm to 90 rpm. The rotating direction of motor can be changed. Rotating rates of magnetic field are from 0.05Hz to 1.5Hz. The other rotating rates of magnetic field can be applied by the exchange of reduction gear unit.

The distribution of magnetic flux density in the x-, y- and z-directions is measured with a gauss meter as shown in Figure 4. The x-direction is normal to the magnet plates and the y-direction is parallel to the magnet plates in the horizontal plane. The z-direction is vertical. The origin of the horizontal axis is the center of melt height and diameter. The distribution of magnetic flux density

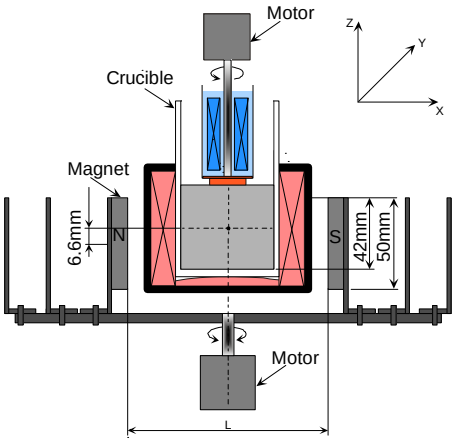

Figure 3. A set up of

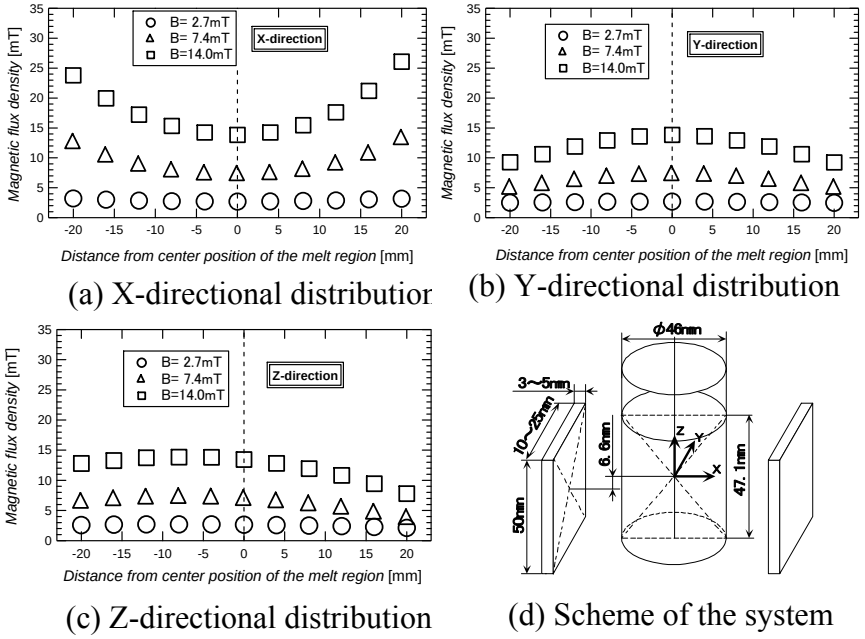

Figure 4. The magnetic flux distribution in the melt.

Table 1
Example of the magnetic set up.

Average magnetic flux density **B**	Magnet size (thickness, wide, height) (The magnetic flux density on the magnet surface)	The distance of magnets **L**
1.0 mT	3x10x50 mm (3300 Gauss)	194 mm
2.7 mT	5x25x50 mm (3400 Gauss)	190 mm
4.5 mT	4x20x50 mm (2800 Gauss)	146 mm
7.4 mT	3x10x50 mm (3300 Gauss)	94 mm
14.0 mT	5x15x50 mm (3200 Gauss)	90 mm

in the x-direction in Figure 4(a) is symmetric and the intensity of magnetic flux density is smallest at the centre. The components of magnetic flux density in the y- and z-directions are largest at the centre. The distribution of magnetic field in the z-direction is asymmetry since the centre of magnet is 6.6 mm lower than the centre of melt in the z-direction. The magnetic flux density varies with the position, so that the average magnetic flux density in the x-, y- and z-directions in the melt region is used for the definition of magnetic flux density B. The relation of the average magnetic flux density B, the size of magnet and the distance of magnets L are shown in Table 1.

Temperature measurement

The temperature distribution in the melt is measured with the K-type (Alumeru-Chromeru) thermo-couples and the locations of thermo-couples are shown in Figure 5. The eight thermo-couples are set in the melt 5.1 mm below the crystal rod. These thermo-couples are located with 45-degree ($\pi/4$ *rad*.) angular interval in the horizontal plane and the distance from the centre is 18 mm. The temperature of crystal rod surface is measured by the K-type thermo-couples whose output is connected to the slip-ring and recorded by the data logger. The temperature of melt, crucible side and bottom walls, ambient gas and crystal rod surface are measured and total measuring points are 20.

In this experiment the temperature is oscillatory and the amplitude of temperature oscillation is less than 1 K. Therefore, the high resolution recorder is necessary for the accurate measurement of transient temperature. The output voltage of thermo-couples in the melt is recorded by the digital multi-meter (KEITHLEY MODEL2000) with multi-scanner card. The resolution of voltage is 0.1 μV (for voltage range of 100 mV) which corresponds to 0.0025 K for the K-type thermo-couples. The cold junction of thermo-couples is kept in the 0 degree Celsius of the distilled water and ice mixture.

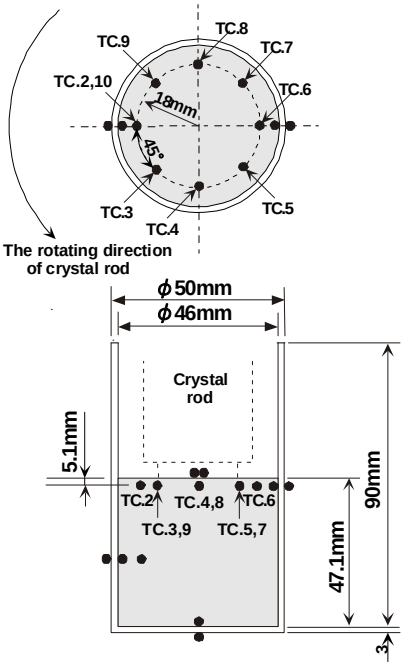

Figure 5. A set up of thermo-couples.

Heating and cooling system

The dummy crystal rod is used in this experimental apparatus. The circular copper plate is set at the bottom of rod which is 23 mm in diameter and 5mm thick. Its surface is covered with the Teflon coating to protect the dissolution of copper surface due to gallium melt. The upper side of this plate is attached to a glass cylinder whose inside is filled with water. The cooling pipe made of aluminium is dipped in the water and the cooling water is circulated through the cooling pipe and the temperature of cooling water is set at 0.0 degree Celsius. The cooling pipe is connected with constant temperature water supply unit (LAUDA RM6S) whose control accuracy is 0.01 degree Celsius. The dummy crystal rod is rotated with the speed controlled motor from 3 to 90 rpm. The outside of crucible side and bottom walls are heated by the hot water. The temperature of water is kept at

60.0 degree Celsius. The hot water is supplied from another constant temperature water supply unit. The nitrogen gas is circulated in the experimental chamber to protect the gallium melt from oxidization. The nitrogen gas temperature and the flow rates affect the heat loss from the gas-melt interface on the gallium melt, and the temperature and the flow rates of nitrogen gas are fixed at 30 degree Celsius and 20 liter per minute.

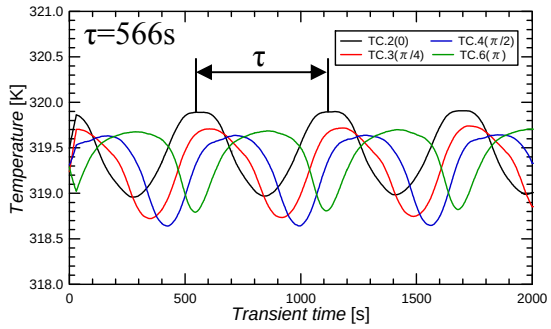
TEST MEASUREMENTS

The temperature of the melt is measured in the melt. The experimental conditions are shown in Table 2. The crystal rod is rotated and the crucible is fixed. The temperature of crucible inner side wall, inner bottom wall and the crystal rod surface slightly change with varying the magnetic flux density and the rotating rates of magnetic field. The rotational rates of crystal rod, the magnetic flux density and the rotational rates of magnetic field are varied in this experiment.

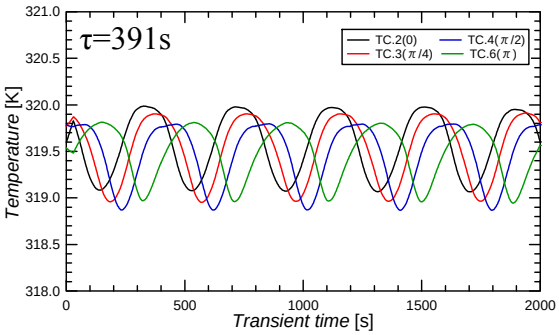
Non magnetic field

Figure 6 shows the transient temperature in the melt for the crystal rotating rates N_{rod} = 30 and 35 rpm with the static crucible and the non-magnetic field (B = 0 mT). Each line corresponds to the measuring position of temperature in Figure 6(c). The temperature in the melt is periodically oscillating for all measuring points. Kakimoto et al. [8] reported the Czochralski melt convection of silicon by using the double X-ray radiography with the tracer. The particle path of tracer was asymmetry and the velocity components in the x-, y- and z-direction were periodically fluctuating. The experimental conditions of this paper are selected to have the oscillatory flow condition to measure the effect of rotational magnetic field. The oscillation period decreases with the increase in the rotating rates of crystal rod. The oscillation periods of temperature at each measuring position are almost the same but the peak timing of each oscillation shifts each other due to the shifted positions in the circumferential positions.

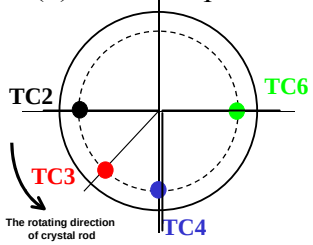
Figure 7 shows the top view of temperature distribution in the melt for the crystal rotating rates N_{rod} =35 rpm under the non magnetic field. This temperature distribution is defined as the temperature difference from the average of oscillating temperature to the measuring temperature at each angular point. Each colour line in the figure corresponds to the time transition of temperature with the interval of τ /4. The temperature distributions turn from black to red, blue and green with time. The temperature distribution is asymmetry and rotates with time. The rotating direction of temperature distribution is counter clockwise whose rotating direction is the same as the crystal rotation for all rotating rates of



(a) N_{rod} = 30 rpm



(b) N_{rod} = 35rpm



(c)Measuring position

Figure 6. Transient temperature in the melt under the non-magnetic field.

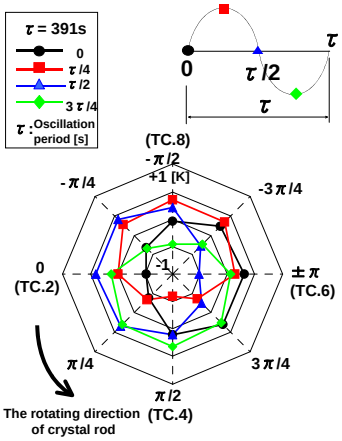


Figure 7. The top view of temperature distribution in the melt under the non-magnetic field at N_{rod} = 35 rpm.

crystal rod. The periodical temperature oscillation at each measuring point in Figure 6 is caused by the rotation of asymmetric temperature distribution.

Static horizontal magnetic field

The static horizontal magnetic field is applied to the melt from B = 1.0 to 19.5 mT and the crystal rotating rate 35 rpm. The other conditions are shown in Table 2.

Figure 8 shows the transient temperature in the melt at B = 2.7 and 14.0 mT. The measuring positions of temperature are the same as those in Figure 6. The observed oscillation period is 397 s at B = 2.7 mT. The oscillation period under the non-magnetic field (B = 0 mT) is 391 s in Figure 6(b), therefore the oscillation period of the horizontal magnetic field is slightly larger than that at non-magnetic field. Temperatures at all four locations are almost constant at B = 14.0 mT to mean infinite long periods.

Figure 9 shows the top view of temperature distribution in the melt at B = 2.7 mT. The bold arrow on the left hand side of picture shows the direction of magnetic field B. The temperature distributions are asymmetric and rotate in the crystal rotating direction. The rotational rate of asymmetric temperature distribution decreases with the strength of the horizontal magnetic field, although the other data are not shown.

Figure 10 shows the inverse of the oscillation period of temperature in the melt versus the magnetic flux density. Lorentz force works for electrically conductive fluid and the oscillation period becomes longer with the strength of magnetic field. Finally, the rotation of fluid flow becomes almost stagnant condition under the strong magnetic field.

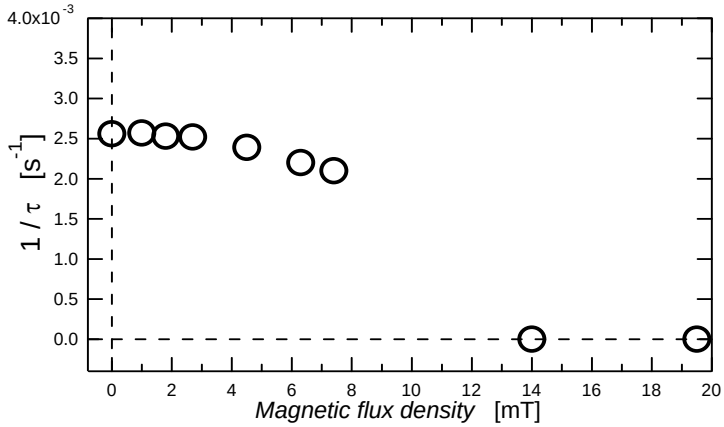

Figure 10. The inverse of oscillation period versus the magnetic flux density under the static horizontal magnetic field at N_{rod} = 35 rpm.

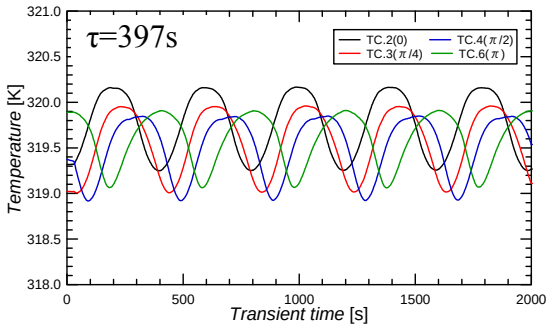
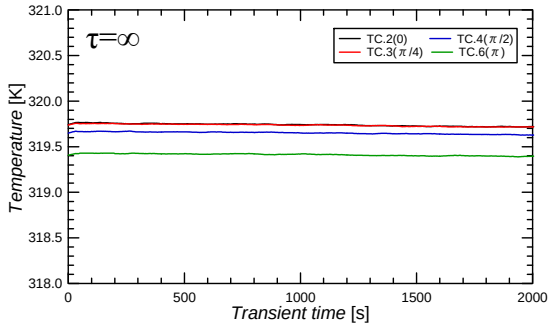


(a) B = 2.7 mT



(b) B = 14.0 mT

Figure 8. Transient temperature in the melt under the static horizontal magnetic field at N_{rod}=35rpm.

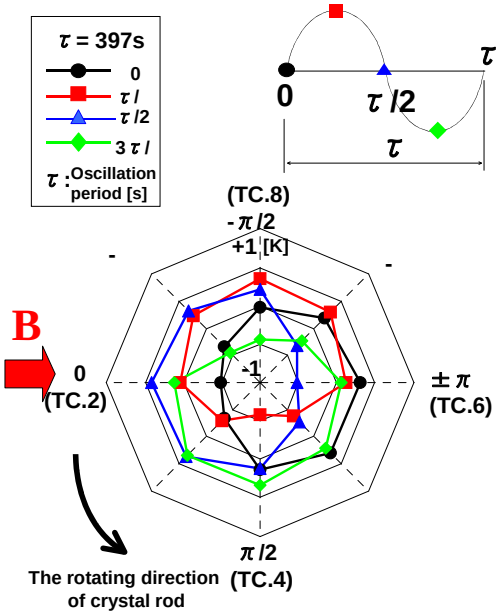


Figure 9. The top view of temperature distribution in the melt under the static horizontal magnetic field at B = 2.7 mT and N_{rod} = 35 rpm.

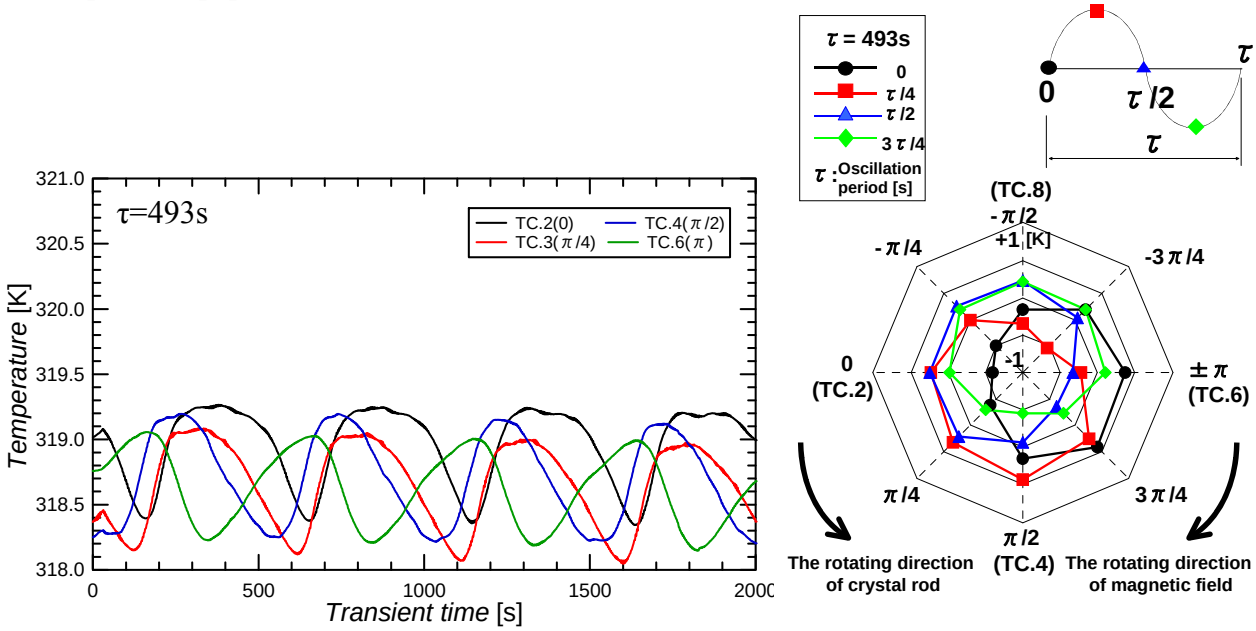
Table 2
Experimental conditions

Item	System parameter
Rotational rate of crystal rod (N_{rod})	30, 35, 40 rpm.
Magnetic flux density (B)	1.0 ~ 19.5 mT
Rotational rate of magnetic field (N_B)	+ 30 ~ − 50 rpm.
Diameter of crystal rod	23.0 mm
Diameter of crucible	46.0 mm
Height of melt	47.1 mm
Temperature of heating water (Th_w)	333.15 K (60.0 degree Celsius)
Temperature of cooling water (Tc_w)	273.15 K (0.0 degree Celsius)
Temperature of heating surface (Th)	318.87~320.05 K
Temperature of cooling surface (Tc)	307.79~314.40 K

Horizontal rotational magnetic field

Figure 11 shows the transient temperature at four points and the top view of temperature distribution under the rotational magnetic field. The rotating rate of crystal rod is N_{rod} = 35 rpm, the magnetic flux density B = 2.7 mT and the rotating rate of magnetic field N_B = - 15 rpm. The negative symbol of N_B means the opposite rotating direction against to the crystal rotation. Under the rotational magnetic field, an induction current may be caused in the thermo-couples due to the variation of magnetic flux density. Therefore, the high frequency noise from the output of thermo-couples is removed by the moving average processing. The oscillation period in Figure 11(a) is 493s and the phase transits from black to green, blue and red. The rotational direction of temperature distribution in Figure 11(b) is the same direction as that of the magnetic field. The rotating direction is opposite in comparison to that for the static horizontal magnetic field in Figures 7 and 9. The rotating direction is switched under the large rotating rates of magnetic field. The detail of experimental result under the rotational magnetic field will be reported in the accompanying paper in this same meeting.



(a) Transient temperature

(b) Top view of temperature

Figure 11. Transient temperature and the top view of temperature distribution in the melt under the rotational magnetic field (N_{rod}= 35 rpm, B = 2.7 mT, N_B = - 15 rpm)

CONCLUSION

The experimental preparation of the rotational magnetic field is described for the Czochralski configuration system. The static horizontal magnetic field and the horizontal rotational magnetic field are applied to the melt and the temperature distribution is measured. The oscillation period of temperature in the melt becomes longer with the increase in the magnetic flux density under the static horizontal magnetic field. The top view of the temperature distribution in the melt is asymmetric and rotates in the crystal rotating direction under the static magnetic field. On the contrary, the temperature distribution rotates in the opposite direction against to the crystal rotation under the reverse directional rotation of magnet field.

EFFECT OF HYDROGEN ON MARTENSITIC TRANSFORMATION OF TiNi SHAPE MEMORY ALLOY PRODUCED BY MECHANICAL ALLOYING

T. Saito*, A. Takasaki
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT. Ti and Ni elemental powders with composition of $Ti_{50}Ni_{50}$ were mechanically alloyed for 30 h, compacted, sintered at 973 K, and annealed at 773 K. Both cathodic and gaseous hydrogen charging were conducted for the bulk samples. The martensitic transformation behavior for the bulk samples after hydrogenation was investigated. The elemental powders turned into amorphous state after mechanical alloying (MA). After compacting, sintering and annealing, however, a B2-TiNi phase with a small amount of Ti_2Ni phase formed in the sample. Martensitic and reverse transformation behaviors were observed in the bulk sample after annealing. The martensitic and reverse transformation enthalpies were reduced by approximately 40% after cathodic hydrogen charging for 24 h in martensitic transformation, while 58% in reverse transformation, although the transformation temperature was not affected by the charging. No martensitic transformation behavior was observed after gaseous hydrogen charging for 120 h, but it was observed again after dehydrogenation.

Keywords: *hydrogen, martensitic transformation, mechanical alloying, current sintering, TiNi shape memory alloy*

INTRODUCTION

TiNi shape memory alloy has been widely used for various industrial fields because of their good mechanical properties, corrosion resistance and fascinating behaviors due to shape memory effect. Especially the application to biomaterials has been increased recently. In terms of the biological application of TiNi shape memory alloy, there are several problems that have to be investigated for the view point of biocompatibility. The influence of hydrogen on TiNi shape memory alloy is one of the issues. It was reported that hydrogen charging in TiNi shape memory alloy resulted in shape recovery phenomenon in martensitic phase, which showed that shape recovery took place during hydrogen charging even below transformation temperature (A_s) [1], martensitic transformation temperature was lowered by cathodic hydrogen charging [2] and hydrogen embrittlement of work-hardened Ni-Ti alloy occurred in acid fluoride solutions [3]. Powder metallurgy has attracted much attention because of the simplicity, cheapness and superior technique to make a complex shape and high quality product as a near-net-shape. Mechanical alloying (MA) process has some advantages to produce intermetallic compounds. It helps to change the local microstructure in the alloys [4], which has possibilities to produce new compositions to improve material properties. In this study, the influence of hydrogen on martensitic transformation behavior of TiNi shape memory alloy produced by a combination of MA and current sintering was investigated.

EXPERIMENTAL PROCEDURE

Commercially pure Ti (99.9%) and Ni (99.9%) powders with composition of $Ti_{50}Ni_{50}$ were mechanically alloyed in stainless steel vials (45 ml) with stainless steel balls whose atmosphere was argon. The MA was performed by a planetary ball mill. The powder after MA was compacted, and sintered at a temperature of 973 K and a pressure of 20 MPa for 10 min under a vacuum condition (2 Pa) by using a current sintering equipment. The bulk samples after sintering were then annealed at 773 K for 1 h under a high vacuum condition (10^{-3} Pa) in a furnace.

Hydrogen charging was conducted by cathodic electrolysis using a 0.9% NaCl aqueous solution at a current density of 50 A/m^2 for several charging times at room temperature. Gaseous hydrogen charging was also conducted at a hydrogen pressure of 4 MPa and a temperature of 473 K for 120 h. The phases of the sample were determined by X-ray diffraction (XRD) measurement using Cu-Kα radiation at 20 kV and 30 mA. The martensitic transformation behavior was investigated by differential scanning calorimetry (DSC). The hydrogen desorption property was measured by thermal desorption spectroscopy (TDS).

RESULTS AND DISCUSSION

Figure 1 shows XRD patterns for the elemental powders after several alloying times. The elemental powders, Ti and Ni, remain at an early stage of MA (10 h). However, a new broad diffraction peak at about $2\theta = 42^\circ$ is observed after MA for 20 h, showing that the elemental powders turned into amorphous state. Compacting, sintering and annealing were conducted for the powders after MA for 30 h.

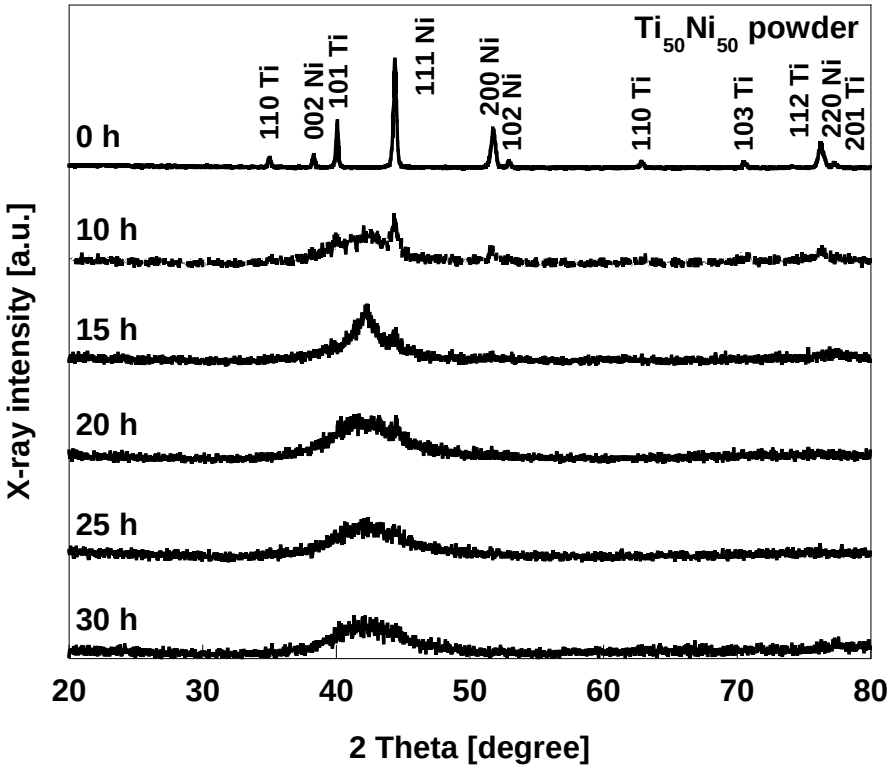

Figure 1. XRD patterns for the powder samples after MA for several alloying times

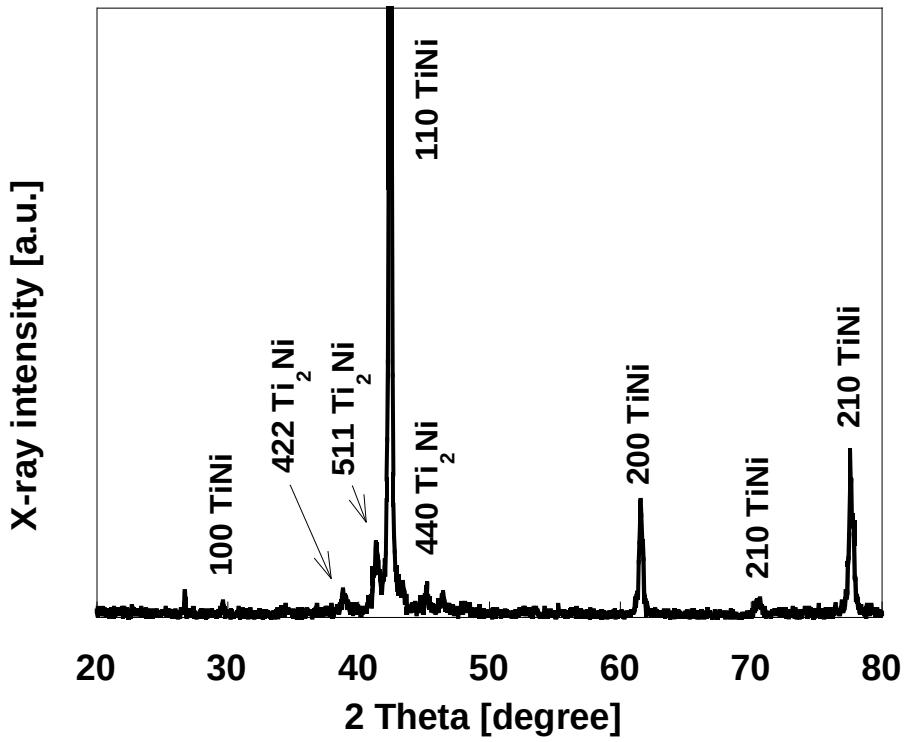

Figure 2. XRD pattern for the compacted sample after sintering at 973 K and annealing at 773 K

Figure 2 shows XRD pattern for the compacted sample after sintering at 973 K and annealing at 773 K. After sintering and annealing, a B2-TiNi phase with a small amount of Ti_2Ni phase formed. Because the B2-TiNi is an intermetallic phase, it shows fundamental and superlattice diffractions in XRD pattern [4]. Both fundamental diffraction at 2θ = 42, 61 and 78˚ and superlattice one at 2θ = 29 and 70˚ are observed. The B2-TiNi is well known as the phase showing shape memory effect (SME) due to thermoelastic martensitic transformation. Bulk density of the compacted sample after sintering at 973 K was 4.8 g/cm^3, which is smaller than that of theoretical calculation, around 6.45 g/cm^3. Therefore it indicates that the sample was porous material.

Figure 3 shows DSC curves for the compacted sample after sintering and annealing. Clear peaks for martensitic transformation (exothermic) and reverse transformation (endothermic) are observed. A transformation temperature width between M_s and M_f (or A_s and A_f) is approximately 20 K. No martensitic transformation behavior was observed for the compacted sample (after sintering) before annealing even if B2-TiNi phase existed in the sample, suggesting that the sample compacted before annealing was not homogenized (martensitic transformation depends deeply on homogenization of the sample). The annealing process homogenized and changed the local microstructure of the sample. In terms of the martensitic and reverse transformation enthalpies, the enthalpies were calculated as 1.65 J/g in the martensitic transformation, while 1.91 J/g in the reverse transformation. However it was reported that a heat of martensitic transformation was 310 cal/mol [5], which is 24.34 J/g. The value is larger than the enthalpies of the sample.

Figure 4 shows XRD patterns for the compacted sample after cathodic hydrogen charging for several times. The XRD intensities of B2-TiNi phase were decreased with increasing charging times and disappeared after charging for 24 h. A TiNi hydride phase, which is thought to form on the sample surface, is observed after charging for 4 h. In case of gaseous hydrogen charging, the TiNi hydride phase is observed after charging for 120 h, as shown in Figure 5. However, the B2-TiNi phase was not detected.

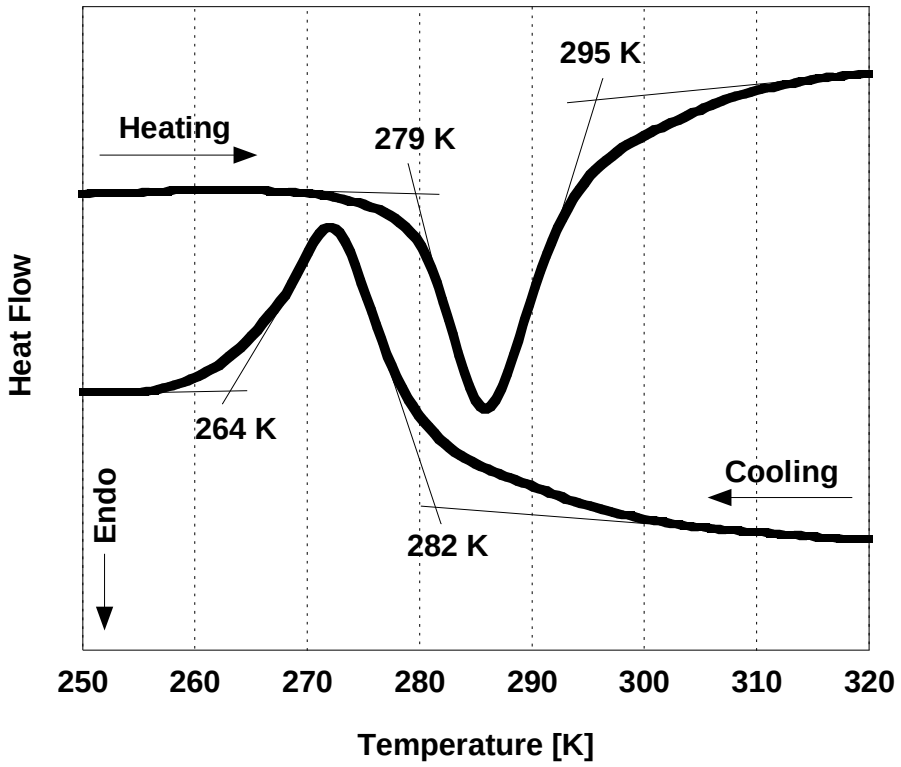

Figure 3. DSC curves for the compacted sample after sintering at 973 K and annealing at 773 K

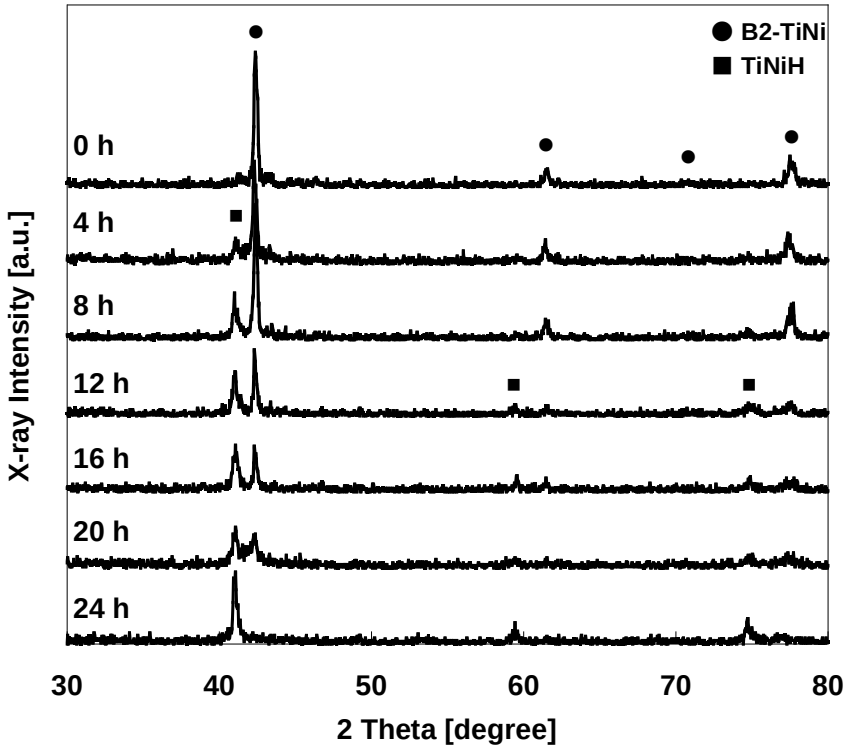

Figure 4. XRD patterns for the compacted sample after cathodic hydrogen charging for several times

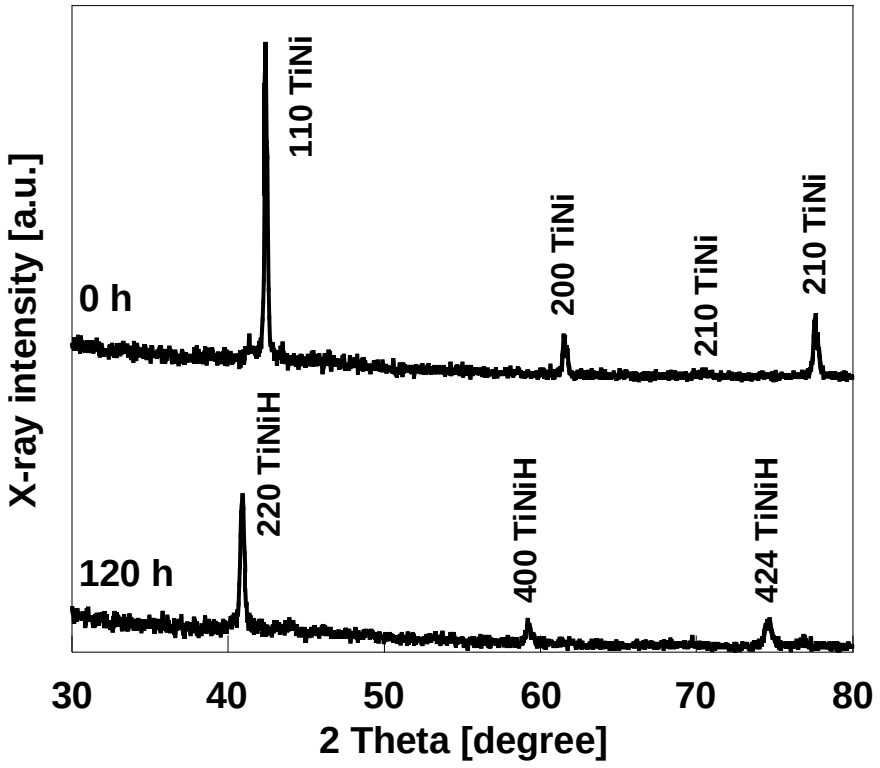

Figure 5. XRD patterns for the sample before and after gaseous hydrogen charging for 120 h

Figure 6 shows DSC curves for the compacted sample after cathodic hydrogen charging for several charging times. Martensitic and reverse transformation behaviors are observed even if the TiNi hydride phase forms after hydrogen charging. Martensitic and reverse transformation enthalpies were reduced with increasing charging times. However, martensitic and reverse transformation temperatures are not affected even after cathodic hydrogen charging. Table.1 summarizes martensitic and reverse transformation enthalpies after several charging times. It shows that martensitic and reverse transformation enthalpies were reduced with increasing charging times, which was reduced by 41% after charging times of 24 h in martensitic transformation, while 58% in reverse transformation.

Figure 7 shows hydrogen desorption curve, measured by TDS, for the compacted sample after gaseous hydrogen charging. Two TDS peaks are observed at 566 and 633 K, showing two different energy levels for the hydride in the sample. Besides, the first peak at 566 K is sharper and more intensive than the second one at 633 K, suggesting that hydrogen bonding of the first peak at 566 K was weaker than the second one at 633 K and the energy level of second peak is stable compared to that of first peak.

Figure 8 shows DSC curves for the hydrogenated sample, by gaseous hydrogen charging, after hydrogen desorption by TDS. Martensitic and reverse transformation behaviors are observed after hydrogen desorption. Therefore, the TiNi phase was recovered after heating the sample because of the hydrogen release. However, the peaks are not clear and the transformation widths between M_s and M_f (or A_s and A_f) is approximately 50 K, which is broader than that before gaseous hydrogen charging. The martensitic and reverse transformation temperatures and enthalpies are lower than those before gaseous hydrogen charging.

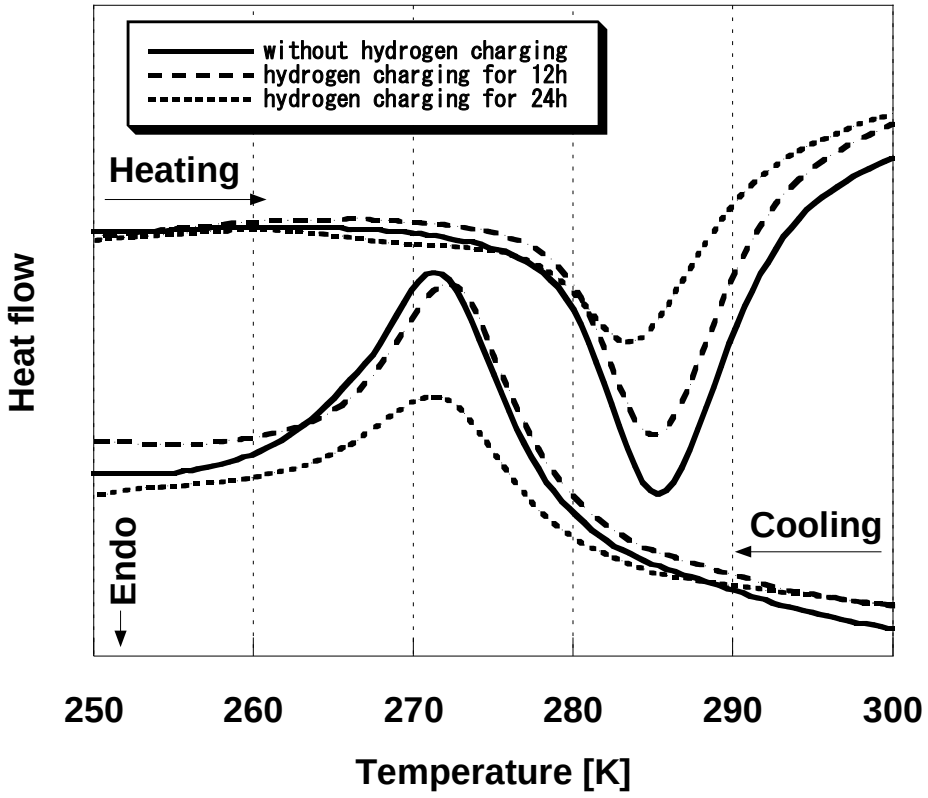

Figure 6. DSC curves for the compacted sample after cathodic hydrogen charging.

Table.1
Martensitic and Reverse Transformation Enthalpies at Several Charging Times

Hydrogen charging time [hour(s)]	Martensitic transformation enthalpy [J/g]	Reverse transformation enthalpy [J/g]

CONCLUSIONS

Ti and Ni elemental powders with composition of $Ti_{50}Ni_{50}$ were mechanically alloyed, compacted, sintered, and annealed. The obtained bulk samples were then hydrogenated by both cathodic and gaseous charging, and the martensitic transformation behaviors were investigated. The results obtained are summarized as follows,

1. The martensitic transformation behavior was not observed for the bulk samples after sintering. The annealing treatment after sintering the bulk sample was required for a recovery of the martensitic transformation behavior.
2. TiNi hydride phase was observed after both cathodic and gaseous hydrogen charging. In case of the cathodic hydrogen charging, XRD intensities of B2-TiNi phase were decreased with increasing hydrogen charging times and disappeared after charging for 24 h. On the other hands, TiNi hydride phase was observed after gaseous hydrogen charging for 120 h. However, the B2-TiNi phase was not detected.
3. The martensitic and reverse transformation enthalpies were reduced with increasing hydrogen charging times, which was reduced by approximately 40% after charging for 24 h in martensitic transformation, while 58% in reverse transformation, however the martensitic and reverse transformation temperatures were not affected by cathodic hydrogen charging.
4. Two different energy levels of hydrogen in the TiNi hydride were identified. The matensitic transformation behavior was observed after hydrogen desorption. However, the martensitic transformation temperature and enthalpy were lowered.

LANGER & MULLER-KRUMBHAAR CRITERION IN THE DESCRIPTION OF THE LIQUID CONCENTRATION AT A GROWING DENDRITE TIP

W. Wołczyński[1,*], R. Martynowski[2], J. Kowalski[2], W. Wajda[1]
Institute of Metallurgy and Materials Science, Polish Academy of Sciences, Kraków, Poland
CELSA "Steelworks Ostrowiec", Ostrowiec Świętokrzyski, Poland

ABSTRACT. Columnar dendrites growth is observed during solidification of some massive ingots of steel or cast iron. The columnar dendrites zone is of special interest in the case of a cast iron rolls solidification. It is postulated that dendrite tip growth follows the criterion of marginal stability formulated by Langer and Muller-Krumbhaar (LMK) as a result of some numerical simulations. An application of the criterion as well as some measurements of *Peclet Number* for a given condition of steel solidification allowed to formulate not only the growth law for a columnar dendrite but the equation for solute concentration ahead of a dendrite tip as well. The differential equation for the solute redistribution after back-diffusion inside the columnar dendrite is also suggested. The solute concentration at the dendrite tip is treated as a boundary condition in solution of above equation for some parts of dendrite appearing sequentially at different growth rates. Each part of dendrite is treated separately in the current analysis. The current model improves the precision of calculation of solute redistribution within a growing dendrite by introducing a new boundary condition changeable with the dendrite growth rate. Additionally a simplified temperature filed for a solidifying ingot or roll is delivered. The simulation of temperature field allows to show the period of time for the columnar dendrite into equiaxed dendrite transition. It is postulated that the period of transition time could be simulated more precisely when the changing solute concentration at the dendrite tip will be taken into account in the simulation of temperature field.

Keywords: *marginal stability, solute redistribution, columnar ➔ equiaxed transition,*

INTRODUCTION

Columnar dendrites or columnar cells zone extends over a large area, especially in some massive ingots of steel or cast iron, Fig.1. The existence of columnar dendrites/cells promote some fissures along the grooves created between dendrites or cells. The fissures propagation could be observed during plastic deformation of some steel ingots (example: forging ingots produced in CELSA "Huta Ostrowiec", Company Limited, Ostrowiec Świętokrzyski) or even during the work of rolls made of steel or cast iron (example: rolls produced in Huta Buczek, Company Limited, Sosnowiec).
The columnar dendrite/cell tip plays essential role in the growth in such kind of morphology. It can be proved that the tip undercooling, ΔT, supersaturation, Ω, and solute concentration of the liquid adjacent to the tip, C_L^*, depend on the radius of curvature of the tip of the dendrite, R.
Additionally, the growth law for columnar dendrite/cell morphology can be developed mathematically to show correlation between three control technological parameters like: tip radius, R, dendrite/cell growth rate, v, nominal solute concentration, C_0, and some material parameters of steel or cast iron.
Finally, the influence of tip radius on solute redistribution and temperature field will be considered.

Fig. 1 presents the massive ingot (as produced in CELSA) with columnar dendrites/cells zone.

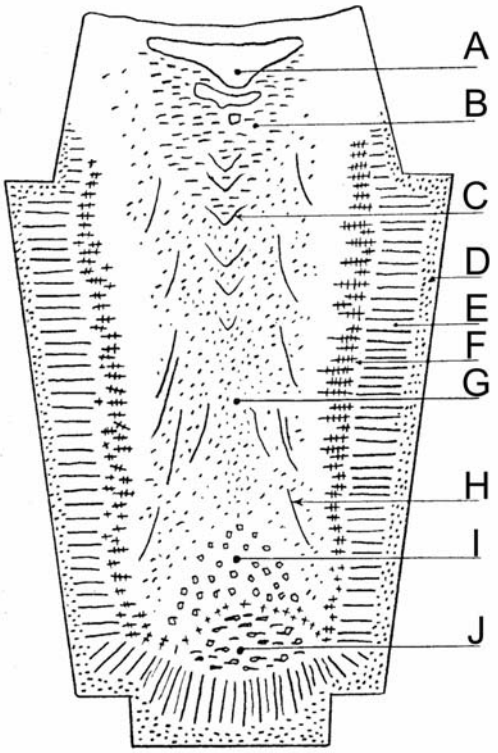

Figure 1. Phenomenological model of the ingot showing some morphological zones:
A – shrinkage cavity,
B – maximum positive segregation area,
C – "V" – type segregation areas,
D – chilled crystals, (equiaxed grains),
E – columnar dendrite/cells,
F – oriented dendrites,
G – high segregation and central porosity,
H – inverted "V" – type segregation areas,
I – negative segregation, (equiaxed dendrites)
J – sedimentary area: oxides and inclusions,
The E and F zones formation is the subject of current model considerations.
The so-called marginal stability criterion shown by Langer and Muller-Krumbhaar, [1] will be applied to a description of the two above zones formation. The LMK criterion is as follows:

$$R_S = \lambda_S \tag{1}$$

MODEL FOR SOLUTE CONCENTRATION AT THE TIP OF GROWING DENDRITE

The LMK marginal stability criterion (equation (1)) which refers to the Glicksman *et al.* [2] measurement and some numerical simulations replaced the conventional maximum velocity condition describing dendritic growth.
The LMK criterion corresponds to the Mullins and Sekerka [3] theory (MS theory) for the solid / liquid (s/l) interface instability.
The minimum wavelength λ_S for planar instabilities results from the MS theory, Fig. 2, and is defined as follows:

$$\lambda_S = 2\pi\sqrt{l\,d_0} \tag{2}$$

The tip radius, R, measurement, Fig. 2, was performed for the set of directional solidification experiments made for steel by the closed *Bridgman* system, [4], to estimate the *Peclet* Number defined:

$$P = 0.5\,v\,R\,D^{-1} \tag{3}$$

The measured *Peclet* Number for carbon steel fulfils the inequality $0.5 < P < 1$ with D - diffusion coefficient. Some observations of dendritic growth proved that the dendrite tip is a paraboloid of revolution, [2]. Therefore, its curvature is equal to $\widehat{K} = 2/R$.
An appearance of the primary branches takes place at a distance which is a number of times greater than the tip radius, R. This behaviour of dendrite / cell is typical and is in good agreement with the LMK analysis of the s/l interface perturbation. It is evident that tip radius plays an essential role in the description of the s/l interface instability (perturbation analysis) and the LMK theory seems to deliver the best criterion to study columnar dendrite growth (is more applicable than conditions of: maximum velocity, or minimum undercooling, or minimum entropy production).

Mode of the dendrite / cell tip radius measurement is shown in details in Fig. 2.

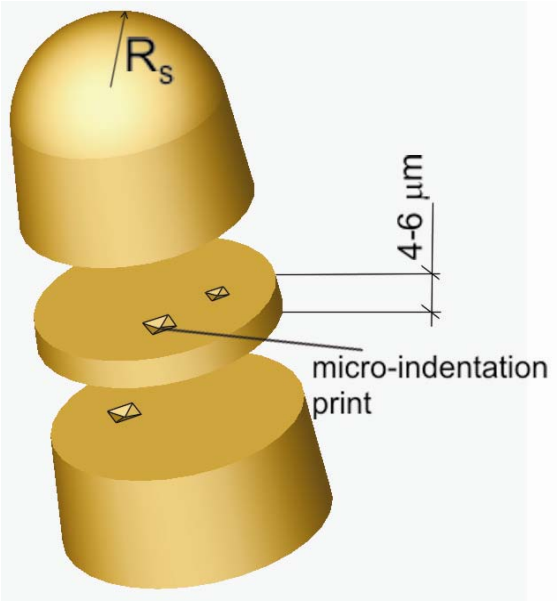

Figure 2. Principle of the dendrite / cell tip radius measurement by the gradual polishing of the smooth part of a dendrite (until first side instability). The polishing allows to measure and reproduce some perimeters of removed slights of 4-6 μm of the thickness. The set of studied perimeters gives possibility of the computer 3D reproduction of the paraboloid of revolution approximately similar to the dendrite tip. The method verifies a hypothesis given by equation (1). $R_{exp.} \approx 22 \pm 4$ μm for the steel containing 0.32 wt % of carbon and solidifying with 1.67 10^{-3} cm/s by the *Bridgman* system. The dendrite is treated as a single crystal so that the 1D mode of solidification is expected for each columnar dendrite / cell, [4].

Transport equations for the columnar structure growth

Mass transport around the dendrite tip growing under steady-state can be successfully described by the *Ivantsov* function, $I(P)$. When the values of *Peclet* Number fulfill inequality $0 \le P \le 1$ the second *Ivantsov* function, $I_2(P)$, is sufficient to be equalized to the supersaturation, Ω,

$$\Omega = I_2(P) = P\exp(P)E_1(P) \approx 2P/(2P+1) \tag{4}$$

The supersaturation is defined as a parameter describing a deviation of the system from an equilibrium:

$$\Omega = \left(C_L^* - C_0\right)/\left[(1-k)C_L^*\right], \qquad 0 \le \Omega \le 1, \tag{5}$$

Both capillarity limit and diffusion limit decide on the value of two control parameters: R and v. An experiment indicates that the tip radius, R, chosen by the solid / liquid system is approximately equal to the lowest wavelength of perturbation of the tip, which is close to the λ_S, Fig. 3. This is referred to growth at the limit of marginal stability for which $R \Rightarrow R_S$, (equation 1).

Perturbation analysis for the dendrite tip

The analysis of perturbation resulting from the MS theory, [3] is shown schematically in Fig. 3.
The rate of a development of perturbation formulated by the MS theory, [3], is given as follows:

$$\frac{\dot{\varepsilon}}{\varepsilon} = \left(\frac{v}{mG_C}\right)\left[-\omega^2\Gamma\left(\omega^* - (1-k)\frac{v}{D}\right) - G\left(\omega^* - (1-k)\frac{v}{D}\right) + mG_C\left(\omega^* - \frac{v}{D}\right)\right] \tag{6}$$

$$\omega = 2\pi/\lambda \tag{7a}$$

$$\omega^* = \frac{v}{2D} + \left[\frac{v^2}{4D^2} + \omega^2\right]^{0.5} \tag{7b}$$

Equation (6) can be useful in characterization of the analysed materials that is steel.

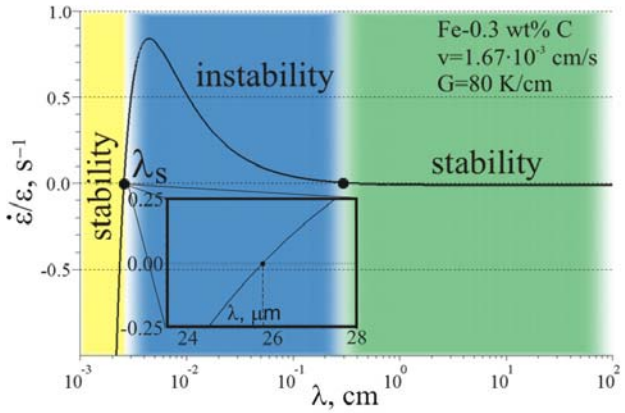

Figure 3. Rate of a perturbation development at the constitutionally undercooled s/l interface. At a very short wavelengths, the value of the $\dot{\varepsilon}/\varepsilon$ parameter (equation (6)) is negative due to curvature damping and the perturbation vanishes. At wavelengths greater than λ_S the instability of solid / liquid interface is observed. The second stability (r.h.s. part of the curve) results from a difficulty of mass transfer over large distances. $\lambda_S \approx 26$ μm according to the calculation.

When $\lambda = \lambda_S$, then the term contained in the square brackets in equation (6) is equal to zero. This occurs when $\dot{\varepsilon} = 0$. As a result the following formula can be obtained:

$$\omega^2 \Gamma = m G_C \xi_C - G, \qquad \xi_C = 1 - 2k / \left\{ \left[1 + (2\pi / P)^2 \right]^{0.5} - 1 + 2k \right\} \tag{8}$$

For $\lambda \le \lambda_S$ the curve is below $\dot{\varepsilon}/\varepsilon = 0$ since the solid /liquid interface curvature damps any perturbation, Fig. 3. At wavelengths greater than λ_S the perturbed interface becomes stable and for high values of the λ again stable plane interface is observed because of the difficulty of mass transfer over large distances.
When the interface is completely stable, the curve will remain below the $\dot{\varepsilon}/\varepsilon = 0$, again.
When the *Peclet* Number is sufficiently small, $0 \le P \le 1$, then $\xi_C \to 1$.
Additionally, a combination of equation (7) and equation (8) with the application of the LMK criterion, equation (1) yields:

$$\lambda_S = 2\pi \left(\Gamma / \left(m G_C \xi_C - G \right) \right)^{0.5}, \qquad \Gamma = \sigma / \Delta S \tag{9}$$

Some rearrangements of equation (4) and equation (5) allows to define one of the important parameters associated with the dendrite tip that is the solute concentration in the adjacent liquid:

$$C_L^*(R,v) = C_0 / \left[1 - (1-k) I_2(P) \right] \tag{10}$$

Simultaneously, the total undercooling of the dendrite tip can be given:

$$\Delta T = \Delta T_C(R,v) + \Delta T_{\bar{K}}(R) = m\left(C_0 - C_L^*(R,v) \right) + 2\Gamma / R = m C_0 \left[1 - 1/\left(1 - (1-k) I_2(P) \right) \right] + 2\Gamma / R \tag{11}$$

Additionally, the solute concentration gradient at the dendrite tip is:

$$G_C(R,v) = dC/dz = -(v/D)(1-k) C_L^*(R,v) = -(v/D)(1-k) C_0 / \left[1 - (1-k) I_2(P) \right] \tag{12}$$

The equation (9) can be simplified when $\xi_C \to 1$ which is justified for the steel/cast iron solidification:
Combination of equations (12) and (9) gives:

$$\lambda_S = 2\pi \left\{ \sigma / \left[\Delta S \left(m (v/D)(k-1) C_0 / \left(1 - (1-k) I_2(P) \right) - G \right) \right] \right\}^{0.5} \tag{13}$$

Growth law for the columnar dendrites /cells array formation

Introducing criterion (1) the following rearrangement of equation (13) can be given:

$$R_S^{\,2}\left(m G_C - G\right) = 4\pi^2 \sigma / \Delta S \tag{14}$$

and after application of equation (12) equation (15) becomes:

$$R_S^{\,2}\left\{m(v/D)(k-1)C_0 / \left[1-(1-k)I_2(P)\right] - G\right\} = 4\pi^2 \sigma / \Delta S \tag{15}$$

According to measurement shown in Fig. 2 the experimental radius of dendrite tip $R_{\text{exp.}} \cong R_S$. Thus,

$$I_2(P) = 2P/(2P+1) = R_{\text{exp.}}\, v/\left(R_{\text{exp.}}\, v + D\right) \tag{16}$$

Taking into account criterion (1) verified experimentally, Fig. 2, and equation (16) it can be given that:

$$m v (k-1) C_0 \left(R_S\, v + D\right)/\left[D\left(D + k\, R_S\, v\right)\right] - G = 4\pi^2 \sigma / \Delta S / R_S^{\,2} \tag{17}$$

Finally, after some rearrangements the so-called growth law for columnar dendrites / cells array formation is obtained:

$$R_S^{\,3}\left[\Delta S\, v\left(m(k-1)C_0\, v - G\, D\, k\right)\right] + R_S^{\,2}\left[\Delta S\, D\left(m v (k-1) C_0 - G\, D\right)\right] - R_S\left[4\pi^2 \sigma\, D\, k\, v\right] - 4\pi^2 \sigma D^2 = 0$$

Equation (18) is a mathematical relationship in which control parameters: R_S, v, C_0, G and materials parameters: $\Delta S, m, k, D, \sigma$ are contained. This formula makes possible to predict R_S - tip radius. However, values of temperature gradient are necessary to be applied in calculation. The temperature gradient can be obtained from a simulation of the temperature field in the solidifying ingot or roll.

MODEL OF TEMPERATURE FIELD IN SOLIDIFYING INGOT / ROLL

In order to predict a period of time during which columnar dendrites transform into equiaxed dendrites a temperature field in solidifying ingot / roll was simulated with the use of the *Fourier* equation, Fig. 4.

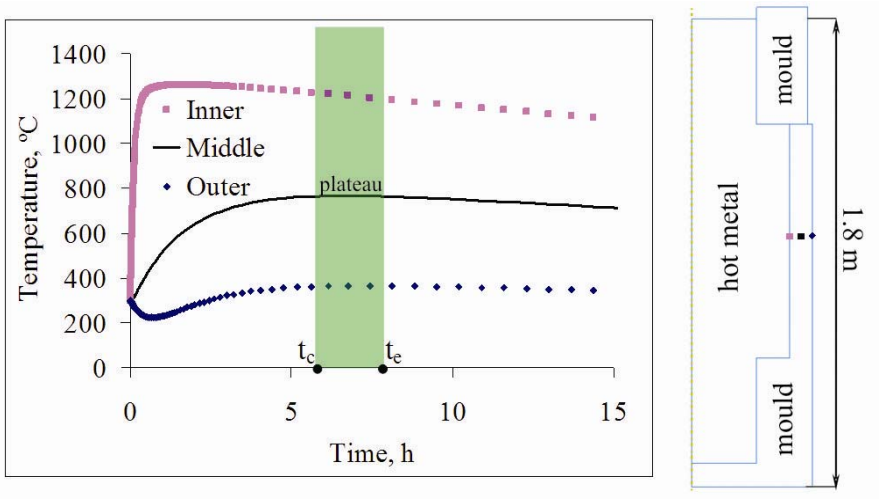

Figure 4. Predicted temperature change in the middle of mould (additionally in inner and outer side) The transition period of time from columnar into equiaxed dendrites is marked as $t_c \leftrightarrow t_e$.

The calculation was performed in the Academic Computer Centre CYFRONET AGH (computer named '*baribal*' was financed from the project MNiSW/SGI3700/PAN/021/2009.
The commercial Finite Element software ABAQUS was used to calculate temperature change in ingot and mould.
The simulation of temperature field includes latent heat, however the convection was neglected. The temperature change in the middle of the mould was associated with period of time necessary for dendrites transition.
It is concluded that the transition occurs when the heat flow through the mould is stable which is visible in Fig. 4 as a plateau, at the middle of the mould curve plotted versus time.

MODEL OF SOLUTE REDISTRIBUTION IN THE GROWING DENDRITE / CELL

Physical bases for present model have already been formulated, [5], in order to improve differential equation, shown by Brody and Flemings, [6]. There are:

- complete mixing in the liquid within the volume element, assumed in Fig. 5,
- increase of solute concentration in advance of the tips of growing dendrites or cells is negligible,
- equilibrium crystal growth and non-equilibrium freezing are integral parts of the current model,
- no assumption is made associated with the movement of the solid/liquid interface,
- a formula for $d\left(x\overline{C}_S\left(x;\alpha\right)\right)$- increment of average solute concentration inside a crystal contains all the factors, which decide on back-diffusion; there are: coefficient of the diffusion in the solid, D_S, amount of growing crystal, x, size of half cell / dendrite, λ^F, rate of dendrite / cell thickening, v_p, and gradient of the solute concentration, $dC_S^*\left(x;\alpha\right)/dx$ in a given layer, dx.

The above assumptions allow to formulate a new differential equation for solute microsegregation, $C_S^*\left(x;\alpha\right)$, as observed at the moving solid / liquid interface:

$$d\left(x\,\overline{C}_S\left(x;\alpha\right)\right)=C_S^*\left(x;\alpha\right)dx+D_S\,/\left(L\,v_p\right)x\left(dC_S^*\left(x;\alpha\right)/dx\right)dx \tag{19}$$

The l.h.s. of equation (19) presents the amount of solute, which entered inside the crystal due to back-diffusion, when the newly growing dx- layer appeared; the first term of r.h.s. of equation (19) presents the amount of solute, which is actually within this layer, (at a solid / liquid interface); the second term of r.h.s. of equation (19) presents the amount of solute which passed across the solid / liquid interface and entered inside the crystal. Equation (19) causes mass balance in the solid-liquid system to not yet be satisfied. Equation (19) determines increase of solute, which is passing from the liquid to the solid across the solid / liquid interface, only, while considering the increment, dx. Taking into account the average thickening rate, v_p, perpendicular to the direction of crystal growth, Fig. 5, the definition of the α - back-diffusion parameter, [6],

$$\alpha=D_S\,t^F\,(\lambda^F)^{-2}=D_S\,/\left(\lambda^F\,v_p\right) \tag{20}$$

can be separated from equation (19). Combining equation (19), equation (20), mass balance consideration for the solid – liquid system, Fig. 5, and assuming that back-diffusion parameter is constant for a given dendrite / cell growth at $v=const.$ the final differential equation is:

$$dC_L^*\left(x;\alpha\right)/dx=\left(1-k\right)C_L^*\left(x;\alpha\right)/\left(1+\alpha\,k\,x-x\right),\qquad k=C_S^*\left(x;\alpha\right)/C_L^*\left(x;\alpha\right) \tag{21}$$

The following initial condition $C_L^*(0,\alpha)=C_0$ allows to solve equation (21):

$$C_S^*(x;\alpha)=k\,C_0\left(1+\alpha\,k\,x-x\right)^{\frac{k-1}{1-\alpha\,k}} \qquad x\in[0,x_K], \quad x_K\in[0,1] \tag{22}$$

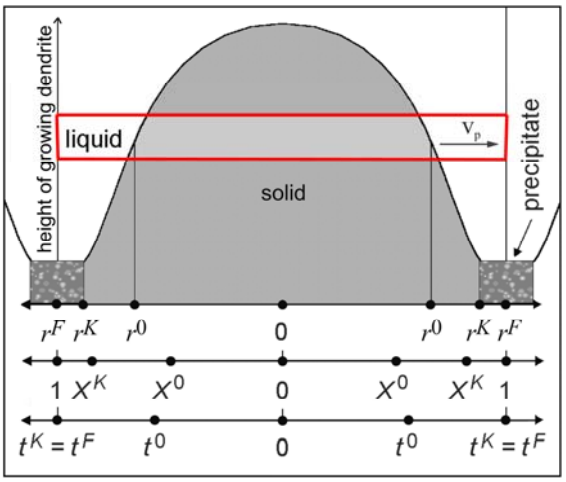

Figure 5. Scheme of the dendrite / cell tip: distance (growing crystal size) ➔ r - axis; crystal amount, dimensionless, ➔ x - axis; local solidification time ➔ t - axis. v_p is the rate of the movement for a generating line of the paraboloid of revolution (rate of the solid / liquid interface motion). r^0, X^0, t^0 define a position on a stopped solid / liquid interface at an intersection with an observation window (solid – liquid volume). r^K, x^K, t^K is a boundary between a crystal and precipitate, at the end of a crystal thickening ($t^K = t^F$).

Finally, the solute redistribution after the back-diffusion inside a dendrite / cell is given as follows:

$$C_B\left(x;X^0,\alpha\right)=C_S^*(x;\alpha)[1+\beta^{ex}\left(x;X^0\right)\beta^{in}\left(X^0,\alpha\right)/k] \tag{23}$$

where $x=X^0$ is a parameter responsible for arrested solid / liquid interface.

CONCLUDING REMARKS

The equation (10) describing the solute concentration at the growing columnar dendrite can be applied to the solution of equation (19) as an initial condition for each section of dendrite. This is explained in Fig. 6 where $C_B(x;1,\alpha)$ means the solute redistribution inside the growing columnar dendrite / cell.

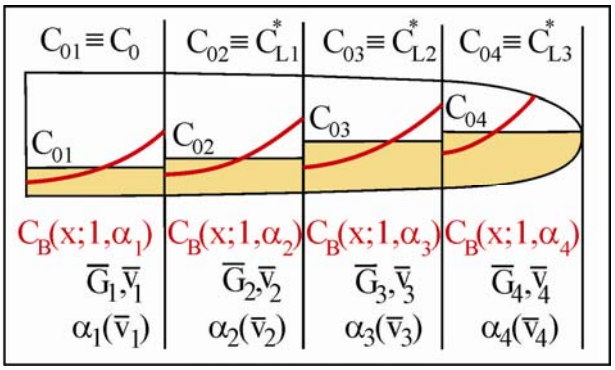

Figure 6. A dendrite / cell divided into four sections. A steady-state growth is attributed to each section. Therefore, average growth rate is $\overline{v}_i = const.$ and average temperature gradient $\overline{G}_i = \partial T/\partial x = const$ in each section. $C^*_{L(i-1)}$ solute concentration at the tip becomes the initial condition for differential equation (19) which should be solved for each section. Thus $C^*_{l(i-1)} \to C_{0i}$ where i is the section number.

The equation (23) describing the solute redistribution after back-diffusion into the growing dendrite / cell can be perfectly mathematically reduced to the description of the equilibrium solidification while applying $\alpha = 1$ and to the description of the non-equilibrium solidification while applying $\alpha = 0$.
The use of $C_L^*(R,v)$ solute concentration (equation (10)) can modify temperature field and localization of the $t_c \leftrightarrow t_e$ zone in Fig. 4. Geometry of mould has also an influence on this localization.

NOMENCLATURE

d_0 thermal capillary length,
D coefficient of diffusion in the liquid,
G temperature gradient in the liquid just at the solid / liquid interface,
G_C solute concentration gradient in the liquid just at the solid / liquid interface,
k equilibrium partition ratio of the solute between the solid and the liquid,
l thermal diffusion length,
m slope of the liquidus line,
β^{ex} coefficient of the extent of solute redistribution inside a growing dendrite / cell, [4],
β^{in} coefficient of the intensity of solute redistribution inside a growing dendrite / cell, [4],
ΔS entropy of melting,
ΔT solid liquid interface undercooling,
ε amplitude of the planar instabilities (perturbation),
Γ capillarity parameter (*Gibbs-Thomson* relationship),
λ wavelength for planar instabilities,
λ_S minimum wavelength for planar instabilities,
σ interfacial energy in the *Gibbs-Thomson* relationship.

MAGNETIC FIELD CONTROL OF CONVECTION IN AN INCLINED FERROCOLLOID LAYER

A. Bozhko[1,*], G. Putin[1], T. Tynjälä[2]
[1]Perm State University, Perm, Russia
[2]Lappeenranta University of Technology, Lappeenranta, Finland

ABSTRACT. Thermomagnetic convection is a feasible method to augment or suppress free convection in non-conducting magneto-polarizable natural media and artificial magnetic nanoparticle fluids (ferrocolloids) especially for small length scale applications or in microgravity. As a rule, nonuniform magnetic fields with gradient directed along or against the acceleration of gravity are used for these manipulations. Present work shows that in the case of an inclined ferrocolloid layer heated from below the similar promotional or overwhelming magnetic field action may be realized by means of external uniform magnetic fields. The understanding of the relation between an applied magnetic field and the resulting heat transfer is necessary for the proper design and control of thermomagnetic devices.

Keywords: *convection, inclined layer, magnetic field, ferrocolloid*

INTRODUCTION

Rayleigh-Bérnard convection in a horizontal cavity heated from below is traditional case to study the formation of convection patterns [1]. Symmetry of the Rayleigh-Bernard convection of horizontal cavity may be destroyed by tilting the layer. As known, thermally driven shear flow in an inclined layer draws up convection rolls in the direction of inclination. In addition, for ferrocolloid with nonuniform magnetic permeability, an external uniform transverse field may cause onset of magnetoconvective motion similar to buoyancy driven natural convection whereas longitudinal magnetic field has orienting effect on convection rolls as in the case of shear flow [2]. For moderate inclination angles a wide variety of different patterns such as longitudinal rolls, tick-like patterns or travelling undulating rolls. Similar observations have been recently made in the absence of magnetic field in [3] and for magnetic liquids with a free surface in [4]. Besides one should note that in the case of ferrocolloids the gradients of magnetic permeability may arise due to both temperature and particle concentration gradients. When ferrocolloid is exposed to the temperature or magnetic field gradient, density gradients within the fluid will be developed due to thermal expansion of the carrier fluid as well as ordinary, thermal and magnetic diffusion mechanisms. In contrast to a horizontal layer in an inclined layer the direction of buoyancy or gravity sedimentation is not parallel with other effects as shown in Figure 1.

One should note that there are two main reasons the generation of concentration inhomogeneities induced by gravity. The former, an effective height of inclined layer increases with the inclination rise and the density drops of barometric origin begin to play a larger role. The latter, the rising–sinking shear flow appearing due to the inclination of a layer, also amplifies the colloidal particles inhomogeneities that is similar to the separation effect in the thermodiffusion column.

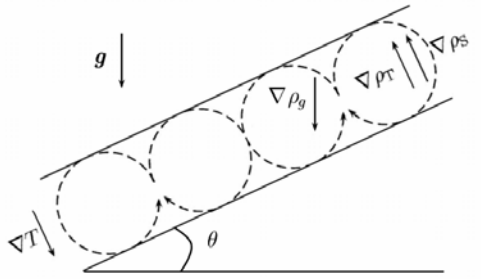

Figure 1. Inclined layer convection - in an inclined layer the direction of temperature gradient is not parallel with gravity acceleration vector. In the absence of magnetic field density gradients inside the layer will be developed due to thermal expansion, gravity sedimentation $\nabla\rho_g$, ordinary $\nabla\rho_T$ and thermal diffusions $\nabla\rho_S$.

RESEARCH METHODS

The stability of buoyancy-driven shear flow and heat transfer in an inclined layer of a ferrocolloid is investigated by experiments and numerical simulations. The stability of mechanical equilibrium as well as intensity of convective motion of non-isothermal ferrocolloid subjected to gravity and magnetic fields are determined by gravitational and magnetic Rayleigh numbers, Ra and Ra_{m}, defined as,

$$Ra = \frac{g\beta\Delta T h^3}{\nu\kappa} \tag{1}$$

$$Ra_{\mathrm{m}} = \frac{\mu_0(\beta_{\mathrm{m}} M\Delta T h)^2}{\rho\nu\kappa(1+\chi)}, \tag{2}$$

where ΔT is the temperature difference across the fluid layer, h is the layer thickness and g is the acceleration due to the gravity. β and β_{m} are thermal expansion and relative pyromagnetic coefficient, M, χ, ρ are the magnetization, susceptibility and density of the ferrocolloid and μ_0 is the vacuum permeability. Whereas gravitational Rayleigh number describes the ratio of buoyant and viscous forces, the magnetic Rayleigh number is ratio of magenetic and viscous forces. Critical Rayleigh number for the onset of convection in horizontal layer is $\mathrm{Ra_{cr}} = 1708$ [1], and for inclined layer longitudinal rolls are predicted to occur at $\mathrm{Ra_{cr}}(\theta) = 1708/\cos\theta$ [3]. The sidewalls influence the formation of the convection patterns significantly when the aspect ratio $A = D/h$ is order of 30 or less [5]. In our case the aspect ratio was varied between 20 and 37.5. Studied ferrocolloid consists of magnetite particles suspended in kerosene carried fluid. The average magnetite particle size was equal to 10 nm, particle volume fraction was 10 % and saturation magnetization $M_{\mathrm{s}} = 48$ kA/m.

Experimental methods

Cross-sectional view one of the test enclosures is presented in Figure 2 [6]. Test enclosures were placed inside of a Helmholtz coil to create uniform external magnetic field parallel to the plane of the layer and while system was tilted in order to study different inclination angles. The cavities with different aspect ratios were used. For the visualization upper copper heat exchanger was replaced with a plexiglass heat exchanger and a temperature sensitive liquid crystal film was attached to the test enclosure. The liquid crystal sheet undergoes its entire color change from brown to blue at temperature interval 24–27^{0}C.

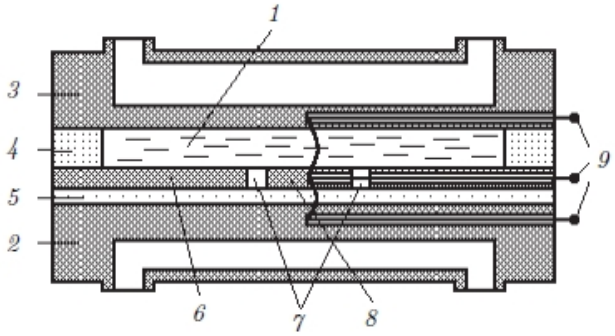

Figure 2. Cross-sectional view of the test enclosure. 1 – ferrocolloid layer; 2, 3 – copper heat-exchangers; 4 – circular plexiglass frame; 5 – fluoroplastic layer; 6 – copper plate; 7 – circular heat-insulating groove; 8 – integral heat flux sensor; 9 –thermocouples. [6]

The onset of convection is determined with the help of thermocouples by well-known method of Schmidt and Milverton [7], where the temperature difference over a fluoroplastic layer was compared with the temperature difference over the cavity filled with the ferrocolloid. As long as the heat across the fluid layer is transported by conduction, the heat flux will increase linearly with temperature difference. This linear relation breaks down at the onset of thermal instability because other modes of heat transport become operative. Average Nusselt number was determined with the help of integral sensor 17 mm in diameter situated in the middle of the cavity [6].

Numerical simulations

Numerical calculations were conducted using a commercial software Fluent. Solver uses finite volume method (FVM) to solve discretized conservation equations. Conservation equations for mass (3), energy (4) and momentum (5) as well as flux function for magnetic scalar potential (6) were solved. In the simulations all fluid properties were defined in mean temperature and held constant, expect for the density and fluid magnetization, for which a Boussinesq type approximation was used. In the method, coefficient of thermal expansion and pyromagnetic coefficient take into account for the temperature dependence of density and magnetization [8]. Fluid properties used in the simulations are shown in Table 1.

$$\nabla \cdot \mathbf{u} = 0 \tag{3}$$

$$\rho_0 \left(\frac{\partial u}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla p + \rho_0 \beta (T - T_0)\mathbf{g} + \eta \nabla^2 \mathbf{u} + \mu_0 \beta_{\mathrm{m}} M_0 (T - T_0) \nabla H \tag{4}$$

$$\left(\frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T \right) = \frac{k}{\rho c_{v,H}} \nabla^2 T \tag{5}$$

$$\nabla \cdot (\mu \nabla \phi_m) = -\beta_m M_0 \nabla T \tag{6}$$

Subscript 0 in above equations refers to the base state at applied external magnetic field H_0 and average temperature between top and bottom walls T_0. Boundary conditions were no slip at the walls, constant temperatures for bottom and top walls, and sidewalls were assumed insulated.

Magnetic scalar potential ϕ_m is use to describe magnetic field inside the simulation domain. Magnetic scalar potential is defined as

$$\mathbf{H} = -\nabla \phi_m \tag{7}$$

According to the Maxwell equations for non-conducting media, following statements for the magnetic induction field B and magnetic field H can be written

$$\nabla \cdot \mathbf{B} = 0 \quad \text{and} \quad \nabla \times \mathbf{H} = 0\,. \tag{8}$$

Magnetic induction field is defined as

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) = \mu_0(\mathbf{H} + \chi\mathbf{H}). \tag{9}$$

In equation (9) χ stands for susceptibility defined as the ratio of magnetic field H and magnetization M. From equations (8) and (9) it can be shown that normal component of the magnetic induction field and tangential component of the magnetic field are continuous across the border between materials with different magnetic permeability. In terms of magnetic scalar potential this means that Laplacian of the magnetic scalar potential is constant at the sidewalls and gradient of the magnetic scalar potential is constant at bottom and top walls. Diameter of the studied cell was 75 mm, height was 3.5 mm were taken as in experiment [6]. The simulation mesh was composed of more than 400 000 tetrahedral cells.

RESULTS AND DISCUSSION

Magnetic field was applied horizontally parallel to the plane of cavity as shown in Figure 3 (a). Due to boundary effects, large magnetic field gradients exist next to the boundaries. Especially for large magnetic field magnitude, boundary effects will create torus like disturbances, as shown in Figure 3 (b). Despite the fact that heat flux was measured only from the center part of the cavity, boundary disturbances are causing some peculiarities to the heat flux calculations at large magnetic field. For moderate aspect ratios, the same effect will limit the simulations to small and medium magnetic field strengths. In the absence of magnetic field, the effect of boundary disturbances will decrease. Liquid crystal visualization of the shear flow in the absence of magnetic is represented in Figure 3 (c). Here white and black regions correspond to hot and cold fluids.

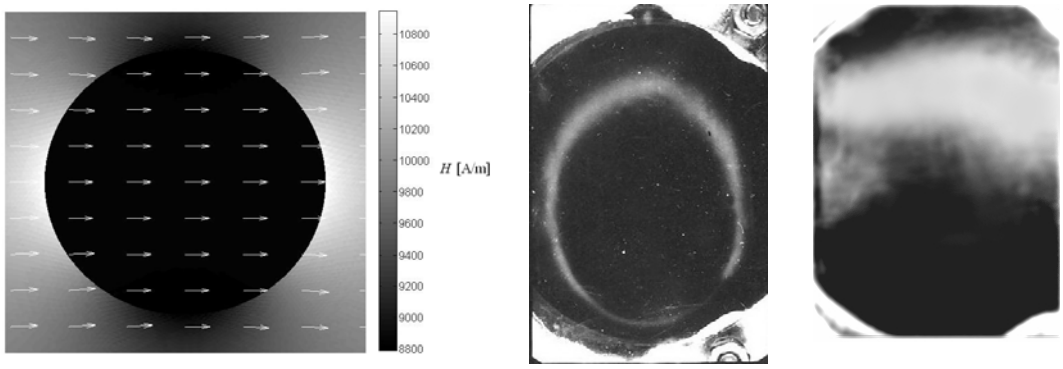

Figure 3. (a) Magnetic field within the horizontal cylinder in the absence of temperature gradient. Arrows show the direction of magnetic field lines. (b) Liquid crystal visualization of torus flow due to boundary disturbances for case $H = 27$ kA/m, $\Delta T/\Delta T_{cr} = 4$, $\theta = 20°$. Magnetic field is parallel with the plane of photo. (c) Temperature stratification in the case of base shear flow for $H = 0$, $\theta = 90°$. The temperature variation from cool (black) to warm (white) liquid is approximately 3 K.

In Figure 4 the Nusselt numbers have been presented for inclination angles 15° and 30°, in the absence of magnetic field. In the absence of magnetic field the increase in convection is more abrupt for smaller inclination angles that for larger ones. Critical temperature difference used in the figures is calculated from horizontal case and for inclined cases at $\Delta T/\Delta T_{cr} = 1$. The spread in experimental values of Nusselt numbers is connected with temperature oscillations which observed in wave convective regimes in inclined ferrofluid layer [6].

In the case of uniform magnetic field, the comparable contribution of mutually perpendicular orientation mechanisms - shear flow and magnetic field - leads to the formation of different types of wave structures in the form of oblique rolls and their superposition. At modest inclination angles it is possible to decrease or increase the heat flux intensity with the help of modulation of the magnetic field value. The decreasing of heat transfer is connected with suppression of gravitational convection rolls whereas the increasing is due to the development of convection rolls oriented along the magnetic field direction.

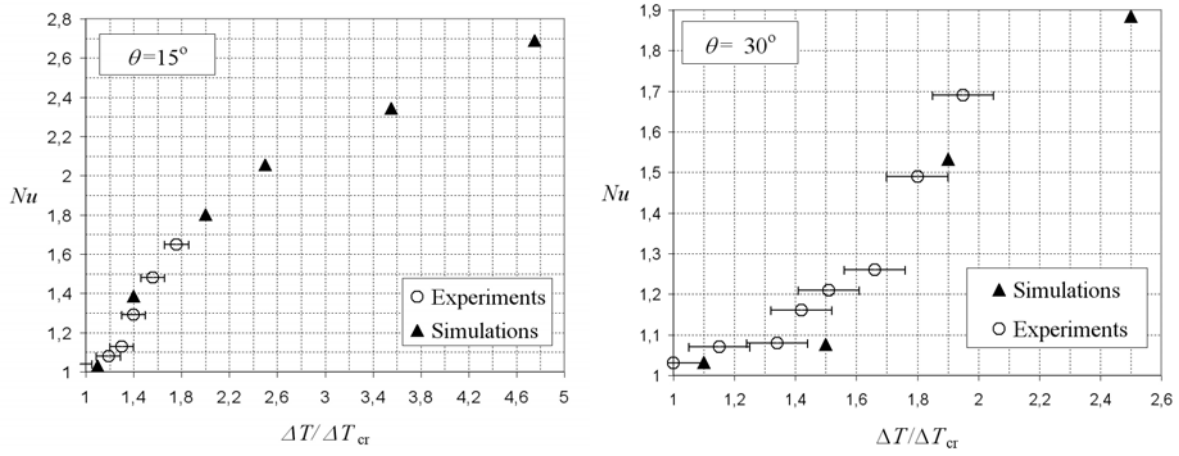

Figure 4. Nusselt number as the function of critical temperature difference for the onset of convection in horizontal layer in the absence of magnetic field for inclination angles 15º (left) and 30º (right).

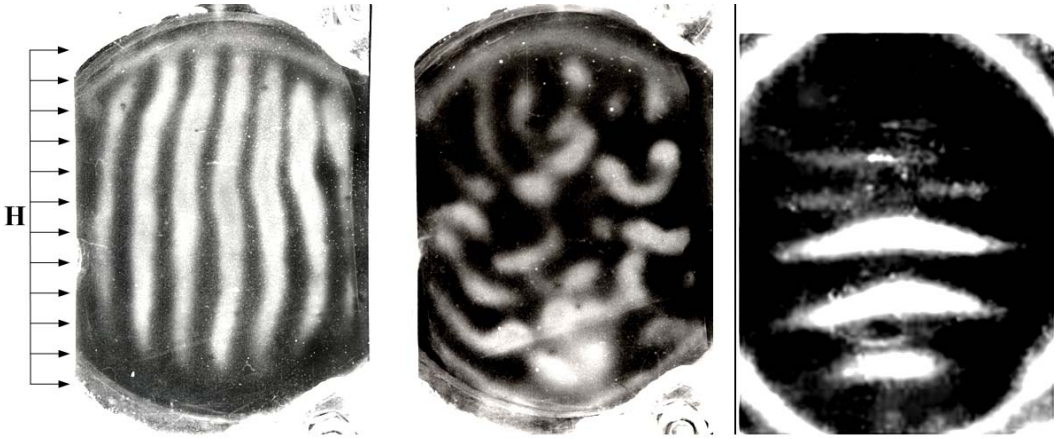

Figure 5. Development of convection rolls in an inclined layer at θ= 15º. Magnetic field is increasing from left to right H = 0, 2 and 10 kA/m. In the figure the upper part of the cavity is elevated

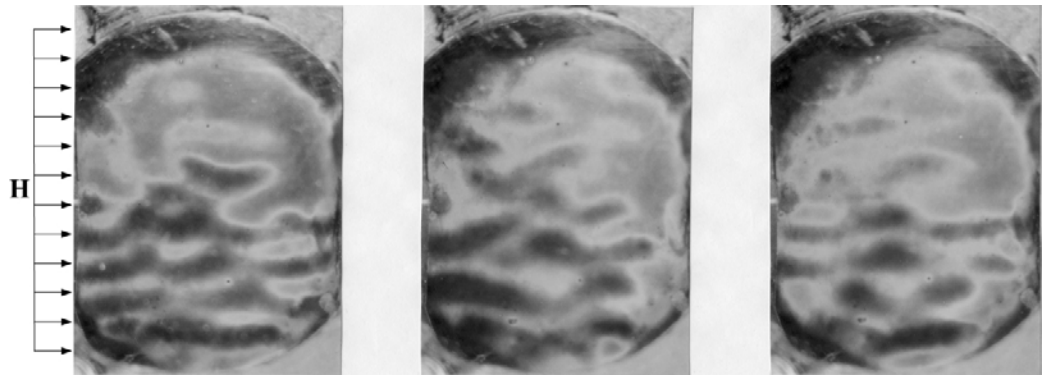

Figure 6. Development of convective rolls for H = 2.5 kA/m and θ= 15°. The time intervals between snapshots are 1 min. In the figure the upper part of the cavity is elevated

Figure 5 shows orientation effect of convection rolls as the magnetic field magnitude increases. If the magnetic field strength and inclination angle are large enough the complete stabilization of Rayleigh convection occurs. The drastic change of heat flux is observed in regimes of travelling rolls and solitary vortices which arise near the boundary of the intersection of gravity and magnetic orientation mechanisms. For small angles and moderate fields, there exist large oscillations in the recorded heat flux. The large oscillations at small magnetic fields correspond to tick-like patterns in Figure 5 for H = 2 kA/m or traveling undulating rolls as shown in Figure 6 for H = 2.5 kA/m.

When the magnetic field is applied the convection rolls orientated in the direction of shear flow are replaced by cells beginning from the lower part of the cavity. In Figure 7 simulation results are shown for the inclination angle 15° after the magnetic field of H = 10 kA/m is turned on. In the upper part of the cavity convective rolls still exist. Increase of inclination angle has an opposite effect on formation of convection. As inclination angle is increased the shear flow takes more place as shown in Figure 8, where simulated convection patterns have been plotted for inclination angles 0°, 15° and 30°, in the presence of magnetic field H = 10 kA/m.

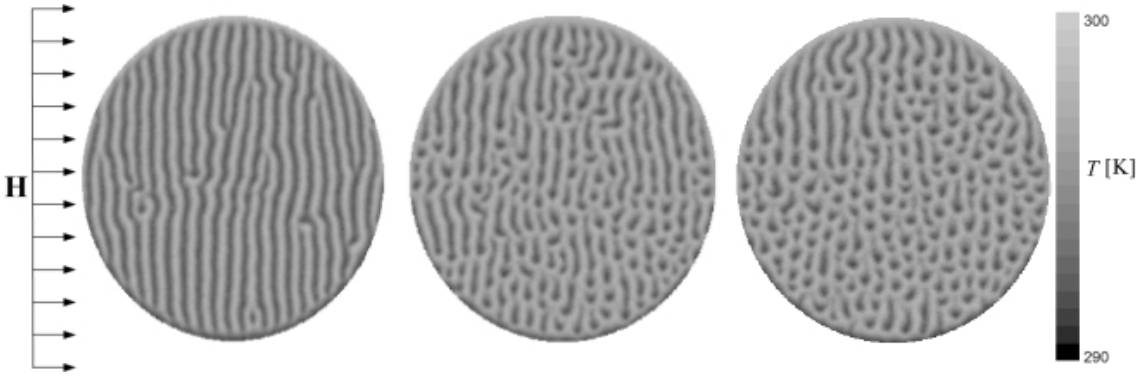

Figure 7. Simulated temperature contours in an inclined layer $\theta = 15°$. When the magnetic field is applied the convection rolls orientated in the direction of shear flow are replaced by cells. In the elevated upper part of the cavity convective rolls still exist.

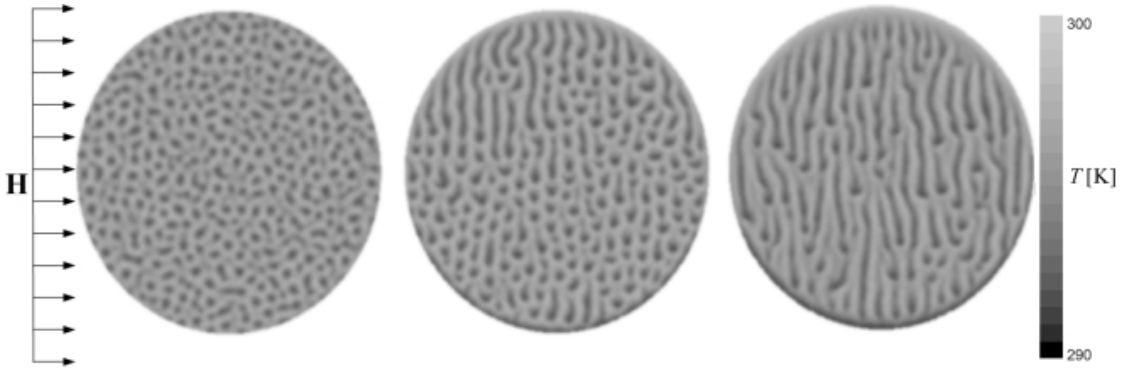

Figure 8. Simulated temperature contours at increasing inclination angles 0°, 15° and 30° from left to right. Here $\Delta T/\Delta T_{cr} = 2$ and $H = 10$ kA/m. In the figure the upper part of the cavity is elevated.

CONCLUSION

Magnetic field control of heat transfer when applied field is applied from the side, parallel with the fluid layer and perpendicular to the inclination angle, may be fulfilled by two main ways. The former is the extinguishing of the convection perturbations along the magnetic field direction at enough large inclination angles. The latter is the alternation of the weakening and strengthening of heat transfer with magnetic field growth when inclination angles are smaller than $\theta = 20°$ and various realignments of convection patterns occur.

ABSTRACT. We focus on coalescence phenomena of liquid droplets with/without suspended particles in confined geometry; in a horizontal creeping tube flow and in a vertical tube in a quiescent fluid. Correlation between the droplets' size and the coalescence time (i.e., period between instances when the relative velocity of two droplets becomes zero after their contact and when the coalescence takes place) are examined. Effects of suspended particles in the droplets on their coalescence are discussed.

Keywords: *Coalescence, Droplet, Creeping motion, Tube, Flow visualization*

INTRODUCTION

Creeping motion of liquid droplets through a capillary tube is generally employed as a fundamental problem for analyzing the flow of multiphase fluids through porous media [1]. Such a phenomenon can be seen, for instance, in enhanced oil recovery, breaking of emulsions in porous coalescers, fluid handling technique, controlling chemical reaction and so on. Preceding works have indicated coalescence time in this system. There exists little information, however, on effects of suspended particles in the droplets concerned on their coalescence. We have paid our attention to coalescence phenomena in the creeping motion of liquid droplets through a capillary tube. In the present study, we focus on this simple, but complex phenomenon in the system that droplets are confined in a narrow tube. We examine two cases; coalescence in a horizontal tube with a forced flow, and that in a vertical tube with a quiescent fluid. We especially focus on effects of particles suspended in the coalescing droplets on coalescence time and induced behavior of the particles as well as the liquid in the droplets.

EXPERIMENT

Figure 1 is a schematic of the experimental apparatus in the case of a horizontal tube creeping flow. Glass tube of 2 or 5 mm in inner diameter, D, and of 1500 mm in length is used as test tube. Silicones oil of 5, 10, 50, 100, 300, 1000 and 10000cSt are employed as the test fluid for the droplet. Glycerol or a mixture fluid of glycerol and pure water is used for a surrounding fluid in the tube. The density of the droplets is matched to that of the surrounding fluid by adding carbon tetrachloride. Ratio of the viscosity between the droplet and the surrounding fluid is defined as $\alpha = \mu_d/\mu_s$, in which the subscript d and s indicate droplet and surrounding fluid, respectively. An over flow tank is used to keep the flow in the tube steady at a designated averaged velocity, V. The test tube is surrounded by a tank filled with a temperature-controlled water to keep the temperature of

the system constant. Droplets are successively injected into the test tube using two pairs of micro-syringes fixed to the tube. Diameters of the leading and following droplets, d_1 and d_2, respectively, are separately controlled. Thus we can control the initial interval between the droplets and their diameters independently. Behaviors of droplets and suspended particles are monitored by a digital video camera placed on a sliding stage. The motion of the stage is electrically controlled to follow the travelling droplets in the tube.

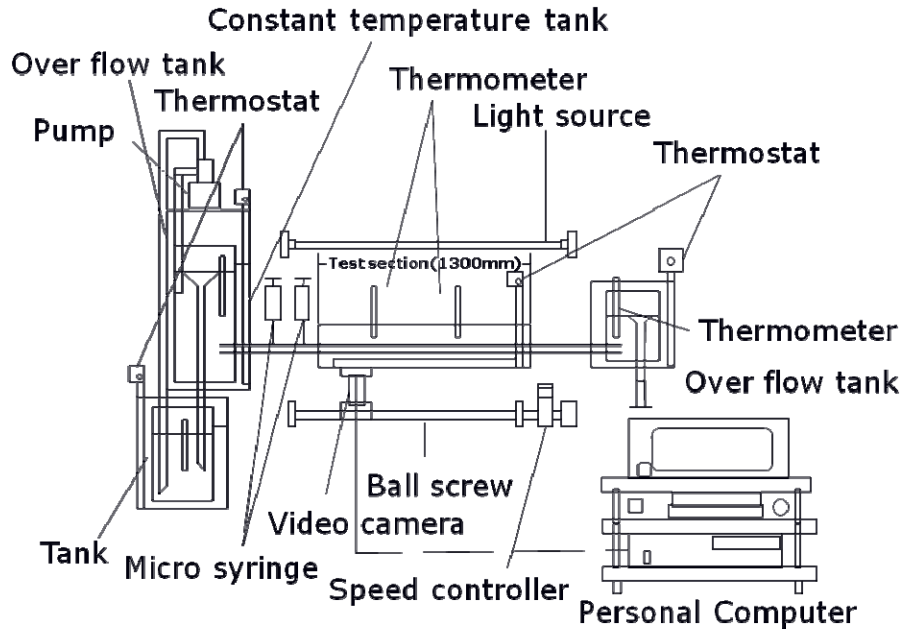

Figure 1. Experimental apparatus for the case of horizontal tube.

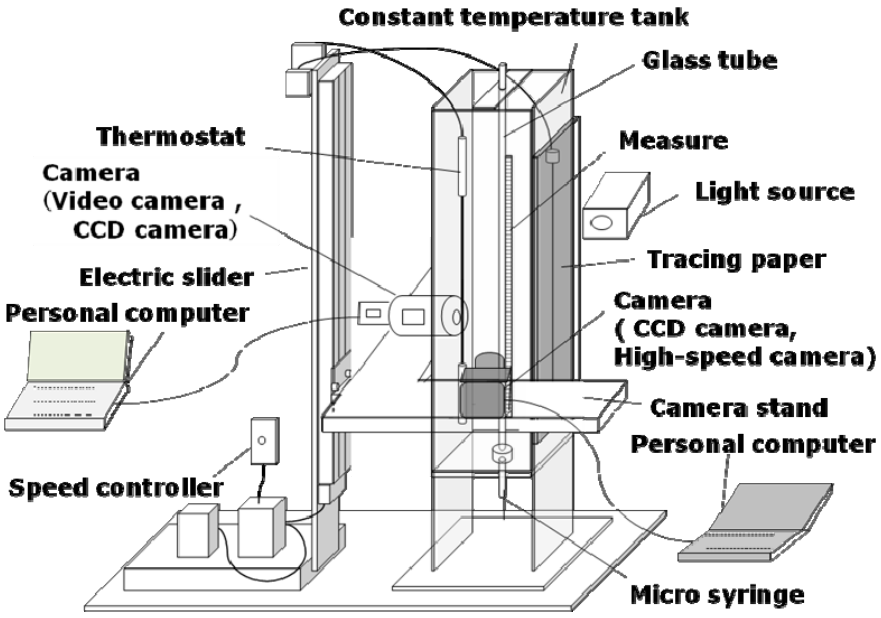

Figure 2. Experimental apparatus for the case of a vertical tube with a quiescent fluid.

Figure 2 is a schematic of the experimental apparatus for the case of a vertical tube with a quiescent fluid. A glass tube of 3.5 mm in inner diameter, 8 mm in outer diameter, and 1500 mm in

length is used as a test tube. Silicone oil droplets are successively injected into the test tube using a single micro-syringe. In this series of experiment, effect of particles suspended in the droplet(s) is examined; gold-coated acrylic particles of 30 μm in diameter and 1490 kg/m^3 in density are employed. Volume concentration of the particles is fixed at 0.13 % in the present study. In the observation system a high speed camera is also employed as well as the digital video camera. The stage for the camera, the test fluid for the surrounding fluid filled with the tube, and the thermal control system for the test section are the same as employed for the experiments with the horizontal tube.

RESULTS & DISCUSSION

Figure 3 shows a typical example of successive images of coalescing droplets without any particles in the tube of D = 5 mm. Experimental condition of this example is $d_1/D = 0.91$, $d_2/D = 0.81$, V = 7.9 mm/s and $\alpha = 0.09$. The kinematic viscosity of droplets is of 564 cSt. Temporal interval between each frame is of 0.5 s. The droplets are colored by adding oil orange for the leading droplet and oil blue for the following. One can clearly see an axisymmetric dynamical motion of following droplet blowing off into the leading one.

Figure 4 indicates coalescence time for different α in the case of D = 2 mm, V = 2.6 mm/s and $d_1/D = 0.984$ against the diameter of the following droplet. Results in the cases of ν_d = 15 cSt ($\alpha = 0.058$), 102 cSt ($\alpha = 0.405$) and 990 cSt ($\alpha = 3.94$) are presented (A surrounding fluid is a mixture fluid of glycerol and pure water). The coalescence time indicates a period between instances when the relative velocity of two droplets becomes zero after their contact and when the coalescence takes place. The coalescence time is non-dimensionalized with D/V followed by a preceding work [2]. In the range of $d_2/D < 0.8$, which corresponds to the experimental range by Ref. [2], the coalescence time decreases as d_2/D increases. This trend corresponds to the one indicated in Ref. [2] In the range of $d_2/D > 0.8$, on the other hand, the coalescence time increases as d_2/D. In order to explain this tendency, one must consider a thin liquid film of R in radius formed between two droplets before the coalescence. Figure 5 represents a diameter of the contact area between the droplets, that is, a diameter of the confined film, against d_2/D. The film diameter takes a maximum value at $d_2/D \sim 0.85$. This value corresponds well with the condition of the minimum coalescence time. This result indicates that the larger the contact area between the droplets, the easier the coalescence takes place.

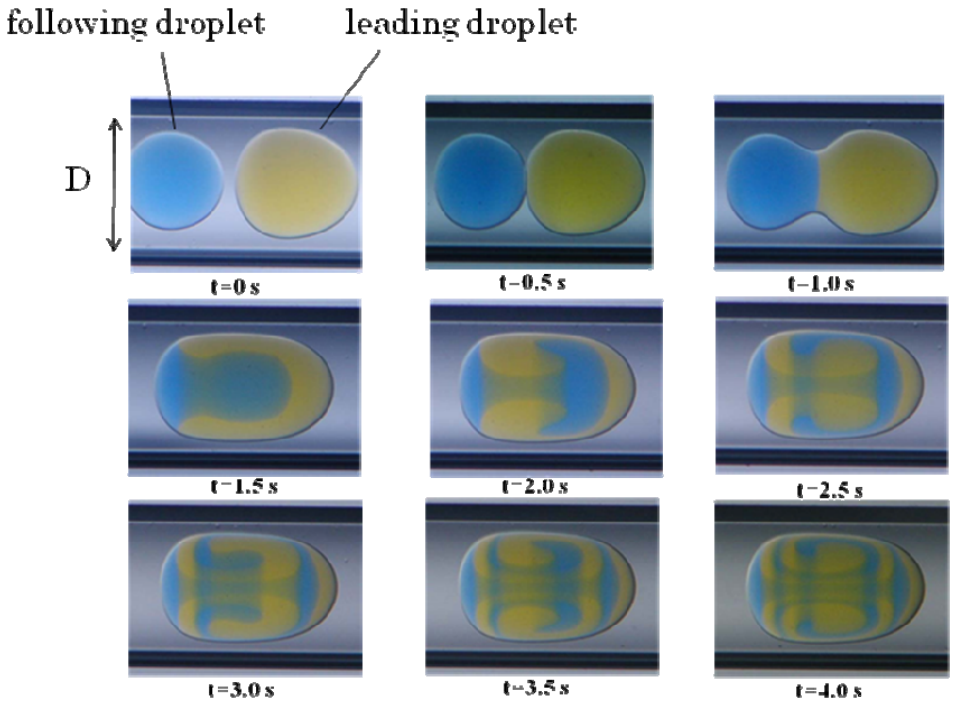

Figure 3. Typical example of coalescence of two droplets flowing in horizontal tube; $d_1/D = 0.91$, $d_2/D = 0.81$, D = 5 mm, V = 7.9 mm/s, $\nu_d = 564$ cSt and $\alpha = 0.09$. Direction of the flow in the tube is left to right.

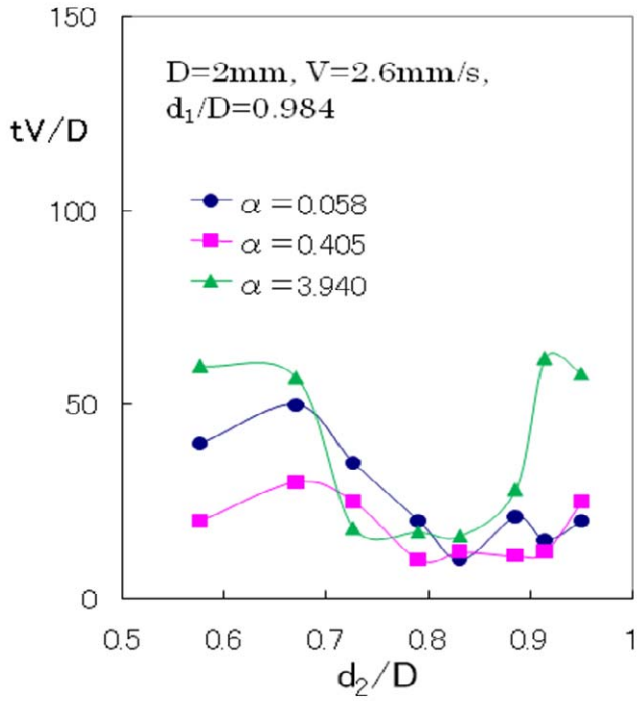

Figure 4. Coalescence time against following droplet diameter for various α in the case of horizontal tube; D = 2 mm, V = 2.6 mm/s and $d_1/D = 0.984$.

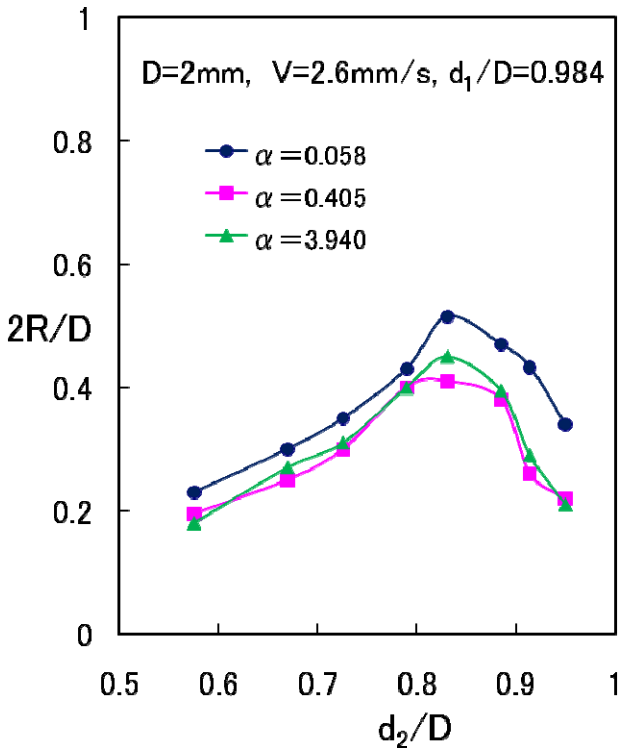

Figure 5. Diameter of contact area between the droplet against following droplet diameter for various α in the case of horizontal tube; conditions are the same as indicated in Fig. 4.

Figure 6 shows an example of temporal variation of droplets' velocities before/after the coalescence in the vertical tube case; U_1 and U_2 indicate the velocities of the leading and following droplets, respectively, and U_3 a velocity of the coalesced droplet. The experimental conditions are $d_1/D = 0.8$, $d_2/D = 0.46$, and the coalesced droplet diameter $d_3/D = 0.87$, and $\alpha = 8.87$. At an early stage of the droplets' travel in the tube, the following droplet pursuits the leading droplet at almost constant velocities. At an instance, interaction between the droplets emerges, and results in making the leading droplet decelerate and the following one accelerating. The relative velocity gradually becomes zero, and they make a contact and flow at a constant velocity for a while. Then the contacted droplets finally coalesce to form a larger droplet, and the coalesced droplet flows at a constant velocity slower than that of the contacted droplet before coalescence. In this case the coalescence time is 21.2 s.

Figure 7 indicates the coalescence time against the diameter of the following droplet under a fixed diameter of the leading droplet and a fixed viscosity ratio. In this figure the coalescence time of the droplets with and without the suspended particles are plotted. The coalescence time takes a minimum value at around $d_2/D = 0.52$ for both cases. Significant effect of the suspended particles is not seen on the coalescent time under this condition.

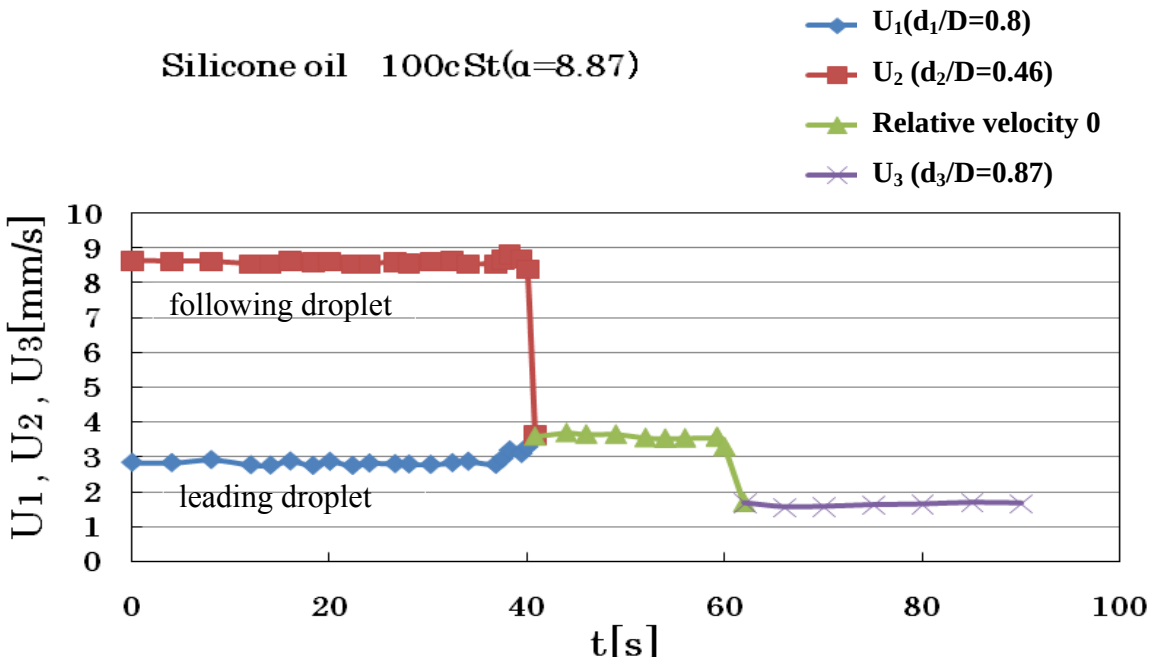

Figure 6. Temporal variations of velocities of leading and following droplets before/after the contact and coalescence.

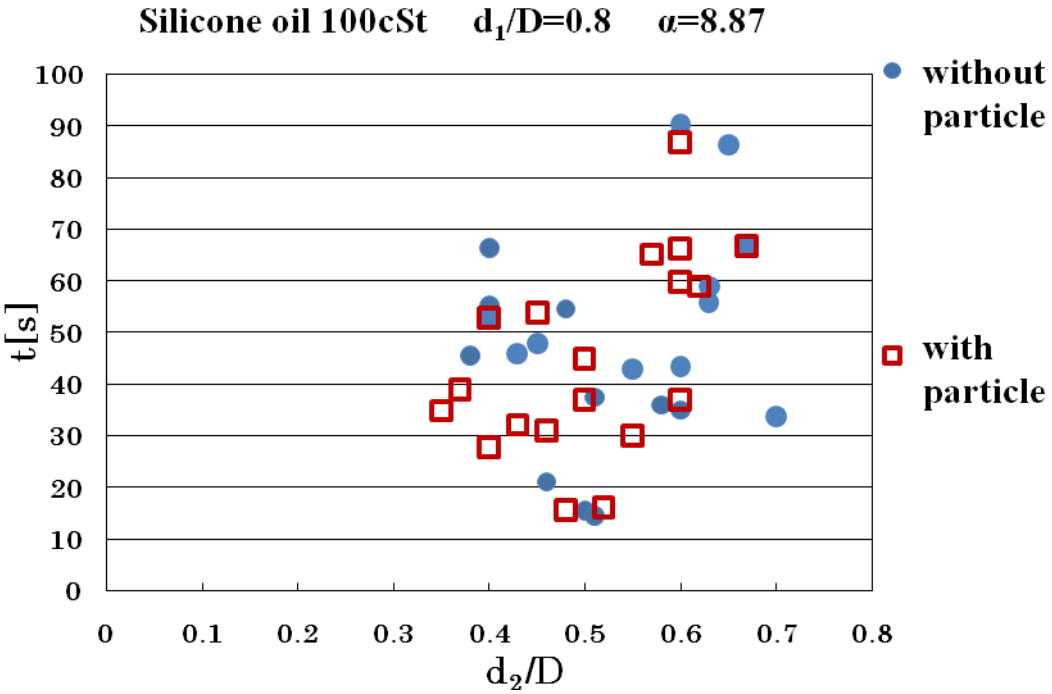

Figure 7. Coalescence time against following droplet diameter; results of droplets with and without suspended particles are plotted.

CONCLUSIONS

Contact and coalescence of droplets in a confined geometry is investigated experimentally. In the case of the horizontal tube creeping flow, induced flow by coalescence of the leading and the following droplets is successfully visualized, and a correlation between the coalescence time (period between the

instances when the droplets make a contact and when they start coalescing) and the contact area between the droplets is illustrated as a function of the following bubble diameter for a various viscosity ratio between the fluids of the droplets and the surrounding fluid in the test tube. In the case of the vertical tube filled with a quiescent fluid, the coalescence time is described as a function of the following droplet diameter for various viscosity ratios. Effect of particles suspended in the droplets on their coalescence of two droplets is examined to find out rather small under this experimental condition.

THE MODEL OF GRAIN LAYER-TO-LAYER DRYING IN HETEROGENEOUS ENVIRONMENT

S. Arhipovs*
Latvian University of agriculture, Jelgava, Latvia

ABSTRACT. Currently, grain drying theory mainly concerns the phenomena of heat and humidity transfer within a grain and the phenomena of heat and mass exchange between grain through space. The nature of drying process is best described by drying curves (humidity - time), drying speed curves (drying speed- humidity) and temperature curves (temperature - humidity). Experimental data is used to construct the curves. However, there system interpretation is difficult because of the separation of the analyses of the diffusion process in the grain and its surrounding environment. The common solution of grain drying problem should consist of full system integration diffusion equations both in the internal environment of a grain layer and in an external environment of a diffusing drying agent.

Keywords: *grain, drying, thermo and moisture diffusion*

INTRODUCTION

The great amount of grain drying experiments prove linear model of this process

$$\frac{dM(t)}{dt} = K(M_e - M) \tag{1}$$

where M - is material moisture, M_e - is material equilibrium moisture, K - is drying coefficient. However, the given model has limits: temperature and speed of drying agent have to be constant, the grain layer, which is exposed to drying, has to be quite thin, but the humidity and the temperature of grain – equally divided through the whole layer when the drying process has an adjusted character.

The differential equation

$$\frac{\partial M(x,t)}{\partial t} = \mu \frac{\partial^2 M(x,t)}{\partial x^2} \tag{2}$$

of moisture transfer is the simplified mass M model diffusion in the homogeneous and passive environment of coordinates x and time t. However in reality natural process of moisture diffusion is often deformed by additional heating of the thermal agent and its compulsory convection. During the drying process the coefficients of moisture and heat transfer usually are not constants. Real diffusion systems are heterogeneous, and there is always an interaction between diffusion mass and environment which changes the conditions of diffusion process passing. Homogeneity and passivity of environment is determined by a diffusion coefficient which is equal to $\mu=\Delta h^2/2\Delta t$ where Δh is a range of diffusion particle in any point of environment for an infinitesimal interval Δt at any moment of system existence. The linear equation of diffusion with constant coefficient is a limit of time and model distance of the elementary scheme particles migration (Figure 1.). Generalization of the elementary discrete scheme

E-mail address: sergejs.arhipovs@llu.lv

of particles migration leads to continuous integral-differential model of diffusion. Thus the dividing condition has to be formulated as a condition of fields overlapping of corresponding heat and humidity potentials of drying agent and grain. The system complexity increases with the variation of environment potentials with time and with integrated heat and mass streams dependencies.

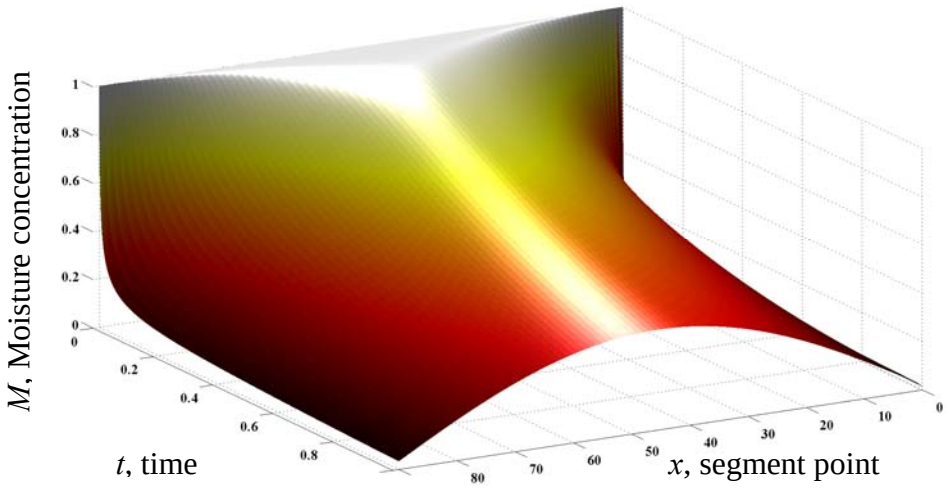

Figure 1. Moisture distribution in segment, during diffusion process with zero moisture concentration on segment boundaries.

For example, the equations describing the process of the drying of a grain layer, where the humidity and the thermal diffusivity are changed with time are so complex that are not always able to be solved analytically. Therefore, in the grain-air system it is necessary to simulate the dynamics of temperature and moisture of the drying agent while it is going through the grain mass, layer-by-layer warming up of grain mass, and also dynamics of coefficients, such as thermal and humidity diffusivity of grain and drying agent.

The solution of such system gives the precise definition of the nature of the drying process under conditions of continuous contact with air. Semantic interpretation of the solution shows not only such concepts as front of drying and its speed, but also allows the analysis of the real mechanism of moisture and heat transfer in grain and the estimation of the influence of various factors on drying process [3]. This also helps to identify the dominant factors of the process and provide an analytical approach to improvements in the process.. This paper describes the construction of the system models for the layer-by-layer drying process of static grain mass with two interactive dynamic potentials of temperature and a moisture. The realization of the given model is related to the integro- differential diffusion equations system solution, which are used in order to model the dynamics of transfer coefficients.

LINEAR MODEL OF GRAIN DRYING

The common solve of a drying problem consists of system integration of the transfer equations in two components - in the material and environment, which surrounds a material [4]. Thus parameters of components depend on each other and dynamically change in time and space. The difficulty of the solving of such systems in engineering calculations leads to used model simplification of drying and very often to its linearization. The use of experimental data linear approximation leads to linear model of drying process (1). The experimental-statistical approach to drying process modeling assumes linear dependence of speed material drying on its humidity and does not explain the nature of process and, moreover, introduces a system error at the initial stage of material warming up , even if to assume that environments is uniform and isotropic.

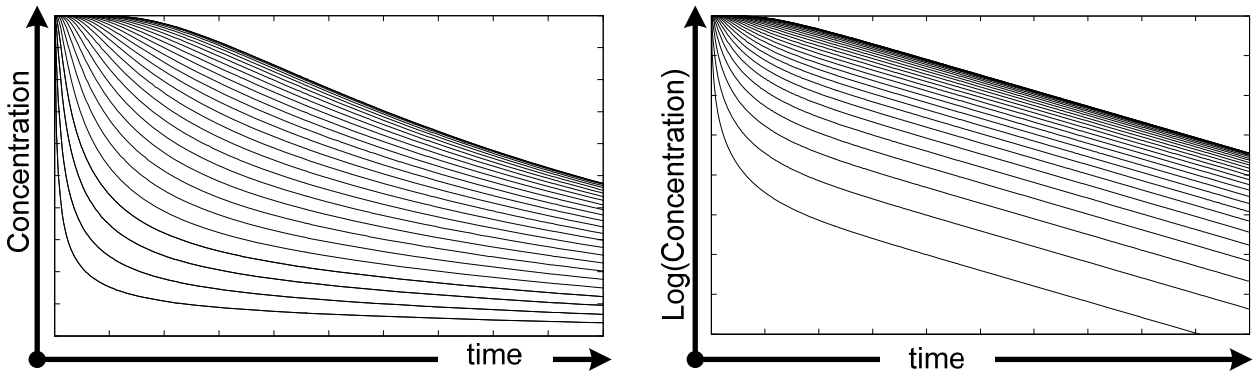

Figure 2. Sub segments humidity concentration curves in dependence on time (left graph) and logarithm of concentration in dependence on time (right graph)

The solution of the linear differential equation well approximates not only experimental data, but also gives good approximation for solutions of the diffusion classical equation (figure 1). In figure 1 distribution of moisture in a one-dimensional core is represented at natural diffusion of moisture through its boundary points. In figure 2 (left graph) drying curves of modelling separate segments core are represented. The bottom curve describes process of core boundary segment drying. An average segment drying of a core is shown by the top curve. The result of drying curves logtransformation is shown in figure 2 right graph. Tails of these data correspond for 100 % to the linear regression model. Thus, the linear model (1) of drying process in some cases adequately describes not only real experiments but also can replace under certain conditions the model of classical diffusion. The purpose of this work is to establish dynamics of moisture and heat moving in one-dimensional thick layer of grain through compulsory aeration from below upwards by the drying agent with the set temperature. The grain bulk is considered in a projection as one-dimensional core of the given length with heat isolated lateral surface. There is a diffusion of a moisture and heat in a core. On the right end of a core there is a constant heat source, the temperature of the core's left end is maintained at temperature equal to zero. Heat moves inside the core with primary and constant drift from the right to the left, that models compulsory aeration or moving of drying agent inside the grain layer aside its surfaces. The moisture moves inside the core with variable diffusion coefficient in each point of a core and which is proportional to the temperature of the core in the given point. At the beginning temperature of a core is equal to zero, the moisture is uniformly distributed on all length of a core and the system "moisture - heat" is in an equilibrium condition [1].

While heating the right end of a core dynamic balance is broken, there is a warming up and, as a result of diffusion increase of moisture coefficient, there is a carrying out of heat and moisture through the right end of a core. It is necessary to construct fields of temperature and moisture distribution on all length of a core in each moment of time.

DIFFUSION OF TWO COMPONET IN GRAIN BULK DRYING

Uniformity and passivity of environment is defined by a constancy of diffusion coefficient. The equation of diffusion (2) with constant diffusion coefficient is a limit on time and model distance of the elementary scheme of particles wandering. The given diffusion model assume that in one-dimensional space the infinitesimal particle in infinitesimal time interval moves from the current position into one of two infinitely neighbour positions. Quantity of particles N in the given point x at any moment $t+1$ is proportional to quantity of the particles which have come from two adjacent points at last time moment and is equal to:

$$N_{x,t+1} = \tfrac{1}{2}\left(N_{x-1,t} + N_{x+1,t}\right) \qquad (3)$$

However, in a reality natural process of moisture diffusion is often deformed by additional heating of the thermal agent and its compulsory convection. At aeration and drying the grain bulk and intergrain air space becomes non-uniform and not isotropic.

Integro- differential equation of diffusion

While drying process coefficient of moisture and heat transfer usually are not constants in time and space. Real diffusion systems are heterogeneous, and between mass and environment there always is an interaction which changes conditions of diffusion process. Therefore generally the particle can change the position for any another and not necessarily adjacent, as in the elementary case. The balance of particles in this case is calculated from recurrent expression

$$N_{x,t+1} = N_{x,t} + \sum_{s \neq x} P(s,x,t) \cdot N_{s,t} - \left[\sum_{s \neq x} P(x,s,t) \right] \cdot N_{x,t} \qquad \sum_{x} P(s,x,t) = 1 \qquad \forall s,t \tag{4}$$

Where *P(s,x,t)* is probability of one particle transition from position *s* into position *x* by the moment of time *t* with restriction on the sum of probabilities. The sums in a limit become integrals and continuous analogue of this relation is the equation [5]:

$$\frac{\partial N}{\partial t} = \int K(s,x,t) N(s,t) ds - \left[\int K(x,s,t) ds \right] \cdot N(x,t) \tag{5}$$

For any particle there can be any preferences in a choice of the new position and, on the contrary, unattractive points for visiting. Such approach leads to necessity of consideration not only classical model of diffusion, but also the generalized diffusion equations, start with the kinetic equation of statistical physics [2].

Heterogenic environment characteristics

The phenomena of heat and moisture transfer inside of grain thick layer during drying are interconnected and mutually caused. Connection among these phenomena is expressed in the form of dependence between temperature and a moisture or an expense of heat for heating of a material and evaporation of a moisture from it during drying. At storage, drying and aeration of real grain bulks in them non-uniform fields of temperature and moisture are created. Thus parameters of heat and moisture transfer also can be dependent on each other. The system "air-grain" is in dynamic balance when absorption or feedback of moisture from air stops.

Dynamic balance is broken as a result of moisture moving in grain bulk among separate grains, and as a result of a temperature difference in various parts of grain bulk. Change of temperature in any site of grain layer is accompanied by moisture moving in a direction of heat stream from places more heated to less heated. Physical assumptions of considered system are expressed in the form of requirements to a kernel $P(s,x,t)$ in the equation (4). If diffusion environment is homogeneous, i.e. the conditions of diffusion are identical in all points, then the kernel $P(s,x,t)$ depends only on distance between points and $P = P(x-s)$. If diffusion environment is homogeneous and isotropic, then $P(x-s) \equiv P(s-x) \equiv P(|x-s|)$. Thus, the relation (3) is a special case of the generalized approach (4), when

$$\forall t \quad P(s,x,t) = \begin{cases} \frac{1}{2} & when \quad |s-x| = 1 \\ 0 & when \quad |s-x| \neq 1 \end{cases} \tag{6}$$

Distribution of probabilities (4) defines equiprobable transition of a particle in one of the adjacent positions for one moment of time. For two moments of time the particle does two equiprobable

jumps and distribution of probabilities corresponds to decomposition members of a degree $\left(\frac{1}{2}+\frac{1}{2}\right)^2=\frac{1}{4}+\frac{1}{2}+\frac{1}{4}$ under the formula of Newton. For three moments of time the particle does three equiprobable jumps and decomposition $\left(\frac{1}{2}+\frac{1}{2}\right)^3=\frac{1}{8}+\frac{3}{8}+\frac{3}{8}+\frac{1}{8}$ answers probabilities of various transitions.

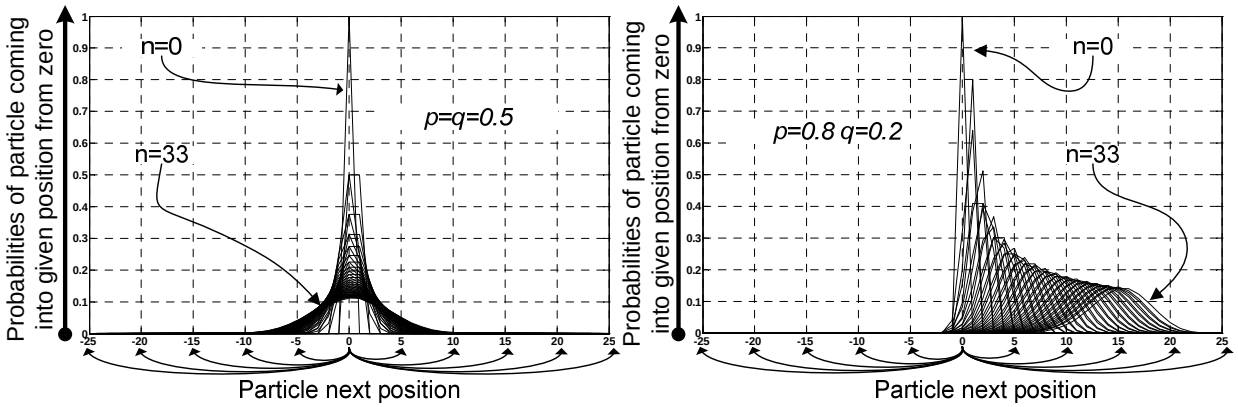

Figure 3. The increase of parameter n in binomial distribution leads to increase in speed of particles transfer in diffusion environment

Thus, if environment is homogeneous and isotropic, then eventually the diffusion process can be slowed down or accelerated, using values of binomial distribution $\frac{n!}{n!\cdot(n-k)!}\cdot\left(\frac{1}{2}\right)^n$ at various values n.

At increase in value n for one discrete moment of time environment is changed also as for n moments of time, only at distribution of probabilities (4).

Uniformity and isotropic of environment is kept if the kernel $P(s,x,t)$ satisfies the binomial distribution $C_n^k p^k q^{n-k}$ at $p=q=0.5$. In this case the discrete relation (4) in a limit aspires to the classical equation of diffusion. At infringement of this relation at diffusion particles there is a drift in the certain side because values of binomial distribution become not symmetric. In figure 3 values of binomial distribution for various probabilities of particle transition which is in a point with zero coordinate are represented. In charts on a horizontal axis there are noted possible positions in which the particle can jump to the present moment from the zero position.

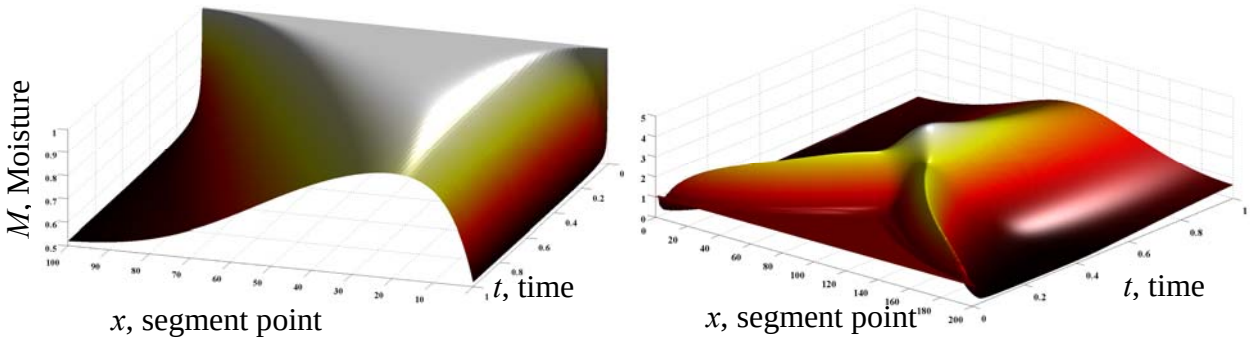

Figure 4. Heating (left graph) and drying (right graph) of one grain layer

On the left chart diffusion environment is characterized by uniformity and isotropy because the identical probabilities the particle can jump as on the left and on the right. When $n=0$ the particle remains on a place. It is the highest peak on the left chart in figure 3. When $n=1$ with probability ½ the particle moves to one position to the left or to the right. With increasing n the cloud of transitions symmetrically creeps away and it increases the speed of particles diffusion. On the right chart coefficients of binomial distributions are represented at $p=0.8$ *and* $q=0.2$, that defines greater

preference to moving to the right and smaller preference to moving on the left. When *n* is high - it is the lowest and most right bell on the right chart, the particle from zero position with the greatest probability will get in position with coordinate *15*, with smaller probability will get in a vicinity of coordinate *15*.

Change of parameter *p* concerning value *0.5* leads to change of environment uniformity. In figure 4 distribution of a mass concentrations field in time are shown. In the beginning the mass has been uniformly concentrated in a all segment, then during time the mass was redistributed as a result of diffusion process (4) with binomial kernel *P (s, x, t)* within parameters *n=33* and *p=0.49*. Discrete process of diffusion was modeled on a segment [0; 100], during an absolute time interval [0;1]. On the ends of a segment the mass value was supported on zero.

Integro- differential model of drying

The task of finding humidity and temperatures fields is related to the solution of integro- differential equations system which is possible to write down as

$$\begin{cases} \dfrac{\partial M}{\partial t} = \int K_M(s,x,t)\cdot M(s,t)ds - \left[\int K_M(x,s,t)ds\right]\cdot M(x,t) \\ \dfrac{\partial Q}{\partial t} = \int K_Q(s,x,t)\cdot Q(s,t)ds - \left[\int K_Q(x,s,t)ds\right]\cdot Q(x,t) \end{cases} \tag{7}$$

$$K_M = K_M(s,x,t,Q),\ K_Q = K_Q(s,x,t,M). \qquad \int K_i(s,x,t)\cdot dx = 1, \quad i=\{Q,M\} \tag{8}$$

Sense of kernels K_M and K_Q consists not only in relative speed of transfer (density of probability of transfer, attributed to time unit) of humidity *M* and temperature *Q* in the moment *t* from position *x* in position *s*. Movement of moisture in grain mass can take place by virtue of temperature difference in the different points of grain mass, therefore a kernel K_M which describes redistribution character of moisture can depend on the environment temperature . A kernel K_Q describes a character of temperature conduction which can depend on humidity consistence in environment. In the case of new particles generation absence on kernels K_M and K_Q limitation of mass saving is laid on because all particles which are in position s in the next moment of time necessarily must appear somewhere. At some additional limits on kernels K_M and K_Q integro- differential equations can be taken to differential equations with particular derivations. The process of drying is modeled by the discrete analogues of integro- differential equations

$$\begin{cases} M_{x,t+1} = M_{x,t} + \sum\limits_{s\neq x} P_M(s,x,t)\cdot M_{s,t} - \left[\sum\limits_{s\neq x} P_M(x,s,t)\right]\cdot M_{x,t} \qquad \sum\limits_x P_M(s,x,t) = 1 \quad \forall s,t \\ Q_{x,t+1} = Q_{x,t} + \sum\limits_{s\neq x} P_Q(s,x,t)\cdot Q_{s,t} - \left[\sum\limits_{s\neq x} P_Q(x,s,t)\right]\cdot Q_{x,t} \qquad \sum\limits_x P_Q(s,x,t) = 1 \quad \forall s,t \end{cases} \tag{9}$$

Distributions of probabilities coincide with the coefficients of the binomial distributing $P_Q = \left\{ \ ...C_{n_Q}^k p_Q{}^k (1-p_Q)^{n_Q-k}... \ \right\}$ and $P_M = \left\{ \ ...C_{n_M}^k p_M{}^k (1-p_M)^{n_M-k}... \ \right\}$, the parameters of which functionally depend on descriptions of environment thermodynamicses characteristics.

Speed n_Q and direction p_M heat propagation can be constants or depend on moisture countenance in the system $n_Q=n_Q(M)$ and $p_Q=p_Q(M)$. Accordingly, speed n_M and direction p_M moving of moisture can be constants or depend on the temperature of the system $n_M=n_M(Q)$ and $p_M=p_M(Q)$ in current time.

SISTEM OF INTEGRO- DIFFERENTIAL EQUATIONS AND HETEROGENIC ENVIRONMENT CHARACTERISTICS

The purpose of conducted numerical experiments is a construction of moisture and temperature fields by the solution of the recurrent expressions system (7) for an analysis and comparison of the summarized results with the classic diffusion equation solutions. A behaviour of the two component system "grain - air" is modelled by a one dimensional segment. In the initial moment of time a temperature equals to zero in all points, and humidity in every point equals the conditional unit. During all time the right border of segment is heated and system temperature component propagate with constant speed which sets to be $n_Q = 22$ in the binomial distribution $P_Q = \left\{ \quad ...C_{n_Q}^k p_Q{}^k \left(1 - p_Q\right)^{n_Q - k} ... \quad \right\}$. The forced aeration of grain mass is imitated by the temperature parameter $p_T = 0.45$ and by temperature values reflection into a segment in relation to his right border. On the left graph of figure 5 the layer segment temperatures dynamics is represented at the constant heating of it border in a point.

Character of moisture distribution is imitated with the use of probabilities distribution $P_M = \left\{ \quad ...C_{n_M}^k p_M{}^k \left(1 - p_M\right)^{n_M - k} ... \quad \right\}$ with the parameter of diffusion speed $n_M = Q_{x,t}$, which is equal to an absolute value the temperature of environment in this point in current time. Like a temperature, the values of layer moisture are reflected into a segment. Analysing dynamics of moisture, on the right graph the characteristic peak of moisture concentration is seen in every layer.

Comparing two graphs it is seen that motion of moisture peak coincides with the layer segment warming up period on all its length. The practical supervisions of grain drying process confirms the brief increase of humidity of corn intermediate layers on the initial drying stages.

EXPERIMENTAL DATA OF GRAIN LAYER-TO-LAYER DRYING

In order to check adequacy of numerical experiment of real processes, a laboratory stand has been planned (figure 6) which is intended for the receipt of information about the amount of moisture in the separate layers of grain mass during all time of the experimental drying, is planned.

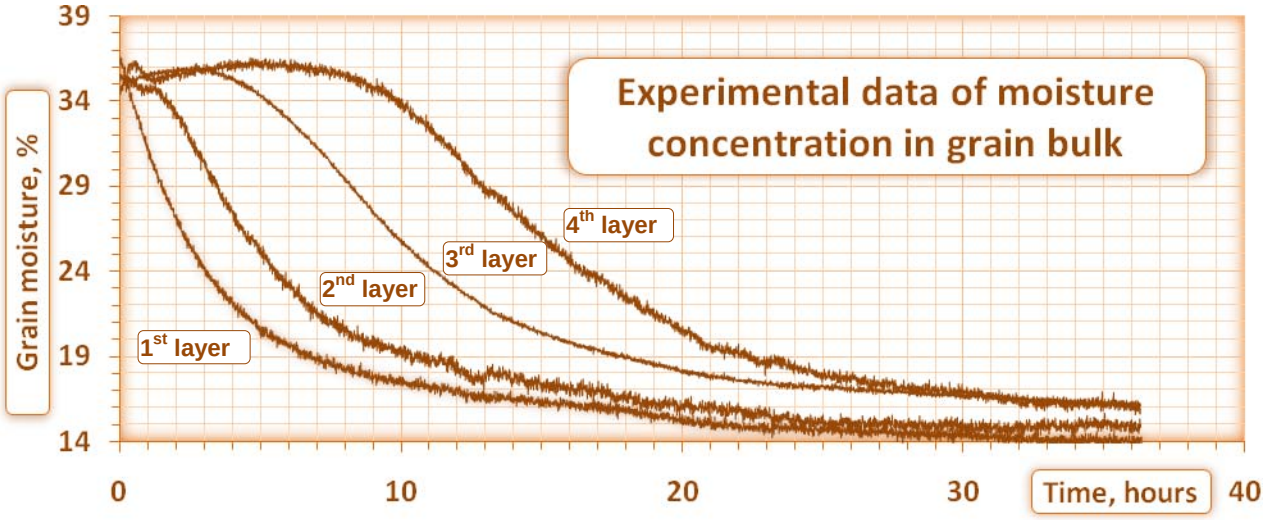

Figure 6. Moisture concentration in four sequences layers of grain bulk during 36 hours of it aeration.

CONCLUSIONS

Generalization of the elementary discrete scheme of particles migration leads to continuous integral-differential model of diffusion. Generally the particle can change the position for another and not necessarily for the next one, as in the elementary case. Movement of a particle can be linear diffusion superposition and convection component. Using the coefficients of the binomial distributing, in integro-differential diffusion model, it is possible to regulate speed of moisture and direction transfer of its motion in time depending on descriptions of thermodynamics environments, which, in same line, can depend on humidity of environment or on other indicators, – for example, pressures. Similarly as classic diffusion, a decision integro-differential diffusion model possesses smoothing property. When numerically solving the system of recurrent correlations – the analogues of integro-differential model, it is possible to build the fields of two or more interactive diffusion component of the system.

INVESTIGATION OF THE HEAT TRANSFER COEFFICIENT DURING QUENCHING IN VARIOUS COOLING AGENTS

A. Buczek, T. Telejko*
AGH University of Science and Technology, Kraków, Poland

ABSTRACT. The paper presents a method of identifying the local heat transfer coefficient (LHTC) at the surface of cooled metal sample during quenching. The quenching speed strongly impacts the product quality and depends mainly upon the type of cooling agent. The choice of the cooler is therefore essential for the elaboration of proper quenching technology. This can be supported by the numerical simulations involving calculations of temperature profiles in the steel product, which enables to trace the rate of cooling and arising thermal stresses. The determination of the temperature field in the cooled body requires unity conditions of the heat conduction equation to be estimated including heat transfer at the surface usually described by the heat transfer coefficient at the cooled item surface. For the extremely intensive and dynamic process it is impossible to measure it directly, so some indirect methods are frequently applied. The boundary heat transfer inverse problem has been solved by the authors to measure LHTC. The basis of the theory and numerical procedures as well as estimation results are also shown for the selected quenchants.

Keywords: *heat transfer, boundary conditions, inverse solution, quenching*

INTRODUCTION

Quenching is the thermal process used to ensure the required mechanical properties of the steel product. The steel item is heated up to the temperature above austenitization and subsequently cooled down at a sufficiently fast rate of cooling. The desired quenching speed is achieved by providing the properly chosen coolants, like water, water polymer solutions, oils, etc. Frequently a choice of the agent is made upon the base of cooling rate curves elaborated in the experimental procedure according to the ISO 9950 [5]. The cylindrical sample 12.5 mm in diameter and 60mm in length manufactured from the Ni-Cr-Fe alloy (INCONEL 600) is cooled down from the temperature equal to approximately 850^{o}C. The temperature measurements made by a sensor placed at the geometrical centre of the sample are recorded. The maximum cooling rate, the respect temperature and the cooling rate at 300^{o}C are the characteristic parameters of the quenchant. The more effective technique is the application of numerical simulation of heat transfer during quenching, when the temperature profiles at selected points of the body can be observed. It also allows to determine the thermal stresses arising from temperature gradients. However solution of heat transfer requires boundary conditions to be known, which can be described by the temperature of coolants and the heat transfer coefficient at the surface. Quenching is the type of heat treatment for which the heat transfer varies with the phase of cooling and heat process is therefore highly nonlinear. The effective procedure applied in such cases is the solution of the boundary inverse problem [2, 4, 6]. The method consists in numerical selection of boundary heat transfer conditions providing a temperature distribution in the body not differing, within the necessary accuracy limits, from the assumed one. The temperature profile is measured by the sensors placed at the selected internal

points of the sample during cooling in the different agents and compared with computation results. Therefore the numerical simulation of the quenching process coupled with the experiment enables identification of heat transfer coefficient at the sample surface.

PROBLEM FORMULATION

In the boundary inverse problem we look for the boundary conditions of heat transfer. The effects of the cooling process are expressed by the temperature variation at the selected points of the test sample. In the calculus procedure the general form of the function approximating the heat transfer coefficient or the heat flux density is assumed. The problem is solved when the particular form of that function is determined under assumed quality criterion. That criterion consists in the minimum error norm value expressed by equation (1)

$$\Phi = \sum_{i=1}^{n} \sum_{j=1}^{m} \left[t_{i,j}^{num}(\tau) - t_{i,j}^{ex}(\tau) \right]^2 \tag{1}$$

Computed temperature values $t_{i,j}^{num}(\tau)$ were obtained from the solution of heat conduction equation given below

$$\rho c \frac{\partial t}{\partial \tau} = \frac{1}{r} \frac{\partial}{\partial r} \left(r k_r \frac{\partial t}{\partial r} \right) + \frac{\partial}{\partial z} \left(k_z \frac{\partial t}{\partial z} \right) + \dot{q}_v \tag{2}$$

The boundary conditions are formulated in the following form

$$-k_r \frac{\partial t(r = R,\, z,\, \tau)}{\partial r} = \alpha_R(\tau) \left[t_w - t(R, z, \tau) \right] \tag{3}$$

$$-k_z \frac{\partial t(r,\, z = 0,\, \tau)}{\partial r} = \alpha_{z=0}(\tau) \left[t_w - t(r, z = 0, \tau) \right] \tag{4}$$

$$-k_z \frac{\partial t(r,\, z = l,\, \tau)}{\partial r} = \alpha_{z=l}(\tau) \left[t_w - t(R,\, l, \tau) \right] \tag{5}$$

while the initial condition is as follows

$$t(r,\, z,\, \tau = 0) \tag{6}$$

The computation was performed using finite element model and self–developed computer program. The inverse problem was solved by conjugate gradients and Choleski methods. The approximation function was formulated by spline function of the Hermite polynomials over the total time of computation $\langle 0, \tau_{end} \rangle$. For each elementary time interval $\langle \tau_a, \tau_b \rangle$ the polynomial describing the heat transfer coefficient *versus* time relation has the form

$$\alpha(\tau) = a_1 H_1^0(\xi) + a_2 H_1^1(\xi) + a_3 H_2^0(\xi) + a_4 H_2^1(\xi) \tag{7}$$

$H_1^0(\xi) = 1 - 3\xi^2 + 2\xi^3$

$H_2^0(\xi) = 3\xi^2 - 2\xi^3$

$H_1^1(\xi) = \left(\xi - 2\xi^2 + \xi^3 \right) \Delta\tau$

$H_2^1(\xi) = \left(\xi^3 - \xi^2 \right) \Delta\tau$

$\xi = \dfrac{\tau_i - \tau_a}{\Delta\tau} \qquad \tau_a \le \tau_i \le \tau_b, \qquad \Delta\tau = \tau_b - \tau_a$

The coefficients a_1, a_2, a_3, a_4 were yielded from the solution of inverse problem for every time interval and for the total time range $\langle 0, \tau_{end} \rangle$. The number and the position of spline nodes were adjusted regarding to the minimal value of the mean temperature error given by equation (8)

$$\Delta t = \frac{1}{m\,n} \sum_{i=1}^{n} \sum_{j=1}^{m} \left| t_{i,j}^{num}(\tau) - t_{i,j}^{ex}(\tau) \right|. \tag{8}$$

The temperature data $t_{i,j}^{ex}, t_{i,j}^{num}$ were obtained from the measurements at some points inside the test sample and numerical simulation of the quenching process respectively. As a result the LHTC *versus* time relation has been found in the form of a spline function of polynomials given by equation (7). For the practical use in numerical applications the heat transfer coefficient was expressed as a function of a surface temperature. That temperature was yielded from the direct solution of the heat conduction equation carried out at every time step.
The validation of mathematical and numerical models have been performed replacing the measurement data with the values obtained from a solution of a direct problem. For the simple boundary condition the numerical model gives the temperature profiles calculated from the inverse procedure were almost identical to the input temperature data [2]. The error of the LHTC approximation did not exceeded 0.5%.

EXPERIMENTAL PROCEDURE

The method of investigations is based upon temperature measurements made at selected locations of the previously warmed-up sample after immersing it in an investigated quenchant.
Thus, the response of the sample temperature profile to an unknown (sought) boundary input was determined in the test. The sample was designed in such a way to achieve nearly unidirectional heat transfer along the sample axis. The schematic sketch is shown in Figure 1.
The main part of the sample is the metal cylinder 20mm in length and diameter placed in a cylindrical casing. The thickness of the casing was equal to 0.5mm. Both cylinder and casing were made of INCONEL 600. Four temperature sensors were located in the holes drilled to the sample axis at the distance 2, 4, 6 and 19 mm from active surface. Temperature was measured using ***K*** type thermocouples with 80 μm diameter wires protected by a 500 μm diameter sheath. The output signal was measured and recorded by high accuracy AC/DC data acquisition system allowing data registration at extremely high frequencies. The sample was heated up to temperature about 850^{o}C in the resistance furnace. After equalizing the temperature profile inside the sample it was immersed in the coolant having various, but steady in time, temperature. The experimental stand allowed to investigate heat transfer in stationary and moveable liquid (Figure 2). In the first case the sample was placed in a agent tank **1**, in the second one – in the column **6** after setting the desired value of liquid flow velocity performed by circulating pump **5** and inverter **12**.

RESULTS OF EXPERIMENTS AND NUMERICAL SIMULATION

The numerous experiments and simulations have been performed for various quenchants. The example of the experimental temperature change recorded by the sensors at different locations is shown in Figure 3. The experiment was carried out during quenching in oil **A** having temperature equal to 40^{o}C. The recorded temperature in points 1, 2 and 3 were supplied to the inverse procedure. The LHTC versus time function was approximated by a spline function consisted of fifteen Hermite polynomials. The nodes of the spline was established at the time equal to 0;1;2;3;4;5;6;7;8;10;15;25;50;100;200s. The mean temperature error given by equation (8) has been checked to establish the number and position of spline nodes. The higher concentration of the nodes at the beginning of the quenching process allowed to provide better accuracy of the simulation results. In this case the calculated mean temperature error using equation (8) was equal to 1.53K. The dependence of the LHTC from time is presented in Figure 4. Surface temperature computed from the direct problem enable to get more practical LHTC *versus* temperature relation (Figure 5). This form can be easily applied in heat transfer calculations of the cooling in liquids. Qualitative estimation of the relation shown in Figure 5 suggests that cooling process proceeds in the way characteristic for local boiling in liquids whereas the quantitative differences occur for various quenchants. The relatively low temperature of the sensor at the start of cooling results in nucleate boiling phase with remarkable first boiling crisis. Figure 6 presents the selected drawings of the LHTC versus surface temperature relations for two different oil quenchants.

In the industrial quenching process the coolant temperature increases with time in spite of applying cooling systems. The temperature growth can achieve even 20K. It is therefore important to know, how the temperature of cooling medium impacts the heat transfer process. The selected results of investigations are plotted in Figure 7. It can be clearly seen that the small coolant temperature change significantly affects the value of LHTC, particularly at the neighborhood of the first boiling crisis. The effect of total working life of coolant on cooling ability can be also interesting for the user regarding its high price and considerable quantities applied under industrial circumstances. It is obvious, that this factor should influence the cooling properties of the medium.

Figures 8 and 9 show the results illustrating the two examples of LHTC curves for the same quenchant differing in working life. There is no an unequivocal direction of the change of coolant properties. In the case of oil **A** the longer exploitation time results in increasing heat transfer coefficient, whereas LHTC significantly decreases for the oil **C**.

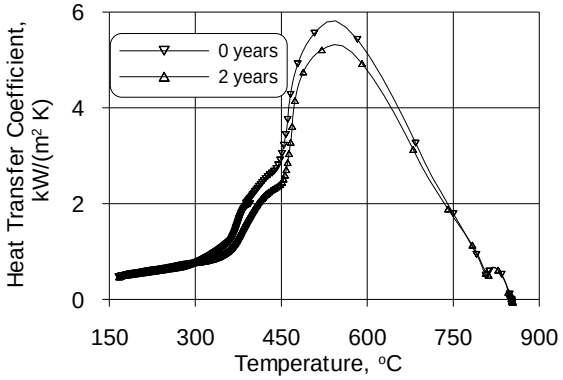

Fig. 9. The effect of coolant working life on LHTC for oil **C**

The synthetic cooling oils are frequently substituted with solutions of organic polymers in water. They have many advantages comparing to other quenchants: they are nonflammable, do not produce smoke or fumes under operation, provide the wide flexibility of quenching speed. On the other hand they are corrosive to tanks and products despite of additions of corrosion inhibitors, so the application are limited only to selected quenching technologies.

The quenching characteristics can be modified by the agent temperature and/or polymer concentration. The performed laboratory tests has proved, that the proposed method can be easily adopted for investigations of heat transfer during quenching in polymer water solutions. The heat transfer characteristic for quenching in water solution at 20% polymer concentration is presented in Figure 10. The polymer has oil-like heat transfer coefficient characteristic, but at some stages the local disturbances are observed, particularly in the range of surface temperature 400–800°C. In this case the sample was immersed in the flowing agent at a rate of 0.2m/s. It should ensure uniform temperature of the quenchant, but agitation resulted in LHTC instabilities. This phenomena can be explained by the inverse polymer solubility in water resulting in reversible creating and disappearing of a polymer film at a cooled surface.

The effect of the investigated factors on temperature profiles in the quenched item can be determined from the numerical simulations using the experimentally estimated boundary conditions defined by heat transfer coefficient. This allows to follow the structure and mechanical properties of the metal and select the proper quenchants and quenching technology to satisfy the quality demands of a final product.

SUMMARY

The presented investigations indicated the succesfull application of the proposed technique for determination of LHTC in quenching process. The tests have been carried out using the different quenchants including cool oils and polymer solutions of water. The heat transfer in these coolants is relatively less intensive comparing to water, so quenching process is easier to controll. The high sensivity of the method enables to examine the effect of various quenching parametrs on the heat transfer. The impact of coolant temperature on LHTC can be pointed out as an example. The variations in LHTC occuring in a limited range of surface temperature can be observed when coolant temperature changes in a narrow interval equal 10K (Fig. 7). The method belongs to dynamic ones, so its accuracy strongly depends on the relatively high temperture differences in the sample affected by cooling process. Therefore it is very important to provide the proper design of the test sample and the precise system of temperature measurement. The boundary inverse problem is ill-posed, so the measurement errors must be limited as much as possible. This remark reffers

both to the quality of the data acquisition system and to exact determination of temperatue sensors location.

It is also worth to underline, that under local boiling circumstances heat transfer at the cooled surface of the sample is limited by the heat conduction in the sample. The transport of heat from the center part of the body to the surface region is limited by thermal parameters of the cooled item, like thermal conductivity, heat capacity and density. In case of numerous materials this factor can not be ommited in investigations of coolant characteristics. The discussion of this problem for metals is presented in literature [3]. The use of the same quenching curves for different materials to be quenched can lead to significant quality loses in final product. This factor is not included in standard quenching characteristics advised by International Standard Organization (ISO 9950).

The presented method was applied to the investigations of cooling process using a sample manufactured of INCONEL 600. Thermal properties of that alloy do not differ much from the most of thermally treated steels. The main advantage of tests using INCONEL is the lack of phase transition in a wide temperature interval (from ambient temperature up to 1000^{o}C). The precise LHTC determination for steel requires modelling heat effect of phase transition, which faces remarkable difficulties. However the ommitting that heat source results in significant errors of LHTC estimation results.

ABSTRACT. Hydrodynamics of the hydrocyclone using an additional water injection is presented. The tangential water injection influence on the main hydrodynamic characteristics is investigated for different feed pressure drop and varied injection water flow rate.
The water injection markedly changes the hydrodynamic field in the hydrocyclone. The effect of non monotonic dependence of the injected water allocated through the underflow aperture has been found.
Based on the experimental results and supported by calculations, the mechanism of injection can be explained. The mechanism is based on the modification of the axial streams which determine the transport of the fines solid material.

Keywords: *hydrocyclone, hydrodynamics, water injection, flow distribution water*

INTRODUCTION

The hydrocyclone is widely used in different fields of process engineering for particle classification, solid-liquid separation or sludge thickening. One of the methods to improve the hydrocyclone characteristics is the injection of water in the conical part [1-6]. In the present work the influence of water injection on the hydrodynamics inside the hydrocyclone is investigated.
The schema of the water injection through the wall at the lower part of the hydrocyclone cone is shown in Fig.1.
Preliminary experiments have shown that the water injection is most effective if installed near the underflow discharge. Water injection is expected to remove fine particles from the wall boundary layer to the axis where these particles are picked up by the upward flow and then discharged through the overflow. Thus, fine particles will not missreported through the underflow discharge. Obviously, the characteristics of the injection (amount of injected water, jet power, zone of injection) have to be optimised.

Experimental test rig and procedures

The water injection cyclone which was used in this work is a conventional hydrocyclone with a modified conical part to have a water injection facility.
The test rig (Fig. 1) consists of a 50 mm hydrocyclone (1) with injector (2), placed above the tank filled with water (3). The water is fed into the hydrocyclone by the pump. The bypass with hydraulic valve (4) regulates the required pressure in the hydrocyclone, which was measured using a pressure gauge (5), located at the entrance of the hydrocyclone. The water injection rate was measured by a digital flow meter (6).

E-mail address: johann.dueck@uvt.uni-erlangen.de

The water injection assembly (2) consists of 2 inlet openings at equal distances. This assembly is connected with a control valve through which the water can be injected through these openings. A digital manometer was fixed near the water injection to indicate the water injection rate.

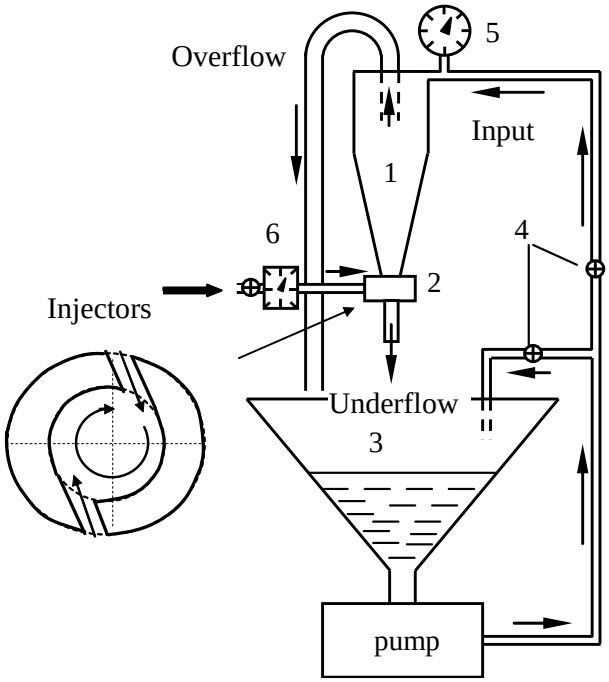

Figure 1. The experimental test rig and the schema of water injection into the hydrocyclone along the tangential velocity of the main flow.

The water was injected in tangential direction with the same swirling direction as the main flow inside the hydrocyclone.
The water injection part was added near the apex of the cyclone without causing any extension of the total cyclone length.
To investigate the effect of water injection rate on the hydrodynamics, samples of the overflow and the underflow were taken at different injection flow rates. From these samples, the feed flow rate, overflow flow rate, and underflow rate can be calculated for every test from which the split - parameter can be estimated.

RESULTS AND DISCUSSIONS

To study the impact of the injection on the hydrodynamics in the apparatus the water flow rates through the underflow and the overflow openings were measured for different injection flow rates and the inlet pressures.

The hydrocyclone without water injection

The measured characteristics of investigated hydrocyclone without injection are: water flow through the feed inlet, which shows the feed water flow rate Q_F^0, flow through underflow opening Q_{UF}^0 and flow through overflow opening Q_{OF}^0.
All measurements are performed for the different values of inlet pressure.

The Fig.2 shows an increasing of feed flow rate approximately proportional to the square root of pressure. This finding agrees with the reviewed empirical equations given by many authors collected in [7]. For example:

$$Q_F^0 = 27.7\, d_{in}\, d_0\, \sqrt{p} \qquad (1)$$

Higher feed pressure results in an increase of both outlet flows in different proportions as shown in Fig. 2.

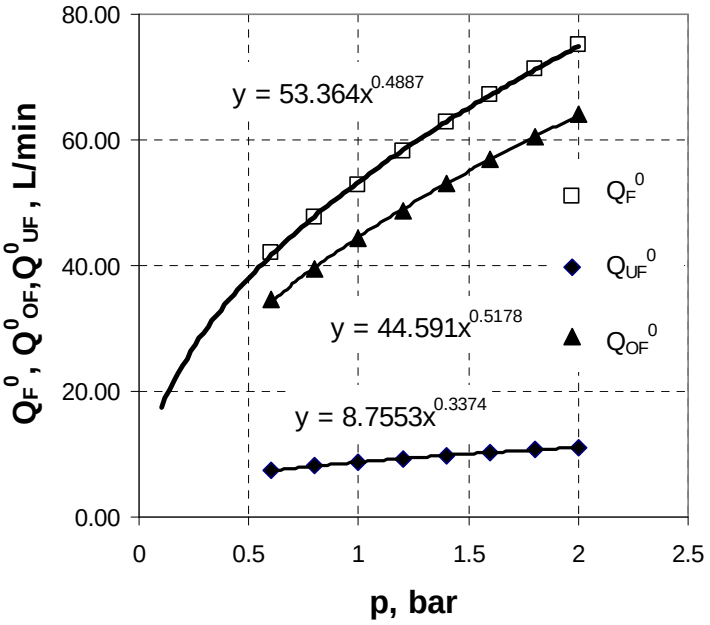

Figure. 2. Dependences of the feed flow rate, underflow rate and overflow rate versus feed pressure.

Empirical relations [8-10], given for the split-parameter $S^0 = \frac{Q_{OF}^0}{Q_{UF}^0}$ assume simplifying only a dependence of S^0 on the diameters of the outlet openings.
The experiments show a moderate dependence of split-parameter on the inlet pressure drop:

$$S^0 = 5p^{0.18} \qquad (2)$$

Other measurements of split-parameter depending on pressure can be found in [11] with much stronger power. Probably the power of dependence S^0 on p is not the universal value and has to be measured for every individual hydrocyclone.

The hydrocyclone with water injection
The hydraulic characteristics of hydrocyclone with water injection depend on the construction of injector.
The experimental results using two tangential openings with the same swirling direction as the main flow inside the hydrocyclone (construction – Fig.1) are presented below in Fig. 3 and Fig. 4.

The flow rate $\Delta Q_{OF} = Q_{OF}^{inj} - Q_{OF}^{0}$ through the overflow due to additional water injection increases monotonically with the growth of flow rate Q_{inj} of injected water.

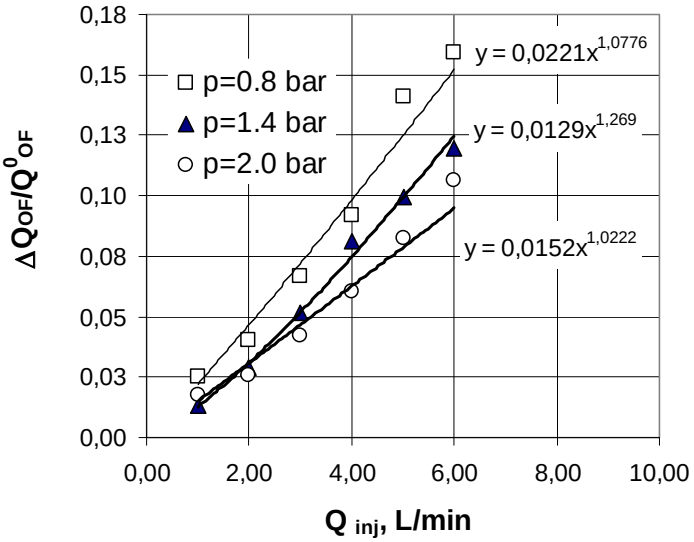

Figure 3. Influence of water injection rate on the overflow of the hydrocyclone.

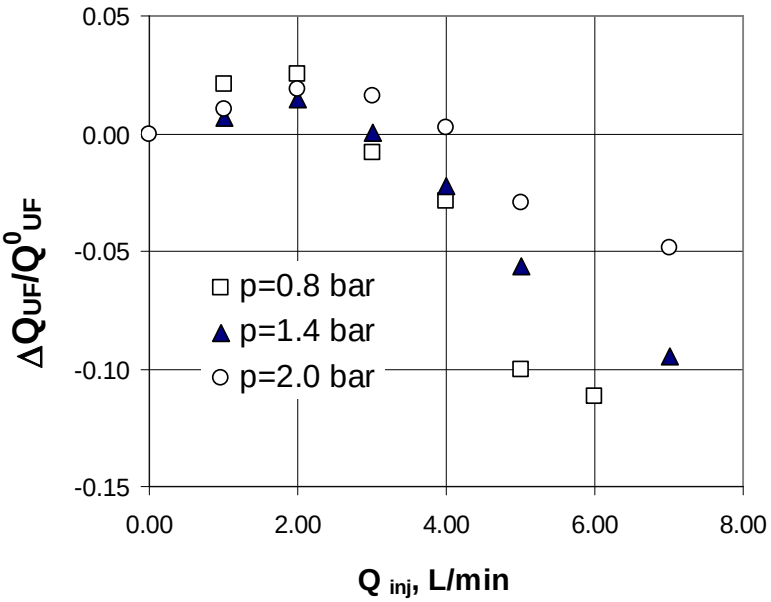

Figure 4. Influence of water injection rate on the underflow of the hydrocyclone.

The dependence of flow rate through the underflow ($\Delta Q_{UF} = Q_{UF}^{inj} - Q_{UF}^{0}$) is more complicated: experiments show that the increase of injection rate Q_{inj} at low values (up to 2-3 litres per minute in dependence of inlet pressure) leads to an increase in the underflow throughput Q_{UF}^{inj}, while at higher Q_{inj} underflow throughput decreases if injection rate increases.

At low injection rates the power of injection flow is relatively weak and is not high enough to overcome the strong swirling motion of the hydrocyclone mean flow. Therefore, it becomes not able to penetrate through the main flow to reach the hydrocyclone axis. Accordingly, it will discharge through the underflow apex which is located near the injection.
The decrease of Q_{UF}^{inj} at higher Q_{inj} can be explained by high hydraulic resistance of the underflow opening which diameter is rather smaller as the overflow opening.
The curves in Fig.3 and Fig.4 demonstrate relatively high influence of the feed pressure.
Based on dimensionless analysis all the measurements can be united to one curve by using the variable Q_{inj}/Q_F^{inj}, where Q_F^{inj} is the feed water flow rate which is influenced by the flow rate of injected water.

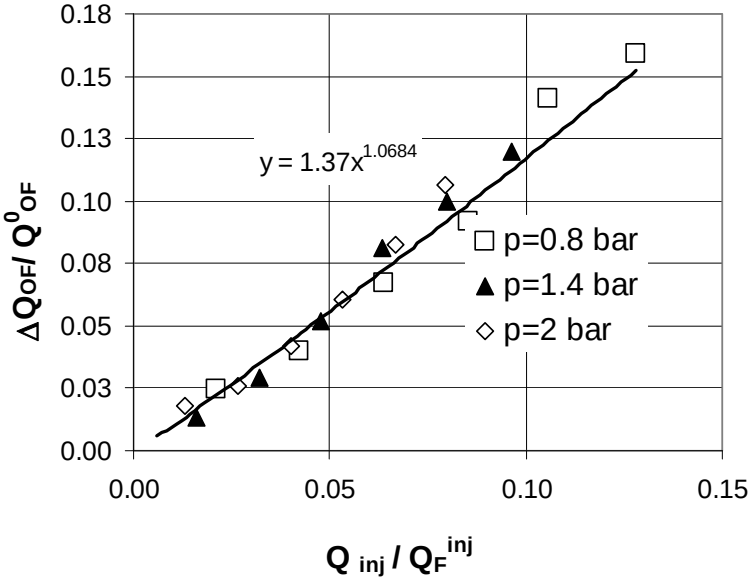

Figure 5. The relative water flow rate through overflow versus the relative injection rate

On the base of graph presented in Fig.5 the equation for the overflow is given in the form:

$$Q_{OF} = Q_{OF}^{0}\left[1+1.37\left(\frac{Q_{inj}}{Q_F^{inj}}\right)^{1.07}\right]. \tag{3}$$

For the underflow (Fig.6) the equation has a more complicated form:

$$Q_{UF} = Q_{UF}^{0} + Q_f\left[0.89\left(\frac{Q_{inj}}{Q_F^{inj}}\right) - 14.85\left(\frac{Q_{inj}}{Q_F^{inj}}\right)^{2}\right]. \tag{4}$$

Q_F^{inj} can be calculated on the base of experimental measurements as follows:

$$\frac{Q_F^{inj}}{Q_F^{0}} = 1 - 0.12\,\frac{Q_{ing}}{Q_F^{0}} \tag{5}$$

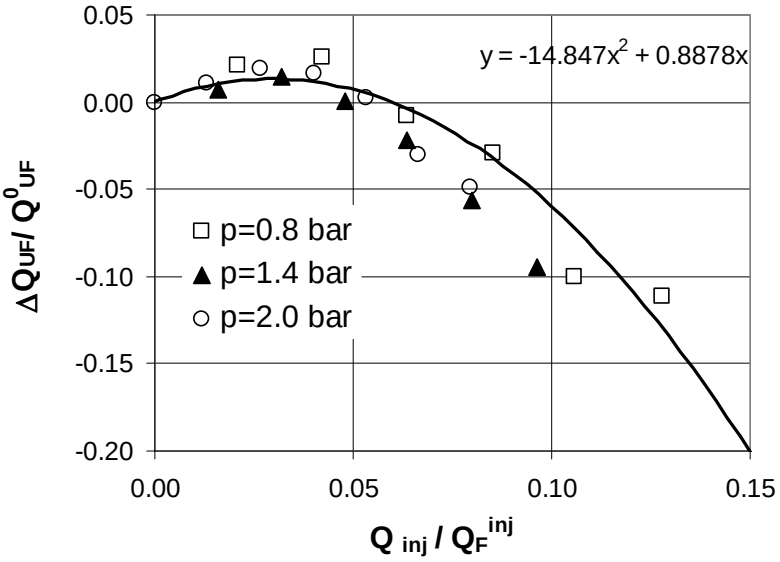

Figure 6. Water flow rate through underflow as a dependence on universal variable

Ratio of flow rates at outlets.

The split-parameter is of great importance to the separation process. Small particles are divided proportional to the ratio of the water flows through these outlets. Fig. 7 shows the change of the split parameter dependent on the throughput of the injected water Q_{inj} at different feed pressures.

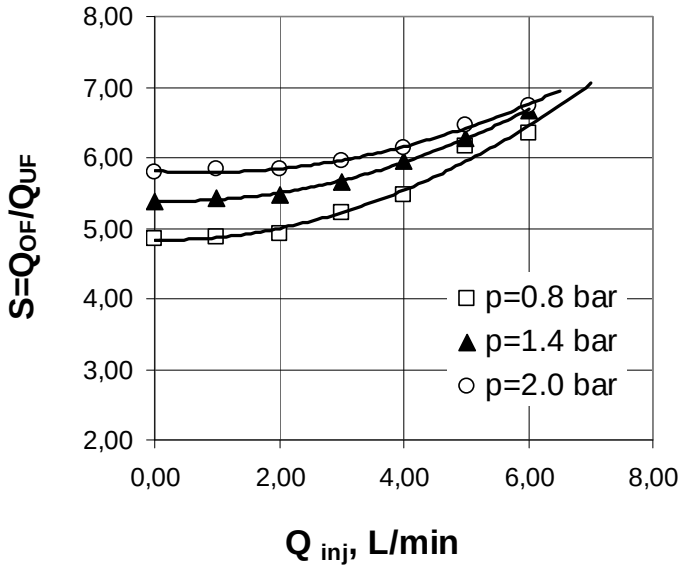

Figure 7. Split-parameter dependent on injected water flow rate

The increase of split-parameter with the increase of injected water flow rate is explained by strong increase of spigot hydraulic resistance compared to the vortex finder hydraulic resistance. Even

here, the dependence of the split-parameter can be presented in dependence on the related injection rate:

$$\frac{S - S^0}{S^0} = 22.1\left(\frac{Q_{inj}}{Q_F^{inj}}\right)^2, \qquad (6)$$

where the equation for S^0 is given by Equation (2).

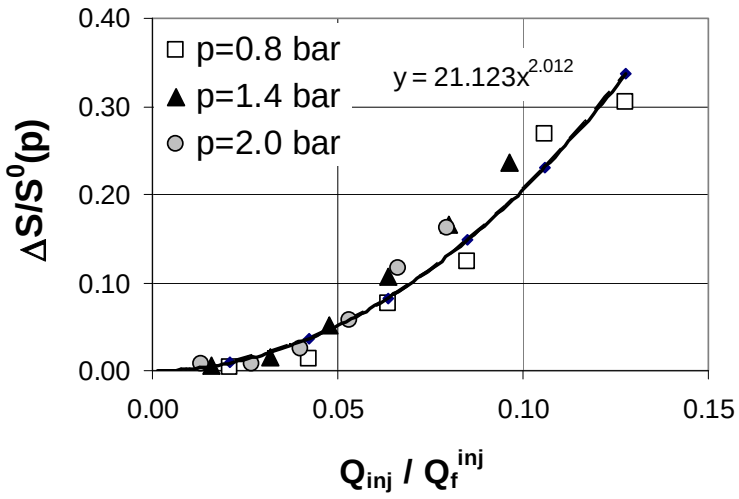

Figure 8. Split-parameter versus related injection rate

The experiments are supported by computer simulations using Fluent 6.3.23.

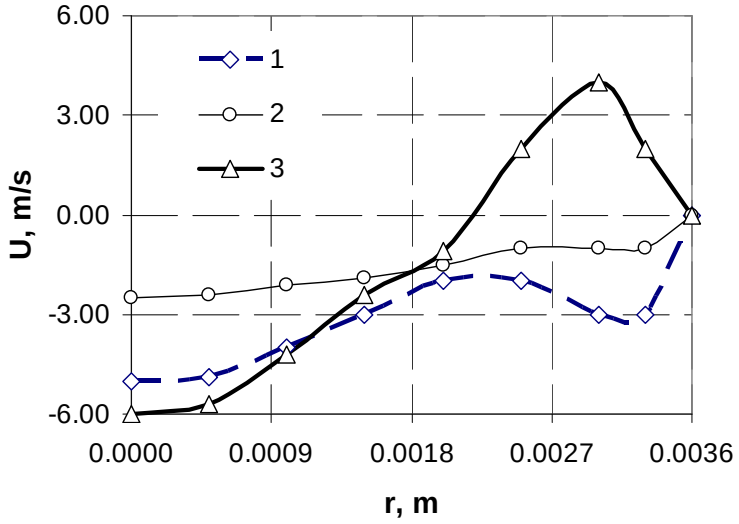

Figure 9. Dependence of the axial velocity distributions above the injector position on radial coordinate r for various water injection rates Q_{inj}. 1 - Q_{inj} = 0 m/s, 2 - Q_{inj} = 4 m/s, 3 - Q_{inj} = 9 m/s.

In Fig. 9 are shown the computed radial profiles of the axial velocity U in the apparatus directly above the injector.
Positive values indicate the flow directed to the overflow.
The injection changes the profiles of water velocity. For high Q_{inj} the rebuilding of the stream as an arousing of strong bottom-up flow can be observed.
In the absence of injection at the observed point no up-stream flow exists and all water is directed downwards to the underflow aperture. In the case of intensive injection because the hydraulic resistance at the underflow is higher than at the overflow, the injected water causes an intensive upstream at the wall.
This suggests a mechanism for the effects of tangential injection: fine particles are attracted by water in the direction to overflow where they are carried by main flow and leave the apparatus through the upper discharge.

ABSTRACT. Combined numerical and experimental studies have been performed in order to provide insights into the dynamics of the surface flow of welding pools. The primary focus of the study is on the influence of the oxygen concentration on the Marangoni convection in the liquid metal pool during laser spot welding of 304 stainless steel. Since during the experiment no shielding gas was employed, the material was exposed to open air, causing an accumulation of oxygen in the weld pool and at its surface. Consequently, the surface tension and its temperature coefficient ($d\sigma/dT$) are altered, affecting the direction of Marangoni stress that can cause the reversal of the weld pool flow.

Keywords: *laser welding, weld pool hydrodynamics, Marangoni convection*

INTRODUCTION

A laser welding process is a typical example where complex interactions between multi-physics phenomena take place. These include intensive heat transfer from a laser beam to an initially solid metal, melting of the metal, combined natural and Marangoni (surface tension) driven convection in the liquid metal pool, and dynamical behavior of the free-surface. In a laser welding process, the character of the fluid flow inside of the liquid metal weld pool is primarily determined by surface tension gradients at the free-surface. This flow plays an important role in the energy transfer from the weld pool to the surrounding heat-affected zone. Additionally, the shape of the weld pool also highly depends on the magnitude and the direction of the liquid velocities in the weld pool. Altering the temperature coefficient of surface tension due to the – intentional or unintentional – addition of surface active elements is known to affect the direction of the Marangoni shear stress at the pool surface [1, 2, 3]. Pure metals usually feature negative values of temperature coefficient of surface tension, causing the weld pool flow to be in the radially outward direction. The presence of surface active elements at a sufficiently high concentration can change temperature coefficient of surface tension to a positive value, resulting in radially inward flow. The temperature coefficient of surface tension as function of temperature and composition of surface active element was formulated in [4], and has been used in many weld pool models. This variable plays important role in the mechanism of flow reversal in the weld pool. The understanding of the flow reversal phenomena is important for a better control of weld pool shapes and weld quality.

MATHEMATICAL FORMULATION

In this work we study the influence of surface active elements on the weld pool flow in a laser welding process. The physical domain of interest is a rectangular stainless steel plate of SS304 type subjected to a laser beam on its top surface, as shown in Figure 1. The present study considers the laser spot welding, i.e. the position of the laser beam is fixed during the process. Additionally, it is assumed that the surface of the weld pool during melting is flat.

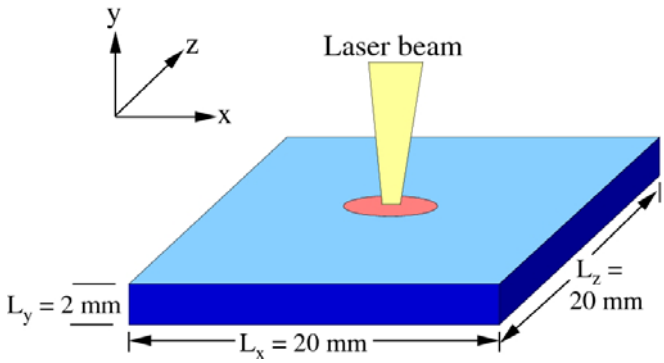

Figure 1. Laser spot welding of SS304

Conservation equations

The mathematical formulation for the above problem is based on a set of conservation equations, namely conservation of mass, momentum, and energy, described as follows.

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{U}) = 0 \tag{1}$$

$$\frac{\partial (\rho \mathbf{U})}{\partial t} + \nabla \cdot (\rho \mathbf{U}\mathbf{U}) = -\nabla p + \nabla \cdot (\mu \nabla \mathbf{U}) + \rho \mathbf{g} \beta (T - T_{ref}) - \mathbf{S}_{\mathbf{U}} \; ; \qquad \mathbf{S}_{\mathbf{U}} = \frac{C(1 - f_l^{\,2})}{f_l^{\,3} + b} \mathbf{U} \tag{2}$$

Here, ρ is the liquid steel density, $\mathbf{U}$ velocity, μ dynamic viscosity, β coefficient of thermal expansion, and p the pressure. $\mathbf{S}_{\mathbf{U}}$ is a momentum sink that accounts for deceleration of the flow due to solidification [5]. It decreases with increasing liquid fraction f_l. C is a large constant, typically 10^6 kg/(m^{3}s), and b is a small number, chosen as 10^{-12}, to avoid division by zero. This formulation leads to zero velocities in the solid region ($f_l = 0$) and a smooth transition of velocities from solid to liquid region ($f_l = 1$).

$$\frac{\partial (\rho C_p T)}{\partial t} + \nabla \cdot (\rho C_p \mathbf{U} T) = \nabla (k \nabla T) + S_T \qquad ; \qquad S_T = -\frac{\partial (\rho \Delta H)}{\partial t} - \nabla (\rho \mathbf{U} \Delta H) \tag{3}$$

In equation (3), C_p is the specific heat and k the thermal conductivity. S_T is the source term contributed by the latent heat ΔH. The latent heat and the liquid fraction are calculated as follows

$$\Delta H = \begin{cases} L & : \quad T > T_L \\ L(T - T_S)/(T_L - T_S) & : \quad T_S \le T \le T_L \\ 0 & : \quad T < T_S \end{cases} \; ; \qquad f_l = \frac{\Delta H}{L} \tag{4}$$

where L is the latent heat of melting.

Boundary and initial conditions

At the top surface, a laser beam of power Q and radius r_q is directed perpendicularly to the center of the domain. The absorbed heat flux from the laser is described by a Gaussian distribution

$$q''(r) = \eta \frac{k_q Q}{\pi r_q^2} \exp\left(- k_q \frac{r^2}{r_q^2} \right) \tag{5}$$

where η is the laser absorption coefficient and k_q is a constant associated with the shape of the Gaussian function. The thermal boundary condition for the top surface is given by the contribution from the absorbed laser heat flux and convective and radiative heat losses.

$$-k \frac{\partial T}{\partial y} = -q''(r) + h\left(T_{top} - T_\infty\right) + \varepsilon\sigma\left(T_{top}^4 - T_\infty^4\right) \tag{6}$$

Here, h is the coefficient of convective heat transfer between the plate and air, T_{top} the top surface temperature, T_∞ the ambient temperature, ε the surface emissivity, and σ the Stefan-Boltzmann constant. At the top surface, the viscous force is balanced by the force due to surface tension. Assuming flat weld pool surface, the vertical velocity is zero.

$$\mu \frac{\partial u_x}{\partial y} = \frac{\partial \sigma}{\partial T} \frac{\partial T}{\partial x} \quad ; \quad u_y = 0 \quad ; \quad \mu \frac{\partial u_z}{\partial y} = \frac{\partial \sigma}{\partial T} \frac{\partial T}{\partial z} \tag{7}$$

At the four side boundaries and the bottom boundary, the thermal boundary condition is given by

$$-k \frac{\partial T}{\partial n} = h\left(T - T_\infty\right) \tag{8}$$

where n is the normal direction pointing outward from the surface. At these boundaries, a no-slip condition for velocities is imposed.

Initial conditions for temperature and velocities are $T = T_\infty = 298$ K and $u_x = u_y = u_z = 0$ m/s, respectively.

Temperature coefficient of surface tension

On the top surface of the weld pool, the dependence of the temperature coefficient of surface tension on the temperature is taken into account according to the following formulation [4]

$$\frac{d\sigma}{dT} = -A - R\Gamma_s \ln\left(1 + Ka_i\right) - \frac{Ka_i}{\left(1 + Ka_i\right)} \frac{\Gamma_s \left(\Delta H^o - \Delta \overline{H}_i^M\right)}{T} \quad ; \quad K = k_1 \exp\left(\frac{-\Delta H^0}{RT} \right) \tag{9}$$

Here, A is the value of surface tension coefficient for pure metal, Γ_s the surface excess at saturation, K the equilibrium constant for segregation, ΔH^0 the standard heat of adsorption, $\Delta \overline{H}_i^M$ the partial molar enthalpy of species mixing in the solution, and a_i the activity of the surface active element (in % weight). In this study, the surface active element of interest is oxygen and the

corresponding constants in equation (9) for the steel-oxygen system [4] are given in table 1, leading to the curves in Figure 2.

Table 1
Constants for formulation of temperature coefficient of surface tension

Constants	Units	Value
A	N/(m K)	4.3 x 10^{-4}
R	J/(kg mole K)	8314.3
Γ_s	kg mole/m^2	2.03 x 10^{-8}
k_1	-	1.38 x 10^{-2}

$\Delta \overline{H}_i^M$	J mole/kg	0

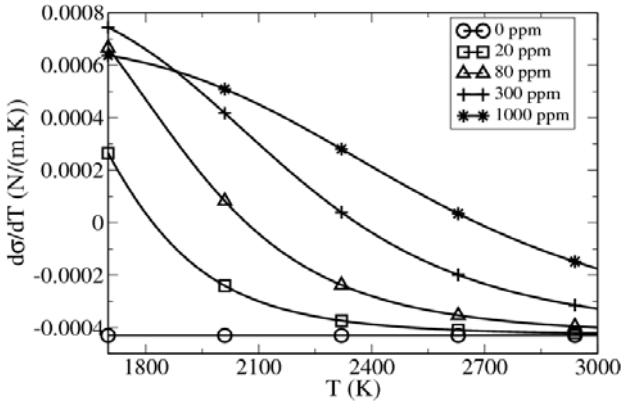

Figure 2. Temperature coefficient of surface tension for different oxygen concentration

The above mathematical model equations have been implemented into the open-source CFD toolbox OpenFOAM [6], which is based on the finite volume method to solve systems of partial differential equations.

SIMULATION SETTINGS

The physical domain in Figure 1 is decomposed into a $N_X \times N_Y \times N_Z = 70 \times 50 \times 70$ grid system, with fine grid spacings in the center and top parts of the domain. The typical cell size near the center of top surface is $\Delta x \times \Delta y \times \Delta z = 50 \times 10 \times 50$ μm. The simulation time step is chosen to be 0.0002 s. The physical properties of the material and process parameters are listed in Table 2. The differential equations are spatially discretized using a second-order central difference scheme. The unsteady terms are treated using a first-order fully implicit time integration scheme.

In the simulation, we try to mimic qualitatively our experimental observation in the weld pool in which we found a flow reversal as time progressed. Since in the experiment the weld pool is exposed to open air, the surface oxygen concentration increases in time. At present, we are assuming that the surface oxygen concentration increases linearly with time, based on the following expression

$$a_O(t) = a_{O,0} + Mt \tag{10}$$

where a_O is oxygen activity, t is time, $a_{O,0}$ is the initial oxygen activity and set as zero, and M is the rate of oxygen increase. The above expression is evaluated every time step and combined with the surface temperature field solution for the calculation of the temperature coefficient of surface tension according to equation (9). Simulations have been carried out for M = 5, 10, 20, and 40 part per million per second.

EXPERIMENTAL SETUP

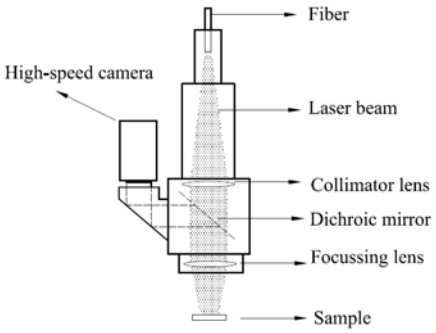

Figure 3. Experimental setup

The experimental welding setup is shown in Figure 3, which includes a high speed camera directed towards the top side of the weld pool. The light reflected from the weld pool surface passes the laser lens and reaches the high speed camera. The high speed camera worked at 3000 frames per second to capture the weld pool surface flow motions and surface particle flow. Chromium oxide (Cr_2O_3) particles formed in the weld pool are used to trace the surface velocities using a Particle Image Velocimetry (PIV) method. The images were post-processed using commercial software (Davis 6.2, LaVision). A more detailed description can be found in [7, 8].

RESULTS AND DISCUSSION

Top views and cross-sectional views of the weld pool at t = 0.65 s for different oxygen increase rates *M* are shown in Figure 4 and 5, respectively. At this time instant, an outward flow is observed for *M* = 5, 10, and 20 ppm/s. For these cases, at 0.65 s the surface oxygen concentrations are 3.25, 6.5 ppm, and 13 ppm, respectively. According to Figure 2, at those concentration levels the temperature coefficient of surface tension is negative over the temperature range in the weld pool. Combined with a negative value of *dT/dr*, this causes the flow to be directed outward. Interestingly, for *M* = 40 ppm/s, two counter-rotating flows are observed because two regions exist with different sign of the temperature coefficient of surface tension. At 0.65 s, the corresponding oxygen concentration is 26 ppm, and the temperature coefficient of surface tension is positive below approximately 1820 K, which is the temperature at approximately halfway from the pool center to the melting front. This causes outward flow in the center part of the pool and inward flow in the outer part of the pool.

Figure 6 shows the radial velocity at the surface as a function of time, for various values of *M*. Except for *M* = 40 ppm/s, the flow is always in the outward direction (positive value of radial velocity) because up to 0.65 s the surface oxygen concentrations still do not reach the level that causes change of sign of $d\sigma/dT$. On the other hand, inward flow (negative value of radial velocity) is observed for *M* = 40 ppm/s in the outer region of the weld pool for t = 0.4 and particularly 0.65 s.

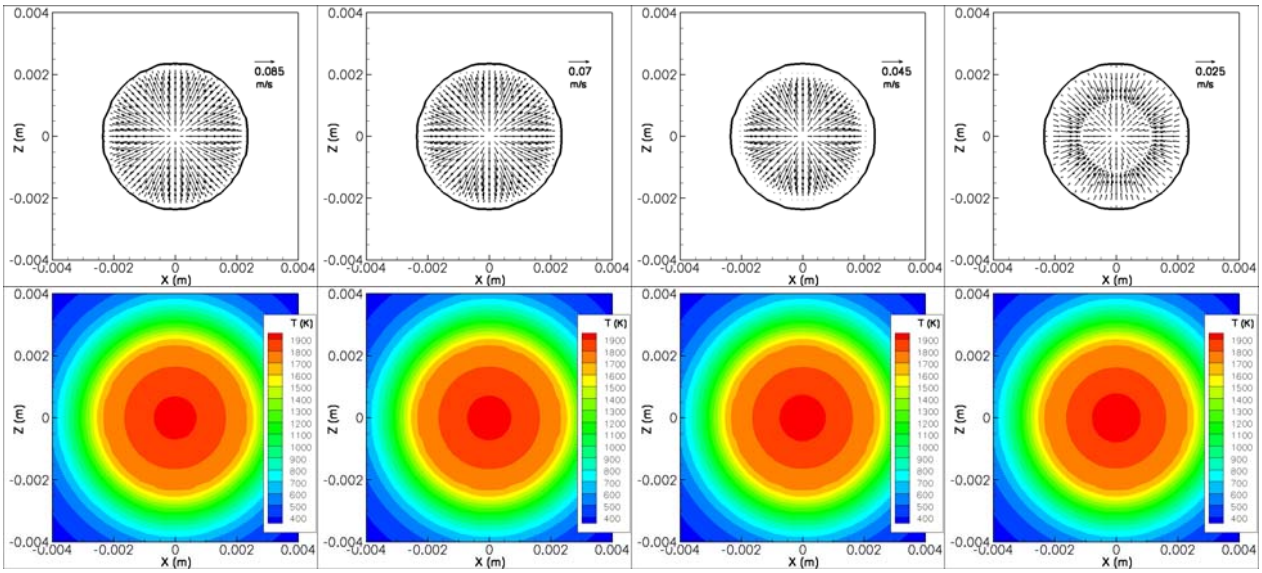

Figure 4. Weld pool velocity vectors (top) and temperature contours (bottom) at t = 0.65 s. From left to right: M = 5, 10, 20, and 40 ppm/s.

Experimental snapshots of the weld pool surface obtained using the high-speed camera are shown in Figure 7 for t = 0.244, 0.403, and 0.813 s. In the first snapshot, the flow is outward, while in the other two the flow is inward. The flow reversal is more quantitatively shown by the experimental velocity vectors obtained by PIV in Figure 8, in which a fully outward flow is initially observed (t = 0.27 s), followed by a combined outward and inward flow (t = 0.413 s), and a fully inward flow (t = 0.954 s). Comparison between simulation and experimental results shows that the predicted weld pool surface velocity behaves more orderly than that in the experiment. This difference is mainly caused by the assumption of linear increase of surface oxygen concentration used in the simulation. In the experiment, where the weld pool is exposed to the open air, the oxygen increase is most likely to be non-linear and not perfectly controlled as in the simulation. Moreover, in the simulation the spatial variation of surface oxygen concentration is not taken into account, whereas in reality a

much more complex mechanism involving adsorption kinetics and convection of surface active elements is present. Accordingly, the spatial variation of surface tension becomes much more complicated and so does the surface flow pattern.

Right: t = 0.954 s, U_{max} = 0.304 m/s.

CONCLUSION

A mathematical model describing the three-dimensional fluid flow and heat transport in a weld pool for laser spot welding process is presented. The model includes surface tension driven (Marangoni) stress at the weld pool surface due to surface temperature gradients. The temperature coefficient of surface tension is calculated as a function of surface temperature and concentration of oxygen as surface active element. The assumption of linear increase of surface oxygen concentration over time is employed and leads to the prediction of a flow reversal in the weld pool as time progresses. The flow reversal occurs if at any given time the surface oxygen reaches a level at which in the weld pool two regions with different signs of temperature gradient of surface tension exist. Comparison with experiment shows that the current model can only qualitatively predict the flow reversal. The current model can not yet reproduce the dynamics of the surface velocity observed in the experiment, since transport of oxygen at the weld pool surface that involves adsorption kinetics and convection mechanism is not taken into account. This suggests that there is a need for implementation of transport of surface oxygen into the current model.

A NOVEL SOUND RESONANCE METHOD FOR MEASUREMENT OF EVAPORATION COEFFICIENT

S. Nakamura[1], T. Yano[2], M. Watanabe[1] and S. Fujikawa[1*]
[1]Division of Mechanical and Space Engineering, Hokkaido University, Sapporo, Japan
[2]Department of Mechanical Engineering, Osaka University, Suita, Japan

ABSTRACT. A new method for measurement of the evaporation coefficient using sound resonance experiment is developed. To demonstrate the applicability of this method, we measure the amplitude of standing sound wave generated in a closed space filled with air at a resonance frequency. The experiments are conducted in two types of resonators, one is closed by a solid wall and the other by a liquid water layer, under the atmospheric condition and a reduced-pressure condition at 0.5 atm. We find that the first few harmonic components are produced by the nonlinearity of sound. The amplitude of the second harmonics appreciably decreases when the liquid water layer is formed on the closed end and this enables us to evaluate the evaporation coefficient with the help of the theory of molecular gas dynamics.

Keywords: *evaporation coefficient, sound wave, wave absorption, resonance, second harmonics*

INTRODUCTION

Evaporation and condensation are physical phenomena having attracted attention of engineers and scientists, because these are concerned with not only a fundamental aspect on their molecular mechanism but also a wide range of practical applications. One of unresolved problems in the fundamental aspect is the kinetic boundary condition at a vapor-liquid interface [1]. It is used as the boundary condition for the Boltzmann equation, i.e. the governing equation for statistical behavior of gas molecules in non-equilibrium states. The kinetic boundary condition contains two unknown parameters called the evaporation coefficient and condensation coefficient. There has been a history over these coefficients for more than one century, and it is still open.

The kinetic boundary condition is given by

$$f^{out} = \left[\alpha_e + (1-\alpha_c)\frac{\sigma}{\rho^*}\right] f^* \quad (\xi_1 - v_l) > 0 \tag{1}$$

where f^* is the distribution function at equilibrium state, ξ_1 is the velocity of molecules normal to the interface between a vapor and its liquid phase, ρ^* is the saturated vapor density, v_l is the velocity of the interface, σ is defined by the incident mass flux, α_e is the evaporation coefficient and α_c is the condensation coefficient. These coefficients are defined by molecular mass fluxes at the interface as follows:

$$\alpha_e = \frac{J_{evap}}{J^*_{out}} \quad \alpha_c = \frac{J_{cnds}}{J_{coll}} \tag{2}$$

where J_{evap} is the evaporation mass flux, J^*_{out} is the outgoing mass flux at equilibrium state, J_{cnds} is the condensed mass flux and J_{coll} is the incident mass flux. From the definitions of the evaporation and condensation coefficients, they are equal in an equilibrium state.

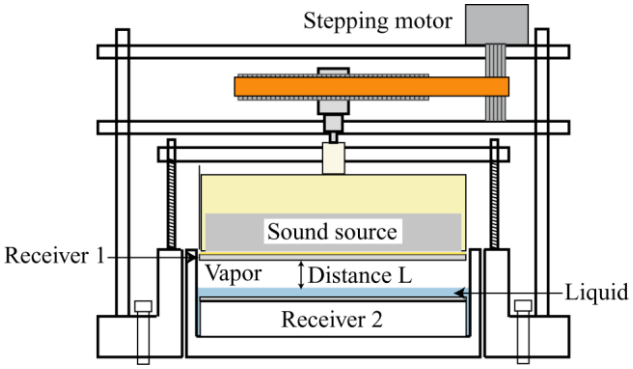

Figure 1. Schematic diagram of experimental setup

The aim of this study is to measure the evaporation coefficient by using sound wave near a very weak non-equilibrium state. In such a state, we can regard these two coefficients as an almost identical one, i.e. evaporation coefficient. In this paper, we describe a new method of evaporation coefficient measurement by sound wave.

MEASUREMENT METHOD

The method by using sound wave was originally proposed by Kogan and Nosik in 1988 [2]. It was theoretically predicted that the evaporation coefficient can be measured using sound absorption by the boundary layer formed on the interface when evaporation or condensation occurs at the interface. Based on this paper, we develop a new method for measurement of the evaporation coefficient, which is based on combination of both sound resonance experiment in a closed vessel with a planar sound source and a liquid layer opposing against the generator and molecular gas dynamics analysis as the counterpart of experiment. Since the variations of pressure, velocity and temperature induced by the sound wave are usually sufficiently small compared with those in a reference state, we conduct the measurement in a weak non-equilibrium state.

Figure 1 shows the schematic diagram of experimental setup. The apparatus consists of the sound source (PZT, diameter: 50 mm, thickness: 10 mm, resonance frequency: 201 kHz), the receiver 1 (PVDF, diameter: 54 mm, thickness: 0.2 mm), the receiver 2 (PVDF, diameter: 54 mm, thickness: 0.2 mm) and the liquid holder. The receiver 1 is attached to the surface of sound source and the receiver 2 is attached to the acrylic plate. The sound source is supported by six columns with springs and its position is controlled by a micrometer which is connected to a stepping motor at the center of top surface. This enables us to change the distance between the sound source and liquid surface L accurately by rotation of the stepping motor. In the measurement, we put the apparatus into the vacuum vessel and adjust the tilt of sound source to make the surface of sound source parallel to the acrylic plate on which the receiver 2 is mounted. Then we infuse the sample liquid into the liquid holder to form a uniform layer (depth: about 2 mm) on the surface of the receiver 2. After that, we close a lid of vacuum vessel and evacuate the contained gas by a rotary pump until the pressure inside the vessel reaches below the saturated vapor pressure. After a while, a condition that the vessel is filled only with the vapor of sample liquid is attained.

The sound source, parallel to the liquid surface, is driven continuously. After a few seconds, the standing wave is formed in the closed space between the sound source and the liquid surface. Also on the surface, evaporation and condensation take place cyclically by the pressure variation induced by the sound wave and part of sound wave is transmitted into the liquid. This affects the amplitude of standing wave. We utilize the sound resonance in the vapor space to increase the amplitude of standing wave and obtain the effect of evaporation and condensation more clearly. At resonance

points, harmonic components are excited. To eliminate the continuous noises generated from the sound source in the received signals, we also use the second harmonics. In this method, we measure the variation of the amplitude of second harmonics by the receiver 1. By comparison with the theoretical analysis using molecular gas dynamics, we can evaluate the value of the evaporation coefficient.

EXPERIMENTAL RESULTS

To demonstrate the applicability of our new method, we conduct preliminary measurements as mentioned below. In this section, we show experimental conditions and results.

The actual measurements are to be conducted under the saturated vapor pressure of sample liquid. In the case of methanol, the saturated vapor pressure at 323 K is about 0.5 atm (55.7 kPa). Under the reduced pressure, owing to the decrease of efficiency of sound emission from PZT and the increase of attenuation rate of sound wave in comparison with the case of atmospheric condition, it is expected that output amplitude obtained from the receiver 1 is decreased. We therefore examine the output of receiver 1 at the following four conditions: (i) solid wall and atmospheric pressure, (ii) solid wall and 0.5 atm, (iii) liquid water and atmospheric pressure, (iv) liquid water and 0.5 atm. In particular, we focus on the amplitude of second harmonics at the resonance point. Note that the saturated vapor pressure of water is 3.2 kPa at the room temperature.

It was extremely difficult tasks to set the distance between the sound source and the liquid (or solid), L, as the predetermined value accurately, and to measure the absolute distance after the experimental device was organized; hence we discuss the relative distance L_1. First the distance between the sound source and the liquid (or solid) was approximately set as one wavelength. We refer to this distance as L_0 hereafter. This distance L_0 was defined as the reference distance, and then L_1 was defined as the relative distance to the reference L_0. The output amplitudes, by changing L_1 from zero to the half of the wavelength with the increment of 0.01 mm, obtained from the receiver 1 are shown in Figures 2 and 3. These amplitudes are mainly composed of three components, i.e., the driving frequency f (f=201 kHz), the second harmonics 2f and the third harmonics 3f. The ambient temperature of the apparatus, T, is shown in the figures. The horizontal axes in Figures 2 and 3 are the relative distance L_1. The left side of vertical axes corresponds to the amplitude of component of driving frequency f and the right side of vertical axes corresponds to 2f and 3f.

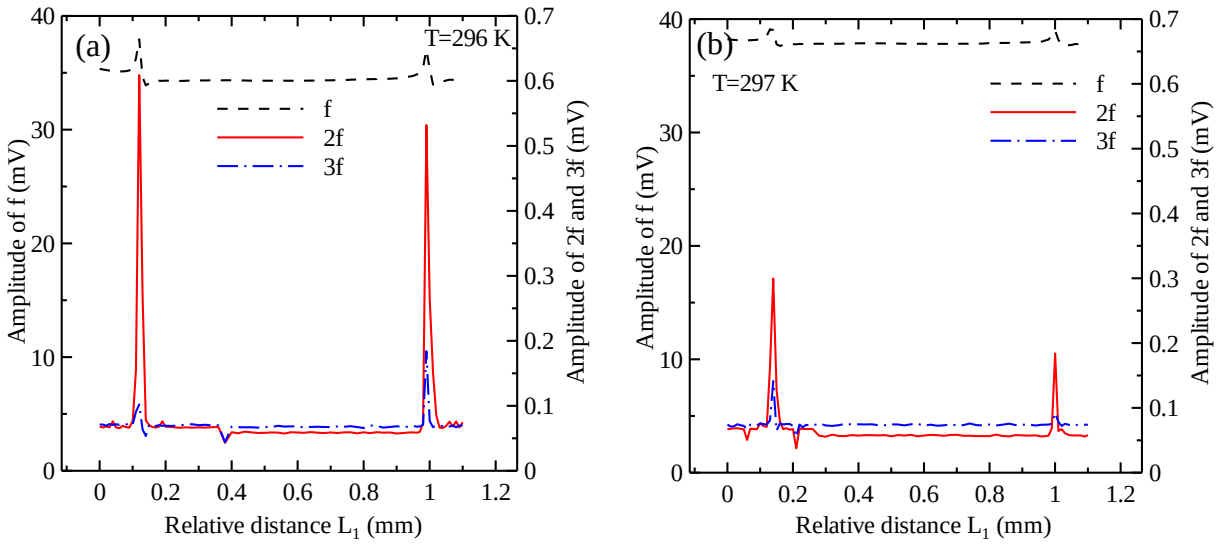

Figure 2. Output amplitude for solid wall: (a) atmospheric pressure, (b) 0.5 atm

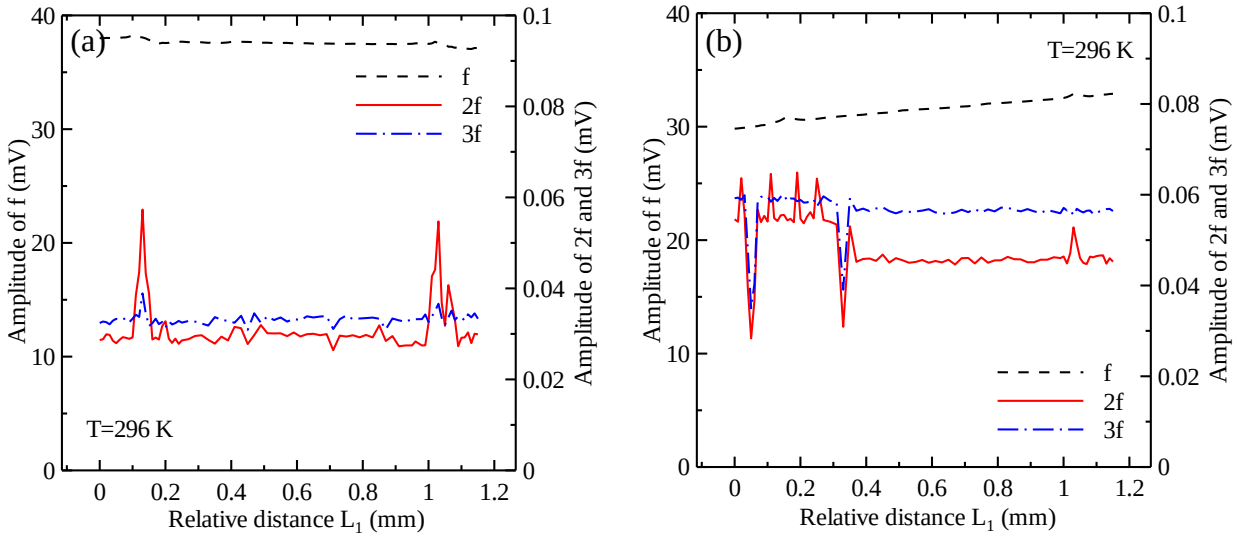

Figure 3. Output amplitude for water: (a) atmospheric pressure, (b) 0.5 atm

Two peaks in Figures 2(a) and 2(b), the results for a solid wall case, show the sound resonance excited in the vapor space, because these differences between two peaks (Figures 2(a) 0.87 mm and 2(b) 0.86 mm) are approximately equal to half wavelength obtained from the sound speed in the air. By comparing Figures 2(a) and 2(b), the maximum amplitude of the second harmonics in the case of Figure 2(b) 0.5 atm is decreased by 50 % as against the case of Figure 2(a) atmospheric pressure.

In Figures 3, the results for the case of liquid water layer, we find two peaks caused by the sound resonance for Figure 3(a). Meanwhile, for Figure 3(b), we can identify only one peak near L_1=1.03 mm as the resonance point because of the noise around L_1=0.17 mm. The maximum amplitudes of second harmonics for Figures 3(a) and 3(b) are comparable. In the measurement for atmospheric pressure, we can find the oscillation of water surface at the resonance point and it weakens with decreasing pressure. Therefore, we suppose the oscillation of water surface affects the output amplitude.

CONCLUSION

For the determination of the evaporation coefficient of methanol in an equilibrium state, we have proposed the evaporation coefficient measurement method using sound wave near the equilibrium state. From the results measured in the atmospheric pressure and 0.5 atm, when the distance L is equal to the integral multiple of half wavelength, the sound resonance occurs in the vapor space and the harmonic components are excited. Even for the case of liquid water layer, the effect of sound resonance, i.e. increase in amplitude of the second harmonics, is actually measurable, although it significantly decreases compared with the case for the solid wall. Therefore, we conclude that our method using sound resonance and second harmonics is effective for the measurement of evaporation coefficient.

EXPERIMENTAL MEASUREMENT OF THE INCIDENCE ANGLE DURING GAS BUBBLE GROWTH AND DETACHMENT

P. Di Marco

Department of Energetics "L.Poggi", University of Pisa, Pisa, Italy

ABSTRACT. A simple experimental apparatus was built to generate nitrogen bubbles in different fluids; high speed images of bubbles were processed via a dedicated software to obtain the main geometrical parameters, i.e. bubble volume, curvature radius at top and incidence angle. From these parameters, it was possible to evaluate the forces acting on the bubbles during quasi-static growth and detachment and compare them with theoretical predictions, to check the overall momentum balance. The agreement with theory was fairly good, although improvement in measurement of incidence angle should be sought.
Keywords: *gas bubble, bubble growth, bubble detachment, incidence angle, bubble momentum balance*

FOREWORD

The study of bubble detachment has interest not only *per se*, but it is mainly intended to open the way to the comprehension of more complex boiling phenomena, in which mass transfer and bubble dynamics play a determinant role. Experimental and theoretical works on this topic are also useful for the optimization of a wide class of industrial processes which involve mass and thermal exchange in bubbly flows. Although the problem of growth and detachment of a bubble in a still liquid can be stated exactly in terms of governing conservation equations, its complete solution is currently beyond our capabilities, even with numerical techniques, due to the variety and complexity of the involved momentum, heat and mass transfer phenomena. The first step is therefore limiting the attention to a simpler system, constituted by a single gas bubble detaching from a circular orifice in a still liquid, which can give useful information for the growth and detachment process. In this way, mass transfer phenomena are suppressed, and for a wide spectrum of conditions the bubble base is bounded to the orifice rim [1], [2], [3], giving a clear boundary condition for comparison with theory. The aim of the present paper is to compare the theoretical prediction of the forces acting on a detaching gas bubble, during its quasi-static growth and detachment, with their experimental evaluation. The conditions under which the detachment can be considered quasi static are discussed in the following section.

MOMENTUM BALANCE ON A GROWING AND DETACHING BUBBLE

Consider a growing gas bubble stemming from an orifice A_o, delimited by a contact line *CL*, with no mass transfer at the surface, but through the inlet orifice (Fig.1). The overall momentum balance on a control volume surrounding the bubble, bounded by the liquid side of the vapor-liquid interface, *S*, and by the gas side of the orifice A_o, can be written in a very general way as

$$\frac{\mathrm{d}}{\mathrm{d}\,t}\int_V \rho_g\,\mathbf{v}_g\,\mathrm{d}V = \int_{CL}\sigma_{fg}\mathbf{t}_{fg}\,\mathrm{d}L + \int_V \rho_g\,\mathbf{g}\,\mathrm{d}V + \\ + \int_S\left[\underline{\underline{\mathbf{T}}}_{v,f} - p_f\,\underline{\underline{\mathbf{I}}}\right]\cdot\mathbf{n}\;\mathrm{d}S + \int_{A_o}\left[\underline{\underline{\mathbf{T}}}_{v,g} - p_g\,\underline{\underline{\mathbf{I}}} + \rho\mathbf{v}_g\,\mathbf{v}_g\right]\cdot\mathbf{n}\;\mathrm{d}A \tag{1}$$

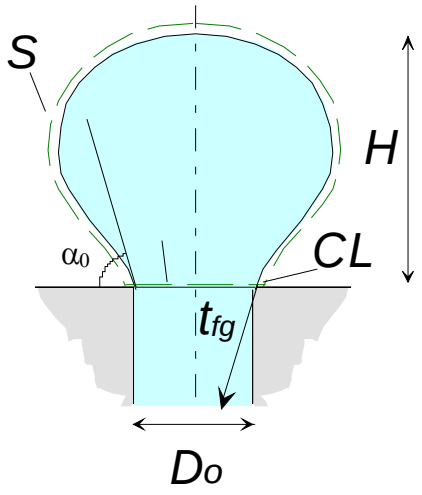

Figure 1. Application of momentum balance on a growing bubble.

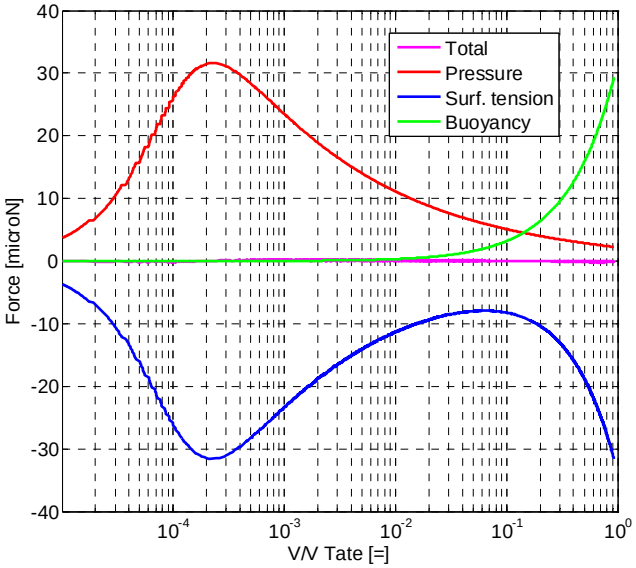

Figure 2. Theoretical force balance for a growing bubble (water properties).

Where, **n** and **t** are the normal outward and tangent (in the meridian plane) unit vectors, respectively, p is the pressure, **v** is the velocity, **g** is the gravity acceleration, $\underline{\underline{\mathbf{T}}}_v$ is the viscous stress tensor, σ is the surface tension. The suffixes g, f are referred to gas, and liquid, respectively. The inertial term in LHS is generally negligible, as only the inertia of the gas has to be taken into account here. Dynamical effects (including the surrounding liquid inertia) are accounted for in the normal and tangential stress distribution around the bubble, which must be evaluated taking into consideration the surrounding fluid motion. Additional surface forces, like the electrical one, may be added to the RHS via an appropriate stress tensor [1].

Influence of dynamical effects on bubble growth

The momentum influx through the orifice gives a lifting force of the form

$$F_u = \int_{A_o} \rho_g \, \mathbf{v}_g (\mathbf{v}_g \cdot \mathbf{n}) \, dA = \beta \rho_g \frac{\pi D_o^2}{4} u_o^2 \tag{2}$$

where D_o the orifice diameter, u_0 the mean flow rate velocity and the parameter β depends upon the velocity profile in the inlet orifice. In particular, for a flat profile, β = 1 while for a parabolic one β = 4/3.

The Rayleigh-Plesset equation describes the pressure p_b inside a spherical bubble growing in a still liquid as

$$\frac{p_b - p_\infty}{\rho_f} = \frac{2\sigma}{\rho_f R_b} + \left[R_b \frac{d^2 R_b}{dt^2} + \frac{3}{2}\left(\frac{dR_b}{dt} \right)^2 \right] + \frac{4\mu_f}{\rho_f R_b} \frac{dR_b}{dt} \tag{3}$$

Although this is not exactly the case of a bubble growing at the wall, an order-of-magnitude estimate of the viscous and inertial contributions to bubble growth may be obtained as the second and third tem in the RHS. In case of constant volumic growth rate, that is

$$Q = \pi D_b^2 \frac{dR_b}{dt} = \text{const} \tag{4}$$

the three dynamic contributions in equations (2) and (3), can be easily evaluated and scaled to the surface tension force, $\pi \sigma D_o$. After some manipulation [1], according to this approach, inlet momentum, inertia and viscous effects are expected to become important when, respectively

$$Eo\,Fr\,\frac{\rho_g}{\rho_f-\rho_g}\gg 1 \quad , \quad Eo^2\,Fr\left(\frac{R_o}{R_b}\right)^3\gg 1 \quad , \quad Ca\left(\frac{R_o}{R_b}\right)^2\gg 1 \tag{5}$$

Where Eötvos, Froude and capillary numbers are defined in the Nomenclature. It is worth noting that both inertial and viscous effects result more significant when the bubble radius is of the same order of magnitude as the orifice radius, i.e. in the early stage of bubble growth. In particular, the second of equations (5) justifies the use of the parameter $Fr^{0.5}\,Eo$, introduced by Tsuge [4] to distinguish static and dynamic regimes of detachment.

Quasi-static bubble detachment

Neglecting momentum, viscous and inertial terms, the integration of the *z*-component (**j** unit vector) of equation (1) can be put as a balance of buoyancy, internal overpressure, and surface tension forces, respectively

$$V(\rho_f-\rho_g)g+\frac{\pi D_o^2}{4}\left(\frac{2\sigma}{R_0}-\rho_f g H\right) = \pi D_o \sigma \sin\alpha_0 \tag{6}$$

where V is the bubble volume, R_0 the radius of curvature at bubble apex, and H the bubble apex height over the orifice. This balance must hold at any stage of bubble growth, by means of an adjustment of the incidence angle α_0 at the orifice rim. Bubble detachment occurs when, further to a volume increase, it is no longer possible to fulfill it. The equation above shows the importance of the incidence angle α_0 in the phenomenon, which determines the amount of the force keeping the bubble attached to the orifice. The term "incidence angle" is intentionally used here in place of "contact angle" to stress the fact that, for a bubble growing on a sharp orifice rim, it may assume a range of values and it is not determined uniquely by a surface tension balance, as in the Young equation. It is clear that the surface tension force has a maximum when the incidence angle is 90°.

It is well known that the shape of a static liquid-gas interface is ruled by the capillary equation [1]:

$$\sigma\left(\frac{1}{R_1}+\frac{1}{R_2}\right)=\frac{2\sigma}{R_0}-(\rho_f-\rho_g)\,g\,y \tag{7}$$

From equation (7) it cam be seen that in the absence of other stresses, the gravitational head is responsible of deviation of the bubble from spherical shape. Starting from Bashfort and Adams in 1892 [5], equation (7) has been integrated numerically with a variety of methods: among the others, in [2], [6], [7], [8], [9], [10], [11], [12]. Detachment of the bubble occurs for the maximum volume compliant with the boundary condition at the orifice [11].

One may wonder about the coherence between the force and capillary approaches. In fact, when capillary equation is solved and the related forces, as in equation (6), are derived from the profile shape, it can be checked that the force equilibrium holds at any stage of the bubble growth, as shown in Figure 2 [1]. Furthermore, it can be noted that initially, for small bubble volume the growth is essentially ruled by a balance of surface tension and overpressure; later on, as the volume increases, the balance is mainly between surface tension and buoyancy, with overpressure playing a reduced but still significant role.

Traditionally, the occurrence of bubble detachment has been considered a tradeoff between buoyancy and surface tension forces. This approach has been extensively credited either to Fritz [7] or Tate [14] although, actually, the related derivation does not appear in their papers. By balancing the two forces, the so-called Tate's detachment volume is obtained:

$$V_T = \frac{\pi D_o \sigma}{(\rho_f-\rho_g)g} \tag{8}$$

In the following paragraph it will be shown that Tate's volume is rather a close approximation of real detachment volume.

Departure volume and detachment volume

According to the preceding analysis, bubble detachment volume may differ from Tate's one, equation (8), for the following two reasons.

- The internal overpressure force gives an additional contribution: this is demonstrated by an elaboration like Figure 2, where it can be noted that all the lines end for a value of $V/V_T = 0.928$. For all the cases considered here, the overpressure force has a lifting role and the departure volume of the bubble is always lower than Tate's one. The discrepancy is larger when the overpressure force is significant, that is for smaller bubbles. From equation (6), by putting $\alpha_0 = 90°$, the departure volume can be derived and scaled to Tate's one as

$$\frac{V_d}{V_T} = 1 - \frac{D_o}{2R_0} + Eo\frac{H}{4D_o} \tag{9}$$

- Once the bubble has departed from equilibrium, the pinch-off of its neck does not occur instantaneously. During the breakup phase, gas is still injected in the bubble, and hence a detached volume greater than the static prediction (but not necessarily greater than the Tate's one) results.

Further to these considerations, it seems appropriate to distinguish a "departure volume" from a "detaching volume", the second being larger than the former one. Wong et al. [10] pointed out that the neck contraction is very rapid and hence the viscous force comes into play, and estimated the pinch-off time of the bubble as

$$t_{p.o.} = 3.8\,\frac{\mu_f\, D_o}{\sigma} \tag{10}$$

which makes it particularly significant in viscous liquids. According to equation (10), the volume increment between departure and detachment, $\Delta V_{p.o.}$, can be scaled to the Tate's volume as

$$\frac{\Delta V_{p.o.}}{V_T} \cong Eo\ \ Ca \tag{11}$$

This is in agreement with Table 1 of [10], where this difference is deemed negligible for low values of *Eo* and *Ca*.

EXPERIMENTAL APPARATUS AND MEASUREMENTS

The experimental cell (Figure 2) consisted of a polycarbonate box of about 2.5 dm^3 volume, open to the atmosphere and monitored by a temperature sensor [11], [13]. A circular orifice (0.14±0.05 mm diameter) was drilled in a polished, flat brass plate 30x30 mm^2, laid horizontally inside it, and gas (nitrogen) was injected through it into the fluid. In order to check the influence of physical properties, four different working fluids were adopted, as detailed in Table 1. The level of the liquid above the plate was varied from a fluid to another in order to keep the hydraulic head constant and equal to 980 Pa (100 mm H_20). To control nitrogen mass flow, a digital mass flow controller (model El-Flow by Bronkhorst) was used: this device guaranteed a stable inlet mass flow (proportional to an input voltage) in the chamber below the orifice. The outlet flow rate from the orifice stabilized at the same value within some seconds. The apparatus was intended to work in a "constant flow" condition, which was achieved mainly by reducing the volume of the gas chamber under the orifice: in fact, the Hughes' parameter, has been calculated as $N_c \approx 10^{-4}$, and "constant flow" conditions are expected to hold until $N_c<1$ [15], [11]. Several consecutive tests were carried out by varying the gas flow rate and hence the bubble frequency and detachment volume.

Measurements and related uncertainties

During the experiments reported herein, measurements of bubble volume V_B was obtained by digital processing of video images taken with a high speed camera (Phantom V4.0 by Vision Research) at a frame rate up to 1500 fps and with a resolution of about 130 pixel/mm. After some attempts, back

illumination with a dc halogen lamp was selected. The digital processing software is based on Matlab "Image Acquisition" toolbox. At first, the region occupied by the bubble is identified by an edge detection routine. Then relevant properties of this region (number and coordinates of pixels, area center of gravity, principal axes of inertia and so on) are evaluated by Matlab's **`regionprops`** utility. It is assumed that the bubble is an axisymmetric body, with its axis inclined of an angle φ with respect to the vertical (φ is determined by image processing and is very close to 0° in any instance). The volume of each bubble is evaluated as

$$V_B = L_s^3 \sum_{j=1}^{N_H} 2\pi r_{p,j} \tag{12}$$

where $r_{p,j}$ is the distance (in pixels) of the pixel j of the bubble region from the symmetry axis, and L_s is the length scale, determined before each test by taking an image of a rod with marks at known distances. In this way, remarkably, no other assumption on bubble shape but axial symmetry is made. To check this assumption, the volume evaluation is performed separately on the N_H pixels on left and right side of the symmetry axis, the two values are compared and an error message is issued if the difference is greater than 1%. The resulting bubble volume is the average of the measured volumes over all the images of the bubbles taken after its detachment (typically 3 to 5 different bubbles, with 15-40 images for each of them). Notwithstanding in some cases the bubble exhibits relevant shape oscillations, in most of cases the sample standard deviation of the volume is less than 1%, and this is another proof of the adequacy of the method.

The volumic flow rate was also evaluated by digital processing of images, by measuring the volume of bubbles crossing a fixed line in the image over a certain time. This method provided more reliable and consistent values with respect to the output of the flow controller, although the agreement was generally good. The detachment period could be determined by counting the frames

intercurring between the passage of two consecutive bubbles across the same line. The period was averaged among 4 to 6 consecutive passages.
The coordinates of the bubble profile were also extracted and stored. From these, it was possible to determine the bubble curvature at its top, R_0, by fitting a quadratic interpolation in the band of the upper five pixels of the bubble. The incidence angle at orifice rim, α_0, was also evaluated by interpolating the bubble profile in the form.

$$r = \sum_{i=1}^{N} A_i \, y^i \tag{13}$$

where r is the bubble radius (from the symmetry axis) and y the height over the orifice, and taking the derivative for $y = 0$. After several attempts, a quadratic interpolation (N=2) over the lower 10 or 15 pixels of the bubble profile was selected as the better compromise between noise reduction and accuracy.

RESULTS AND DISCUSSION

Detachment volume

Bubble detachment volumes, scaled to Tate's one, are reported versus $Fr\ Eo^2$, in Figure 4. The bubble volume is nearly constant for $Fr\ Eo^2 < 0.2$, thus demonstrating that the dynamical effects are negligible in the range considered, according to the criterion in equation (5). It can be noted that , in quasi-static regime, detachment volumes are lower than the Tate's one.
The velocity of the center of gravity of the bubble is reported for some cases in Figure 5 versus the volume $V' = V/V_d$ (i.e., scaled on the departure volume predicted by equation (9)). it can be seen that the velocity increases for $V' > 1$: this seems to indicate that the bubble has started its detachment, departing from equilibrium.

Contact angle and curvature at bubble top

The measured values of the radius of curvature at bubble top, R_0, scaled on the Laplace length, $a = \{\sigma / [(\rho_f - \rho_g)\ g]\}^{0.5}$, are plotted versus dimensionless bubble volume in Figure 6, and compared with the theoretical prediction based on integration of the capillary equation: the agreement is quite good, and proves the validity of the adopted measurement technique.
In a similar way, the measured values of incidence angle are plotted versus dimensionless bubble volume in Figure 7, and compared with the theoretical prediction. The agreement, although qualitatively good, is less accurate in this case. It can be seen that generally the incidence angle is overestimated at small values of the bubble volume and underestimated for large bubble volume. This tendency is the same regardless of the degree of the interpolating polynomial and the chosen interpolation range over the bubble base. The reason for that is very probably the insufficient resolution of the region of the interface close to the orifice, where the incidence angle undergoes large variations.

Overall balance of forces

The overall force balance on the growing bubble, evaluated on the basis of experimental parameters, is reported for different fluids in Figures 8, 9 and 10. The results are qualitatively good, but are clearly affected by the inaccuracy in the measurement of the incidence angle. It is thus evident that a further improvement in the measurement techniques of the incidence angle, both in terms of optical resolution of the images and mathematical methods in digital processing, is necessary to accomplish a more accurate evaluation of the forces acting on a growing bubble in quasi-static regime.

CONCLUSIONS

The aim of the present paper is to compare theoretical consideration on quasi-static bubble growth with experimental measurements. Conditions in which the detachment can be considered quasi static are discussed in the paper, and a link was established between momentum balance and

capillary equation. A simple experimental apparatus was built to generate nitrogen bubbles in different fluids. Bubble images were taken with a high speed camera and processed via a dedicated software to obtain the main geometrical parameters, i.e. bubble volume, curvature radius at top and incidence angle. From these parameters, it was possible to evaluate the forces acting on the bubble to check the overall momentum balance during bubble growth. The experimental results show a generally good agreement with theory: the main source of discrepancy is the measurement of contact angle, whose measurement technique should be further improved

NOMENCLATURE

CONJUGATE GRADIENT METHOD APPLIED TO INFRARED THERMOGRAPHIC DATA FOR THE INVERSE ESTIMATION OF THE CONVECTIVE HEAT TRANSFER COEFFICIENT

F. Bozzoli*, S. Rainieri and G. Pagliarini
Department of Industrial Engineering, University of Parma, Italy

ABSTRACT. The conjugate gradient method formulated with the adjoint problem is here employed to solve the 2-D Steady State linear Inverse Heat Conduction Problem with the aim of estimating the local convective heat transfer coefficient on a given surface by using the temperature distribution, acquired by an infrared acquisition system, as input data. This solution technique, already successfully adopted in literature for the Unsteady formulation of the Inverse Heat Conduction Problem, is here newly applied to state state tempertaure maps in order to restore the local heat transfer performance of a surface in a turbulent channel air flow by reconstructing the local energy balance in the wall.

Keywords: *Parameter Estimation, Inverse Problem, Infrared Thermography*

INTRODUCTION

In the estimation of the local convective heat transfer coefficient at the interface between a fluid and a given surface, it is mandatory to solve the Inverse Heat Conduction Problem (IHCP) in the solid domain. The well known difficulties involved in IHCPs stem primarily from the fact that they are often ill-posed and, consequently, very sensitive to small perturbations in the input data. A simple application of this approach consists in adopting the steady state temperature surface distribution as input data of the so called Steady State Inverse Heat Conduction Problem in which the unknown quantity is represented by the local heat transfer coefficient. A suitable experimental technique for this application is based on infrared thermography, which enables to acquire high spatially resolved temperature maps without disturbing the fluid layer adjacent to the wall.

A growing number of papers published in the open scientific literature report solution techniques of the Unsteady Inverse Heat Conduction Problem (UIHCP) while the Steady Inverse Heat Conduction Problem (SIHCP) has been less extensively investigated. Although it can be regarded as a special case of the UIHCP, some care is needed in the application of standard inverse solution strategies. In fact the elliptic nature of the partial difference equation, expressing the steady state local energy balance, makes the estimation procedure based on the solution of the SIHCP more complex, being the destructive effect of noise amplified by the necessity of estimating the wanted information from the signal Laplacian and not from the signal first temporal derivative, as it often happens in the classical formulation of the IHCP. The peculiar difficulties of the SIHCP in which the unknown is the spatial distribution of the heat transfer coefficient are mainly related to the high number of degrees of freedom of the problem, and therefore to the computational cost of the solution algorithm. This peculiarity makes most of the available solution strategies unfeasible.

A general approach, capable of recovering the local surface heat transfer coefficient in 2-D domains, is the one formulated by Rainieri and Pagliarini [1,2]. It is based on an iterative procedure aimed to the forced matching between experimental data and calculated data, derived by the solution of the corresponding direct problem. A more sophisticated methodology, based on the consecutive

application of the Wiener filter on the raw infrared thermograhyic data has been successfully applied to the same problem [3]. The same steady state energy balance equation is instead solved directly by Ay et al. [4] by processing temperature distributions, acquired by infrared thermography, in order to recover both local and average heat transfer coefficient in a tube-and-fin assembly both in in-line and staggered arrangements. The authors perform a direct calculation of the discrete Laplacian of the temperature distribution without specifying the approach followed to handle the well-known ill-posed nature of the problem with regards to the estimation of the signal's second derivative.
To the Authors' knowledge no other inverse solution techniques have been applied to this problem, which can be regarded as a fundamental problem in the design of heat exchanger. In fact the heat transfer coefficient is the fundamental parameter which is likely unknown not only on some portions of the domain's boundary, as it is often assumed, but on the whole heat transfer surface.
The present investigation is intended to extend the study of this inverse problem by adopting the conjugate gradient method with adjoint problem formulation as solution method. This well known method [5] has been here newly applied to the two-dimensional SIHCP in which the unknown quantity is represented by the local distribution of the surface heat flux and then by the local convective coefficient, which is recovered by estimating the Laplacian of the experimental temperature maps acquired by means of an infrared thermographic system.

THE ESTIMATION PROCEDURE

Under the assumption of constant thermal properties, thin fin approximation and steady state condition, the local energy balance is expressed in Cartesian coordinates x,y by the following elliptic partial differential equation:

$$\frac{\partial^2 T(x,y)}{\partial x^2} + \frac{\partial^2 T(x,y)}{\partial y^2} = \frac{g(x,y)}{s \cdot \lambda} \quad , \qquad (x,y) \in D \tag{1}$$

where $g(x,y)$ is the arbitrarily distributed heat flux density over the domain D, s and λ the wall respectively thickness and thermal conductivity. By assuming a Dirichlet's condition on the domain's boundary, the partial differential equation is completed as follows:

$$T(x,y) = T_b(x,y) \quad , \quad (x,y) \in \partial D \tag{2}$$

In the inverse formulation here considered the heath flux distribution $g(x,y)$ is regarded as being unknown, while surface temperature is assumed to be known from experimental data. This condition is then expressed by the following constraint:

$$T(x,y) = \Theta(x,y) \quad , \qquad (x,y) \in \partial D \tag{3}$$

where $\Theta(x,y)$ is the measured temperature map. The extreme sensitivity of the governing equation to even small errors or noise in the input experimental data, makes the problem ill-conditioned and then ill-posed. The strategy here adopted to inversely estimate the unknown heat flux distribution $g(x,y)$ is the Conjugate Gradient Method (CGM) with the adjoint equation approach which represents a suitable solution strategy in problems involving many design variables and a limited number of cost function [6]. It is a gradient-based optimization procedure which, by using the steepest descent method firstly evaluates the search direction, the gradient of the objective function with respect to the design variables and, secondly, it searches iteratively in this direction the minimum of the performance function.
Under the adjoint equation approach, such minimization procedure requires the solution of auxiliary problems, known as the sensitivity and the adjoint problem. These equations are then solved

iteratively in order to minimize the objective function, represented by the error between the estimated and measured temperature distributions [5].The functional to be minimized in the problem under investigation is then:

$$J[g(x,y)] = \sum_{i=1}^{M} [T(X_i, Y_i) - \Theta(X_i, Y_i)]^2 \tag{4}$$

where matrix $T(X_i,Y_i)$ and $\Theta(X_i,Y_i)$ express respectively the estimated and measured temperature discrete map, having a total number of elements equals to M. The above equation can be suitably rewritten on the whole domain D as follows:

$$J[g(x,y)] = \iint_{(x,y)\in D} [T(x,y) - \Theta(x,y)]^2 \cdot \delta(x - X_i) \cdot \delta(y - Y_i) \cdot dxdy \tag{5}$$

where δ is the Dirac delta function. With the aim of estimating $g(x,y)$, the iterative procedure of the CGM is written as follows

$$g^{K+1}(x,y) = g^K - \beta^K q^K(x,y) \ , \quad K=0,1,2,\ldots \tag{6}$$

where β^k is the search step size at iteration K, and q^K is the direction of descent, obtained as a linear combination of the gradient direction with descent direction of the previous iterations. The step size β^k is determined minimizing the functional $J[g(x,y)]$ given by Eq. (5) with respect to β: after rearrangement, the following expression can be obtained for the search step size β^k

$$\beta^K = \frac{\int_{(x,y)\in D} \Delta T[q^K(x,y)] \cdot [T[g^K(x,y)] - \Theta(x,y)] \cdot \delta(x - X_i) \cdot \delta(y - Y_i) \cdot dxdy}{\int_{(x,y)\in D} [\Delta T[q^K(x,y)]]^2 \cdot \delta(x - X_i) \cdot \delta(y - Y_i) \cdot dxdy} \tag{7}$$

The calculation of $\Delta T[q^K(x,y)]$, representing the change in $T(x,y)$ with respect to a change in the heath flux distribution $g(x,y)=q^K(x,y)$, can be performed either by direct calculation of incremental ratios for each term, unfeasible in the present problem because of the high computational cost consequent to the high number of variables, or by solving the sensitivity problem:

$$\frac{\partial^2 \Delta T(x,y)}{\partial x^2} + \frac{\partial^2 \Delta T(x,y)}{\partial y^2} = \frac{\Delta g(x,y)}{s \cdot \lambda} \ , \quad (x,y) \in D \tag{8}$$

$$\Delta T(x,y) = 0 \ , \quad (x,y) \in \partial D \tag{9}$$

In which $\Delta g(x,y)$ is set equal to $q^K(x,y)$ [4]. Considering equation (6), the direction of descent for the CGM can be written as:

$$q^o(x,y) = J'^o(x,y), \quad q^K(x,y) = J'^K(x,y) + \gamma^K q^{K-1}(x,y) \tag{10}$$

where $J'^K(x,y)$ is the gradient of the functional $J(g(x,y))$ and γ is the conjugation coefficient obtained as follows:

$$\gamma^0 = 0 \ , \ \gamma^K = \frac{\int_{(x,y)\in D} \left[J'^K(x,y)\right]^2 dxdy}{\int_{(x,y)\in D} \left[J'^{K-1}(x,y)\right]^2 dxdy} \qquad K=1,2,... \tag{11}$$

The convergence of above the above iterative procedure in minimizing the functional J is proved by Alifanov [5].
The calculation of the gradient $J'^K(x,y)$ of the functional $J[g(x,y)]$ to be minimized, under the adjoint equation approach, ends in the solution of a single direct problem.

$$2\cdot\left[\Theta(x,y)-T(x,y)\right] = \frac{\partial^2 J'(x,y)}{\partial x^2} + \frac{\partial^2 J'(x,y)}{\partial y^2} \quad , \quad (x,y)\in D \tag{12}$$

$$J'(x,y) = 0 \ , \quad (x,y)\in \partial D \tag{13}$$

After developing the expressions for the search step size β^k and for the gradient direction, the iterative algorithm of the CGM can be implemented until a given stopping criterion is satisfied, as discussed in the following.
Since the experimental temperature data are inevitably affected by uncertainties the stopping criterion can be defined by adopting the approach formulated by Alifanov [5], named *discrepancy principle*. According to this principle, the inverse problem solution is regarded to be sufficiently accurate when the difference between estimated and measured temperatures is close to the standard deviation σ of the measurements. Thus the stopping criterion is as follows:

$$J\left[g^K(x,y)\right] = \sum_{i=1}^{M}\left[T(X_i,Y_i)-\Theta(X_i,Y_i)\right]^2 \cong M\cdot\sigma^2 \tag{14}$$

where M is the total numbers of experimental data. The direct, sensitivity and adjoint problems are here solved by adopting the finite-difference method implemented in Matlab® environment.
Once the heat flux density has been restored, the convective heat transfer coefficient distribution can be estimated by knowing the wall to fluid temperature difference, as follows:

$$h(x,y) = \frac{g(x,y)}{T(x,y)-T_f} \tag{15}$$

EXPERIMENTAL VALIDATION

The above described estimation technique has been applied to experimental data regarding a typical condition to be found in plate and fins heat exchangers, that is to the surface temperature distribution occurring on the wall of a plane channel which delimits a turbulent air flow. The experimental apparatus adopted consists of a closed-loop wind tunnel schematically shown in figure 1. In order to regulate the air temperature, the stream is forced, by a fan with adjustable output power, through a finned tube heat exchanger connected to a heat bath. It enters then into a settling chamber and then into a methyl methacrylate (Perspex®) channel, 2 m long and having a rectangular section with a width to height ratio of 10, where the test section is arranged. On one vertical wall of the Perspex channel, a window with a section of 300 mm×180 mm and fitted with a 3 mm thick aluminium plate, is placed.

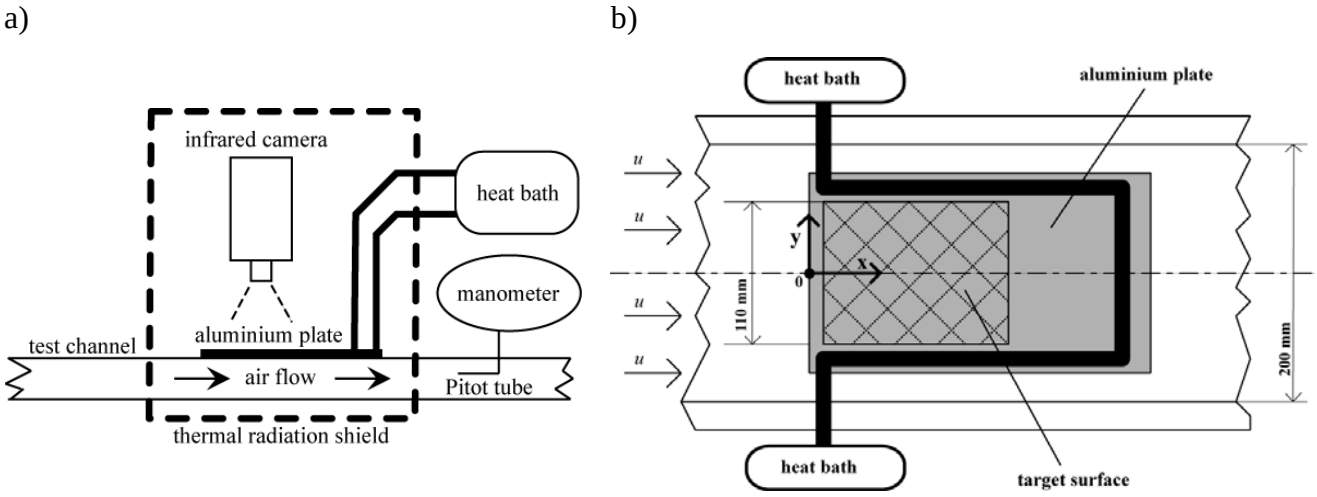

Figure 1. Scheme of the experimental apparatus

A particular attention has been paid to not creating surface geometrical discontinuities on the channel's wall on which the aluminium plate is fitted. The test section is located 1.20 m downstream the channel inlet section, in order to assure that a fully developed boundary layer is achieved for the whole Reynolds number range under investigation.
The temperature along three sides of the metallic fin is controlled by means of direct contact with a copper tube where a fluid coming from a circulator bath flows, as shown in figure 2.
The external surface of the metallic plate has been coated by a thin film of opaque paint with uniform and known emissivity. The surface temperature distribution has been acquired by means of an infrared thermographic system, namely the ThermoVision A20-M by Flir Systems.
By adopting Focal Plane Array Technology, it measures the energy emitted by the object surface by means of 180x120 microbolometer sensors matrix, active in the wavelength range 7.5-13 μm. The sensitivity reported by the instrument manufacturer is 0.12 K at 303 K, while the stated accuracy is ± 2 K. The instrument performance, declared by the manufacturer, can be significantly enhanced, in relation to the aim of restoring the Laplacian of the surface temperature distribution, by adopting the optimal data acquisition and data processing methodology addressed in [7].
The mean inlet and outlet air temperature is measured with a precision of 0.1 K by means of type-K thermocouples connected to a precision HP multimeter, model 3458A.
A Pitot tube, fitted in the downstream end of the test section and connected to a micro-manometer Kimo, model MP120, having a 3mm external diameter, has been used to measure the fully developed air flow velocity profile in the test channel.
The whole experimental equipment has been shielded by using black curtains in order to limit the effects of uncontrollable radiation coming from the surroundings.

RESULTS AND CONCLUSIONS

The investigation has been performed by heating the aluminium plate on the frame and considering two different stream air velocity values. The corresponding Reynolds number values, together with the corresponding stream and average surface temperature values are reported in Table 1.
Figure 2 reports the experimental temperature map obtained for the representative case corresponding to the highest velocity value. The inevitable presence of noise makes the direct calculation of its Laplacian unfeasible, by making necessary the inverse solution approach.

Table 1
Test conditions

Test	u (m/s)	Re	T_f (K)	$\overline{T(K)}$
1	10.7	$24 \cdot 10^3$	295.4	318.1
2	17.6	$40 \cdot 10^3$	295.4	316.0

In the present investigation the local heat flux density, and then the heat transfer coefficient distribution on the surface have been restored by adopting the conjugate gradient method with the adjoint problem formulation previously described. In particular, the convective heat transfer coefficient has been estimated by subtracting from the total heat flux density the heat exchanged by radiation and by natural convection evaluated under the assumption of grey surface behaviour for both the internal and external surfaces and of free convection laminar boundary layer for the external side.

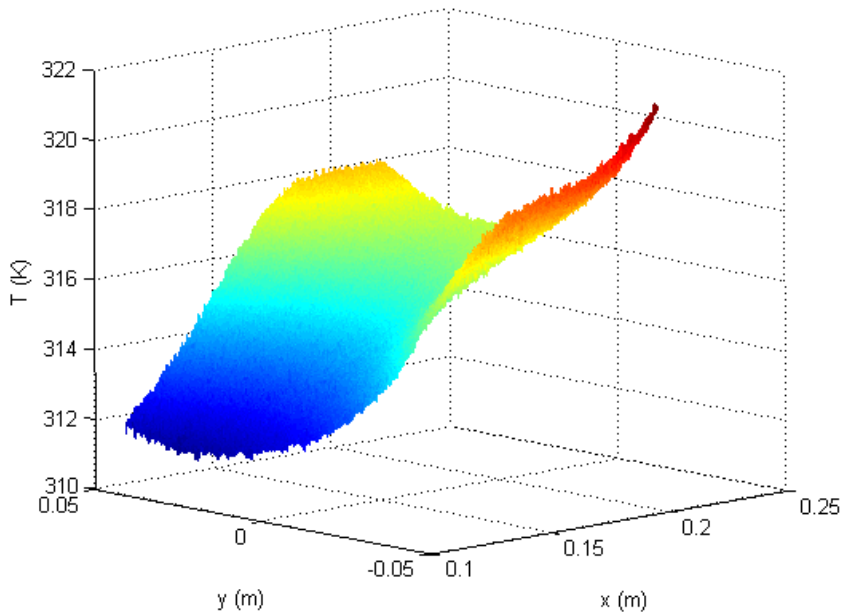

Figure 2. Experimental temperature map for u=10.7 m/s

In the formulation of the stopping criterion based on the discrepancy principle, a data standard deviation of 0.1 K has been assumed. Figure 3 compares the raw temperature map and the restored function on the domain centreline which, as expected, results to be a smooth function, doubly differentiable, in which the experimental noise has been filtered out. Figure 4 shows the estimated convective heat transfer coefficient on the centreline of the aluminium plate versus the longitudinal coordinate for the two different air flow velocity values considered in the present investigation.
The classical method of Kline and McClintock [8] has been applied in order to estimate the uncertainty to be associated to the heat transfer coefficient values: the maximum value for the uncertainty on the local heat transfer coefficient results of ± 10%. Further considerations on the uncertainty of the above experimental apparatus and data processing technique are reported in [2].

The results are also compared to the values predicted by the Dittus-Böelter correlation, holding for the fully developed turbulent internal flow in which all the fluid properties have been evaluated at the inlet mean air temperature and in which the channel hydraulic diameter has been adopted as the characteristic length.

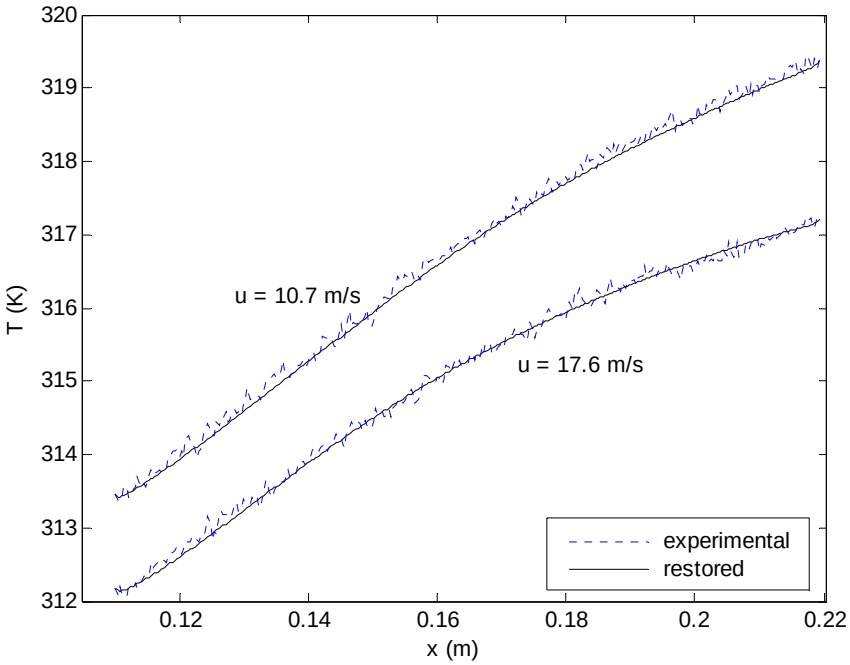

Figure 3. Experimental and restore temperature distributions on the centreline of the plate

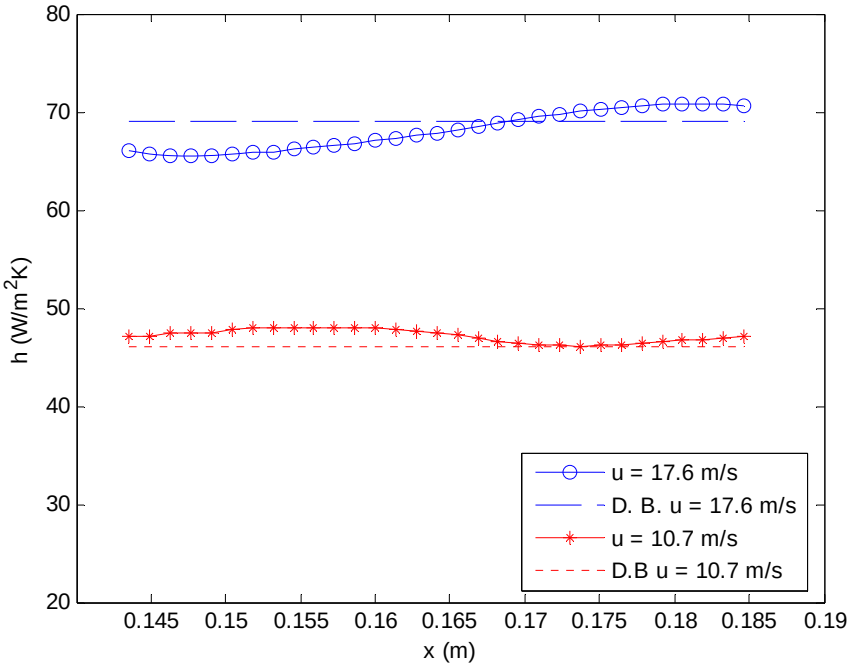

Figure 4. Experimental heat transfer coefficient on the centreline of the plate and comparison with the Dittus-Böelter correlation.

The good agreement between the reconstructed distribution of te convective heat transfer coefficient and the asymptotic fully developed values predicted by the Dittus-Böelter correlation confirms the

robustness of the Conjugate Gradient Method in the solution of the 2-D SIHCP characterized by a high number of degrees of freedom, that is in the inverse heat transfer problem aimed to the restoration of the convective heat transfer coefficient distribution. This approach provides then an effective strategy in the estimation of the heat transfer performance of a given surface by offering a useful tool in heat exchanger design.

HEAT TRANSFER AND FLOW CHARACTERISTICS AROUND FINNED TUBE BANK HEAT EXCHANGERS

H. Umekawa[1*], R. Honda, G. Kommoda and M.Ozawa[1*]
[1]Kansai University, Osaka, Japan

ABSTRACT. Fluidized-bed has high heat transfer performance which mainly caused by the particle convection. This particle convection is generated by the void movement, thus the visualization of the fluidized-bed is very useful mean to understand the heat transfer characteristics. In this investigation, simulated fluidized-bed heat exchanger with annulus fin was visualized by using the neutron radiography, and local and overall heat transfer characteristics were measured. This annuls fin also worked as the annulus obstacles of the particle movement, and it made clear the difference of the influence of the tube arrangement. As the result the staggered-arrangement took higher heat transfer performance than the in-line arrangement under low fluidized velocity, and the opposite tendency was observed under higher fluidized velocity. These tendencies could be explained by the bed-material movement well.

Keywords: *Fluidized-bed, Heat exchanger, Finned-tube banks, Heat transfer, Void fraction, Neutron radiography*

INTRODUCTION

Heat transfer characteristics of fluidized-bed heat-exchanger have been widely investigated so far[1-10], and the dominant heat transfer mechanism could be classified into three categories, i.e. solid convection, gas convection and radiation. Characteristics of these principal components depend on the particle size, and the solid convection is dominant in the particle size of the fluidized-bed heat exchanger.

The high heat transfer characteristics of solid convection is caused by the large specific surface of the particle, the large heat capacity of the particle, and the high mixing rate of particles. Thus to keep the high heat transfer ability as heat exchanger, continuous high exchange rate of the solid particle will be required. This characteristic, of course, is strongly influenced by the particle diameter, tube diameter, tube arrangement and fluidized velocity, etc.

Consequently, understanding of the solid movement around the heat exchanger is important to understand the fluidized bed heat exchanger. For this purpose, the movement of the individual solid has also been investigated so far [3,6,7]. As alternative approach, Author evaluated the void fraction characteristics around the fluidized-bed heat exchanger, and this manner based on the concept the solid movement is caused by the void fraction movement [8-10]. In this investigation, similar estimation has been done against the fluidized-bed heat exchanger with annulus fin.

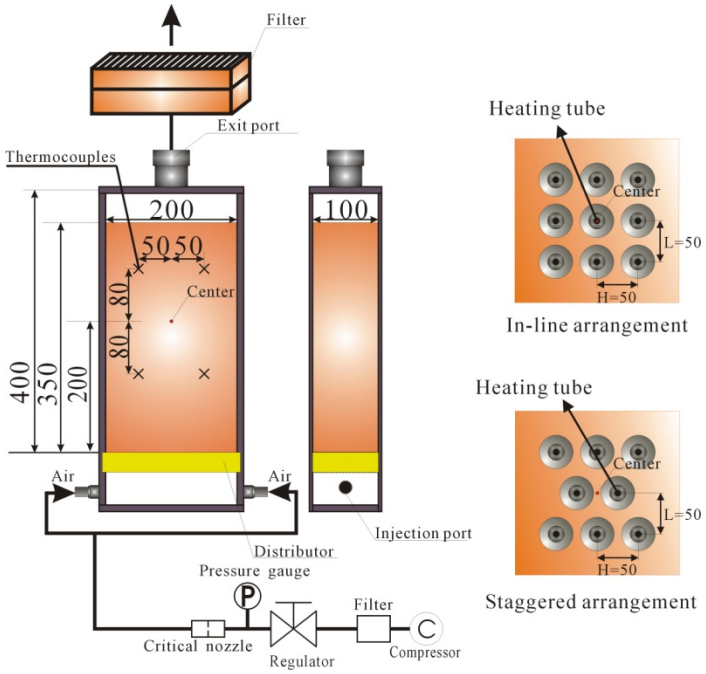

Figure 1 Experimental apparauts

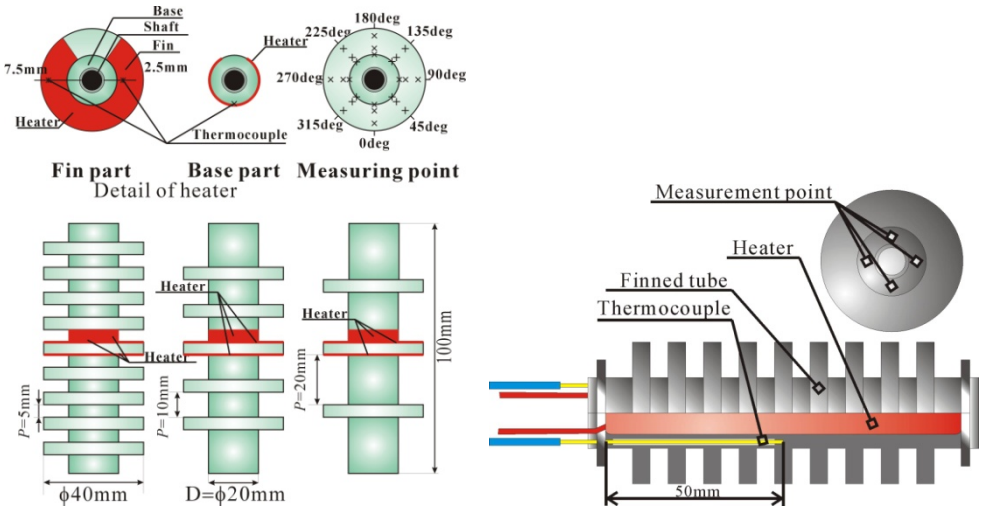

Figure 2 Detail of the fin-tube

The experimental setup, shown in Figure 1, is a slender rectangular fluidized-bed with inside dimensions of 200mm width, 400mm height and 100mm depth. The wall material of the test-section was aluminium which is transparent against the thermal neutron, and the bed material was silica sand (mean diameter 0.17mm, density 2555kg/m^3). The stagnant bed height is 350mm, and the minimum fluidization velocity J_{Gmf}=0.045m/s. The detail of the tube is shown in Figure 2, and the core tube diameter D=20mm. The thickness of the fin is 5mm and outer diameter of fin is 40mm, and fin pitches are 5mm, 10mm and 20mm, respectively. In the experiments, these tubes are arranged in staggered or in-line arrangements as shown in Figure 1, and the centre of these arrangements locate at 200mm height from the distributor plate. The horizontal pitch H/D=2.5, the lateral pitch L/D=2.5. Bulk temperatures of the fluidized-bed were measured at four points as shown in Figure 1 by using the Φ=1mm sheathed thermocouples (Type-K).

In this investigation, three kinds of the experiments, i.e. the visualization by neutron radiography, the measurements of the local heat transfer characteristics and the measurements of the overall heat transfer characteristics, were conducted. In the experiment of the neutron radiography and the

experiment of the overall heat transfer characteristics, fin-tubes were made of aluminium. In the case of the overall heat transfer characteristics, cartridge heater (Φ=20mm × 100mm) and four Type-K sheathed thermocouples(Φ=1mm) are inserted. For the experiment of the local heat transfer characteristics, fin-tube was made of acrylic resin, and the 3 μ m nichrome foil heater is pasted upon the surface. Nichrome foil was heated by Joule heating of A.C. power. Under the nichrome heater, three Type-K bare thermocouples (Φ=0.2mm, surface of core-tube, surface of fin (Δr=2.5, 7.5mm)) are equipped, and the heating tube was rotated every 45deg. Consequently, the number of measuring points around the heating surface becomes twenty-four locations as shown in Figure 2.
The fluidized gas was air supplied from the compressor through the oil filter and mist separator, was regulated by means of a critical flow nozzle. The volumetric gas flux J_G was set in the range of 0.04-0.18m/s (J_G/J_{Gmf}=1.0-4.0), and injected into the fluidized-bed through the distributor. After the test section, air ejected to the ambient through the HEPA filter.
The thermal neutron radiography system of JRR-3 in Japan Atomic Energy Agency (JAEA) was used for the visualization, and the image processing will be briefly described in the next section.

Image processing

Thermal neutron radiography is one of non-destructive inspection methods, and is quite similar to X-ray radiography. Owing to the difference of the attenuation characteristics, the neutron radiography is suitable for the visualization of fluidized-bed. In the case of this investigation, aluminium of test-section and silica sand are both transparent against the neutron radiography. Moreover the attenuation of the silica-sand is easily controlled by using the aqueous solution of gadolinium sulfate.
The visualization area of thermal neutron radiography system of JRR-3 is 220mmwidth and 250mm height, and the visualization image was recorded by using SIT-tube camera in video rate.
The visualization image can be expressed as next equation,

$$S_{(x,y,t)} = G_{(x,y)} \exp\left\{\rho_W \mu_W \delta_{W(x,y)} - \left[1-\varepsilon_{(x,y,t)}\right]\rho_S \mu_S \delta_S\right\} + O_{(x,y)} \tag{1}$$

and by using the image of the test section without fluidized bed material $S_{W(x,y)}$, fluidized-bed under static condition $S_{0(x,y)}$ and dark current image $O_{(x,y)}$, the void fraction can be estimated by using next equation.

$$1-\varepsilon_{(x,y,t)} = \frac{\log(S_{W(x,y)} - O_{(x,y)}) - \log(S_{(x,y,t)} - O_{(x,y)})}{\left[\log(S_{W(x,y)} - O_{(x,y)}) - \log(S_{0(x,y)} - O_{(x,y)})\right]\left(1-\varepsilon_{0(x,y)}\right)} \tag{2}$$

The error of the measurement accuracy of the void fraction is less than 10%, and more detail information of the visualization of the neutron radiography can be found elsewhere[8,9].

Flow pattern and void fraction distribution

The examples of the visualization results of void fraction are shown in Figure 3 as successive image. As shown in this figure, the void fraction movement is clearly obtained as the projection image. In the case of the staggered arrangement, the direction of the void movement is strongly controlled by the tube which located at the upstream position, and the void directly hits to the bottom of the tube which located at the downstream position. These movements of void in staggered arrangement can be observed under all gas volumetric flux conditions.
On the contrary, the movement of the void fraction in-line arrangements depends on the gas volumetric flux value. In the case of the low gas volumetric flux condition, the void simply rises up through the path between tubes. But, under high gas volumetric flux condition, inrush of void to the bottom of the tubes can be observed.

Figure 4 Time averaged void fraction image

These successive image, or video image, is useful to understand the movement of the void fraction, but

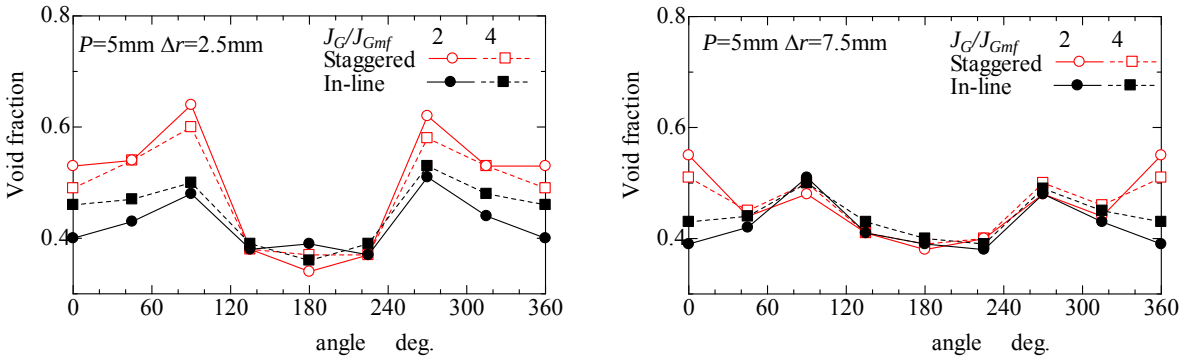

Figure 5 Void fraction along the circumferential direction

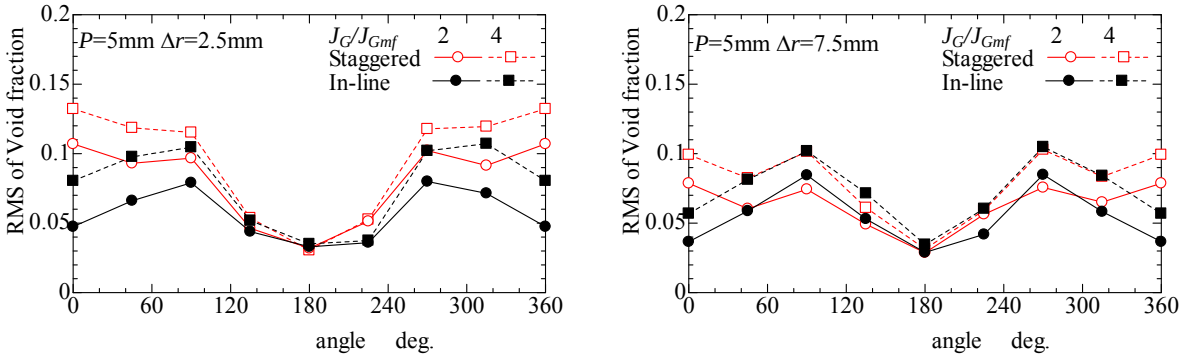

Figure 6 RMS of void fraction along the circumferential direction

it is difficult to use as the information of the heat exchanger design. To understand the flow characteristics of fluidized-bed heat exchanger in macroscopic view point, the time averaged images, "flow pattern", are calculated as Figure 4. These figures are the time averaged value among 20 seconds, and the flow characteristics which mentioned above can be perceived.

On the basis on these data, the void fraction profile along the circumferential direction and RMS of void fraction are plotted in Figure 5 and 6, respectively. An each estimated region of the data in Figures 5 and 6 was the area with dimensions of a.2mm×a.3mm at the temperature measuring point in Figure 2.

Firstly general tendency of void fraction and RMS will be explained.

At the top of the tube (180deg) the stagnant cap is constructed, and the void fraction takes the quite low value under all conditions. On the other side, the bottom of the tubes (0, 360 deg.) take the slightly high value which corresponds to the gas-packet. But, the peaks of the void fraction locate at the side (90, 270deg). It is because the void which hit the tubes is ejected to the side as clearly observed in Figure 4.

Similar profiles are also observed in RMS, and high RMS value means the frequently contact of void, and it may correspond to the intense movement of the bed material. These tendencies are common characteristics of this experiment, and next the detailed characteristics will be explained.

At the middle of the fin (Δr=7.5mm), influences of the tube arrangements and J_G/J_{Gmf} on void fraction can be observed at only the bottom part, but the influences of J_G/J_{Gmf} on RMS value are clearly observed. This means that the bubble frequency increases with the increase in J_G/J_{Gmf}, but the bubble passes through these locations. Thus the influence on the void fraction did not clearly appear, except the extremely high frequency part at the bottom.

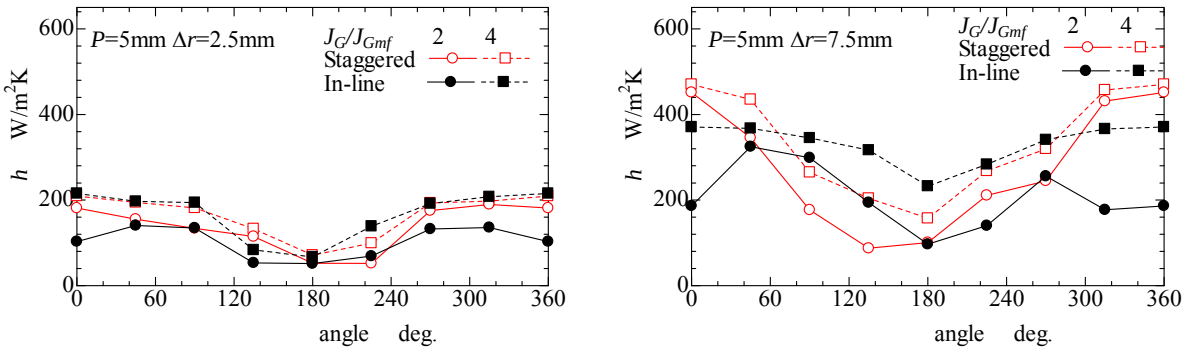

Figure 7 Local heat transfer coefficient

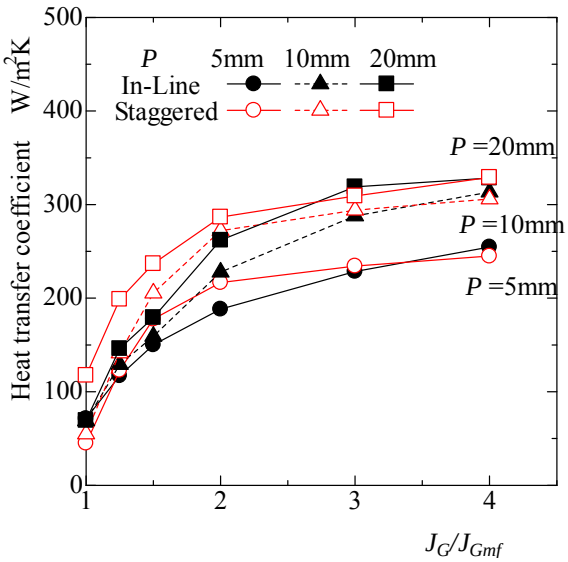

Figure 8 averaged heat transfer coefficient

At the adjacent region of the core tube (Δr=2.5mm), void fraction and RMS take the quite different tendency with the results of Δr=7.5mm. In this region, high void fraction is observed at the wide region of bottom part. Although the influence of the tube arrangement can be observed clearly in both figures of void fraction and RMS, the influence of the J_G/J_{Gmf} is not clear in the case of the void fraction of the staggered arrangement. The increasing of the void and RMS at the bottom of the tube is caused by the sliding of bubble along the core tube, and the weak influence of void fraction may mean the saturation of the void.

Heat transfer characteristics

Figure 7 is the local heat transfer coefficient at Δr=2.5mm and 7.5mm. These heat transfer coefficient characteristics can be roughly correlated with the void fraction and RMS except the data at J_G/J_{Gmf}=4 of in-line arrangement. Generally, high void fraction and high RMS value means the intense of the solid movement, thus the heat transfer coefficient at those locations become the high value.

The reason of that the heat transfer of Δr=2.5mm is roughly half of that of Δr=7.5mm can be considered as the results of the dilution of solid. On the contrary, the high heat transfer coefficient at Δr=7.5mm may be partially induced by drag of the wake by the void movement at Δr=2.5mm.

The heat transfer mechanism of the top of the tube at J_G/J_{Gmf}=4 of in-line arrangement may be caused by the different movement. On the basis on the visualization results, the stagnant cap causes the oscillatory movement with constant void fraction, and strong oscillation was especially observed in the case of the in-line arrangement. This oscillatory movement cause the mixing of the solid particle, thus the high heat transfer coefficient, but it cannot be detected by the void fraction or RMS.

Figure 8 is the overall heat transfer plotted against the J_G/J_{Gmf}. In this experimental range, heat transfer coefficient increases with the increase in J_G/J_{Gmf}, and decreasing tendency is not observed.
As shown in this figure, overall heat transfer coefficient of the staggered arrangement takes the higher value than that of the in-line arrangement. As the explanation of the local heat transfer coefficient, this difference is caused by the void movement induced by the influence of the upstream tubes. Under high J_G/J_{Gmf} condition, heat transfer coefficient of inline arrangement becomes slightly higher than that of the staggered arrangement owing to the difference of the particle movement at top of the tubes.
In this paper, the influence of the tube arrangement has been mainly explained. As final part of this paper, the influence of the fin pitch will be explained briefly. As shown in Figure 8, the strong deterioration of heat transfer coefficient can be observed in P=5mm compared with another fin pitches. Of cause this deterioration can be considered as the results of the restriction of the bed material caused by the annulus fin. But in the view point the heat transfer performance, P=5mm takes the highest value owing to the large heat transfer area.

CONCLUSION

In this paper, heat transfer characteristics and void fraction characteristics of fluidized-bed heat exchanger with annulus fin were experimental explained. In this investigation, simulated fluidized-bed heat exchanger with annulus fin was visualized by using the neutron radiography, and local and overall heat transfer characteristics were measured. This annuls fin also works as the annulus obstacles of the particle movement, and it makes clear the difference of influence of the tube arrangement. As the result the staggered-arrangement took higher heat transfer performance than in-line-arrangement under low fluidized velocity, and the opposite tendency was observed under higher fluidized velocity. These characteristics can be explained by the void movement characteristics well.

ABSTRACT. We describe a method and an experimental system to measure the thermal conductivity and the thermal diffusivity of a fine wire simultaneously by a T type probe. In T type probe, a short hot wire is subjected to both an alternating and a direct current, and a thermally infinite long test wire is attached to the midpoint of the hot wire with an interstitial material. Theoretical analysis shows that, the thermal effusivity of the test wire can be obtained when the hot wire is heated by an alternating current, and the thermal conductivity is determined by the conventional steady state method. The present method is tested by measuring a platinum wire at room temperature, our results agree well with the literature reported values.

Keywords: *T type probe, thermal conductivity, thermal diffusivity, thermal effusivity*

INTRODUCTIONS

Investigations of measurement techniques for thermophsical properties, including the thermal conductivity and thermal diffusivity, of solid materials are of great importance in relation to new material research, space technology and applications of solar energy. For wire specimen, a number of measurement techniques have been developed, including Ångström method [1], transient heating method [2], constant-rate heating method [3], self-heating 3ω method [4] and others [5, 6]. The first periodic temperature method to gain widespread acceptance was Ångström method to accurately determine the thermal diffusivity, where one end of the long rod was subjected to a periodic temperature as the boundary condition [1]. The self-heating 3ω method [4] was well developed to measure both thermal conductivity and thermal diffusivity of a metallic wire in low and high frequency range, respectively. However, it can not be applied to the nonmetallic wire, and the fit results have the frequency dependence [4].

The present authors developed a technique for the measurement of the thermal conductivity and thermal diffusivity of a fine wire, using a T type probe. The conventional steady state T type probe was introduced by Zhang *et al.* [7], to measure the thermal conductivity of fine wires. In the steady state T type probe, a short hot wire is subjected to a direct current, and the test wire, nonmetallic or metallic wire, is attached to the midpoint of the hot wire at one end using an interstitial material, with the other end connected to a heat sink to maintain a constant temperature. Then, the thermal conductivity of the test wire, λ_s, can be obtained by comparing the average temperature rise of the hot wire with and without the test wire.

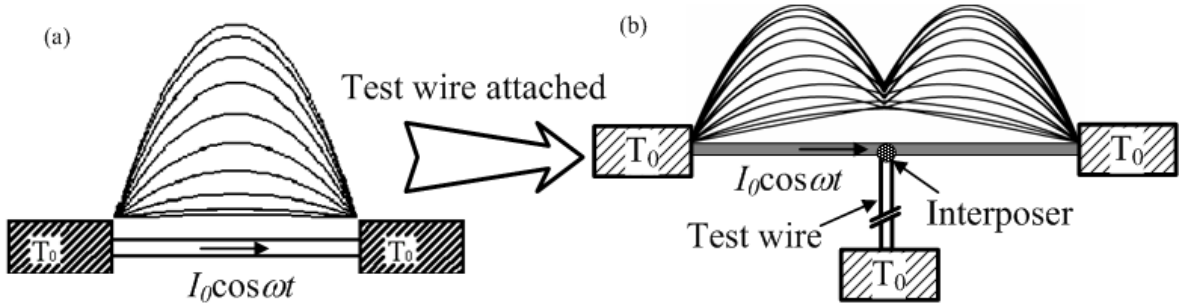

Figure 1. Principle for the present method to determine the thermal effusivity of a fine wire, (a) temperature distribution of the hot wire without test wire attached; and (b) that with the test wire.

To measure the thermal diffusivity, we apply an alternation current (ac) to the hot wire in the T type probe. If the thermal penetration depth [8], given by $4(\alpha_s/2\omega)^{1/2}$ (α_s is the thermal diffusivity of the test wire, ω the current angular frequency), in the test wire is much smaller than its length, the thermal effusivity, b_s, defined by $b_s=(\lambda\rho C_p)_s^{1/2}$ with the thermal conductivity λ, density ρ, and specific heat C_p, of the test wire can be obtained. Thus, the thermal diffusivity, α_s, is calculated by $\alpha_s=(\lambda/b)_s^2$.

MEASUREMENT PRINCIPLE

Figure 1(a) shows the temperature distribution of the hot metallic wire in the self-heating 3ω method, where an ac current, $I_0\cos(\omega t)$, was applied to the hot wire, which serves both as a thermometer and the heater. Neglecting the radial heat loss from convection or radiation, the heat conduction equation for the hot wire can be written as

$$\frac{1}{\alpha}\frac{\partial \Delta T}{\partial t}-\frac{\partial^2 \Delta T}{\partial x^2}+\frac{I_0^{\,2}R'}{\lambda l S}\cos^2(\omega t)\Delta T=\frac{I_0^{\,2}R}{\lambda l S}\cos^2(\omega t) \tag{1}$$

where ΔT is the temperature variation from the initial temperature, $\Delta T=T-T_0$, R' is the temperature coefficient of electrical resistance, R is the initial electrical resistance, λ is the TC of the hot wire with length l and cross section area S. If the heating power inhomogeneity caused by the resistance fluctuation is neglected, Lu *et al*. [4] gives exact solution using the impulse theorem. For this classical 3ω heating problem, only the steady transient temperature component needs to be concerned. The solution of equation (1) is in the form of $\Delta T(x)=\mathrm{Re}\{u(x)e^{i2\omega t}\}$, where Re denotes the "real part of ", i is the imaginary unit, and the complex temperature oscillation, $u(x)$, containing both the amplitude of the temperature oscillation and phase relative to the driving current, is expressed as

$$u(x)=\frac{I^2R}{lS\lambda\beta}\left[1-\frac{\cosh(\sqrt{\beta}x)}{\cosh(\sqrt{\beta}l/2)}\right] \tag{2}$$

Here, β is defined by $i2\omega/\alpha$, I is the root mean square (rms) value of I_0. As a sequence, the average temperature oscillation of the hot wire is

$$\bar{u}=\frac{I^2R}{lS\lambda\beta}\left[1-\frac{2}{\sqrt{\beta}l}\tanh(\sqrt{\beta}l/2)\right] \tag{3}$$

As shown in Figure 1(b), one end of the test wire is contacted to the midpoint of the hot wire using an interstitial material (interposer), with the other end connecting to the heat sink. If an ac

current with relative higher frequency to keep the thermal penetration depth shorter than the test wire, the temperature distribution along the test wire can be written as

$$\frac{1}{\alpha_s}\frac{\partial \Delta T_s}{\partial t} - \frac{\partial^2 \Delta T_s}{\partial x^2} = 0 \tag{4}$$

In this quasi steady state experiment, the thermal impedance of the interposer at the junction is assumed to be equivalent to the thermal contact resistance multiplying a ratio function, f. Taken into the account of the thermal impedance at the junction between the hot wire and the test sample, the boundary condition at the junction is

$$\frac{\Delta T\left(x = l/2\right) - \Delta T_s(x_s = 0)}{fR_r} = -\left(\lambda S\right)_s \left.\frac{\partial\left(\Delta T_s\right)}{\partial x_s}\right|_{x_s=0}$$

$$2\lambda S \left.\frac{\partial\left(\Delta T\right)}{\partial x}\right|_{x=\frac{l}{2}} = \left(\lambda S\right)_s \left.\frac{\partial\left(\Delta T_s\right)}{\partial x_s}\right|_{x_s=0}$$

As a consequence, the average temperature oscillation of the hot wire with the test wire attached is obtained as

$$\bar{u} = \frac{I^2 R}{\lambda S \beta l} + \frac{2I^2 R}{\lambda S \beta^{3/2} l^2}\left\{e^{-\sqrt{\beta} l/2} - 1 - \left[\cosh(\sqrt{\beta} l/2) - 1\right] \times \frac{b_s S_s\left(1 - e^{-\sqrt{\beta} l/2}\right) + 2bSe^{-\sqrt{\beta} l/2}\left(1 + \sqrt{i2\omega} b_s S_s f R_r\right)}{b_s S_s \sinh(\sqrt{\beta} l/2) + 2bS\cosh(\sqrt{\beta} l/2)\left(1 + \sqrt{i2\omega} b_s S_s f R_r\right)}\right]\right\} \tag{5}$$

where b is the thermal effusivity of the hot wire, R_r is the thermal contact resistance at the junction, b_s is the thermal effusivity of the test wire with cross section S_s. Compared with the average temperature oscillation of the bare hot wire using equation (3), equation (5) introduces two unknown parameters: thermal impedance, fR_r, indicating the influence of the interposer; and the thermal effusivity multiplying across area of the test wire, $(bS)_s$.

As long as the average temperature oscillation is obtained, the third harmonic voltage (rms value) across the hot wire with and without the test wire can both be calculated by

$$V_3 = \frac{1}{2} I R' A B S\{\bar{u}\} \tag{6}$$

by substituting equation (3) and equation (5) into equation (6), respectively. For bare hot wire, the result from equation (3) is consistent with that of Lu *et al*. [4], but in another expression.

As in the steady state T type probe, the thermal effusivity measurement also proceeds in two steps: The thermal properties of the hot wire is calibrated using the self-heating 3ω method, by fitting the experimental data using equations (3) and (6), the thermal conductivity and thermal diffusivity are simultaneously obtained. Thus, the thermal effusivity of the hot wire is derived from:

$$b = \frac{\lambda}{\sqrt{\alpha}} \tag{7}$$

In the next step, the test wire is attached to the midpoint of the hot wire [as shown in Figure 1(b)], and the third harmonic voltages across the hot wire are measured again. By fitting the data to equations (5) and (6), the thermal effusivity of the test wire can be obtained.

THERMAL IMPEDANCE OF THE INTERPOSER

As in the previous discussion, the thermal impedance of the interposer at the junction in 3ω measurement is different from the steady state thermal contact resistance, which is taken to be the steady state thermal resistance multiplying a complex ratio function, f. The ratio function, which is

a function of the frequency, is introduced to take account for the effect of the geometrical and thermal properties of the interposer.

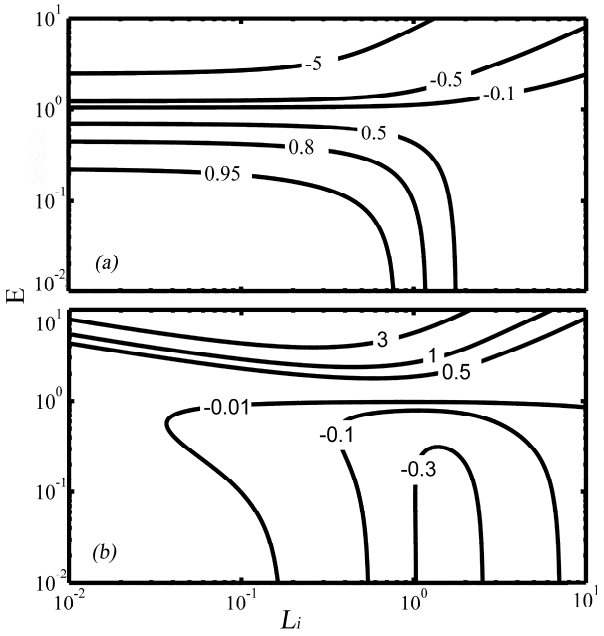

Figure 2. Ratio function, *f*, varies with dimensionless thickness L_i and dimensionless thermal effusivity multiplying cross area *E*, the values illustrated in plotted lines denote (a) the real part and (b) the imaginary part of the ratio function.

Theoretical analysis [9] shows that, *f* depends on two dimensionless ratios, including dimensionless thickness, L_i, i.e., the ratio of the idealized thickness of the interposer to its thermal penetration depth, and dimensionless thermal effusivity multiplying cross area, *E*, i.e., the ratio of the thermal effusivity multiplying cross area of the interposer to that of the test wire. Figure 2 shows the real part [Figure 2(a)] and imaginary part [Figure 2(b)] of the ratio function at various L_i and *E*. It is found that, when these two dimensionless ratios are much smaller than 1, the real part of *f* approaches to the limit of 1, and the corresponding imaginary part can be neglected, i.e., the thermal impedance of the interposer is equivalent to its thermal contact resistance. In the case of E>>1, *f* is a complex value, and the thermal characterization of the interposer is a function of frequency. In the case of E~1, the thermal impedance of the interposer can be ignored.

For the preliminary experiment in this study, platinum wire with diameter of about 100μm is used as the test wire. As a result, a small amount platinum black is used as the interposer. The platinum black, with purity over 99.9%, was manufactured by Ishifuku Metal Industry Corporation in Japan, the average grain diameter was about 0.5μm. A stable junction is formed when the platinum black is solidified, which can be easily washed off by ethanol. If the idealized interposer thickness is assumed to be 1 μm and has the thermal properties of platinum, the thermal penetration depth is calculated to be 5.6 to 17.8 mm with the corresponding heating frequency 1 to 0.1Hz. In such case, as shown in Figure 2, the ratio function, *f*, is taken to be a real number, and the thermal impedance of the interposer is so small that can be neglected.

EXPERIMENTAL TESTS

Replacing the commercial lock-in amplifier, a Labivew-based virtual lock-in is developed to measure the third harmonic voltages. The schematic of the experimental apparatus and the electrical

circuit is as shown in Figure 3. The experiment system consists of a function generator (Agilent 33220A), a series resistor (ZX74B), A/D board (PXI 5922), industrial computer (PXI 8106) and a homemade pre-amplifier. PXI 5922 can trade sampling rate for resolution to sample from 24 bits at rates of 500 kS/s to 16 bits at 15MS/s. Other than the third harmonic voltages of the hot wire, the virtual lock-in can simultaneously measure the first harmonic voltage across the series resistor to get the supplied current. Using the commercial lock-in amplifier, e.g., to measure 0.1Hz signal, the corresponding time-constant of 100s is needed, thus, it is tedious to get a single data out. Comparatively, the virtual lock-in simplifies the measurement to get rid of the time constant setting, and takes few minutes to get the stable voltage, even when current frequency is 0.1Hz.

In the measurements, platinum wire (purity over 99.98%) is used as the hot wire with about 30 μm in diameter and 8mm in length. With a precision resistance spot welder, both ends of the hot wire were welded to 1mm diameter copper leads, which are mounted on a homemade copper substrate. In order to insulate the copper leads and the substrate, each lead was first inserted into a ceramic tube, and the ceramic adhesive was used among the ceramic tubes, copper leads and the substrate. The substrate was then loaded into a vacuum chamber (Oxford Instrument, Optistat DN-V), which was continuously evacuated by a vacuum pump (R5614Y-Z, 1400 rpm) and a molecular pump (Leybold TW70H, 72000 rpm). All the measurements are carried out at a vacuum level of below 1×10^{-3}Pa, and the convection heat transfer could be neglected.

When the chamber temperature is stable (TC601, 0.1K), a very small direct current, such as 0.1mA, is supplied to the hot wire to get the initial electrical resistance, R, in equation (2). The steady state measurement system is detailed in [10]. Then, the third harmonic voltages of the hot wire are measured in the frequency range of 0.1 to 6Hz. The fitting procedure is performed using the least square method based on the relative error for the frequency dependent third harmonic voltages. By fitting the experimental data using equation (6) [substituting equation (3) into equation (6)], the thermophysical properties, including the thermal conductivity and thermal diffusivity, of the hot wire are obtained. Finally, the thermal effusivity is calculated using equation (7). After calibrating the metallic sensor, the test wire is attached to the midpoint of the hot wire with fine powder platinum black, and the third harmonic voltages of the hot wire are measured again. As for the bare hot wire, the fit results vary with the applied frequency range, therefore, the same frequency range is applied in the measurement when the test wire is attached.

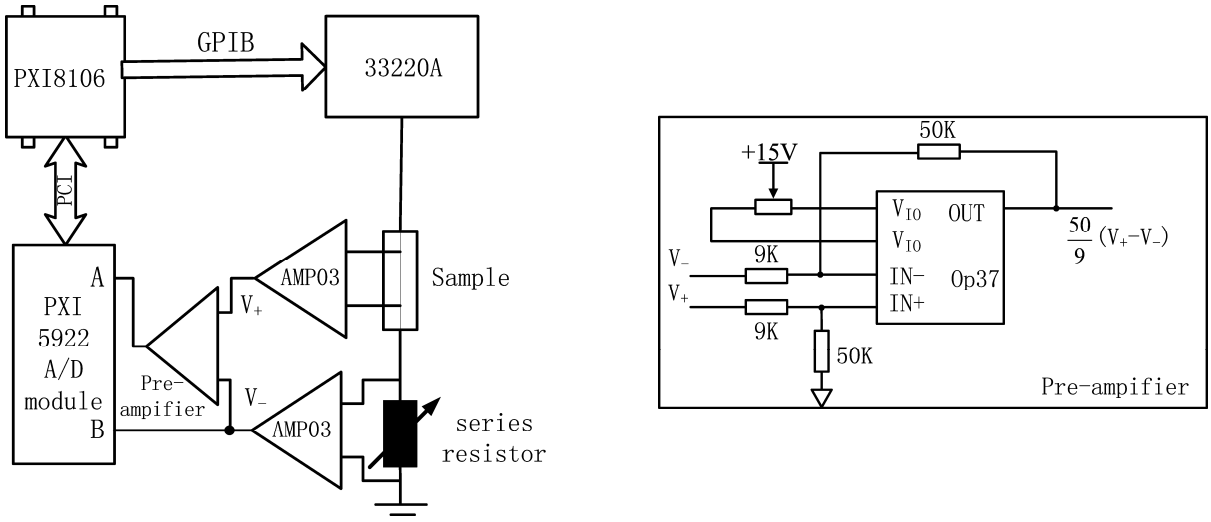

Figure 3. Schematic of the experimental apparatus and the electrical circuit, right block is a schematic diagram of the homemade pre-amplifier circuit.

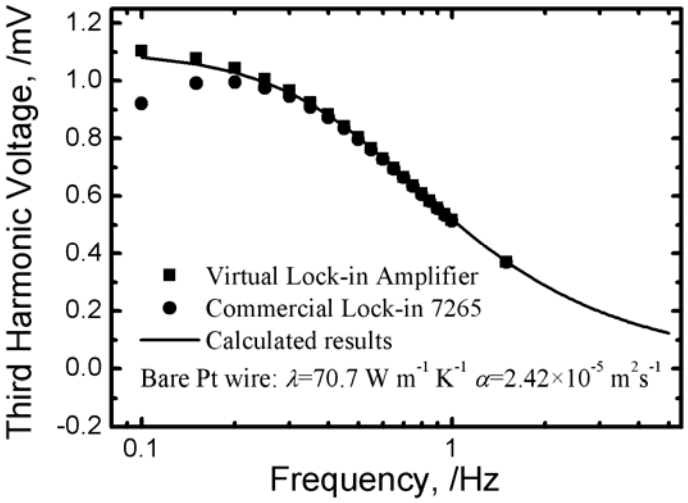

Figure 4. Comparison of the third harmonic voltages measured by virtual lock-in with that by commercial lock-in amplifier 7265, the solid line is the fit using equations (3) and (6), giving the thermal conductivity of a platinum wire 70.7 Wm^{-1} K^{-1}, and thermal diffusivity 2.42×10^{-5} m^2 s^{-1}.

RESULTS AND DISCUSSIONS

Before the thermal effusivity measurement, the accuracy of the virtual lock-in is first verified by measuring a bare platinum hot wire. The measured third harmonic voltages are compared with that by commercial lock-in amplifier 7265, as shown in Figure 4. Using the commercial lock-in amplifier, the external reference mode is selected with TTL reference signal. It is found that, in low frequency range, the third harmonic voltages measured by virtual lock-in are in good agreement with the theoretical predictions using equations (3) and (6), but always larger than that measured by the commercial lock-in amplifier. The possible explanation for the poor performance of the commercial lock-in amplifier in low frequency range is the frequency tracking, e.g., 0.099Hz is detected while the exact current frequency is 0.1Hz, leading to a smaller voltage value. The relative difference in frequency tracking decreases with the increasing frequency, as shown in Figure 4, causing the voltages measured by commercial lock-in amplifier first increase and then decrease with the frequency. In high frequency, the same third harmonic signal is obtained for both virtual and commercial lock-in.

The present method is then verified by measuring a high purity platinum wire (99.98%, diameter ~100μm), which is purchased from Ishifuku Metal Industry Corporation in Japan. Figure 5 shows the measured third harmonic voltage with respect to the current frequency. In high frequency, the third harmonic voltages of the hot wire with and without the test wire are close to each other, since the influence range of the temperature oscillation along the test wire decreased with the increasing frequency. In the frequency range of 0.1 to 1Hz, obvious difference is achieved between these two voltages, indicating the thermal properties of the test wire have a non-negligible effect on the hot wire temperature distribution. Thus, the thermal effusivity of the test wire is fitted to be 1.41×10^4 J m^{-2} K^{-1} $s^{-0.5}$, using equation (6) [substituting equation (5) into equation (6)], with the thermal properties of the hot wire which are obtained from the bare hot wire measurement. From equation (5), the across area of the test wire has a significant effect on the thermal effusivity measurement, as a result, the diameter is accurately measured to be 95.40μm with a Scanning Electron Microscopy.

The previous quasi steady state measurement can be easily transfer to measure the thermal conductivity of the test wire using the conventional steady state method, without changing the test T type probe. The schematic of experimental apparatus for the steady state T type probe is presented in [9]. Figure 6 shows the average temperature rise of the hot wire with respect to the heating rate. Neglecting the radial heat loss from convection or radiation, the thermal conductivity of the test platinum wire is found to be 69.8 W m^{-1} K^{-1}. Finally, the thermal diffusivity of the test wire is calculated to be 2.45×10^{-5} m^2 s^{-1} using $\alpha_s=(\lambda/b)_s^2$. Both the thermal conductivity and thermal diffusivity agree well with the literature reported value [11].

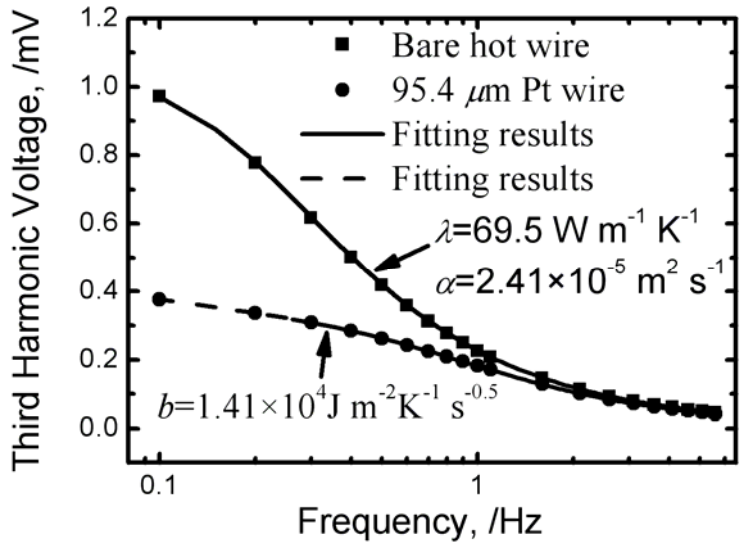

Figure 5. Third harmonic voltage *vs.* frequency, the obtained thermal effusivity of the platinum wire is 1.41×10^4 J m^{-2} K^{-1} $s^{-0.5}$, the solid line is the fit using equations (3) and (6), and the dashed line is the fit using equations (5) and (6).

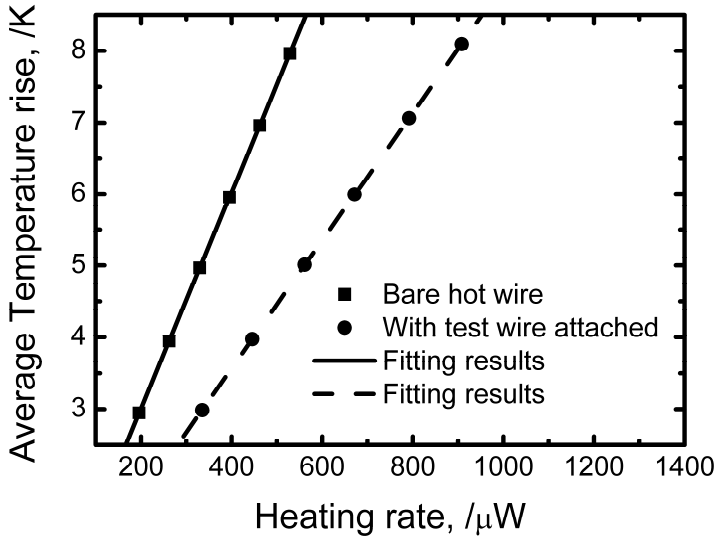

Figure 6. Average temperature rise vs. heating rate, the obtained thermal conductivity of the platinum wire is 69.8 W m^{-1} K^{-1}. (■) denotes the hot wire without the test wire attached, and (●) denotes that with the test wire.

CONCLUSIONS

We have developed a quasi steady state T type probe to measure the thermal effusivity of a fine wire, when the hot wire is supplied by an ac current. A Labview-based virtual lock-in has been designed to obtain the third harmonic voltage across the hot wire. Compared with the commercial lock-in amplifier, the virtual lock-in has the advantage in low frequency detection. To eliminate the influence of the thermal impedance of the interstitial material, a fine powder platinum black with high purity is selected to contact one end of the test platinum wire to the midpoint of the hot wire. The thermal effusivity is fitted from the third harmonic voltage with respect to the current frequency. If a direct current is applied to the hot wire, the same T type probe can be transfer to measure the thermal conductivity of the test wire. Thus, both thermal conductivity and thermal diffusivity of the test wire can be obtained. To verify the present method, a fine platinum wire is measured, the thermal conductivity and thermal diffusivity of is found to be 69.5 W m^{-1} K^{-1} and 2.41 m^2 s^{-1}, both agree well with the literature reported value.

ABSTRACT. Evaporation of volatile liquids in capillary tubes of square internal cross section is studied experimentally. The distinguishing feature of evaporation in a square tube is the presence of liquid films which are trapped by capillarity along the tube internal corners and which control the evaporation kinetics. Gathering experimental data on these liquid films is therefore crucial to better understand and model the evaporation process. An experimental technique allowing measurement of the liquid films thickness during evaporation is presented. Together with measurements of the evaporation rate and of the liquid films length, the film thickness data are used to analyse the result of a typical evaporation experiment and to shade light on the physical mechanisms at play.

Keywords: *Evaporation, capillary tubes, corner flow, meniscus, geometrical optics.*

INTRODUCTION

Evaporation from a meniscus plays an important role in many applications such as capillary pumped loops, heat pipes, fuel cells and drying of porous media. In this context, the study of evaporation of a liquid confined in a capillary tube can be regarded as a first step before more complex situations such as, for example, networks of interconnected capillaries [1]. Here, we study evaporation from a single capillary tube of square internal cross section when evaporation is driven by the vapour diffusion mass transfer between the air-liquid interface and the surrounding air. This corresponds to the classical situation of slow evaporation of a volatile liquid in stagnant air at room temperature. As sketched in Figure 1a, the distinguishing feature of evaporation in a square tube when the volatile liquid is sufficiently wetting is the presence of liquid films trapped by capillarity along the internal corners of the tube as the bulk meniscus recedes into the tube. These corner films provide a pathway for the capillary-driven transport of the liquid from the receding bulk meniscus up to the film tips. This explains why evaporation is generally much faster in a square tube compared to a classical circular tube where the only mechanism to transport the volatile species up to the tube entrance is the poorly efficient vapour diffusion transport. As discussed in previous modelling works, [2, 3], the evaporation kinetics depends on the dynamic of the corner films, which depends in turn on the competition between the capillary, viscous and gravitational forces acting in the system. This leads to delineate different regimes depending on the relative influence of these forces. However, there is a lack of experimental data and therefore of quantitative comparisons between the available models and the experimental data. The general objective of the present work is to contribute to fill this gap by combining careful experimental studies with a proper modelling.

Experimentally, a major difficulty is to obtain quantitative measurements of the corner films characteristics (length and thickness), both due to the capillary tube small size (inferior to 1 mm)

and the tricky geometry of the system. In [4], we described how an infrared thermography technique could be used to measure the evolution of the film length during evaporation. Notably, it was shown that there is a maximal film extension, beyond which the films tip ceases to be pinned at the tube entrance and begins to recede into the tube. This maximal film extension is caused by the limiting effects of gravity and viscous forces that oppose to the capillary pumping of the evaporating fluid within the films from the bulk meniscus up to the tube entrance. In the present work, we present an optical technique allowing the study of the evolution of the film thickness during the evaporation experiment. Together with the infrared thermography technique, this opens up the way to a complete characterization of the liquid films. In the following, the experimental set-up is presented first. Then, details on the experimental techniques are presented and, finally, some typical results are discussed.

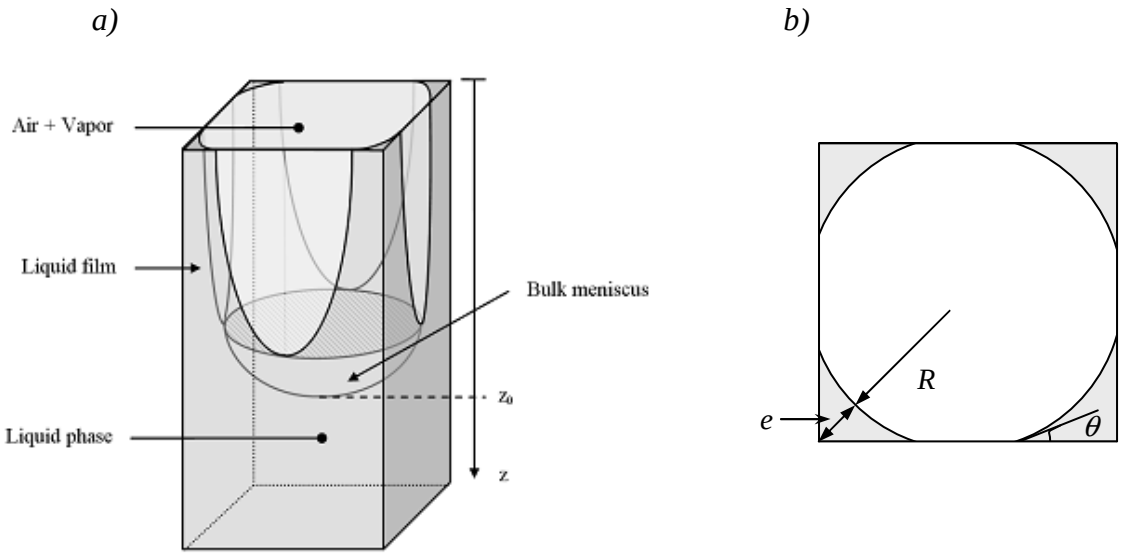

Figure 1. *a)* Sketch of liquid films in a square capillary tube. *b)* Radius of curvature R and film thickness e, in the tube cross section plane; $e = (\sqrt{2}\cos\theta - 1)R$, where θ is the fluid contact angle.

EXPERIMENTAL SET-UP

The 10 cm long square (Vitrocom) capillary tubes used in the present study are made of borosilicate glass: the internal side length d of the tubes is either 1 mm or 0.4 mm, the wall thickness is 0.2 mm. The capillary tube is glued by an epoxy resin silicone adhesive directly to a syringe tip. The syringe is placed on a precision syringe pump (PHD 2000, Harvard apparatus) allowing accurate filling of the tube by the volatile liquid (n-hexane). The room temperature is controlled by an air-conditioning system. The experimental set-up is placed inside a Plexiglas enclosure, see Figure 2, which helps further stabilize the temperature in the environment of the tube. The air temperature inside the enclosure is monitored by thermocouples and remains constant for the entire duration of the experiment, which can last several hours. This temperature control is crucial to avoid the possible effect of dilatation/contraction of the liquid with variations of the ambient temperature, which can distort the evaporation rate measurement.

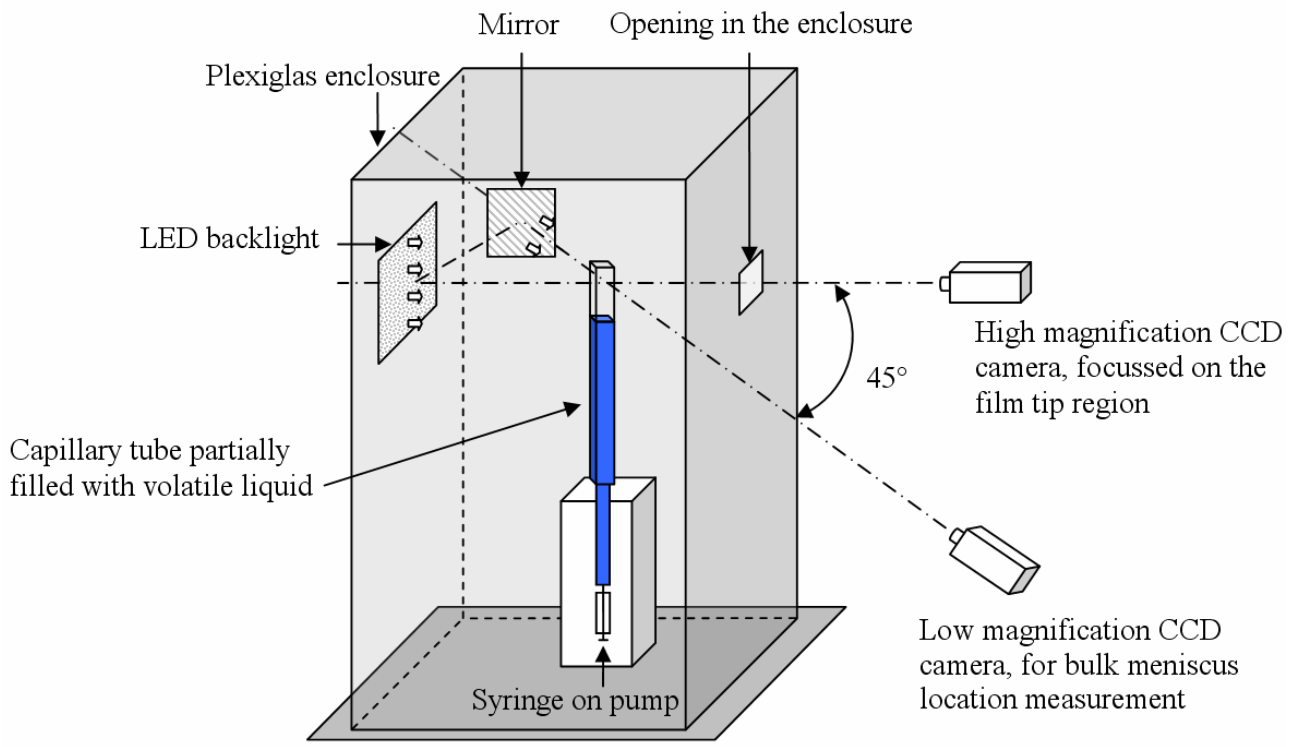

Figure 2. Sketch of the experimental set-up.

The tube is visualized with two CCD cameras (Sensicam, PCO). The first one, equipped with a regular 60 mm objective, images the whole tube and is used to determine the evolution of the bulk meniscus position along the tube (spatial resolution: 13 pixels/mm). The second one is equipped with a 200 mm Medical Nikon objective and images the tube top at high magnification (spatial resolution: 654 pixels/mm). The corresponding visualizations, see Figure 3 for a typical image, are used to measure the corner films thickness (see next section). As shown in Figure 2, the two optical axes make an angle of 45°. The first camera is facing one of the tube sides, and the second one is then focused on one of the corner of the square capillary. This latter relative positioning of the camera and the tube was chosen to limit parallax effects. A Phlox white LED backlight is used as a light source. It provides a constant and uniform light intensity and does not release heat in the strobe mode used in the present experiments. The backlight is facing the CCD camera equipped with the high magnification objective. An opening in the Plexiglas enclosure permits to avoid any distortion of the light rays, while a mirror is used to reflect some of the light towards the other camera. As the tube is placed between the light source and the cameras, an ombroscopy configuration, often used to detect gas-liquid interface, is obtained. As far as the camera imaging the whole tube is concerned, the liquid and gas phases regions appear as bright on the images whereas the bulk meniscus appears as dark because light rays are deviated by the curved interface. Therefore, after binarization of the images, the bulk meniscus position, defined as the most advanced point of the gas phase into the tube (see Figure 1a), can easily be detected. The way to obtain the liquid film thickness from the high magnification visualizations is detailed in the next section.

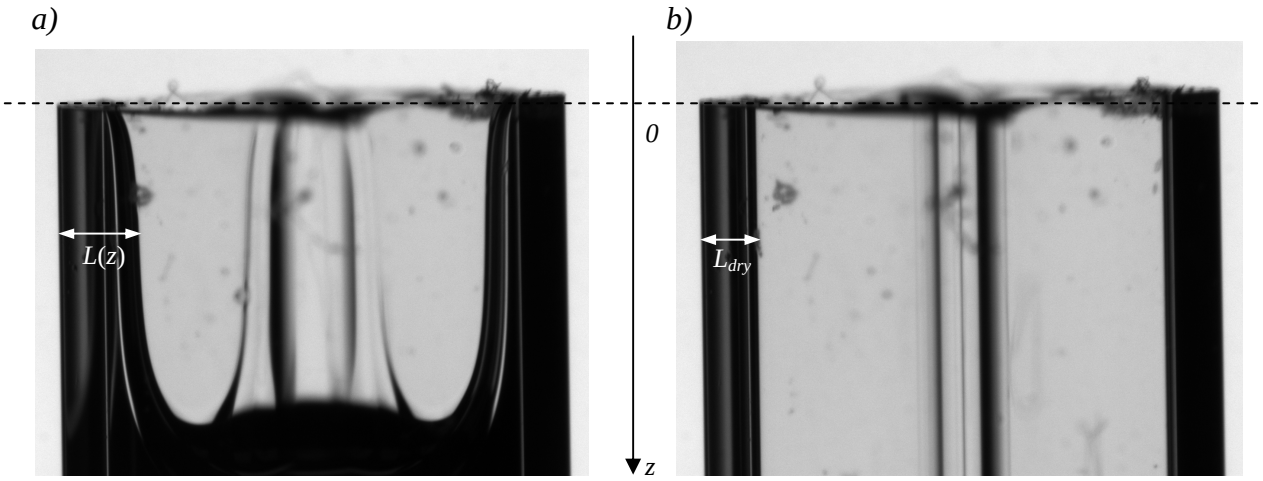

Figure 3. Typical images of the capillary tube top, at high magnification. *a)* This image was taken at the beginning of an evaporation experiment. The bulk meniscus is still in the field of view. The width of the dark region L can be measured at any z position. *b)* Image obtained at the end of the experiment when the tube is dry. The width of the dark region L_{dry} can then be measured.

CORNER FILM THICKNESS MEASUREMENT

Using the ombroscopy configuration presented above, the curvature radius R of the corner film meniscus in the tube cross-section plane can be obtained from the images obtained with a high magnification. Note that the curvature radius R and the film thickness e are directly related, see caption of Figure 1b. This measurement is performed at least one tube diameter below the tube entrance, so that the axial curvature (i.e. along the z direction) of the corner meniscus can be neglected. Note this is an usual assumption in the analysis of corner flows, which is correct in the developed film region but is in error at the film tip, as can be appreciated in Figure 3a. As far as the measurement of R is concerned, the argument is based on the tracing of the light rays paths through the imaged capillary tube corner, using the Snell-Descartes' law (with the respective indices of refraction of air, liquid and glass being such that $n_{air} < n_{liq} < n_{glass}$), and the assumption that the LED backlight is a parallel light source. As sketched in Figure 4, a distinction can be made between light rays that remain parallel to the optical axis after they have travelled through the many interfaces present in the system and those that are deviated, for instance by the curved liquid-gas interface. The latter are not collected by the receiving optics as the camera is positioned far enough from the tube.

Consequently, a dark region of width L is expected on the images and is indeed observed as can be seen from Figure 3a. The width L (in pixels) is a function of the corner film curvature radius R and can be measured after image binarization for any given distance z from the tube entrance. As can be seen from Figure 3b, such a dark region, of width L_{dry}, also exists when the tube is empty because of the roundedness of the tube internal and external corners. When the fluid contact angle is 0, the value of the corner film curvature radius, R, is given by:

$$R - r_0 = \frac{L - L_{dry}}{S \sin \phi}, \tag{1}$$

where S is the spatial resolution, in pixels/mm, ϕ is the angle between the optical axis and the normal to the tube face located between the camera and the observed corner (see Figure 4) and r_0 is the curvature radius of the tube internal corner. By imaging a cross section of each capillary tube used in the present study, it was found that the corners internal shape could be well fitted by a

quarter-circular arc. The corresponding values for the curvature r_0 were found to be r_0 = 0.100 mm for d = 1 mm, r_0 = 0.032 mm for d = 0.4 mm (these values are an average over the four corners, the standard deviation being lower than 10 %).

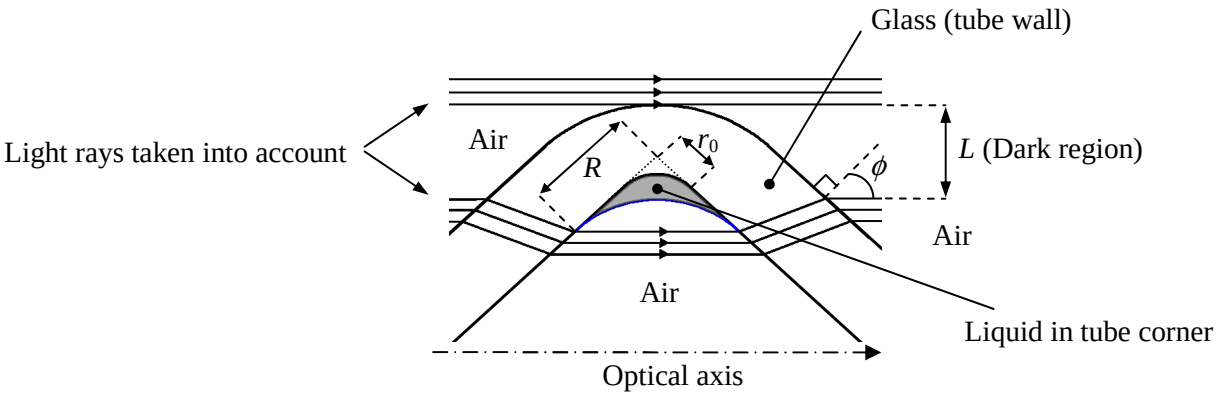

Figure 4. Light rays trajectories used for film curvature radius measurement.

The validity of this measurement technique, which only involves simple geometric optics, is first tested within the framework of a simple experiment of hydrostatic equilibrium. To this end, a capillary tube held vertically is partially filled with a silicone oil. The oil is non volatile and perfectly wetting on borosilicate glass so that corner films develop and reach a hydrostatic equilibrium state. Several corner film lengths are obtained, by tuning the capillary tube filling. Visualizations are performed taking care to avoid any liquid films dynamic state by waiting until the liquid films return to a hydrostatic equilibrium state after each bulk meniscus displacement imposed by the syringe pump. The meniscus curvature radius is determined using the measurements of L and L_{dry} as explained above and compared to the expected value that can be predicted from a simple hydrostatic analysis, [4]:

$$Bo(z_0^* - z^*) = \frac{1}{R_h^*(z^*)} - \frac{1}{R_h^*(z_0^*)} \qquad 0 \le z^* \le z_0^* \tag{2}$$

where $Bo = (\rho_l g d^2)/\gamma$ is the Bond number, ρ_l is the liquid density, g is the gravitational acceleration and γ is the surface tension. In equation (2), R_h is the curvature radius provided by the hydrostatic analysis, z_0 is the bulk meniscus position and the superscript * denotes that the variables are made dimensionless by d. As shown in [5], $R_h^*(z_0^*) = 1/3.77$ for a perfectly wetting liquid in a square tube geometry.

Figure 5 shows the hydrostatic curvature radius R_h predicted by equation (2) as a function of the measured curvature radii difference R-r_0 obtained from experimental measurements of L and L_{dry} and the use of equation (1), for the two tube internal sizes, d = 1 mm and d = 0.4 mm. In both cases, the measured curvature radii difference R-r_0 is proportional to R_h. As can be seen, the data are well fitted by linear functions (shown as solid lines in Figure 5a and 5b). However, the proportionality coefficient is not equal to 1 and is different for the two tube sizes. This could come from the oversimplified vision of the optical problem presented above. Also, it must be noted that it is tricky to perfectly set the angle ϕ at the required value of 45 ° because of the small tube size compared to the size of the others elements in the set-up, which may induce another uncertainty in the use of equation 1. Nevertheless, the linearity between the measured and the predicted values allows for measurement of the films curvature radius value evolution, relative to its initial value or to the curvature radius at the bulk meniscus, which is sufficient to get valuable pieces of information in the present case.

As can be seen from Figure 5, the value of the constant of the linear regression is very close to the value of the tube internal corner curvature radius r_0. This is fully consistent with the hydrostatic analysis since R_h cannot become lower than r_0 in a square tube with rounded internal corners. In other words, equation (2) can be used to predict the maximum film length of a non volatile liquid in a square capillary tube with a non zero internal corner curvature radius.

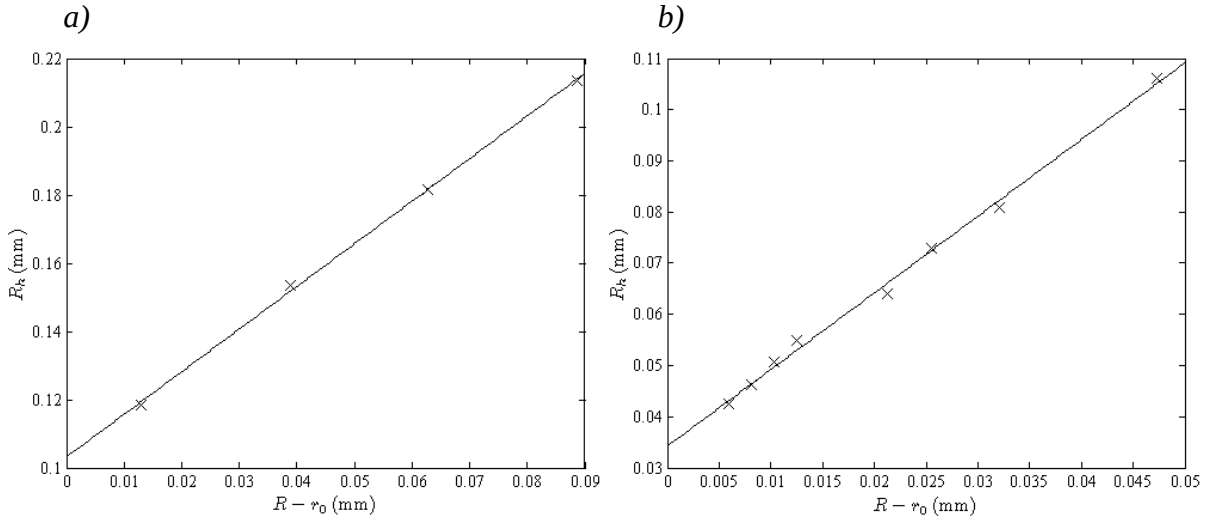

Figure 5. Curvature radius R_h, obtained from the hydrostatic analysis, equation (2) as a function of the optically measured curvature radii difference R-r_0, for several static liquid films lengths. *a)* d = 1 mm, measurement and prediction are made at $z^* = 1$. *b)* d = 0.4 mm, measurement and prediction are made at $z^* = 1.7$. For both cases, the best fitting linear function is shown as a solid line. The linear regression gives $y = 1.25x+0.103$ and $y = 1.50x+0.034$ for the 1 mm and 0.4 mm tubes, respectively.

EXPERIMENTS WITH A VOLATILE LIQUID

In this section, we present some typical experimental results on evaporation of a volatile liquid in a capillary tube of square cross section. The insights on the evaporation process brought by the measurement of the corner films thickness, together with the evaporation rate measurement, will be emphasized.

A tube of internal side length d = 0.4 mm is held vertically and filled with n-hexane (a volatile and perfectly wetting fluid on borosilicate glass). The tube opened top is placed in a stagnant air environment under ambient temperature and atmospheric pressure. The evaporation rate E is obtained straightforwardly from the measurement of the evolution of the bulk meniscus location as a function of time, $z_0(t)$, $E=\rho_l(d^2-\lambda R_h(z_0)^2)(dz_0/dt)$, where λ is a geometrical coefficient, [6]. In Figure 6a, E is plotted as a function of the bulk meniscus position z_0. In Figure 6b, the film thickness, made dimensionless by its value e_0 at the bulk meniscus, is plotted as a function of z_0 (note that because of the tube internal corner roundness, the film thickness is given by $e = (\sqrt{2}-1)(R-r_0)$).

As already discussed in [4], two main evaporation periods can be distinguished. In the first one, the corner films tip stays located at the tube entrance. The second period starts when the films tip ceases to be pinned at the tube entrance and start to recede inside the tube. Measurements of the critical film length z_{0c} when the depinning occurs was obtained in [4] by infrared thermography and it was found to be $z_{0c} \approx 11$ mm. Interestingly, as be seen from Figure 6a, the evaporation rate remains essentially constant during a significant part of the first period, i.e. up to $z_0 \approx 9$ mm. This can be explained by the diffusional screening effect in the tube exit region. As illustrated in previous

numerical simulations of the vapour diffusion transport in the gas phase, [2, 7], the diffusional screening effect refers to the fact that the hexane vapour partial pressure field in the $z = 0$ tube cross section plane is uniform and very close to the hexane saturation vapour pressure (the air is saturated in hexane vapour) when the films are sufficiently thick in the tube entrance region.

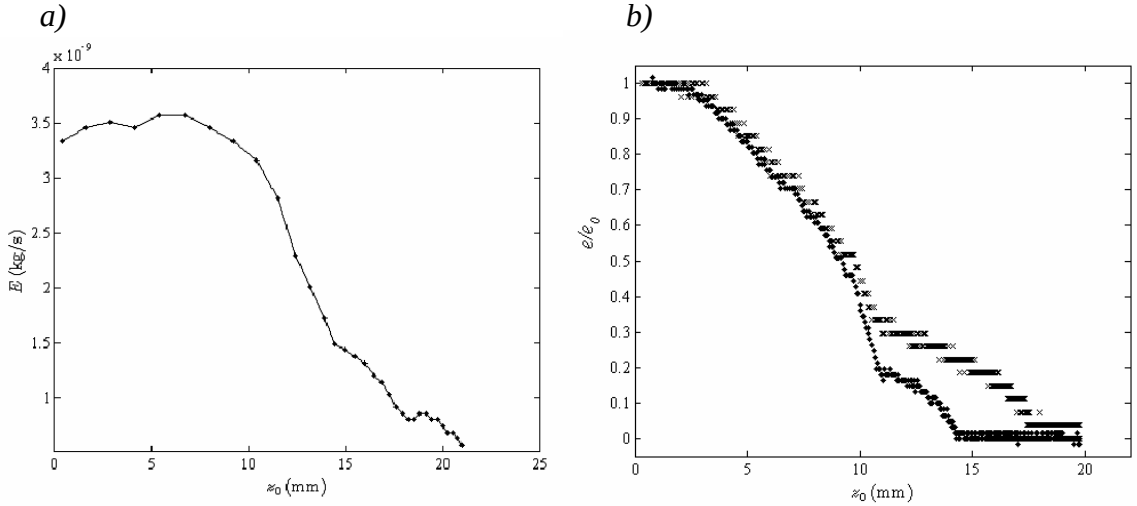

Figure 6. *a)* Evaporation rate E as a function of the bulk meniscus position z_0. *b)* Film thickness e, made dimensionless by its value at the bulk meniscus $e_{0,}$ as a function of z_0, for two different distances from the tube exit, $z = 0.45$ mm (dots) and $z = 1.15$ mm (crosses).

Hence, in the presence of a sufficiently effective diffusional screening effect, the evaporation rate does not depend on the respective distribution of the liquid and gas phases in the tube entrance region and therefore must be constant, which is confirmed by the present experimental results. Note this remains true for $0 < z_0 < 9$ mm, even though the film thickness decreases in the meantime under the conjugated action of gravity and viscous effects. However, just before the films depinning, the evaporation rate begins to decrease slightly as soon as $z_0 > 9$ mm, even if the film tips are still "attached" at the top of the tube, see Figures 6a and 6b. This would simply indicate that the diffusional screening effect becomes less effective when the films become sufficiently thin in the tube entrance region. Hence, the hexane vapour partial pressure field would no longer be uniform at $z = 0$ and would begin to become lower than the hexane saturation vapour pressure on average.

As can be seen from Figure 6, the transition towards the second period takes place at the critical film length $z_{0c} = 11$ mm, which is in good agreement with the infrared thermography result. As already mentioned, the curvature radius of the film was not measured at the very top of the film, where the effect of the axial curvature cannot be neglected. As can be seen from figure 6b, the film thickness is not yet 0 at the two locations where the film thickness is measured, $z = 0.45$ mm and $z = 1.15$ mm when the films depinning occurs at the tube top. The curves in Figure 6b, for $z_0 \geq 11$ mm, display in fact the film tip shape when it passes in front of these two measurement locations. Note that the depinning of the four corner films does not occur simultaneously (the observed differences in term of films length are always lower than one tube size d), which may explain, together with the end of the period of very effective diffusional screening effect, why the evaporation rate decreases before the films depinning. Elucidating the relative importance of these two mechanisms is crucial for a good understanding of evaporation in a square capillary tube and is the subject of ongoing works.

CONCLUSION

In this work an experimental method to measure the corner film curvature radius of a liquid film in a square glass capillary was presented. It is based on simple geometrical optics considerations and on the use of a high magnification ombroscopy visualization technique. Despite the fact that this method does not lead to an absolute measurement of the film thickness, it was shown that it permits to access to the evolution of the film thickness. This technique was used to measure the evolution of the film thickness during the evaporation of a volatile liquid in a square capillary tube. Insights on the evaporation process were obtained by combining this measurement with the determination of the evaporation rate, which was deduced from the evolution of the bulk meniscus position using also a visualization technique. In particular, these measurements reveal that the evaporation rate remains constant during a first period despite the decrease in the film thickness within the tube entrance region. As confirmed by an independent measurement based on an infrared thermography technique, the presented experimental visualization technique also permits to determine the films tip depinning, i.e. the exact moment when the films tip begins to recede into the tube as well as the shape of the film tip as it recedes inside the tube. The experimental data presented here will be exploited in a future work to assess the validity of theoretical models of evaporation in square tubes.

ABSTRACT. Diode laser absorption sensor with 2f detection of wavelength modulation spectroscopy is developed and applied to the swirl-stabilized combustor controlled by secondary fuel injection. The sensor provides temperature of H_2O molecule in the path of laser beams at 1 kHz. The combustor is operated without secondary fuel injection and with continuous or intermittent injections. Mean and rms values of temperature measured at several positions of the combustor show that the sensor provides important information related to the pressure fluctuation in combustor and combustion noise even for measurement in the recirculation zone near the exit of swirl nozzle. In addition, characteristics of temperature oscillations which are related to the interaction between premixed flame and secondary fuel can be detected by applying the sensor to middle of recirculation zone. These results prove that the diode laser absorption sensor with 2f detection is effective for detection of the combustion condition controlled by secondary fuel injection.

Keywords: *diode laser absorption sensor, wavelength modulation spectroscopy, 2f detection, swirl-stabilized combustor, secondary fuel injection*

INTRODUCTION

In active controls of combustion, sensors with high temporal resolution and high accuracy have been required to monitor combustion condition and to give appropriate control signals for controllers. Pressure transducers used in many researches on active combustion control only provide global information on combustion condition, which may limit control algorithm, since combustion is one of the complicated three-dimensional phenomena. Diode laser absorption techniques have been developed for monitoring of combustion fields. In the previous studies, diode laser absorption techniques for H_2O [1], CO and CO_2 [2], CO and H_2O [3] and NO_2 [4] have been developed. Wavelength modulation spectroscopy, such as 2f detection, is used to improve signal-to-noise-ratio (SNR) of the sensor. Theory of wavelength modulation spectroscopy was experimentally verified by Reid and Labrie [5]. Since these techniques can provide characteristics of selected molecule along the line of sight, the diode laser absorption sensor is a candidate for space-resolved sensors monitoring combustion state in many engineering applications. For combustion controls, the diode laser absorption sensors have been utilized for monitoring combustion state of Hencken burner [6], 5 kW dump combustor [7], a pulse detonation engine [8]. Li et al. [9] applied the sensor to a swirl-stabilized combustor controlled by a loudspeaker. Effectiveness of the sensor, however, should be confirmed with a greater variety of control actuators or algorithms.

In this study, diode laser absorption sensor with 2f detection has been developed and applied to measurements of temperature of H_2O molecule in the recirculation zone which is generated in a swirl-

stabilized combustor without and with passive controls by secondary fuel injection. Availability of the diode laser absorption sensor for active combustion control using secondary fuel injection is investigated.

EXPERIMENTAL METHOD

Second-harmonic detection of wavelength modulation spectroscopy

The theory of wavelength modulation spectroscopy was extended to account for effects of intensity modulation of laser on 2f signal by Philippe and Hanson [10]. Wavelength and intensity of laser modulated by a cosine wave of angular frequency ω and amplitudes, a and i_0, can be represented by

$$\nu(t) = \bar{\nu} + a\cos\omega t \tag{1}$$

$$I_0(t) = \bar{I}_0 + i_0\cos(\omega t + \phi) \tag{2}$$

where $\nu(t)$ is the instantaneous optical frequency and $I_0(t)$ is the incident intensity of laser and ϕ is the difference of phase between modulations of optical frequency and laser intensity. Averages of the frequency $\bar{\nu}$ and the intensity $\bar{I}_0$ are scanned slowly relative to ω across the range of absorption feature (scanned-wavelength method). Transmission coefficient $\tau(\nu(t))$ is an even function of time and can be expanded in Fourier cosine series.

$$\tau(\nu(t)) = \sum_{n=0}^{\infty} H_n(\bar{\nu}, a)\cos n\omega t \tag{3}$$

$$H_0(\bar{\nu}, a) = \frac{1}{2\pi}\int_{-\pi/\omega}^{\pi/\omega} \tau(\bar{\nu} + a\cos\omega t)dt \tag{4}$$

$$H_n(\bar{\nu}, a) = \frac{1}{\pi}\int_{-\pi/\omega}^{\pi/\omega} \tau(\bar{\nu} + a\cos\omega t)\cos n\omega t dt \tag{5}$$

where $H_n(\bar{\nu}, a)$ is the n-th Fourier component. Transmitted intensity can be represented by

$$\begin{aligned} I(t) &= I_0(t)\tau(t) \\ &= \{\bar{I}_0 + i_0\cos(\omega t + \phi)\}\left(\sum_{n=0}^{\infty} H_n(\bar{\nu}, a)\cos n\omega t\right) \end{aligned} \tag{6}$$

2f signal $S_2(\bar{\nu}, a)$ can be obtained by multiplying equation (6) by cosine wave of frequency 2ω and arbitrary phase ψ, and by extracting direct component.

$$S_2(\bar{\nu}, a) = \frac{i_0}{4}H_3(\bar{\nu}, a)\cos(2\psi + \phi) - \frac{\bar{I}_0}{2}H_2(\bar{\nu}, a)\cos(\psi + \phi) + \frac{i_0}{4}H_1(\bar{\nu}, a)\cos\phi \tag{7}$$

The arbitrary phase ψ should be set to $-\phi$ to increase signal-to-noise-ratio. 2f signal is mainly dominated by the second harmonic component $H_2(\bar{\nu}, a)$ due to small intensity modulation. At the line center of absorption, 2f signal is not affected by $H_1(\bar{\nu}, a)$ and $H_3(\bar{\nu}, a)$ components, since the components are odd functions of $\bar{\nu}$.

Temperature measurement

2f signal can provide original absorption feature theoretically. However, loss of incident intensity due to particles or dirty optical access may disturb the conversion. Effect of loss can be removed by calculating peak ratio of 2f signals as follows;

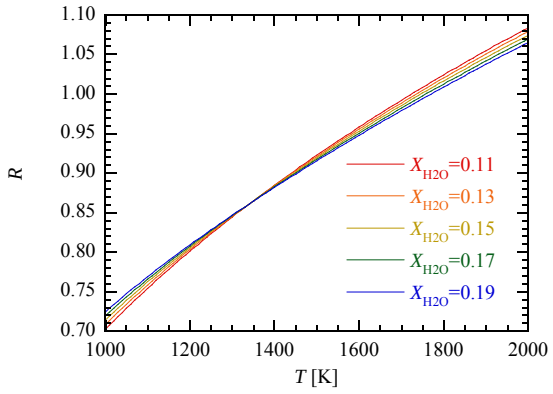

Figure 1. Ratio of simulated 2f signals around 7185 cm^{-1} and 7444 cm^{-1} as a function of temperature for several cases of H_2O mole fraction in burnt gases.

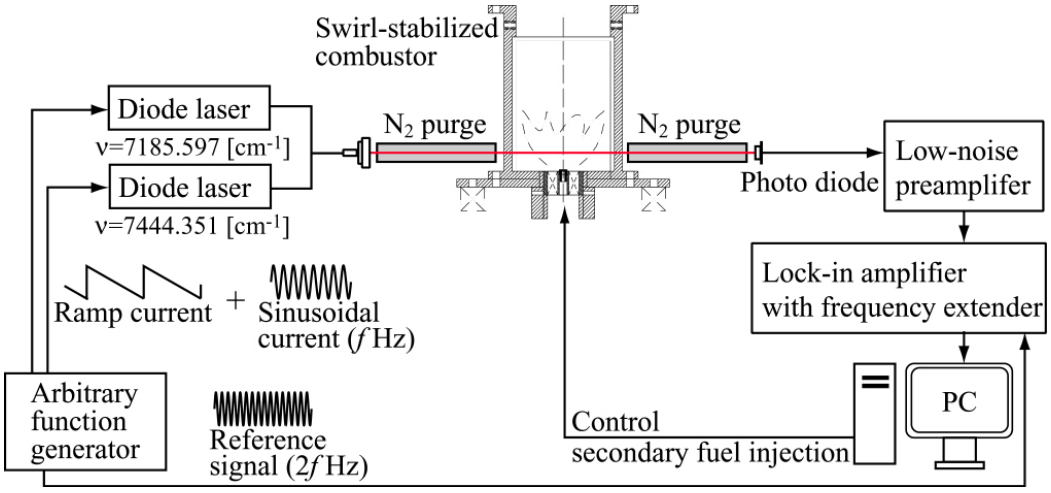

Figure 2. Schematic diagram of diode laser absorption sensor with 2f detection of wavelength modulation spectroscopy

$$R_{2\,fpeak} = \frac{\bar{I}_{0,1}\int_{-\pi/\omega_1}^{\pi/\omega_1} \tau(\nu_1(t))\cos 2\omega_1 t dt}{\bar{I}_{0,2}\int_{-\pi/\omega_2}^{\pi/\omega_2} \tau(\nu_2(t))\cos 2\omega_2 t dt} \tag{9}$$

The ratio depends not only on temperature, but also composition of absorption medium. Figure 1 shows ratio of simulated 2f signals around 7185 cm^{-1} and 7444 cm^{-1} as a function of temperature for several cases of H_2O mole fraction in simulated burnt gas. This set of wavelength was used by Baer et al. [1]. Although relation between the ratio and temperature varies in accordance with the composition of the burnt gas, effect of variation of H_2O mole fraction on temperature measurement is small. For instance, 0.04 variation of H_2O mole fraction correspond to difference of 30 K in the case of $R = 1.0$. In addition, fluctuations of peak heights cause some errors. In the measurement in constant temperature and humidity cell, rms of fluctuation of peak height ratio was about 1.2 %. This fluctuation corresponds to difference of about 30 K.

Experimental setup

Scanned-wavelength method with 2f detection of wavelength modulation spectroscopy is adopted to monitor temperature fluctuations of burnt gas in inner and outer recirculation zones of the swirl-stabilized combustor. Figure 2 shows schematic diagram of experimental set-up. Lasers near 7185 cm^{-1} (1392 nm, $2\nu_1$ and $\nu_1 + \nu_3$ bands transitions) and 7444 cm^{-1} (1343 nm, $\nu_1 + \nu_3$ band transition) are

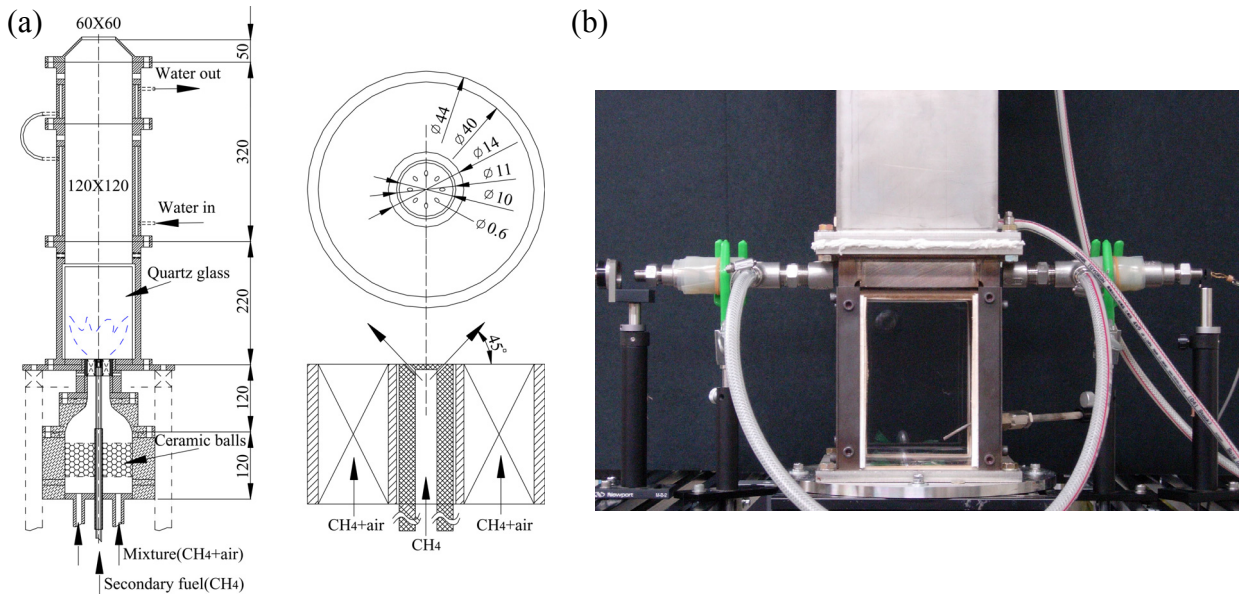

Figure 3. Apparatus of swirl-stabilized combustor and swirl nozzle with hub of secondary fuel injection holes (a) and photo of diode laser absorption sensor installed to the combustion chamber (b)

driven by 1 kHz ramp current summed with 250 kHz and 410 kHz sinusoidal current, respectively. Therefore fluctuations of temperature up to 500 Hz can be detected. Absorption by H_2O in ambient air is eliminated by N_2 purged pipes. In one side of the pipe near photodiode, focusing lens is installed to suppress beam steering. Transmitted signal is amplified and led to lock-in-amplifiers with frequency extenders. Pressure transducer is attached to the combustion chamber about 500 mm downstream from the exit of swirl nozzle.

Figure 3 (a) shows apparatus of swirl-stabilized combustor. The combustor is comprised of a contraction section, the swirl nozzle and the combustion chamber. The swirl nozzle of 14 mm inner diameter and 40 mm outer diameter is mounted on the contraction section and has 8 swirl vanes inclined at 45° from central axis of the combustor. A hub of secondary injection hole is attached at the center of the swirl nozzle and has 8 injection holes inclined at 45° from main stream direction. Secondary fuel injection can be modulated by solenoid valve installed at the position of 750 mm upstream from exit of injection holes. On each side of the combustion chamber, silica glass plate is installed to allow optical access. Figure 3 (b) shows a photo of installation of diode laser absorption sensor to the combustion chamber. Relative position of the sensor to the chamber can be changed in the region of the silica glass. In the previous study [11], characteristics of the swirl-stabilized combustor have been investigated in detail. For the case of ϕ=0.790 and 300 L/min, the sound level is about 110 dB. If the secondary fuel is injected continuously, peak frequency of the pressure fluctuation changes and noise level reduces to about 100 dB. If the secondary fuel is injected intermittently with appropriate frequency of 40 Hz, the pressure fluctuation becomes the minimum and the combustion noise is further reduced by about 5 dB [12]. Note that pressure fluctuation and noise level increases again if frequency of the secondary fuel injection exceeds 40 Hz. Noise levels are 98 dB for 10 Hz, 95 dB for 40 Hz and 104 dB for 70 Hz, respectively [12].

Experimental conditions

Experiments were conducted for the cases of no secondary fuel injection, continuous injection and intermittent injections at 10 Hz, 40 Hz and 70 Hz. Flow rate of main methane-air premixed gas was set in 300 L/min and equivalence ratios of the premixed gas were 0.790 for no control case and 0.717 for the cases of continuous and intermittent injections. Total equivalence ratio for injection cases was 0.819 including 3 L/min of secondary pure methane fuel. Note that air used in premixed gas is once

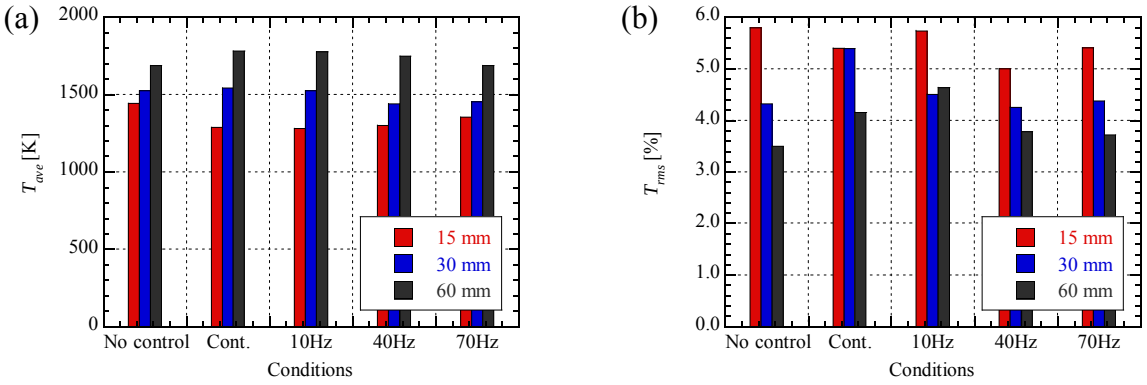

Figure 5. Mean (a) and rms (b) values of measured temperature for each injection case at three measurement heights

compressed to about 8 atm and dried, and therefore most of H_2O in the air is removed. As for the position of path of laser beams, lines passing the center axis of the combustor at 15, 30 and 60 mm downstream from exit of swirl nozzle are selected.

RESULTS AND DISCUSSIONS

The sensor for active control of combustors should detect the characteristics of the combustion state. Figure 4 (a) shows examples of time series data of 2f signals of 7185 cm^{-1} and 7444 cm^{-1} without control. The ratio of peak heights of 2f signals provides temperature in the path of laser beams at 1 kHz. Figure 4 (b) shows examples of time series data of obtained temperature without control and with continuous injection. In the case without control, the diode laser sensor detects large fluctuations of temperature. For the case of continuous injection, the diode laser absorption sensor reveals that fluctuations of temperature are suppressed. On the other hand, temperature becomes low, which might be caused by spread of flame due to secondary fuel jet as shown in the previous study [13]. Figure 5 (a) and (b) show mean and rms values of measured temperature at three measurement height. As for the case without injection, mean temperature at 15 mm is higher than that for the other cases and that at 60 mm is lower. Therefore, spatial variance of mean temperature is relatively small in the range of measurements. However, rms of temperature at 15 mm is larger than the other cases. This result corresponds to the large fluctuation of pressure and noise. In contrast, rms values are relatively small in

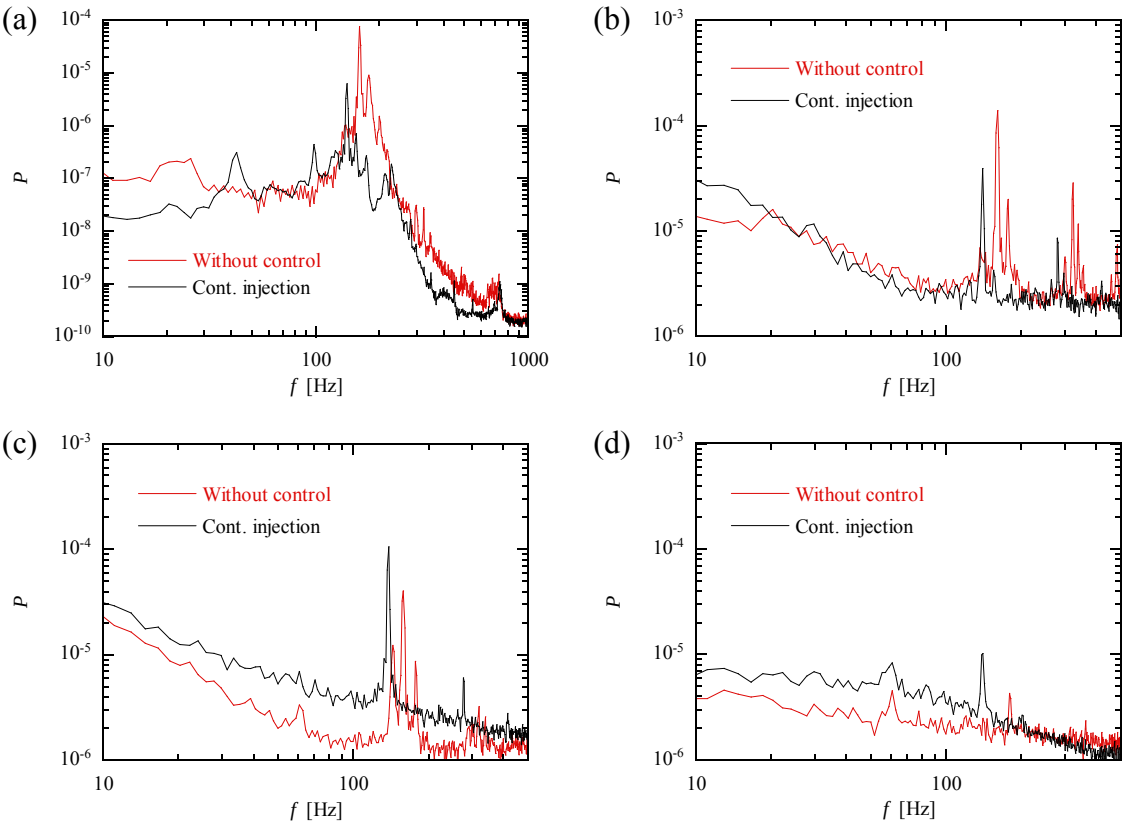

Figure 6. Power spectra of pressure fluctuation (a) and temperature at 15 mm (b), 30 mm (c) and 60 mm (d) without control and with continuous injection

the downstream regions, such as 30 mm and 60 mm. For continuous secondary fuel injection case, spatial variance of mean temperature is larger than the other injection cases. Rms values at 15 mm are reduced compared with no secondary fuel injection case. However, those at 30 mm and 60 mm show high value. In the cases of intermittent secondary fuel injections, mean temperature at 15mm increases and that at 60 mm decreases with increase of injection frequency. Compared with continuous injection case, rms values at 15 mm for 10 Hz and 70 Hz are larger and, on the other hand, rms value at 30 mm for intermittent injection cases is lower, which means that intermittent injection suppresses fluctuations of flame front and resultant burnt gas near flame region. In addition, 40 Hz injection case shows lower value than the other cases at 15 mm and 30 mm, which correspond to the results that noise is reduced by 40 Hz secondary fuel injection [12]. Note that diode laser absorption sensor which is assuming homogeneous absorption medium cannot provide distributions of precise temperature in combustion fields. However, these results suggest that diode laser absorption sensor with 2f detection can indicate characteristics of pressure fluctuation and noise by measuring temperature of H_2O in recirculation zone near the exit of swirl nozzle.

Figure 6 represents power spectra of pressure and temperature fluctuations without control and with continuous injection for 3 height cases. The peak frequencies of pressure fluctuation are found in about 160 Hz and 180 Hz without control in Figure 6 (a). The energy at the peak frequency is decreased by the secondary fuel injection in accordance with the decrease of the combustion noise measured in the previous study [11], and peak frequency is shifted from about 160 Hz to 140 Hz. Peak frequencies of power spectra of temperature at 15 mm (shown in Figure 6 (b)) coincide with those of pressure fluctuation. At 30 mm (Figure 6 (c)), energy at peak frequency for continuous injection case is larger than that for no injection case. At 60 mm (Figure 6 (d)), energies at peak frequencies for no injection case and even for continuous injection case are much lower. Since apparent peaks are observed in power spectra of pressure fluctuation, it seems that temperature fluctuation of burnt gas is not small as

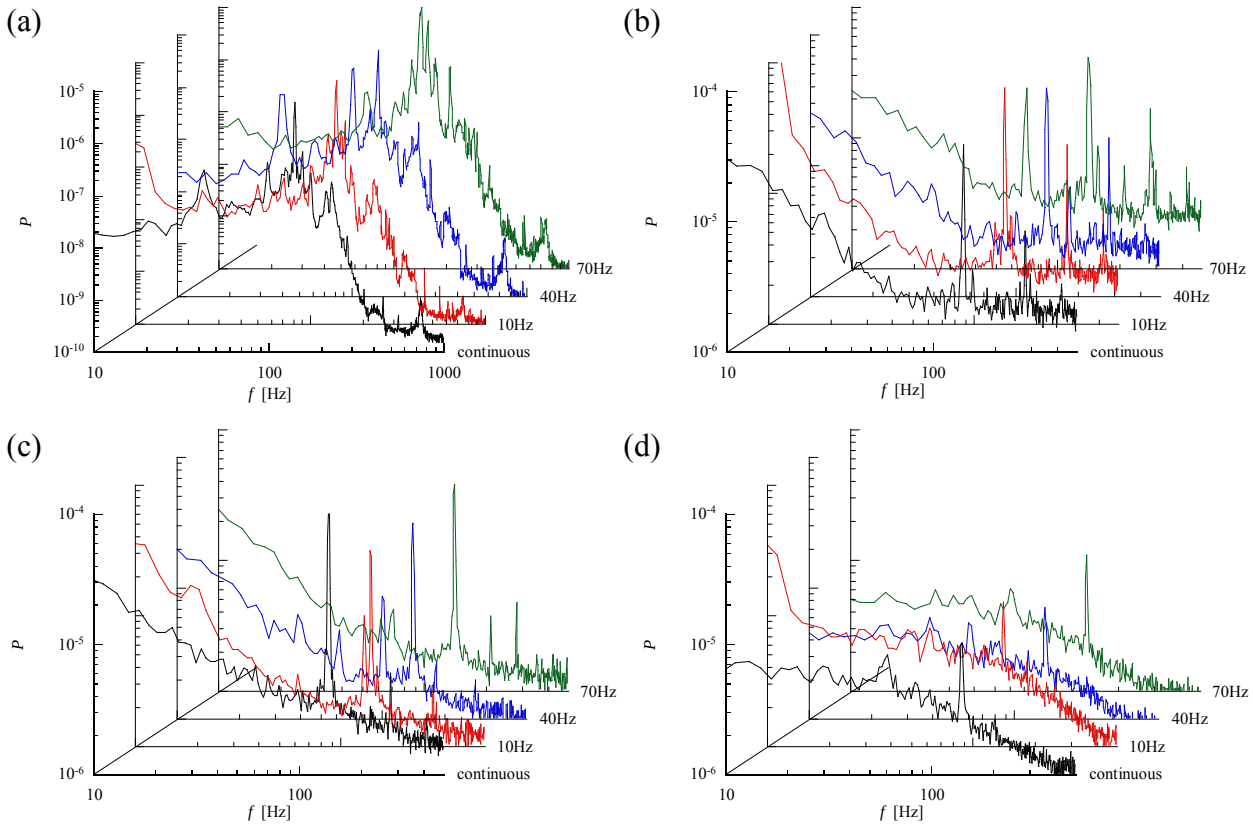

Figure 7. Power spectra of pressure fluctuation (a) and temperature at 15 mm (b), 30 mm (c) and 60 mm (d) for continuous and intermittent secondary fuel injection cases

a whole. Therefore, measurement at 60 mm is not suitable for detection of combustion oscillation.

Figure 7 shows power spectra of fluctuations of pressure and temperature at 15 mm, 30 mm and 60 mm for continuous and intermittent secondary fuel injection cases. In addition to the dominant frequency of about 140 Hz, pressure oscillation occurs at the same frequency with injection and beat between the dominant and injection frequencies. In the case of 10 and 70Hz, temperature measured at 15mm oscillates largely at injection frequencies, whereas 40 Hz injection does not induce large temperature fluctuation. As for 30 mm shown in Figure 7 (c), continuous injection case which has large value of rms shows large energy at the dominant frequency. In the cases of intermittent injections, peaks both at the injection and beat frequencies appear even for 40 Hz injection. The beat caused by the interaction between premixed flame and secondary fuel can be detected at the height. As for the case of 60 mm shown in Figure 7 (d), energy at the dominant frequency is most reduced for 40 Hz injection. For the cases of continuous and intermittent secondary fuel injections, oscillation at the dominant frequency can be observed even in relatively downstream region. However, the energy shows lower value than that in upstream region. Therefore, SNR of the sensor for detection of combustion oscillation can be set higher by applying it to lower positions in the recirculation zone. The diode laser absorption sensor provides characteristics of temperature fluctuations depending on the measurement path. Therefore, installation to the proper positions makes the sensor effective for the active combustion control by secondary fuel injection.

CONCLUSIONS

Diode laser absorption sensor with 2f detection of wavelength modulation spectroscopy was developed and applied to the swirl-stabilized combustor. The combustor was operated without

secondary fuel injection and with continuous and intermittent secondary fuel injections. The sensor can indicate characteristics of pressure fluctuation and noise by measuring temperature of H_2O molecule in recirculation zone near the exit of swirl nozzle. In addition, oscillation characteristics can be detected by applying the sensor to lower positions. The sensor provides information depending on the position of laser path. The characteristics of interaction of premixed flame and secondary fuel can be apparently measured only in the middle of measurement position. Therefore, space-resolved sensor has potential to innovate control algorithms different from those for the traditional active combustion control which defines pressure fluctuation as a control object. These results prove that the diode laser absorption sensor with 2f detection is a great candidate for active combustion control by secondary fuel injection.

ABSTRACT. Based on the qualitative considerations that the flow durability in the combustor plays an important role not only in combustion enhancement but also in heat transfer enhancement, the main attention is paid on the flow durability in the cooling period after the pressure attains maximum. Four types of constant-volume combustors are used; a cylindrical combustor with a hemi-sphere-shaped divided chamber, one with a pan-cake-shaped divided chamber, a fan-stirred combustor and a simple cylindrical combustor. The latter is used for getting standard combustion properties. Enhancement behavior of combustion and heat transfer is examined by analysing pressure histories after the spark ignition. Flow visualization in the fan-stirred combustor is made using a cold water flow. It is found that the fan-stirred combustor can realize and maintain a complex flow pattern in the cooling period and realize simultaneously strong heat transfer enhancement and moderate combustion enhancement.

INTRODUCTION

To develop a combustion-driven, portable, reciprocal and self-sustainable impact machine, which utilizes the steep pressure increase due to combustion as driving force; basic properties of combustion and heat transfer enhancement have already been studied using a quasi-constant volume and divided chamber combustor [1, 2]. In these papers the physical and chemical properties of multiple flame jets and their influences on the combustion augmentation mechanism have been qualitatively elucidated by making basic reference to the accumulated information concerning the divided chamber combustors [3 ~ 9]. Detailed considerations on the results can clarify that the laminar flame propagation in the sub-chamber produces multiple radial flame jets issuing into the main chamber and the multiple radial flame jets realize effective combustion enhancement for its small sub-chamber volume, through homogeneous and thorough mixing all over the main chamber. Even in this case, however, cooling of combustion gas by heat transfer to the walls after the pressure reaches to its maximum becomes insufficient and results in slow and incomplete returning of the piston to its original position.

The main attention in this investigation is focused on the qualitative considerations that the long flow durability in the main chamber may effectively promote not only the burning process in the main chamber just after the ignition in the main chamber, but also the cooling process after the combustion terminates. To clarify the difference in the enhancement processes in combustion and heat transfer, four types of constant-volume combustors using DME-air mixture are prepared; two types of divided chamber combustors of hemi-sphere type and pan-cake type, a fan-stirred constant volume combustor and a normal cylindrical constant volume combustor. In this paper the burning and cooling processes are examined for four types of constant-volume combustors by analysing the pressure histories in the

main chamber. Their fundamental properties; such as the maximum pressure, the maximum pressure increasing rate, the total burning time, the net burning time and the total cooling time are then compared with those of the normal cylindrical combustor for examining qualitatively the interrelation between the enhancement effects for burning and cooling. Finally a cold flow pattern in the fan-stirred combustor without combustion is visualized by replacing it with a cold water flow field under the standard pressure and temperature conditions.

EXPERIMENTAL APPARATUS AND METHODS

The schematic diagram of the experimental system is shown in Fig. 1. The system is composed of a constant volume combustor, a mixture supply line, a measuring circuit for main chamber pressure, an ignition circuit and a control PC-circuit. The construction of four types of constant volume combustors is given in the inset to Fig. 1, as indicated by each abbreviated character; FD: fan-stirred, NC: normal cylindrical, HS: hemi-spherical type divided chamber and PC: pan-cake type divided chamber. All combustors have a cylindrical shape of 84.5 mm diameter and 46.5 mm height and a total volume of $V_m = 260$ cm^3, except for the fan-stirred combustor of $V_m = 266$ cm^3.

The hemi-sphere is made of iron of 2 mm thickness and has a volume of $V_s = 62.4$ cm^3. The ratio of the sub-chamber volume to the main chamber volume, $a = V_s/V_m = 24$ %. Forty small nozzles having a diameter of $d = 1.6$ mm are regularly arranged over the hemi-sphere surface and has a total sectional area of 80.4 mm^2. The pan-cake type divided chamber combustor is constructed by dividing the main chamber into two parts using a flat plate. The sub-chamber volume is $V_s = 106$ cm^3 and has a volume ratio of $a = 40$ %. The flat plate has a thickness of 3.2 mm and a diameter of 84.5 mm, and six nozzles with a diameter of 2.1 mm and six nozzles having a diameter of 3.2 mm are coaxially and alternately arranged on the plate. The total sectional area of 12 nozzles is 69.0 mm^2. A fan consisting of four blades of a twisted angle of 30° and having a diameter of 60 mm is driven by a DC-motor in the range of n = 6,000 ~ 12,000 rpm. The configuration and dimensions of four kinds of combustors are summarized in Table 1. By the way, the specifications of two divided chamber combustors are so determined based on the preceding studies [1, 2] that they indicate the highest enhancement effect in the main chamber combustion.

The fuel used is dimethyl ether, abbreviated to DME in the following, whereas air is supplied by a compressor. DME and desiccated air are filled into a mixing chamber at an absolute pressure of 0.13 MPa to form mixture having an assigned equivalence ratio. The mixing chamber is equipped with a fan, which is driven indirectly by magnetic force of a rotating magnet. The equivalence ratio is varied in the range of $\phi = 0.8 \sim 1.4$ at 0.2 intervals. The mixture with an assigned equivalence ratio is charged into the combustor, which is discharged to a vacuum in advance. After balancing the combustion chamber pressure against the atmospheric one using a control valve, an electric plug is discharged at

ignition energy of 24.5 mJ. Synchronizing with the spark discharge, the main chamber pressure is measured using a water-cooled semi-conductor type pressure transducer having a maximum response frequency of 10 kHz (Toyota Koki Co. Ltd., PMS-5M-20H).

In this paper flow visualization is also made by replacing the mixture flow in the fan-stirred combustor before ignition with a fan-stirred water flow in the model combustor, while Reynolds number is kept constant. The model combustor with the same dimensions as those of the FD-combustor is made of transparent plastics. Reynolds number is defined using the fan diameter and the tangential velocity at the fan diameter as the characteristic length and velocity. In this case the kinematic viscosity of air at room temperature of 300 K is greater than that of water by about 16 times. This enables visualization of the water flow under extremely low fan revolution ranging 320 ~ 640 rpm. Fine polyethylene terephthalate resin powder, abbreviated to PET-powder in the following, having a density of $\rho = 1.38 \times 10^3$ kg/m^3 and diameters ranging in $d = 100 \sim 125$ μm is used as tracer particles. One gram of PET-powder is added to the deaerated water and incandescent light is applied in the side direction. Reflected light from PET-particles is photographed using a high-speed CCD video camera (Photron; FASTCAM-PCI) at a framing speed of 500 fps.

EXPERIMENTAL RESULTS AND DISCUSSION

Combustion behavior in four types of constant-volume combustors

Comparison of pressure characteristics. Temporal variations of the pressure and its increasing rate are presented in Fig. 2 for four types of combustors; the HS-, PC-, FD- and NC-combustor, where the equivalence ratio is assigned to $\phi = 1.0$. The upper figure gives the pressure history and the lower the pressure increasing rate, where the abscissa shows the time after the spark ignition in the sub-chamber. The upper figure of Fig. 2 shows that a moderate pressure increase and a relatively low maximum pressure are obtained in the NC-combustor due to the slow and smooth laminar combustion. In cases of the divided chamber combustors the same moderate pressure increase as that in the NC-combustor is observed in the initial stage of combustion. This is because the initial stages in both the HS- and PC-combustors do not substantially differ from that in the NC-combustor, but is dominated by the same slow laminar flame propagation. The pressure histories in the HS- and PC-combustors, therefore, overlap with each other in the first stage. During the initial stage, however, multiple jets are driven by the laminar flame propagation through the nozzles and thoroughly disturb the mixture in the main chamber. Due to the thorough mixing by the multiple jets, rapid turbulent flame propagation follows multi-point ignitions by flame kernels and/or flamelets in the main chamber and realizes steep pressure increase and high maximum pressure. It is confirmed that the multiple jets exert extreme effects on combustion enhancement in the constant volume combustors. Also found is that, although the volume ratio of the HS-combustor of 24 % is smaller than that of the PC-combustor of 40 %, being only 0.6 times, the effects of combustion enhancement in the former due to a series of radial and multiple flame jets can compare with those of the latter caused by a coaxial set of flame jets.

The combustion behavior in the FD-combustor can be clearly distinguished from those in the other

two types of constant volume combustors. In the divided chamber combustor, the multiple flame jets are suffered from intense cooling both by the nozzle walls in their passages through them and the cold mixture entrained by the high-speed flame jets just after the nozzle exits, resulting in an extreme long ignition delay time. In the ND-combustor, no disturbance extends to all over the combustion chamber at the beginning of spark ignition, resulting in the slow and moderate laminar flame propagation. These differences in the burning conditions realize not only early ignition due to laminar flame propagation from the flame kernel around the spark discharge, but also quick transition from laminar to turbulent flame propagation. As a result, the early pressure rise and steep pressure increase appear.

The lower figure of Fig. 2 presents clearly the differences in the pressure properties caused by the ignition patterns and the methods of combustion enhancement. The maximum pressure increasing rates in the four combustors indicate the following numerical values; $(dp/dt)_{max}$ = 1.02 MPa/ms in the HS-type, 0.87 MPa/ms in the PC-type, 0.38 MPa/ms in the FD-type and 0.06 MPa/ms in the NC-type. These numerical values clarify the extreme effects of multiple flame jets on the process of combustion enhancement in the constant volume combustors [6 ~ 9].

Variations of the maximum pressure and maximum pressure increasing rate with the equivalence ratio.
Variations of the maximum pressure, p_{max} and maximum pressure increasing rate, $(dp/dt)_{max}$ with the equivalence ratio of DME-air mixture are given in Fig. 3(a) and (b) respectively by simply averaging over eight data, where the equivalence ratio is varied in the range of ϕ = 0.8 ~ 1.4 at 0.2 intervals. Figure 3 shows that both the maximum pressure and the maximum pressure increasing rate become larger as the types of combustors change in turn of NC, FD, PC and HS. However, a small difference in the maximum pressure up to about 10 ~ 12 % appears among the four types of combustors, whereas a great difference can be found in the maximum pressure increasing rate. In cases of ϕ = 1.0 and 1.2 the maximum pressure increasing rate in the divided chamber combustors of HS and PC takes a value much greater than that in the NC-combustor by about 12 times and greater than that of the FD-combustor by about 2.4 times. This fact shows again the remarkable influence of the multiple jets on combustion augmentation in the constant-volume combustors. It is found that the HS-type divided

(a) Pressure profiles (b) Pressure increasing rates

Figure 3. Variations of the pressure increasing rate (upper) and maximum pressure (lower) with the equivalence ratio in four types of constant volume combustors

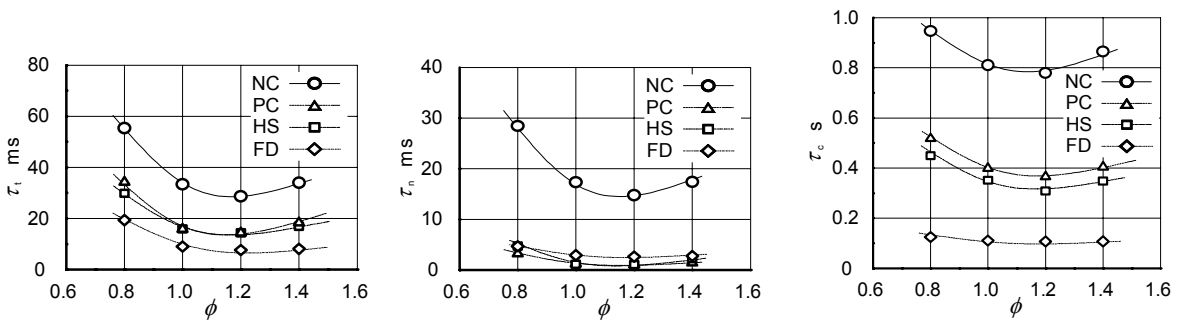
chamber combustor is most useful and effective, when the instantaneous and intense pressure increase in the combustor is focused in the portable, reciprocal and self-sustainable impact machine.

In the divided chamber combustors of HS- and PC-types, the maximum pressure increasing rate exhibits rather strong dependency on the equivalence ratio by comparing with other two types of FD- and NC-combustors. This is because that the thorough mixing and intense turbulence due to high-speed continuous and multiple jets exert more prominent cooling effects on the flame propagation processes of weak mixture of $\phi = 0.8$ and 1.4 than those of strong mixture of $\phi = 1.0 \sim 1.2$.

Variations of three characteristic times with the equivalence ratio. Variations of three kinds of characteristic times with the equivalence ratio; the total burning time τ_t, the net burning time τ_n and the total cooling time τ_c are given in Fig. 4(a), (b) and (c) respectively by simply averaging over eight data. The first is defined as the time when the pressure attains its maximum after the spark ignition, whereas the second is defined as the time duration between the time of initiation of pressure rise and the time of maximum pressure. The third is estimated, on the other hand, using the pressure history by evaluating the time duration between the time of maximum pressure and the time when the pressure decreases to 10 % of its maximum. Figure 4 indicates entirely that three characteristic times exhibit the concave dependency to the equivalence ratio, showing minimum at $\phi \approx 1.2$. The total and net burning times in the NC-combustor take values in the ranges of $\tau_t = 29 \sim 56$ ms and $\tau_n = 15 \sim 28$ ms, respectively, indicating that the slow and moderate laminar flame propagation dominates the entire combustion process in the constant volume combustor.

The dependency of total burning time τ_t on the types of combustors is then considered. The HS- and PC-combustors have longer total burning times than the FD-combustor by 1.7 ~ 2.1 times due to the slow and moderate laminar flame propagation in the sub-chamber. Augmented by the thorough mixing by the multiple jets, however, they complete overall combustion in the main chamber in shorter time periods than the NC-combustor by about 0.5 times. When the behavior of net burning time is focused in Fig. 4(b), it is found that the divided chamber combustors can accomplish such short net burning times ranging in $\tau_n = 1.1 \sim 2.4$ ms that they become about a half of that of the FD-combustor in the range of $\tau_n = 2.2 \sim 4.9$ ms. This experimental fact indicates the effects of combustion enhancement due to the multiple flame jets in the divided chamber combustor are superior to those by the stirring fan in the FD-combustor.

In the reciprocal and self-sustainable impact machine under consideration, the returning time of the piston to its original position after the spark ignition constitutes another key factor. The interrelation between the cooling effects and the methods of combustion enhancement is examined, based on the dependency of τ_c on the types of combustors. Figure 4 (c) indicates that the total cooling time becomes longer as the types of combustors change in turn of FD, HS, PC and NC, and that in the FD-combustor τ_c takes a very short time in the range of $\tau_c = 0.11 \sim 0.13$ s and is almost kept constant. Also found is that τ_c in the NC-combustor becomes longer than the other three combustors by about 2



(a) Total burning time (b) Net burning time (c) Total cooling time

Figure 4. Variations of the total and net burning times and the total cooling time with the equivalence ratio in four types of constant volume combustors

~ 9 times and has a value in the range of $\tau_c = 0.79 \sim 0.96$ s.

The total cooling time in the divided chamber combustors of HS- and PC-types is then considered. As discussed earlier in this paper, the multiple flame jets issue into the main chamber, stir the entire main chamber and promotes effectively combustion after ignition in the main chamber. In spite of these positive influences of the multiple jets particular to the divided chamber combustor, the cooling time short enough to realize reciprocal and self-sustainable combustion can not be attained. The following two reasons are considered. First, the stirring effect of multiple jets in the divided chamber combustor is effective only in the combustion period in the main chamber and does not continue to the cooling stage after the combustion terminates. Second, the highly viscous character of high temperature combustion gas may attenuate flow and turbulence and result in quick disappearance of stirring motion in the main chamber. The combined effects of these two negative factors are the key reason for producing longer cooling times than the FD-combustor. In the FD-combustor the stirring motion is forcedly sustained in the entire combustion and cooling periods and promotes heat transfer to the entire walls of combustor and piston. It is concluded that the FD-type constant volume combustor which combines both remarkable enhancement effects of combustion and heat transfer is most suitable for applying it to the potable, reciprocal and self-sustainable impact machine.

High-speed photographing of combustion process and cold flow visualization in the fan-stirred combustor

Combustion process in the fan-stirred combustor. Eight images extracted from a series of high-speed movie of the combustion process in the FD-combustor are presented in Fig. 5 on the pressure history, where the number of fan revolution is set at $n = 8000$ rpm, the mixture equivalence ratio is set to $\phi =$ 1.0, and the framing speed is 1000 fps. The timings of eight images correspond to the typical stages shown on the pressure profile. In the images the direction of fan revolution is anti-clockwise, as indicated by a white arrow circle. Although ambiguity in the images is indispensable in photographing high-speed phenomena such as combustion in the constant volume combustor, the following characteristic behavior can be observed in Fig. 5. The pressure begins to increase at $t = 3 \sim 4$ ms after the spark ignition, whereas weak but uniform flame emission is apparent in the entire combustion chamber at $t = 6$ ms almost in accordance with the appreciate pressure rise. Once combustion due to turbulent flame propagation occurs, the steep pressure increase proceeds almost synchronized with quick spreading of flame emission in the short time duration of about 4 ms. Following its maximum at $t \approx 10$ ms, the pressure decreases gradually with the uniform and gradual reduction of flame emission. Temporary variation of flame emission from its appearance to disappearance takes place almost uniformly in the entire volume of combustor, being one of the typical behaviors in the FD-combustor.

Flow visualization in the fan-stirred cold water model flow. Nine reflection images extracted from a

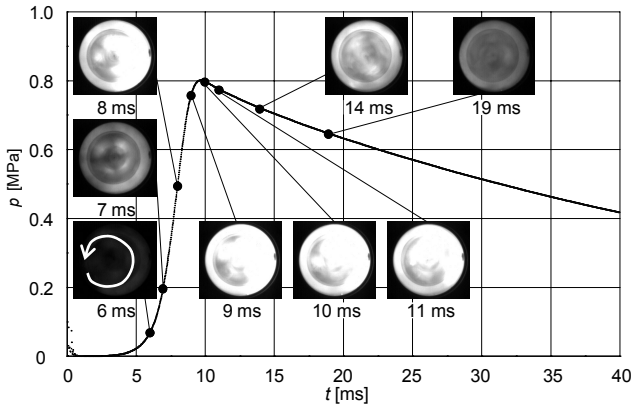


Figure 5. Typical eight images of combustion process on a typical pressure profile in the FD-combustor, where the fan is rotated at $n = 8000$ and $\phi = 1.0$

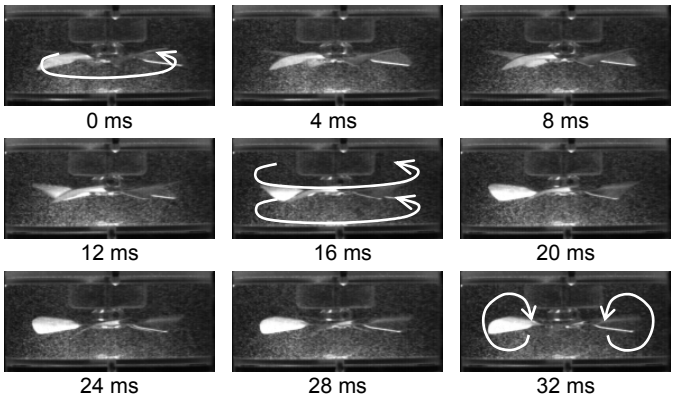

Figure 6. A series of high-speed reflection images from PET particles in the fan stirred model water flow, where the fan is driven at n = 340 rpm

movie of cold water flow in the model FD-combustor are presented in Fig. 6, where the fan rotates at n = 340 rpm and the framing speed of the movie is 500 fps. The water flow simulates the cold gas flow generated in the FD-combustor at the fan revolution of n = 6,500 rpm. As indicated by a white arrow circle in the first image of Fig. 6, the fan rotates in the clock-wise direction. Although it is difficult to understand and construct the flow patterns in the combustor based on still images such as given in Fig. 6, detailed and careful observation of the high-speed movie makes clear the following two basic flow patterns particular to the fan-stirred constant volume combustor.

As indicated by two sets of white arrow circles in the image at t = 16 ms, at first, the fan induces a strong swirling flow in the cylindrical combustion chamber due to the centrifugal force. The swirling flow may play an important role in heat transfer enhancement to the cylindrical wall. The fan produces another flow, secondly, as illustrated by two white rings in the image at t = 32 ms. The axial flow driven by the fan flows downward across the fan, diverges radially and uniformly outward at the bottom, ascends up along the cylindrical wall and join the original downward flow to constitute a doughnut-like ring flow. The ring flow may also play an important role in thorough mixing in the combustor. Based on detailed observation of the high-speed movie, it can be considered that the flow field in the FD-combustor consists of the two typical flows; one is the strong fan-induced swirling flow and the other is the doughnut-like ring flow, and constitutes a complex composite flow.

Flow measurements using a hot-wire anemometer show that, by the way, the time-averaged maximum velocities of the swirling and ascending flows take values of about 10 m/s and 5 m/s, respectively, and the turbulence intensity takes high values in the range of 0.5 ~ 2.0 m/s. Although quantitative discussion on the flow properties is difficult because of the peculiarity of flow measurements using the hot-wire anemometer, the fan-driven composite flow with intense turbulence is found to plays effective roles in combustion enhancement. However the convergent and divergent flows along the upper and bottom end walls and the composite ascending flow along the cylindrical wall may exert negative effects, suppressing turbulent flame propagation near the combustor wall through enhanced heat transfer from hot combustion gas to the wall. Based on the considerations on the pressure characteristics, these flow properties particular to the FD-combustor reduce both the maximum pressure and maximum pressure increasing rate on one hand, and enable to shorten the returning time of the piston to its original position due to augmented heat transfer after the pressure attains to its maximum, on the other.

Detailed considerations concerning the pressure histories and high-speed movies suggest that the FD-combustor combining simultaneous enhancement of combustion and heat transfer is suitable for the portable, reciprocal and self-sustaining impact machine. However, since the HS-type divided chamber combustor exhibits conspicuous enhancement for combustion, it is still extremely useful for the same application. To obtain the best configuration of the HS-combustor which realizes simultaneously enhancement of combustion and heat transfer, the overall influences of the volume ratio and the number, arrangement and diameter of nozzle on the enhancement mechanisms of both combustion

and heat transfer should be precisely examined, being the future experimental problems.

CONCLUDING REMARKS

The results obtained in this paper are summarized as follows.

(1) When the dependency of the pressure on the equivalence ratio is examined from the viewpoint of combustion enhancement, the mixture of $\phi \approx 1.2$ indicates the highest pressure, the steepest pressure increasing rate and the shortest net burning time. Concerning the dependency of the maximum pressure increasing rate on the methods of combustion enhancement, the HS-combustor realizes the most pronounced effects and the shortest net burning time.

(2) Concerning the dependency of the total cooling time on the equivalence ratio, it varies moderately in the concave manner and takes the minimum at $\phi \approx 1.2$, independent of the types of combustors. The dependency of the total cooling time on the types of combustors, however, becomes remarkable and the cooling time becomes longer as the types of combustors change in turn of FD, HS, PC and NC. The total cooling time in the FD-combustor takes the shortest value of $\tau_c \approx 0.10$ s.

(3) The intense and continuous turbulent flow in the FD-combustor realizes simultaneously moderate combustion enhancement and continuous heat transfer augmentation. As a result, the combustion process consists of the initiation of weak but uniform flame emission, the steep but uniform growth of flame emission and the gradual but uniform attenuation of flame emission. It is found that the FD-combustor combines suitable combustion enhancement and intense heat transfer promotion.

(4) The fan-induced flow pattern in the FD-combustor consists of two basic flows; one is the strong swirling flow and the other is the doughnut-like ring flow, both being driven by the fan. This complex composite flow makes possible simultaneous enhancement of combustion and cooling in the constant volume combustor and constitutes one of the most suitable combustion patterns for realizing the combustion-driven, portable, reciprocal and self-sustainable impact machines.

MEASURING OF THERMAL CONDUCTIVITY OF LIQUIDS USING PHOTOTHERMAL RADIOMETRY

A. Kusiak [*], C. Pradère, J.-L. Battaglia
Laboratoire TREFLE "Transfert, Ecoulement, Fluide, Energétique", UMR CNRS 8508, Esplanade des Arts et Métiers, 33405 Talence Cedex, FRANCE

ABSTRACT. A method for the estimation of thermal conductivity of liquids is proposed. The measurement is based on the front face modulated photo thermal radiometry usually used for studies of solid deposit (thin film) on substrate systems. The system considered here, is in the three-layers form, the intermediate layer being the investigated liquid. An experimental setup has been developed in order to avoid the drawbacks of the classical methods like flash or hot wire measurement. The measurement is carried out with low temperature oscillations and the studied liquid is confined in specific (low thickness) container. This configuration leads to very low Rayleigh number and permits to eliminate the convection phenomena during the experiment and to characterize very small (~1 µl) volume of liquid. This is an important feature for metrology of expensive or hazardous samples.
According to the knowledge of the thermo physical properties of the two external to liquid solid layers, the phase lag between the thermal perturbation and the response of the sample is used as the experimental data. The measurement was validated using two well known liquids: water and sunflower oil.

Keywords: *photo thermal radiometry, thermal conductivity, liquid*

INTRODUCTION

The knowledge of thermal conductivity of liquids is very important in many industrial sectors. The estimation of this thermal parameter is well treated in the literature. The principle of the methods used for this purpose is similar as for the solids. The studied medium is submitted to a calibrated thermal solicitation and then the temperature response is recorded. The fitting of a theoretical model of heat transfer in the used experimental configuration to the carried out measurement leads to the required thermal parameter.
The principal classification of the existent methods is based on the temporal evolution of thermal solicitation. In this way, it can be found some techniques based on steady state heat transfer [1]. The technique seems to ensure good results but requires relatively complex and expensive equipments. Moreover, the minimal volume of liquid that can be characterized is generally large what is the major inconvenient in the case of expensive fluids. Another family of methods is based on the response of the studied sample to a transient excitation. The hot wire, the flash or the thermal oscillation are the common techniques. The hot wire measurement is performed using electrically heated metallic wire immersed in the liquid [2, 3, 4, 5, 6]. The change of the electrical resistivity with temperature leads to the simultaneous measurement of temperature and imposed heat flux. The measurement is easier to carry out but the question of the large volume of liquid is still present. On the other hand, the measurement must be carry out with precautions in order to avoid the convection phenomena. The flash method has been initially developed for measurement of the thermal diffusivity of solids [7]. In

this method the studied sample is heated by a short and high heat flux pulse and the temperature at the rear face is measured. Temporal evolution of this temperature permits to determine the diffusivity of the sample. Such an application for liquids can be found for example in [8, 9, 10]. The major drawback of this technique is that the convection phenomena may occur due to high temperature elevation at the short times. To avoid such phenomenon, the temperature oscillation measurement seems to be the best compromise. The temperature variation during the measurement may rest small and an appropriate design for the sample container permits to study a small volume of liquid. This an important advantage face to the convection phenomena and the price of the sample [11, 12]. New approaches based on photo thermal radiometry or pump-probe technique appeared recently [13, 14].
In this work we present a method for the determination of the thermal conductivity of liquids. The measurement is an extension of the periodic front face photo thermal radiometry developed for studies of thin film on substrate systems [15, 16]. The system considered here is in the three-layer form, the intermediate layer being the investigated liquid considered here as opaque for thermal (infrared) radiation. The thickness of the liquid layer is very small (500 µm). This value with low temperature oscillation (2 K) ensures that no natural convection occurs in the liquid layer. Therefore only the heat diffusion is considered for the modelling of heat transfer in the sample. In section EXPERIMENTAL SETUP, the experimental heating-measuring system and the sample are presented. Section HEAT TRANSFER MODEL describes the governing equations used for the heat transfer description in the studied system. The behaviour of this model according to its different parameters is presented in section SENSITIVITY OF THE MODEL. Finally, the results of validation and the measurement using water and sunflower oil are presented in section RESULTS OF VALIDATION.

EXPERIMENTAL SETUP

The schematic view of the experimental setup is presented in Figure 1 a).

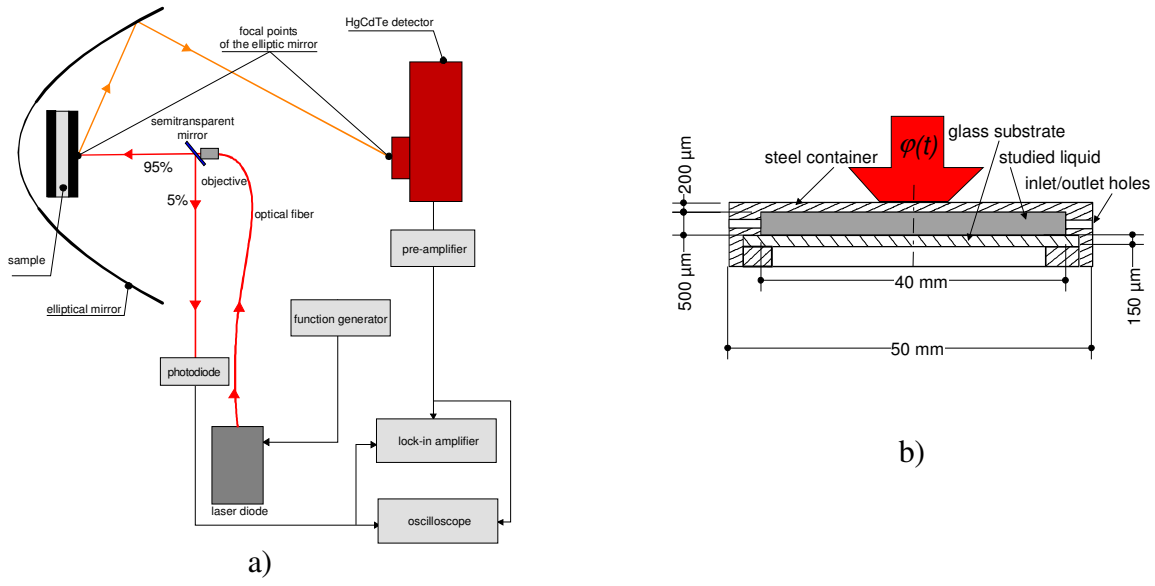

Figure 1. Schema of: the experimental setup a), the sample b)

The thermal excitation is generated on the sample front face by a laser diode of 920 nm wavelength and 2.5 W maximal power. The laser diode is directly modulated by its driver using the sinusoidal signal issued from a function generator. The allowed modulation frequency range is up to 20 kHz. The laser beam is brought to the sample by an optical fiber equipped with a microscope objective allowing to focus the laser beam at desired diameter on the sample surface. The laser beam has a Gaussian profile of power repartition on the spot of 5 mm in diameter at $1/e^2$. A very fast photodiode (Thorlabs DET10A/M) is used to measure the reference signal in order to avoid the phase lag due to the laser

diode driver. The thermal response is measured by an infrared detector based on HgCdTe (Infrared Associates 2C-13-1.0). The measurement wavelength range is comprised between 5 and 13 µm. The elliptical mirror coated with high reflective rhodium (reflectivity of 98% in the infrared detector wavelength band) is used to collect the emitted infrared radiation and to focus it on the infrared detector. In fact, the heated surface of the sample is located at the interior focal point of the mirror and the sensitive element of the detector at the exterior one, what results in a conjugate focuses system. The incident laser beam is centred and aligned on the focal axis of the mirror. The detector wavelength band is largely greater than that of the laser, what gives the advantage that the measurement is not disturbed by the excitation source. The zone viewed from the detector is the image of the infrared sensitive element on the sample; it corresponds to a circle of 1 mm in diameter.

The signal from the detector is amplified with an adapted preamplifier (Infrared Systems MCT-1000), and then is visualized on a digital oscilloscope with the photodiode signal. A lock-in amplifier is used to measure the amplitude and the phase lag between the reference source and the detector signals versus the frequency.

For the sample, the system considered here is in three layers form. The first layer is constituted of steel. This metallic layer submitted to the laser beam leads to surfacic absorption of the heat flux. The second layer is the studied liquid (opaque for thermal radiation), and finally the last one made of glass, is transparent in the visible band and opaque in the infrared. This glass layer permits to verify that the sample is well filled with liquid.

For the sample size, a large ratio between the diameter and the thickness was chosen in order to neglect the heat transfer at the periphery and to emphasize the heat diffusion in the transverse direction of the sample. In fact, considering the thermal diffusivity of the first steel layer (that is the highest in this system) the radius of the sample (20 mm) was chosen to ensure the heat diffusion time from the centre to the periphery be largely greater than that corresponding to the frequency explored during the measurement. The geometrical characteristics of the sample are represented in Figure 1 b).

HEAT TRANSFER IN THE SAMPLE

During the experiment the cylindrical sample is submitted to a heat flux from a laser on its metallic layer ($z = 0$) (see Figure 2). r_0 and r_m correspond to the heating and the measurement radius respectively, e_i describes the thickness of each layer.

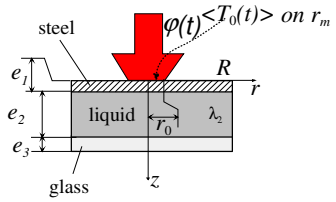

Figure 2. Schema of the geometrical configuration of the sample considered for the model

Such a heat flux is applied at the centre of the sample in order to ensure the axis-symmetry condition. The external surfaces of the steel and the glass layer are submitted to natural convection described by the coefficient h. The convective exchange at the periphery is neglected because of the small surface and the heat diffusion time largely exceeding the heat flux modulation period. The temperature in the system is described by the set of equations in the cylindrical coordinates with r, z space, and t time variables:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T(r,z,t)}{\partial r}\right)+\frac{\partial^2 T(r,z,t)}{\partial z^2}-\frac{1}{\alpha_i}\frac{\partial T(r,z,t)}{\partial t}=0$$
$$i=1,\ 2,\ 3 \tag{1}$$
$$0<r<R,\ 0\le z\le e_1,\ e_1\le z\le e_2,\ \ e_2\le z\le e_3,\ \text{t>0}$$

The index i corresponds to the layer 1: steel, 2: liquid and 3: glass and α_i and λ_i are the thermal diffusivity and the thermal conductivity of the layer i. The used initial and boundary conditions are:

$$\frac{\partial T(r,z,t)}{\partial r}=0,\ r=0,\ r=R,\ 0<z\le e_1+e_2+e_3,\ t>0 \tag{2}$$
$$-\lambda_1\frac{\partial T(r,\ z,\ t)}{\partial z}=\begin{cases}\varphi_0(r,\ t)+hT(r,\ z,\ t)\ \ 0\le r\le r_0\\ hT(r,\ z,\ t)\ \ r_0\le r\le R\end{cases} \tag{3}$$
$$z=0,\ t>0$$
$$-\lambda_3\frac{\partial T(r,\ z,\ t)}{\partial z}=hT(r,\ z,\ t) \tag{4}$$
$$0\le r\le R,\ z=e_1+e_2+e_3,\ t>0$$
$$T(r,\ z,\ t)=0$$
$$0\le r\le R,\ 0\le z\le e_1+e_2+e_3,\ t=0 \tag{5}$$
$$\lambda_1\frac{\partial T(r,\ z,\ t)}{\partial z}=\lambda_2\frac{\partial T(r,\ z,\ t)}{\partial z} \tag{6}$$
$$0\le r\le R,\ z=e_1,\ t>0$$
$$\lambda_1\frac{\partial T(r,\ z,\ t)}{\partial z}=\lambda_2\frac{\partial T(r,\ z,\ t)}{\partial z} \tag{7}$$
$$0\le r\le R,\ z=e_1+\mathrm{e}_2,\ t>0$$

The application of Laplace and Hankel integral transforms on the time t and radius r variables [16] in this set of equations leads to the expression of the average temperature investigated on the metallic surface as a function of the applied heat flux in the Laplace domain:

$$\left\langle\theta(z=0,\ p)\right\rangle=Z(p)F(p) \tag{8}$$

$Z(p)$ being the transfer function:

$$Z(p)=\frac{r_0^2}{R^2}\frac{\beta_z}{1-h\beta_z}+\sum_{k=0}^{\infty}\frac{4r_0^2J_1(\alpha_k r_m)}{\alpha_k r_m R^2 J_0(\alpha_k R)^2}\frac{\beta_z}{1-h\beta_z}\exp\left(-\frac{\alpha_k^2 r_0^2}{4}\right) \tag{9}$$

where:

$$\beta_z=\frac{M^*_{1,1}+hM^*_{1,2}}{M^*_{2,1}+hM^*_{2,2}},\ M^*=\prod_{i=1}^{3}M_i,\ M_i=\begin{pmatrix}A_i & B_i\\ C_i & D_i\end{pmatrix} \tag{10}$$

and:

$$A_i = \cosh\left(\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2 e_i}\right),\ B_i = \frac{1}{\lambda_i\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2}} \sinh\left(\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2 e_i}\right), \tag{11}$$

$$C_i = \lambda_i\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2}\ \sinh\left(\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2 e_i}\right),\ D_i = \cosh\left(\sqrt{\frac{p}{\alpha_i} + {\alpha_k}^2 e_i}\right)$$

$$\alpha_k = \pi\left(k + \frac{1}{4}\right) - \frac{3}{8\pi\left(k + \frac{1}{4}\right)},\ \alpha_0 = 0,\ k = 1...\infty \tag{12}$$

The equivalence of $p = j\omega$ permits to compute the phase of the transfer function as:

$$\phi(j\omega) = \arctan\left(\frac{\mathrm{Im}\left(Z(j\omega)\right)}{\mathrm{Re}\left(Z(j\omega)\right)}\right) \tag{13}$$

with j imaginary unit and $\omega = 2\pi f$ the heat flux (laser) pulsation.
The heat transfer model in the sample only takes into account the heat diffusion in the three layers. To ensure the best reliability of the estimation of the thermal conductivity it is important to avoid the natural convection phenomena while heating during the measurement. This phenomenon, characterized by Rayleigh number, depends on the type of fluid, the dimensions of the container and the temperature oscillations. Several transition regions those occur in a horizontal layer of fluid for a given Rayleigh number in the function of Prandtl number are given in the literature [17]. These numbers are defined as:

$$\mathrm{Ra} = \frac{g\beta\Delta T {e_2}^3}{\upsilon\alpha_2} \text{ and } \mathrm{Pr} = \frac{\upsilon}{\alpha_2} \tag{14}$$

where g is the gravity acceleration; β is the thermal expansion coefficient; ΔT, υ, α_2, e_2 are the temperature variation, the kinematic viscosity, the thermal diffusivity and the thickness of the studied liquid. For a wide range of Prandtl number (10^{-2} to 10^4, that cover the majority of liquids) and the Rayleigh inferior to 2.10^3 the region where no motion occurs exists. The sample of studied liquid must be designed to fulfil the Ra limit. For this purpose, the two parameters ΔT and e_2 may be adjusted. The simulation using precedently described model with absorption of 50% (largely exceeding the experimental configuration) of the maximal laser power leads to the temperature oscillation around 2 K, therefore the thickness e_2 was fixed equal 500 µm in order to cover a wide spectrum of liquids, keeping Ra inferior to the mentioned limit 2.10^3.

SENSITIVITY OF THE MODEL

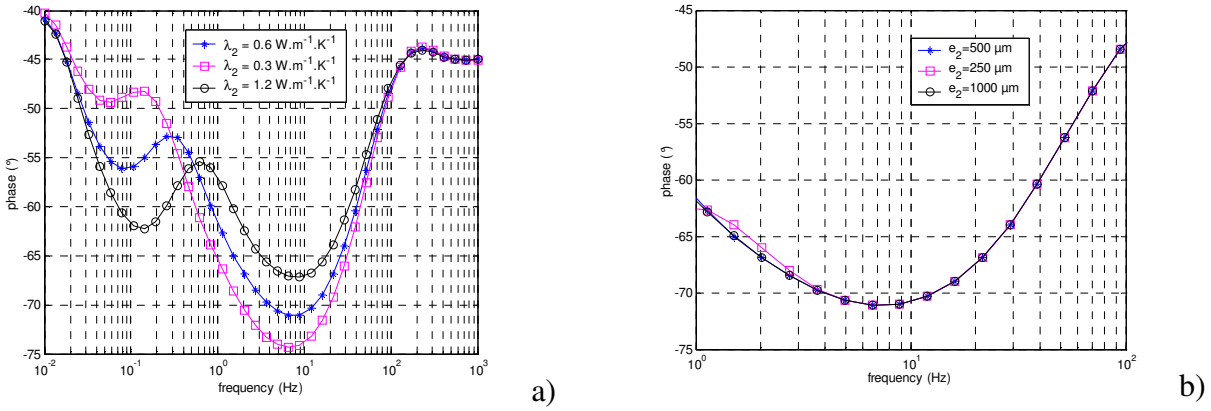
The described previously thermal model (equation 1) depends on different geometrical (the heating and the measurement radius r_0 and r_m and the thickness e_i of each layer) and thermo physical parameters (the thermal diffusivity α_i, the thermal conductivity λ_i, and the convective heat transfer coefficient h on the front and back face of the sample).
The geometrical parameters may be measured directly and are considered here as perfectly known. The properties of the steel and the glass layer were obtained by using the Hot Disk technique for the thermal conductivity and the Differential Scanning Calorimetric technique for the specific heat.

The specific heat and the density of the studied liquid are considered also as known. In the application, the literature values are used for water ($C_2 = 4180$ J.kg^{1}.K^{-1} and $\rho_2 = 1000$ kg.m^{-3}) and sunflower oil ($C_2 = 2741$ J.kg^{1}.K^{-1} and $\rho_2 = 918$ kg.m^{-3}) [18, 19]. For an unknown liquid, these parameters may be obtained by DSC experiment and volumetric measurement. The coefficient h was taken equal to 5 W.m^{-2}.K^{-1}. The simulations have shown that the model is not sensitive to this convective parameter on frequency range exploited in the application. In this way, it leads that the thermal conductivity of the liquid layer is the unique parameter to estimate.

Table 1
Known parameters used in the measurement and the analysis of model

i	1	2	3
λ_i [W.m^{-1}.K^{-1}]	24,8	-	1,1
ρ_i [kg.m^{-3}]	7784	-	2600
C_i [J.kg^{-1}.K^{-1}]	438	-	384
e_i [µm]	200	500	150
r_0 [mm]	r_m [mm]		R [mm]
5	0,5		20

In order to determine the frequency range where the measurement of phase varies with the thermal conductivity of liquid, a simulation using the parameters reported in Table 1 for solid layers and those for water as liquid (second layer) was performed. Figure 4 a) shows that the phase varies strongly in the frequency range from 10^{-2} to 10^{2} Hz. To make the experiment as rapid as possible and to fulfil the experimental conditions (frequency response band of the infrared detector) the frequency range between 1 and 50 Hz seems interesting for the measurement. The variations of the phase in this frequency range are sufficient to estimate the thermal conductivity of the liquid. Figure 4 b) represents the variation of the phase with the thickness of liquid layer. It clearly shows that over the chosen frequency range the measurement is not affected by small variations/errors of the second layer thickness. This ensures also that the third layer (glass) does not influence the measurement. Meanwhile, the thermal properties of the first (steel) layer must be perfectly known to make a reliable identification of the thermal conductivity of the second layer.



a) b)

Figure 4. Sensitivity to: the thermal conductivity of liquid a), the thickness of the liquid layer b)

RESULTS OF VALIDATION

Two series of measurements were performed: one on water filled sample and the second with sunflower oil. The Rayleigh numbers are equal to 6,56 and 0,55 and the Prandtl numbers are 5,42 and 410 for water and for oil respectively. These values were obtained using the literature data [18, 19, 20, 21, 22].
The values of Ra numbers are very small in comparison with the limit given by [17]. This allows assuming that no convective motion occurred during the experimentation. The used frequency range resulting from the sensitivity analysis is comprised between 5 and 50 *Hz* . The thermal conductivity of liquid is estimated by minimizing the quadratic gap between the theoretical and the experimental values of the phase [23]. The fits of the experimental points of phase lag measurement are presented in Figure 5.

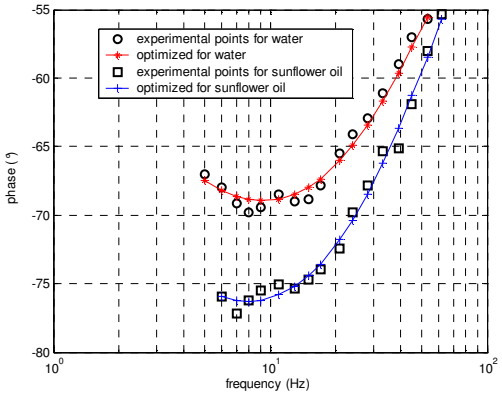


Figure 5. Optimization of the experimental points of phase lag in water and sunflower oil measurement

These fits lead to the following values of thermal conductivity: $0,61 \pm 0,02$ W.m^{-1}.K^{-1} for water and $0,22 \pm 0,02$ W.m^{-1}.K^{-1} for sunflower oil. These values are in agreement with the literature and the tests performed using the hot wire measurement. The uncertainty is lower than 5%. The obtained results prove the reliability of the used method.

CONCLUSION

An application of photo thermal radiometry to the measurement of thermal conductivity of liquids at ambient temperature was presented. The developed small sample dimensions and the low temperature oscillation ensure that the convection does not occur during the measurements and only heat conduction model for describing the experiment may be used. The measurement requires only a small quantity of liquid (~1 µl) what gives an important advantage for studies of expensive or hazardous samples.
The proposed system of measurement may be easily extended for studies at different temperatures by controlling of the temperature of the sample cell. For the liquids transparent or partially transparent in IR band the modelling of heat transfer must be completed by the radiative part.

EXPERIMENTAL INVESTIGATION OF TEMPERATURE DISTRIBUTIONS IN BULK MATERIALS

F. Weigler*, T. Hoffmann, M. Naumann, M. Peglow, E. Tsotsas
Thermal Process Engineering, Otto-von-Guericke-University Magdeburg, Universitaetsplatz 2, 39106 Magdeburg, Germany

ABSTRACT. In view of a better description of the heating behavior of bulk systems, a new experimental method which permits the measurement of temperature distributions of single particles in beds of spheres was developed. The experimental investigations are carried out with particles which are coated with thermo-chromic pigments. By change of particle temperature the pigment color changes as a result of structural phase transition. With the help of a suitable calibration the change of pigment color, which corresponds to the change of particle temperature, is correlated in a way that allows the temperature distribution in the bed to be measured by photo-optical analysis. The measuring technique enables the experimental description of temperature distributions in the disperse phase, so that the heat transfer process can be described at the single-particle level. In the present work first measurements carried out in stagnant particle systems are presented and compared with DEM (discrete element method) simulations. The DEM provides the possibility to treat the problems of mechanical movement and heat transfer between particles simultaneously, so that it is easily extendable to agitated beds.

Keywords: *heat penetration, thermal DEM, thermo-chromic pigments, particle systems*

INTRODUCTION

The thermal treatment of powdery or granular products in tray, drum or paddle equipment by contact with the hot wall, shaft or inserts of the apparatus belongs to the most common processes in chemical engineering. Mixing in rotating drums is often coupled with heating from the wall of the drum, and has often a large influence on the rate of heat transfer to the particles. To control the drying process in contact dryers one needs to determine the heating behavior of the material in the dryer. In order to evaporate the moisture, heat must be transferred from a heating surface to the static or mechanically bed of particles. The heat transfer takes place by first overcoming a thermal conduction resistance between heating surface and the bed (first particle layer) and then by overcoming a penetration resistance inside the bed. The two heat transfer resistances are connected in series.
Continuum models are traditionally used for the description of the process [1]. An example is the penetration model (PM), which approximates the heating process of the particles by means of a sequence of penetration periods and subsequent mixing periods. This means that the bed is assumed to lie motionless for a certain time, followed by a perfect mixing of the particles, which is assumed to take place instantaneously. This cycle is then repeated, starting with a further static period.

The most important limitations of the penetration model are that the link to the mechanics of motion of the granular material is missing and that quasi-homogeneous behavior is assumed. Therefore, the use of the thermal version of the Discrete Element Method (thermal

DEM) is a new and promising approach [2, 3]. By the thermal DEM the mechanical behavior (including deterministic patterns of particle motion) is directly coupled to the heat transfer and vice versa. This would be a change of paradigm for the considered class of problems, opening (due to easier scale-up and real access to the density functions of distributed particle properties) completely new opportunities for process and product engineering. In fact, mechanical DEM has attained maturity in the last decade and demonstrated many successes in the solution of problems, including mixing of granules by mechanical agitation. However, several issues concerning thermal DEM are still open, with experimental validation probably being the most important [2, 3].
Therefore, the goal of the present work is to develop an experimental setup to validate the numerical simulations of inter-particle heat transfer in stagnant and agitated beds.
To this purpose, the presumably simplest possible problem of thermal equilibration between two groups of spherical particles in a two-dimensional drum without inserts will be considered. The two particle groups are initially stratified in the drum and have different temperatures (cold and hot particles).
The experimental setup and the functional principle of thermo-chromic pigments are first described in this paper. Then, the experimental procedure and modeling by thermal DEM are discussed. Subsequently, selected experimental results (measured distributions of particle temperature) are presented and compared with the results of thermal DEM. The paper ends with a brief summary and outlook.

EXPERIMENTAL SETUP

To validate the thermal DEM simulation a novel experimental system has been developed. With this system the temperature distributions emerging in beds of particles during heat transfer processes can be measured. In the present investigation the particles were alumina spheres coated with thermo-chromic pigments. Thermo-chromic pigments are pigments that change from colored to colorless by increasing the temperature. This color change is reversible. It is the result of a structural phase transition of the pigment with temperature (see figure 1). The structural phase transition is accompanied by a change of the absorption spectrum of light. Optical thermometers are a typical, every-day application of thermo-chromic pigments.

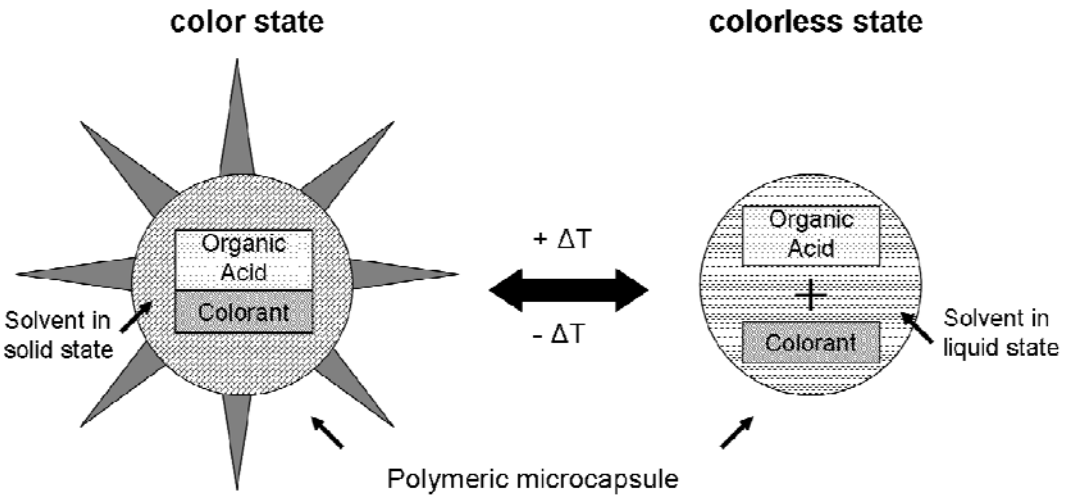

Figure 1. Functional principle of thermo-chromic pigments

The interrelation between the hue of the pigments (that means the color within the range of visible light wavelengths) and the temperature is non-linear and depends on several parameters, for example on the viewing angle and the source of light. To eliminate external influences on the intensity of the hue and to guarantee steady lighting conditions, the whole experimental setup, which consists of an acrylic glass box, is mounted on a lighting rack. Each source of light of the lighting rack consists of two fluorescent lamps. Since our goal is to investigate the heat transfer between particles, heat transfer from the particles to their surroundings should be controlled and minimized. To this purpose, the entire box is tempered to a constant temperature by means of air heated by a heating element and circulated by a radial fan with a permanent and constant flow rate. Two thermocouples and one mercury thermometer measure and control the gas temperature in the box. In the front side of the acrylic glass box an optical window is inserted, which allows to film into the box without disturbing the process. The video system that is used to record the color change of the spheres stands in front of the box. To minimize the reflection of light on the windowpane, the video system is aimed vertically at the window and at the drum, where the thermal equilibration process between the particles takes place (see figure 2).
To be consistent during the entire experimental investigation, the parameters of the used high-resolution video camera such as screen (iris), signal strengthening (gain), focus, zoom, white comparison and the distance to the drum are kept constant. In order to recognize unwanted changes in the experimental set-up, a test stripe with three basic colors (red, green and blue) is placed beside the test drum. The hue values of the test stripe must be the same in every experiment in order to ascertain the precise reproduction of the hue values of the particles. The recorded images of the color change of the particles are evaluated photo-optically by an image analysis program from Olympus called AnalySIS pro**.**
AnalySIS pro determines the hue of every single pixel from the image. The hue represents the dominant wavelength, which depends on temperature. With the help of a suitable calibration the hue can be correlated with the temperature of the particle. The calibration is the main focus for the analysis of the thermal experiments. The calibration curve provides an explicit correlation between the temperature and the hue. Though the temperature measurement is based on the RGB model (Red-Green-Blue), RGB information alone is not sufficient for an explicit correlation of hue and temperature. The latter is therefore achieved by the HSI model (Hue-Saturation-Intensity). The HIS model is based on the physiological perception of colors by the human eye. Because of the separation of intensity and color, the HSI model is often used in image processing.

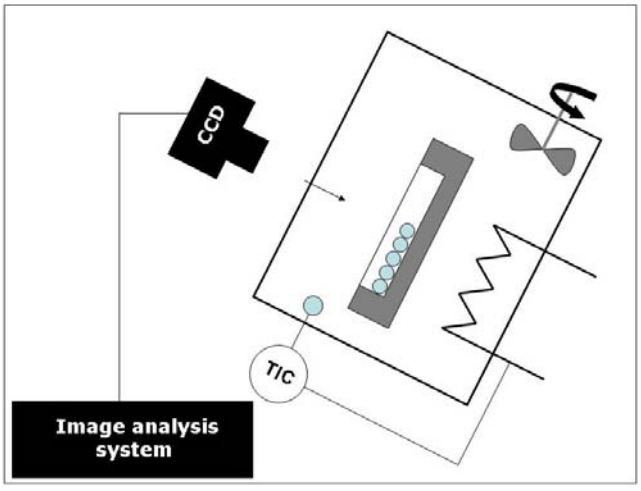

Figure 2. Scheme of the experimental setup

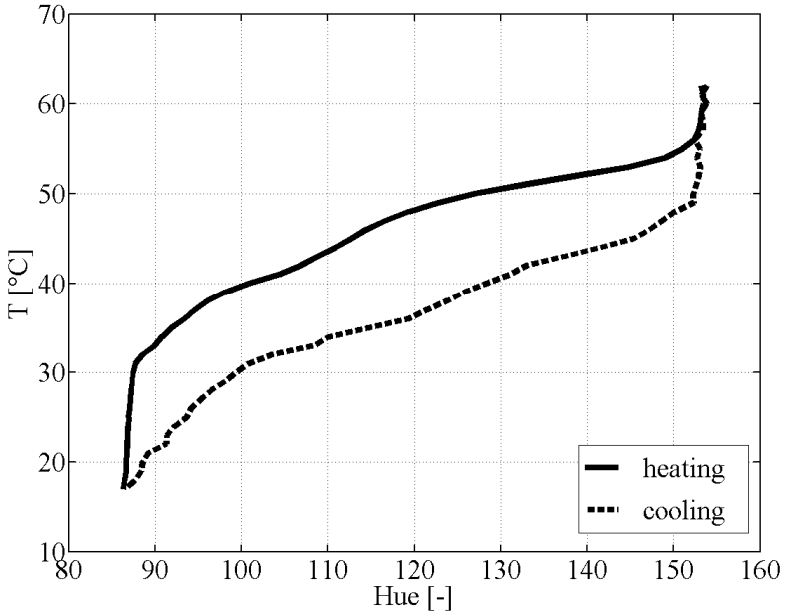

Figure 3. Calibration – correlation of the hue with the temperature of the pigment mixture (red RT38 / green GT43 / blue BT50 / orange OT55)

Calibration was conducted in-situ, by imposing selected temperatures on the acrylic glass box, the drum and the particles and measuring the respective values of the hue. The already mentioned tempering facilities were used to this purpose. This was done twice, once with incrementally increasing and a second time with incrementally decreasing temperature, in order to account for the hysteresis behavior between heating and cooling of the pigments (see figure 3). Such behavior is well known and characteristic for thermo-chromic pigments. The examined temperature measuring range goes from 18°C to 62°C.

THERMAL EXPERIMENTS

For the thermal experiments, alumina spheres with a diameter of 4 mm were coated in a fluidized bed process with a mixture of pigments (red RT38 / green GT43 / blue BT50 / orange OT55). This was done to increase the working range for the experiments, because every pigment has a different color change temperature. All experiments were carried out in a flat drum with an internal diameter of D = 0.05 m with the mentioned spherical particles (d = 4 mm). The particle density for alumina is $\rho = 2700$ kg/m^3 and the specific heat capacity is c_p = 900 J/kg K. All experiments were conducted with 70 coated alumina spheres divided in two equal fractions (35 particles each). One fraction was tempered with the help of a thermostat to 50°C and the other fraction to 25°C. Then, the two fractions were piled up successively in the insulated flat drum, resulting in a stratified arrangement with one fraction at initially 25°C and the other at initially 50°C (see figure 4). The arrangement is two-dimensional (it has a thickness of just one particle diameter in the direction parallel to the axis of the drum). Then the drum with the spheres was put in the preheated isothermal acrylic glass box and was exposed to the camera. The recording with the high-resolution camera started while putting the drum in the box. To quantify the influence of heat exchange between the particles and their surroundings (which is undesired but unavoidable) the temperature of the chamber and the material of the drum (polyurethane, polystyrene) were varied.

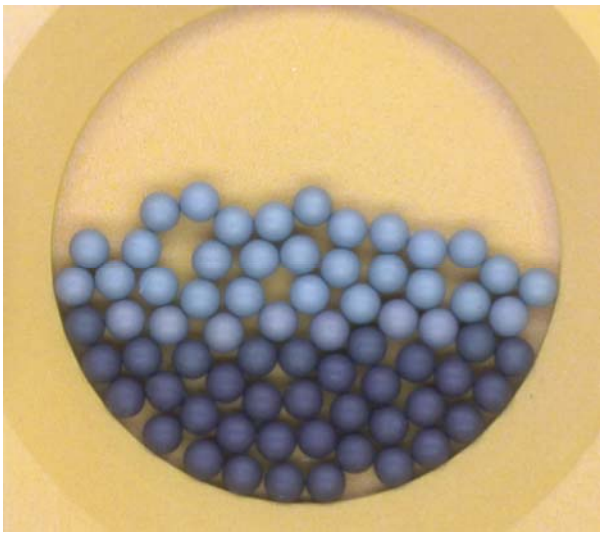

Figure 4. Coated alumina spheres of different temperature piled up in an insulated drum in a two-dimensional way

The experiment runs until equilibration of the temperature inside the bed (until all particles have reached the same, then constant temperature). The temperature of every individual particle during this thermal relaxation process can be evaluated with the help of the image analysis program. To this purpose, the temporal change of the hue was analyzed out of the recorded images. The received information about the hue of every single sphere is correlated with the temperature using the calibration curve. Because of the hysteresis behavior of the calibration curve, it is necessary to carefully distinguish between hot spheres and cold spheres. Therefore, the average bulk temperature must be determined. Spheres with a temperature higher than the average bulk temperature are assumed to cool down and spheres with a temperature lower than the average bulk temperature are assumed to heat up. With this method, the two groups of hot and cold spheres corresponding to the two branches of the calibration curve can be separated from each other. The individual temperatures obtained for each of the 70 spheres at a certain point of time define the distribution of temperature in the bed at that time.
The first thermal experiments were carried out with stagnant beds. Then, experiments with a rotating drum were also realized. The rotational speed of the drum was 12 rpm – with otherwise the same conditions as in the stagnant drum experiments. Due to the inclination of the flat drum (see figure 2), the 70 spheres stay in two-dimensional arrangement throughout the run. The analysis of the resulting images was more complicated and more time-consuming than for stagnant beds, because of the motion of spheres of different temperature. However, it is possible to derive the temperature distribution of the bed with the previously mentioned method even in the case of rotating drum.

MODELING

The penetration model traditionally used for the heating of agitated beds in contact with a hot wall [1] is not applicable to the present problem of temperature equilibration. Therefore, simulations in this work are realized with discrete methods. Specifically, the discrete element method (DEM) is employed to simulate both the thermal and the mechanical behavior of the particle system in 2D. The DEM treats the particles individually, instead of considering the bed as a continuum.
All simulations are carried out for a drum with an internal diameter of D = 0.05 m and spherical particles with d = 4 mm. The particle density and specific heat capacity of the alumina particles

are set to ρ = 2700 kg/m^3 and c_p = 900 J/kg K, respectively. Since the heat transfer between the spheres is expected to be the dominant heat transfer mechanism, the particle-to-particle heat transfer coefficient α_{pp} is the key model parameter. In the present work, α_{pp} was calculated from heat conduction in the gas gap between two spheres according to an equation developed by Schlünder [4]:

$$\alpha_{pp} = \frac{2 \cdot k_g}{d}\left[\left(1+\frac{2 \cdot l}{d}\right)\cdot \ln\left(1+\frac{d}{2 \cdot l}\right)-1\right] \qquad (1)$$

For the present materials and experimental conditions a value of $\alpha_{pp} = 93\ [W \cdot m^{-2} \cdot K^{-1}]$ is obtained from equation (1).

The equalization of temperature inside a stagnant bed was simulated in two different ways.

The first way establishes a network of heat reservoirs representing the single particles, incorporating the heat transfer mechanisms between particles, wall and gas. The alignment of the spheres (particle coordinates) is obtained directly from the experimental images and used as a contact network in a Matlab program (see figure 5) to simulate the structure of the bed and the contacts of each particle. The heat transfer in the bed is calculated by means of an enthalpy balance for each particle. Heat transfer between the spheres is assumed to be the main heat transfer mechanism, expressed by the coefficient α_{pp}. Heat transfer from the spheres to the gas by convection, as well as heat transfer from the spheres to the drum wall by radiation and conduction are combined in one further heat transfer coefficient denoted by α_{CRW}.

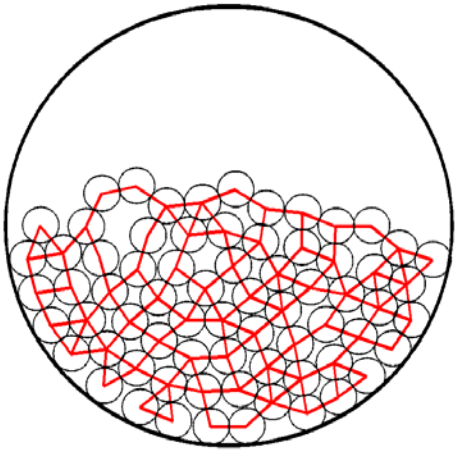

Figure 5. Network of thermal contacts / Simulation with Matlab

This coefficient must be established empirically, because it is hardly possibly to exactly compute separate heat transfer coefficients for convection between the spheres and the gas, for conduction between the spheres and the wall, and for radiation between the spheres and their entire external surroundings. Additionally, the surfaces available for each of these heat loss mechanisms can also not be defined exactly, because the spheres are exposed to the gas at their one side and simultaneously contact the rear wall of the drum, which is made of insulating material, at their other side. Therefore, the product $\alpha_{CRW} \cdot A$ is determined experimentally and incorporated in the heat balance

$$\frac{d\vartheta}{dt} = \frac{\alpha_{PP} \cdot A_{PP}}{m_P \cdot c_P} \cdot \overline{CM} \cdot \overline{\vartheta} + \frac{\alpha_{CRW} \cdot A}{m_P \cdot c_P} \cdot \left(\vartheta_g - \overline{\vartheta} \right) \tag{2}$$

Here, $\overline{CM}$ is a structural parameter called the contact matrix. In this matrix, the contact information between all spheres in the bed is saved. $\overline{\vartheta}$ is the sphere temperature vector.

Another way to compute particle temperatures is simulation with commercial DEM software. In the present work the DEM software from Itasca called PFC, which is an upgrade of the discrete element method introduced by Cundall and Strack [5], was used. In this software, the interaction of the particles is treated as a dynamic process with states of equilibrium developing whenever the internal forces are balanced. The contact forces and displacements of an assembly of particles are found by tracing the movement of individual particles. The program associates to each particle a heat reservoir and a thermal pipe to each contact. Starting with an initial temperature field, the temperature of each particle is updated. The simultaneous solution of the mechanical and the thermal problem in PFC increases the computational time by a factor of 10 in comparison to the Matlab simulation. Therefore, the Matlab simulation is used for comparison between experimental and simulation results for stagnant beds in the present work.

RESULTS

Only results with a stagnant bed will be presented here. Experimental results of this kind are plotted in figure 6 in form of cumulative temperature distributions. The two plots correspond to gas temperatures closely below and closely above the average caloric temperature of the particle system (here: 37.5°C). The average caloric temperature of the particles would be the equilibrium temperature if heat losses were not present. In presence of heat losses, the final temperature is equal to the gas temperature. It is approached from above or from below, depending on whether the average caloric temperature of the particles is larger or smaller than the gas temperature.

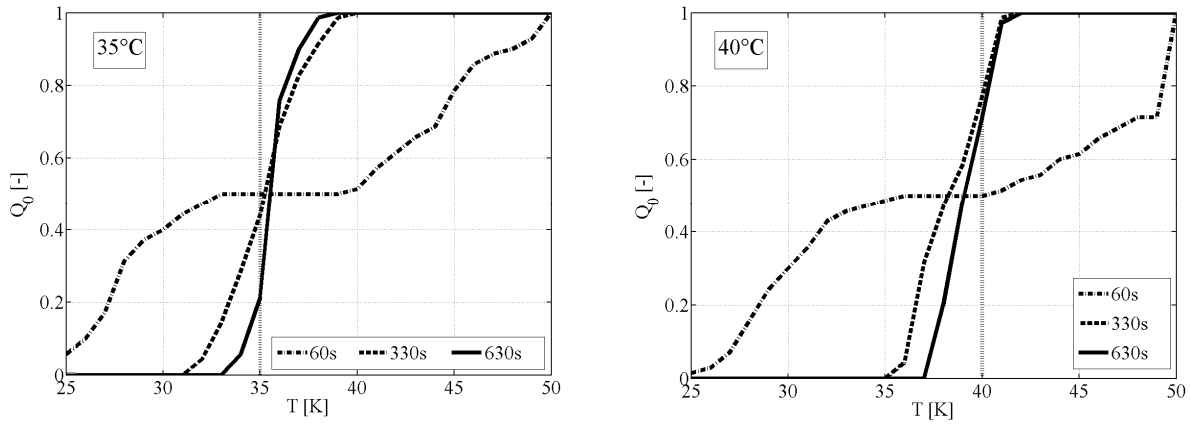

Figure 6. Measured temperature distributions in a stagnant bed, initial temperatures of spheres 25°C and 50°C, α_{PP} = 93 W·m^{-2}·K^{-1}, ϑ_g = 35°C, ϑ_g = 40°C

Because of the discrete recording of sphere temperatures, temperature distributions such as those depicted in figure 6 are available and can be compared with the results of discrete thermal simulations. Simulation results were obtained with the parameter $\alpha_{CRW} \cdot A$ fitted to a

value of $\alpha_{CRW} \cdot A = 4,0 \cdot 10^{-4} [W \cdot K^{-1}]$. Related to the surface of one sphere, this corresponds to a value of $\alpha_{CRW} = 8\ [W \cdot m^{-2} \cdot K^{-1}]$. In comparison to the heat transfer coefficient between the spheres $\alpha_{PP} = 93\ [W \cdot m^{-2} \cdot K^{-1}]$, the loss heat transfer coefficient α_{CRW} is much smaller. This confirms the assumption that – despite unavoidable heat losses – the heat transfer between the spheres is the dominant factor in the conducted experiments. Simulated temperature distributions are compared with measured temperature distributions in figure 7. This figure is typical for the good agreement that could be reached between experiment and simulation (both discrete).

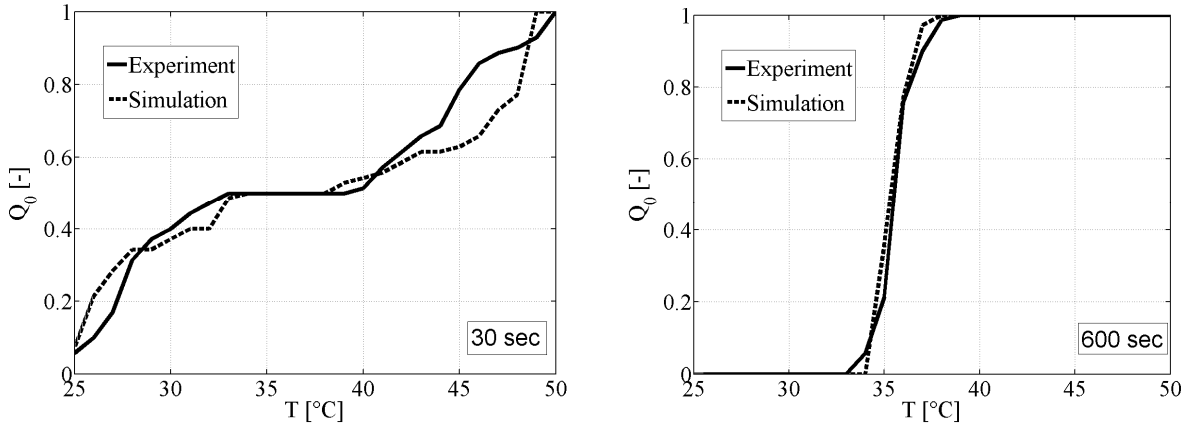

Figure 7. Measured and calculated temperature distributions in a stagnant bed, initial temperatures of beads 25°C and 50°C, α_{PP} = 93 W·m^{-2}·K^{-1}, ϑ_g = 35°C

SUMMARY

Heat transfer between the particles in flat drum has been determined for stagnant and agitated beds with a novel experimental setup by means of thermo-chromic coated alumina spheres. The experimental technique allows the determination of temperature distributions in the disperse phase, so that data for quantitative comparison with the results of discrete simulations are provided. Such comparison has been conducted with the thermal version of the Discrete Element Method (DEM). A combined heat transfer coefficient accounting for heat losses by radiation and convection had to be fitted to the experimental results, but simulations were otherwise predictive. The comparison between the simulated and measured distributions of particle temperature shows for stagnant beds a good agreement. In future the experimental investigation should be expanded to agitated beds and systems of higher particle number. The first experimental results and the results of the discrete thermal simulation indicate that we are at the beginning of the development of a powerful new tool to interpret thermal processes in contact apparatuses.

ABSTRACT. Vortex generators (VGs) have been studied extensively in the literature owing to their ability to enhance heat transfer at modest pressure drop penalties. VGs are incorporated in heat exchanger design and are more fundamentally studied on heated flat surfaces or in channel flow. The techniques used to investigate the flow phenomena associated with VGs are classically IR imaging, particle image velocimetry (PIV), five hole pressure probes and the naphthalene sublimation technique which relates mass transfer to heat transfer by evoking the heat and mass transfer analogy. Typically, the results presented using these techniques are in time-averaged form and this implies that the majority of information that relates to enhanced heat transfer, i.e. unsteady flow phenomena, is lost.

Hotwire and PIV images were obtained downstream of a delta winglet pair placed on an unheated flat surface and comparisons are made between instantaneous and time-averaged flow features using both techniques. Reasonable comparisons were obtained between the time-averaged PIV and hotwire measurements demonstrating that useful information can be gained with the use of a 1D hotwire measurement in a complex 3D flow.

Examining the instantaneous flow features reveals the true nature of the unsteadiness and also elucidates some of the more complex flow phenomena. Some of the key observations from the instantaneous PIV are that at any given time the vortices shed from each delta winglet can vary in size, strength, and location from wall. These variations cause the two counter rotating vortices to sweep across the lower wall while at the same time they move towards and away from the wall causing compression and extension of the underlying boundary layer. All of these complex unsteady flow phenomena may result in enhanced heat transfer.

Keywords: Vortex generator, Boundary layer, Delta winglet, PIV, Hotwire

INTRODUCTION

Vortex generators increase heat transfer by a number of mechanisms; (a) they enhance mixing due to the swirling motion of the vortices; (b) secondary flows are set up normal to the main streamwise flow which cause local thinning of the boundary layer, i.e. when the secondary flow is directed towards the surface and (c) the unsteady separation of the flow from the VG causes unsteady flow downstream of the VG. VGs are examined extensively in heat exchanger design due to their use in varied applications such as automotive, air conditioning, process plant and geothermal [1]. Extensive reviews of the literature are available from a number of sources [2, 3]. A brief review of some of the more important results relating to the present investigation are given here.

Gentry and Jacobi [4] examined the effects of introducing delta wing VGs into flat plate and channel flow. They used flow visualization, vortex strength measurements and naphthalene sublimation techniques to characterize the vortices. They found local heat transfer enhancements of up to 300% compared to the baseline measurements. They found that the vortex strength increased with Re, Aspect ratio and Angle of Attack (AoA) and that the vortex strength decayed downstream of the VG. Similar results have been shown by a number of investigators into enhanced heat transfer using VGs [5-8].

It has been shown that longitudinal vortices maintain their coherence over long streamwise distances and for this reason they exhibit better heat transfer characteristics over transverse vortices [4, 9]. Counter rotating vortex pairs have been shown to create the greatest heat transfer enhancement [10, 11]). These studies illustrate the benefits of using vortex generators for enhanced heat transfer applications. It is for the above reasons that in the current investigation a delta winglet pair is studied in the common-flow-down condition with an angle of attack resulting in a longitudinal vortex.

It is noted that for the most part only time-averaged results are presented in the majority of investigations available in the literature, as described above. There are few investigations that examine the instantaneous flow structures and heat transfer characteristics downstream of delta winglets. One investigation performed numerical simulations of the unsteady flow downstream of bars and baffles that acted as vortex generators [12]. In [12] they presented instantaneous isotherms, instantaneous Nusslet number and friction factors illustrating the influence of the VGs.

This investigation examines the flow downstream of a delta winglet pair using PIV and hotwire anemometry. The two main goals of the current study are: (1) gain greater insight into the underlying flow mechanisms that lead to enhanced heat transfer by examining the instantaneous PIV and hotwire results and (2) compare the time-average hotwire results to those gained using the PIV thereby allowing an estimation of the accuracy of measuring an inherently 3D flow with a 1D hotwire measurement.

EXPERIMENTAL FACILITY AND MEASUREMENT TECHNIQUES

Experimental facility

The PIV and hotwire measurements were performed in a small size wind tunnel. The wind tunnel consists of honeycomb, contraction and screen sections upstream of the test section inlet to reduce the background turbulence intensity of the flow. The test section is made from Plexiglas of internal dimension 610x406x77mm and is powered by two 12W axial fans that are placed downstream of the diffuser section. The inlet turbulence intensity of the wind tunnel at the test section entrance was measured at 0.4% using the hotwire system detailed below.

One delta winglet pair was tested in this investigation with a height of 15mm and chord length of 30mm (Figure 1a). The VG had a wall thickness of 1mm and was made from plastic. The delta winglet pair was placed on one surface of the test section wall using double sided tape and one AoA was examined in the current investigation (Figure 1) with the leading edge transverse separation between each winglet maintained at 4mm and the trailing edge separation of 30mm resulting in an AoA of 26°.

A boundary layer traverse was obtained with a single-normal hotwire probe without a VG in place and this served as a baseline measurement for boundary layer profile shape, boundary layer thickness and RMS measurements. Each boundary layer traverse consisted of 60 measurement locations away from the wall with the measurement resolution increasing closer to the wall. A number of boundary layer traverses were obtained downstream of the VG as illustrated in Figure 1b. Four spanwise locations were investigated at three different streamwise distances at the given AoA. In the results sections, the measurement location is described by the streamwise (X) and the spanwise (Z) location, e.g., the measurement in the centreline of the VG (Z0) and at the first streamwise position downstream of the VG (X30) is described as X30Z0.

The cross plane PIV measurements were obtained at the same streamwise distances downstream of the VG at 30, 70 and 110mm. In the cross plane measurements, the laser is directed in the z-plane and the camera is directed in the x-plane. The cross plane measurements are used to demonstrate the decay in vorticity downstream of the VG and also the instantaneous vortical flow patterns. PIV data were also obtained in the streamwise plane where the laser was directed in the x-plane and the camera was directed in the z-plane. These measurements are used to obtain the mean streamwise velocities.

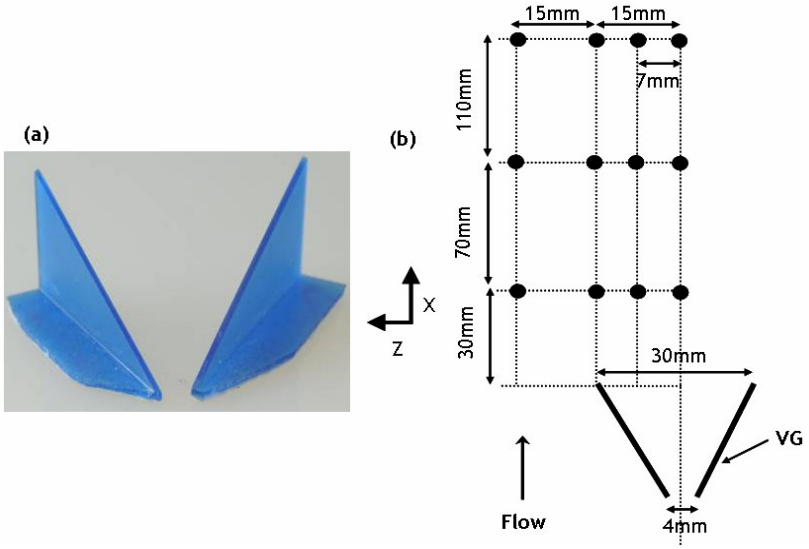

Figure 1. (a) Picture of the delta winglet pair. (b) Schematic of the VG placement and downstream measurement locations indicated by the filled circles. Measurement locations shown are for 26° AoA.

Measurement techniques

Mean and fluctuation velocities were measured using a TSI IFA300 constant temperature anemometer system. The hotwire was operated at an overheat temperature of 250°C and measurements were recorded over 13 seconds at a sampling rate of 20 KHz and were then low-pass filtered at 10KHz to remove any noise at higher frequencies. During any boundary layer traverse the temperature in the test section was maintained to within ±0.1%. The hotwire calibration was achieved by measuring the velocities in the wind tunnel with a Pitot-static probe and relating these velocities to the bridge output voltage from the IFA300 via a 5^{th} order polynomial fit. The hotwire is mounted to a Velmex slide and stepper motor which are powered by Parker ViX drives and a parker power supply. In the current investigation the smallest incremental movement was 10µm in the near-wall region.

PIV measurements were obtained using a TSI PowerView digital particle image velocimetry (DPIV) system [13]. The PIV system consisted of a 200mJ double-pulsed New Wave Nd-YAG laser with a cylindrical lens and spherical lens combination which was used to generate the laser sheet of thickness less than 1mm at the measurement plane. The camera used was TSI PowerView 4MP CCD camera having a resolution of 2048 X 2048 pixels and 12 bit greyscale. Data was obtained at a frame rate of 7Hz and a total of 40 image-pairs were captured per acquisition set. Data was acquired and processed using TSI Insight 3G software. The PIV algorithm used to process the particle images was a 2D fast Fourier transformation algorithm with 50% overlap on the interrogation spots. Spot sizes of 64 by 64 pixels initially set, going down to 32 by 32 using a recursive processing scheme [14]. Erroneous vectors were removed using a global velocity magnitude and local median filtering mechanism. Data was interpolated using a local mean interpolation scheme [15]. Seeding in the wind tunnel was implemented using a TSI six-jet atomizer generating oil particles of 1µm diameter.

RESULTS

Comparison between time-averaged PIV and hotwire measurements

Figure 2 illustrates the comparison between time-averaged velocity profiles obtained via hotwire and PIV measurements. Two profiles are shown in Figure 2, one at X30Z15 and one at X70Z15. This location (Z15) was chosen as the worst case scenario for comparing the hotwire and PIV measurements as it represented the flow downstream of the VG tip and hence should contain highly 3d flow. It can be seen from Figure 2 that the PIV and hotwire measurements are qualitatively similar and both measurements compare reasonably well.

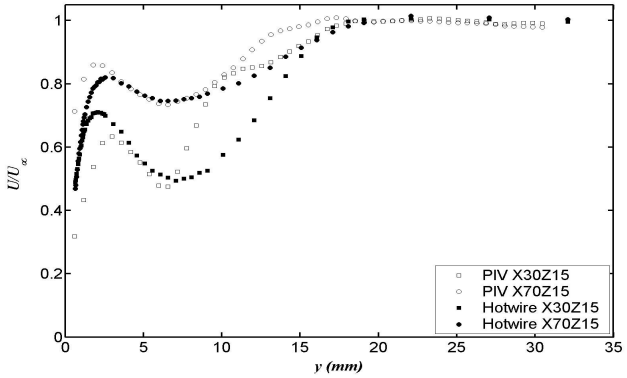

Figure 2. Comparison between time-averaged hotwire and PIV measurements of the mean velocity downstream of a delta winglet pair at 26° AoA.

It must be noted that after the PIV measurements were obtained it was discovered (while obtaining a detailed hotwire traverse across the depth of the test section) that there was a problem with the flow conditioning within the wind tunnel test section entrance. It was found that the rubber seal between the contraction and test sections was protruding slightly into the flow causing unsteadiness and disruption to the mean velocity in the centre line of the test section. This protrusion was removed for the hotwire measurements presented in this paper but the PIV measurements remain affected beyond the 35mm position shown in Figure 2. It is not believed that the flow field modified by the VG is significantly affected by the disruption to the centreline flow. Further PIV measurements will have to be performed to fully understand the effect of the protrusion on the flow field.

Hotwire measurements

It was shown in the last section that good comparison between the PIV and hotwire measurements from a single-normal hotwire probe was possible. This section will present detailed hotwire measurements downstream of the VGs. One of the main advantages of hotwire measurements over PIV measurements is the greater temporal and spatial resolution which can further elucidate some critical flow features that may lead to enhanced heat transfer.

All of the mean velocity profiles obtained with the hotwire downstream of the VG are shown in Figure 3 and the effect of placing a VG in the flow is seen immediately. In Figure 3a it is observed that in the centreline between the two delta winglets (Z0), the near-wall velocity has increased substantially (approximately doubled) over that without the VG in place. Another interesting point to observe from Figure 3a is that the boundary thickness in the VG centreline is less than that without the VG in place. This corresponds to previous studies which have demonstrated the effect of the counter rotating vortex pair on thinning the boundary layer in the centreline thereby resulting in enhanced heat transfer. Figures 3b and 3c illustrate the mean velocity profiles at Z7 and Z15, respectively. The effect of the downward flow directed towards the lower wall and the effect of the vortex core are observed in these figures. Near the wall there is an increase in the mean streamwise velocity due to the compression of

the flow owing to the downward motion of the counter rotating vortex pair. As the hotwire traverses towards the vortex core, there is a decrease in velocity. Similar phenomena are also seen in the PIV images discussed in the next section. Different trends are observed when examining Figure 3d. The near-wall velocity does not increase substantially above the no VG case and the trends also show a widening of the vortex in the spanwise direction at X=110mm. This widening effect is evident due to the fact that in the near-wall region the velocity has increased above the no VG case and as the hotwire traverses farther away from the wall a constant velocity region in encountered which is indicative of the vortex core.

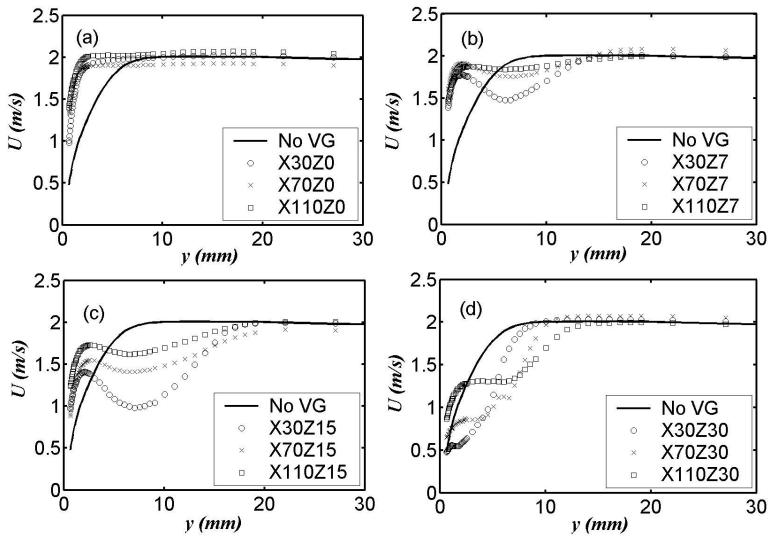

Figure 3. Time-averaged hotwire measurements of the mean velocity downstream of a delta winglet pair at 26° AoA.

Figure 4 illustrates the RMS profiles for the same conditions shown in Figure 3. In Figure 4a it can be seen that when the VG is placed in the flow there is an immediate enhancement in the unsteady flow phenomena due to the increase in peak RMS over the no VG case. Figure 4a also illustrates that a peak develops in the RMS close to the wall farther downstream. This peak RMS value and its proximity to the wall (Figure 4a) along with the increase in near-wall velocity (Figure 3a) aids in explaining the enhanced heat transfer measured in this region by other investigators. In Figure 4a the peak RMS increased with downstream distance from the VG. In Figures 4b and 4c, as the hotwire moves well into the vortex enhanced flow, it can be seen that the peak RMS increases significantly over the no VG and Z0 cases. The peak RMS values have now moved farther away from the wall and occupy a much broader region of the flow. It is noted that near the wall in Figure 4b and 4c the RMS values are reasonably low but higher than the peak values shown in Figure 4a. In Figures 4b and 4c the trend of increasing RMS values downstream of the VG (as shown in Figure 4a) has reversed where the streamwise location nearest to the VG now has the highest peak RMS value. A change in the flow structure is observed as the hotwire moves to the Z30 location (Figure 4d). In Figure 4d it can be seen that at X30Z0 the vortex has not spread to the Z30 location and only causes a slight change to the flow at y~6mm where a small peak is observed.

Figure 5 illustrates the development of the boundary layer thickness downstream of the VG at each transverse location estimated from the hotwire profiles. These measurements again corroborate other studies that demonstrated in the centreline of the VG (Z0) there is a thinning of the boundary layer while in the vortex enhanced flow there is a thickening of the boundary layer at Z7 and Z15.

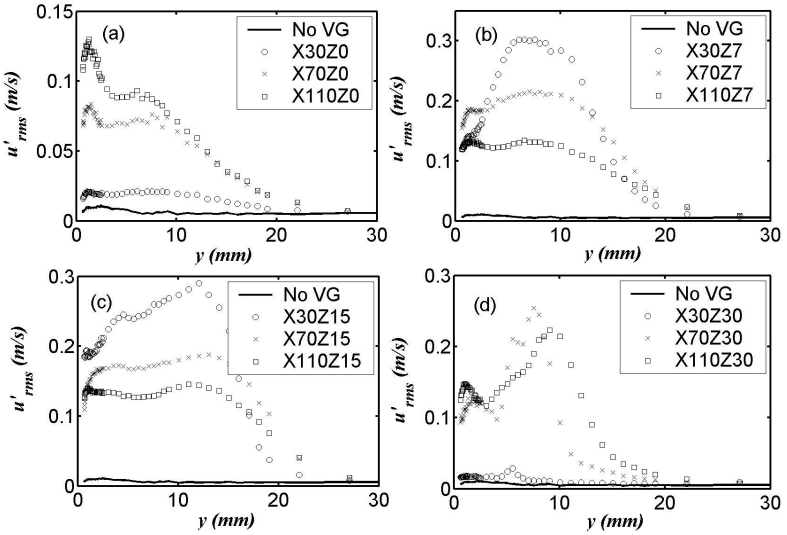

Figure 4. Time-averaged hotwire measurements of the RMS velocity downstream of a delta winglet pair at 26° AoA.

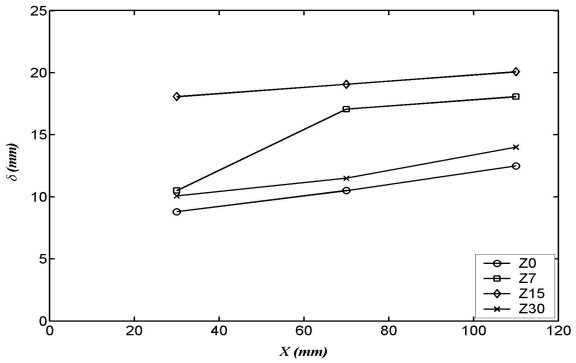

Figure 5. Boundary layer thickness (δ) development downstream of the VG.

Instantaneous PIV and hotwire measurements

Figures 6a and 6b are instantaneous cross plane PIV images of the flow 30mm downstream of the VG. The colour bar represents the vorticity and the vectors show the direction of the flow. Figure 6c is the time-averaged image of the vortex pair. There is a marked difference between the instantaneous images of the flow which seem almost chaotic compared to the time-averaged view showing a nicely formed counter rotating vortex pair. In Figure 6c it can be seen that the VGs significantly disrupt the flow and increase the boundary layer thickness from 8mm (no VG case) to 20mm in Figure 6c. To the right hand side of Figure 6c are two fluctuating velocity traces from the hotwire. In the near-wall region the fluctuation levels are significant over both the positive and negative range. As the edge of the boundary layer is reached it can be seen that the mean fluctuating velocities are reduced considerably; however, large negative spikes in the fluctuating velocity are observed (at t~0.4s).

Figures 7a and 7b are instantaneous PIV images of the flow 70mm downstream of the VG. Figure 7c is the time-averaged PIV image. Comparing Figure 6c and 7c it is clear that the peak vorticity levels are reduced with downstream distance and also the size of the vortices has increased and they have spread farther apart. This effect was also observed in the hotwire measurements (Figures 3b and 3c) where the velocity profiles flattened with downstream distance.

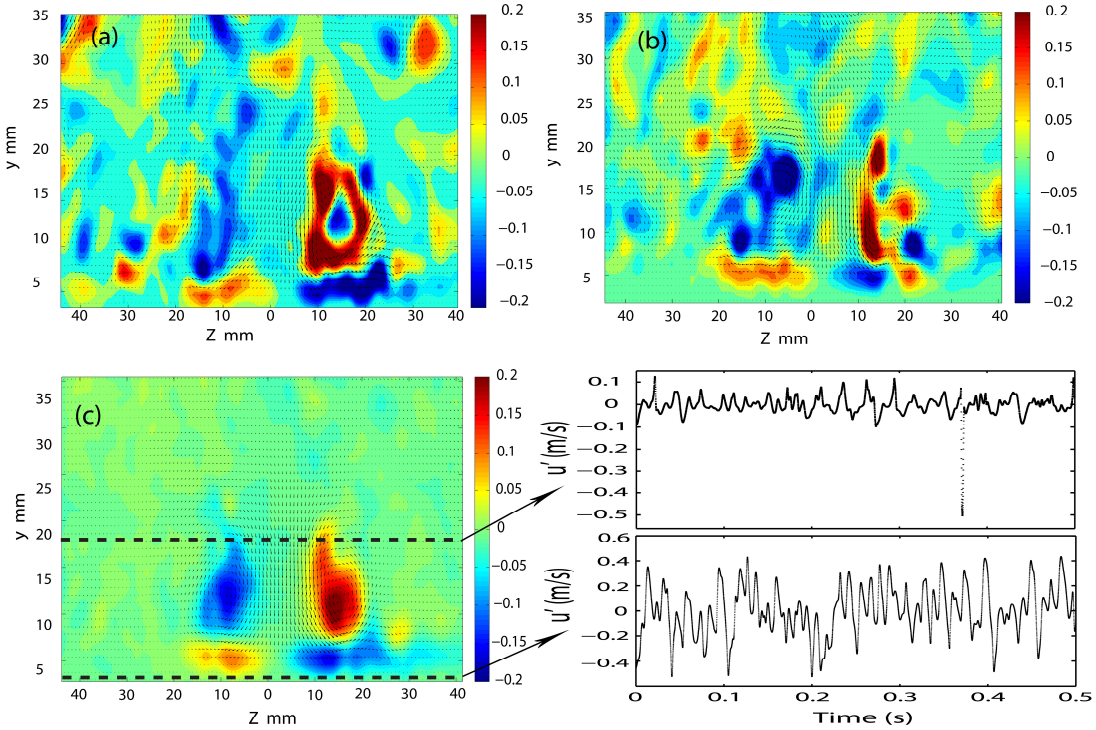

Figure 6. (a) and (b) are instantaneous PIV images of the vorticity generated 30mm downstream of the delta winglet pair at 26° AoA and (c) is the time-averaged image of the flow and on the right hand side of (c) are instantaneous hotwire traces of the flow at y ~ 0.6mm and 19mm.

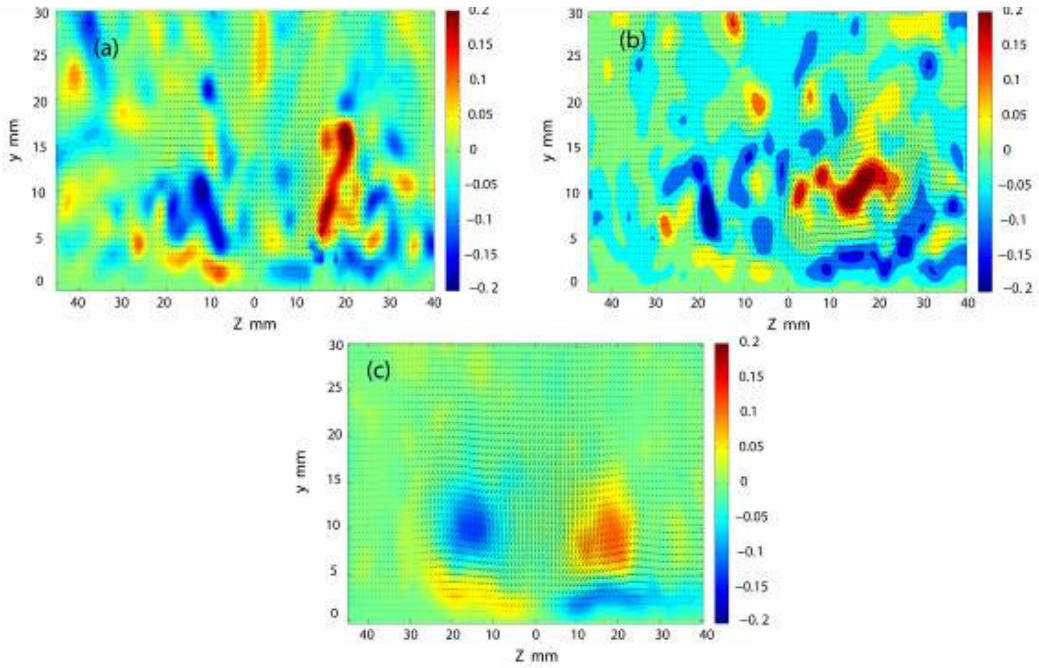

Figure 7. (a) and (b) are instantaneous PIV images of the vorticity generated 70mm downstream of the delta winglet pair at 26° AoA and (c) is the time-averaged image of the flow.

Figures 8a and 8b are the instantaneous PIV images of the flow 110mm downstream of the VG. Figure 8c is the time-averaged PIV image. It is again clear that farther downstream of the VG the peak vorticity decreases and the size of each vortex increases and spreads away from the centreline.

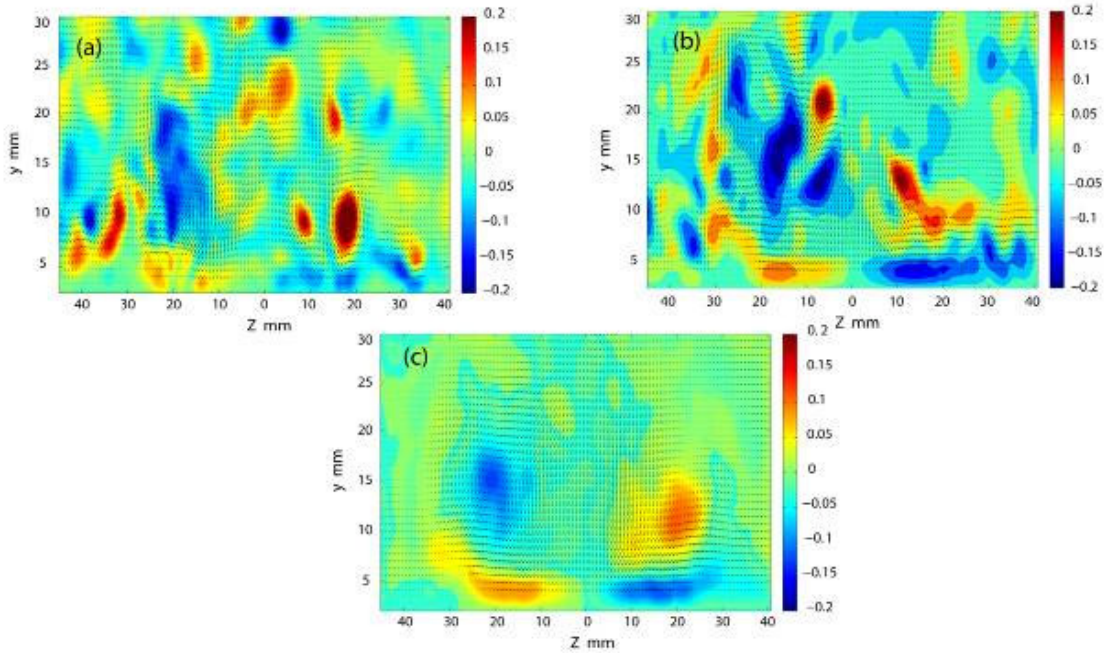

Figure 8 (a) and (b) are instantaneous PIV images of the vorticity generated 110mm downstream of the delta winglet pair at 26° AoA and (c) is the time-averaged image of the flow.

CONCLUSIONS

Hotwire and PIV measurements were taken downstream of a delta winglet pair at 26° angle of attack on an unheated flat surface within a wind tunnel test section. Time-averaged PIV and hotwire measurements were compared in 3D flow to determine the applicability of using a single normal (1D) hotwire probe to obtain data in a 3D flow field. Comparison between mean velocity profiles using both of these techniques was promising allowing interesting conclusions to be drawn from the hotwire measurements downstream of the VGs. The hotwire measurements demonstrated the extent to which the introduction of a VG disrupts an otherwise laminar flow field. The hotwire measurements demonstrated the regions of the flow most affected by the VG and allowed for detailed insight into the change in flow structure via RMS profiles and instantaneous fluctuating velocity traces.

Instantaneous PIV images of the flow were examined and compared to the time-averaged image of a nicely formed counter rotating vortex pair. It was shown that the instantaneous flow structures are complex and highly random. This instantaneous view of the flow field helps to further elucidate the complex flow features that lead to enhanced heat transfer with the inclusion of VGs in an otherwise uninterrupted laminar flow. The time-averaged PIV data also demonstrated the decrease in vortex strength (decrease in vorticity) and the enlarging vortex flow downstream of the delta winglet. These results also compared well with the time-averaged hotwire measurements which show qualitatively similar flow features.

ACKNOWLEDGEMENTS

Bell Labs Ireland would like to thank the Irish Development Agency (IDA) for their continued financial support. The authors would like to thank Liam McGarry and John Mullins for their technical assistance during the measurement phase and TSI Incorporated for supplying the PIV equipment.

HEAT FLUX EFFECTS ON FALLING FILM EVAPORATION INSIDE A VERTICAL TUBE

Th. Storch, Ch. Philipp, A. Doeg, U. Gross*
Institute of Thermal Engineering, Technische Universität Bergakademie Freiberg
D-09596 Freiberg, Germany

ABSTRACT. Falling film evaporation has widely been investigated in the past. This has been done for pure liquids and mixtures covering wide ranges of liquid Re and Pr numbers, various geometries, cocurrent and countercurrent vapor flow and stagnant, and finally at heating conditions yielding nucleate boiling or not. Nevertheless, for Re < 100 and conditions without bubble formation in the superheated liquid film, only a few references are published. Therefore the heat-flux effect has been investigated while measuring the evaporation heat transfer coefficient inside a vertical tube at zero shear stress. Results for isopropanol are presented in the article where influences of Re, Pr and Ka numbers on heat transfer are discussed, correlated and compared with the literature.

Keywords: *Falling film evaporation, Heat flux, Heat transfer, Vertical tube, Wave factor*

INTRODUCTION

Falling film evaporation and condensation inside vertical tubes is found in industrial applications like heat exchangers and chemical process columns where heat transfer is always affected by the vapor-side shear stress. This acts cocurrent or countercurrent to the liquid film depending on the vapor flow direction. The open literature provides lots of publications about heat transfer measurements, both for evaporation and condensation, and also studies of the hydrodynamics of falling liquid films. For this see, e.g., [1] regarding falling film evaporation, [2] for condensation, and [3] for the hydrodynamics.

Film structure and heat transfer results are found to depend on the wall-surface geometry which may be concave (with the film flow at the inner surface of a tube), flat or convex (film flow at the outside surface, which possibly may be part of an annular flow passage).

The present authors performed extended reflux-condensation heat transfer measurements inside a vertical tube with water, ethanol, and isopropanol in the countercurrent flow situation with the focus directed to shear stress effects on heat transfer, see [4], [5] and [2]. The excellent reproducibility (± 1 % for water, ± 0.5 % for isopropanol) allows extrapolation of the measured data to zero shear stress. The resulting Nusselt number, see Fig. 1, has been referred to Nusselt's solution [6] and F_{wave} has been obtained as the enhancement factor, see Fig. 2. The condensation heat transfer data have been correlated in the range of laminar-wavy film flow, see [7] and [8], evaluated from experiments with water, ethanol and isopropanol. This was done for three sub-ranges corresponding to wave characteristics as obtained from visual observations (for definitions, see equations (4) - (10) below):

$$F_{wave} = 1.028 \qquad (Re\,Ka^{0.09} < 0.8) \qquad (1)$$

$$F_{wave} = 1.096\ Re^{0.141}\ Ka^{0.0126} \qquad (0.8 \le Re\,Ka^{0.09} < 4.2) \qquad (2)$$

$$F_{wave} = 1.270\ Re^{0.040}\ Ka^{0.0036} \qquad (4.2 \le Re\,Ka^{0.09} < 7.3) \qquad (3)$$

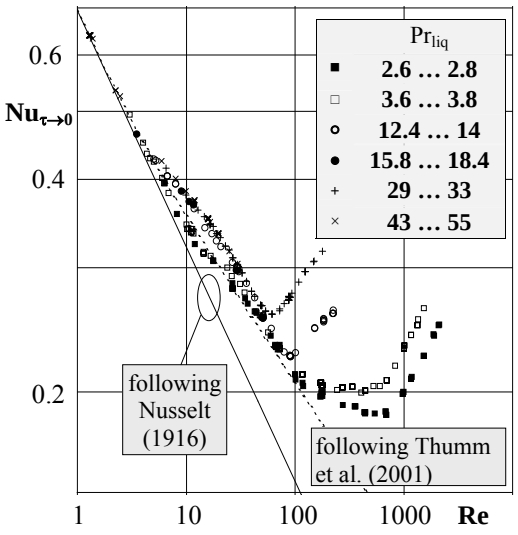

Figure 1. Condensation heat transfer for the limiting case of zero shear stress

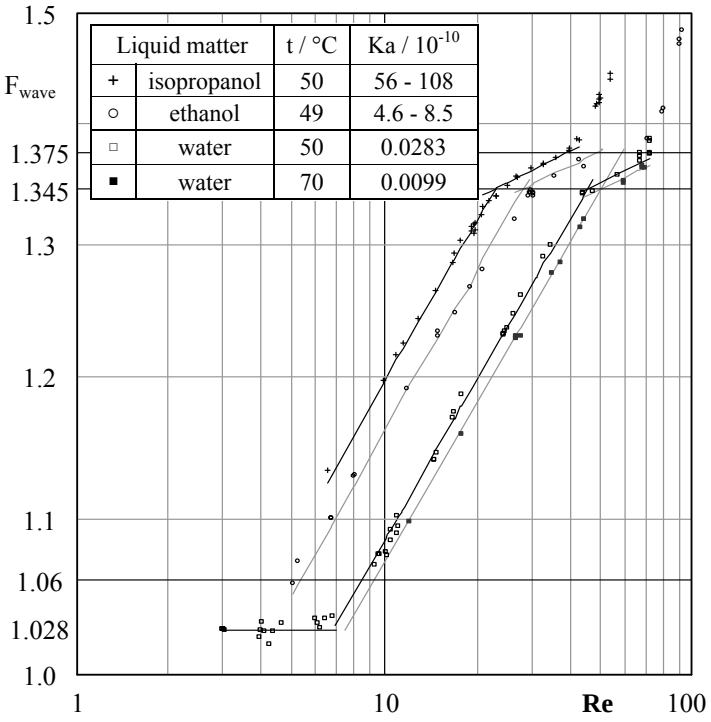

Figure 2. Wave factor vs. Re number (condensation heat transfer data)

Based on additional visual observations of surface waves, the effective wave frequency as the leading effect on heat transfer enhancement has been evaluated from slow motion videos, see [9]. Various characteristic ranges have been obtained from both studies with clear criteria for the transition from the range of occasional small waves with a limited heat transfer enhancement of about 2.8 %, equation (1), to two-dimensional waves with low effective wave frequency, equation (2), and finally three-dimensional waves with increased effective wave frequency, equation (3), bringing enhancement factors up to 34.5 % and 37.5 %, respectively.

EXPERIMENTS

Test plant

The falling-film evaporation experiments have been carried out after some modifications of the test facility. These enable both cocurrent and countercurrent vapor flow, and the limiting case of zero shear stress can now be established by means of a special control system.

The experimental plant (Fig. 3) consists of a vertical brass tube with a total length and inner diameter of 4.2 m and 28 mm, respectively. Three cycles are established, one for the liquid and two for vapor, which can be operated independent from each other. Liquid isopropanol is pumped at a constant temperature to the top of the tube where it penetrates a porous sintered steel section. A uniform liquid film is created which flows downward at the inner wall surface with a total hydrodynamic entrance length of about 1580 mm. The uppermost part of the tube is surrounded by

a water jacket for heating where the liquid film is partially vaporized. The heating water can be fed into three different inlets of the evaporation section, permitting three different lengths of the heating zone (378, 828, 1628 mm). The measuring level of local heat transfer coefficients is located in the middle of the third heated section. The present experiments have been done with the thermal entrance length of 740 mm (mainly) and 1540 mm. Vapor is created in the evaporation section and it can be forced to flow upwards, i.e. countercurrent to the liquid film (vapor cycle I), and / or downwards, cocurrent to the liquid film (vapor cycle II). This is managed by the respective operation of two condensers. The condensate is finally brought together with the excess liquid coming from the separation device at the bottom of the tube.

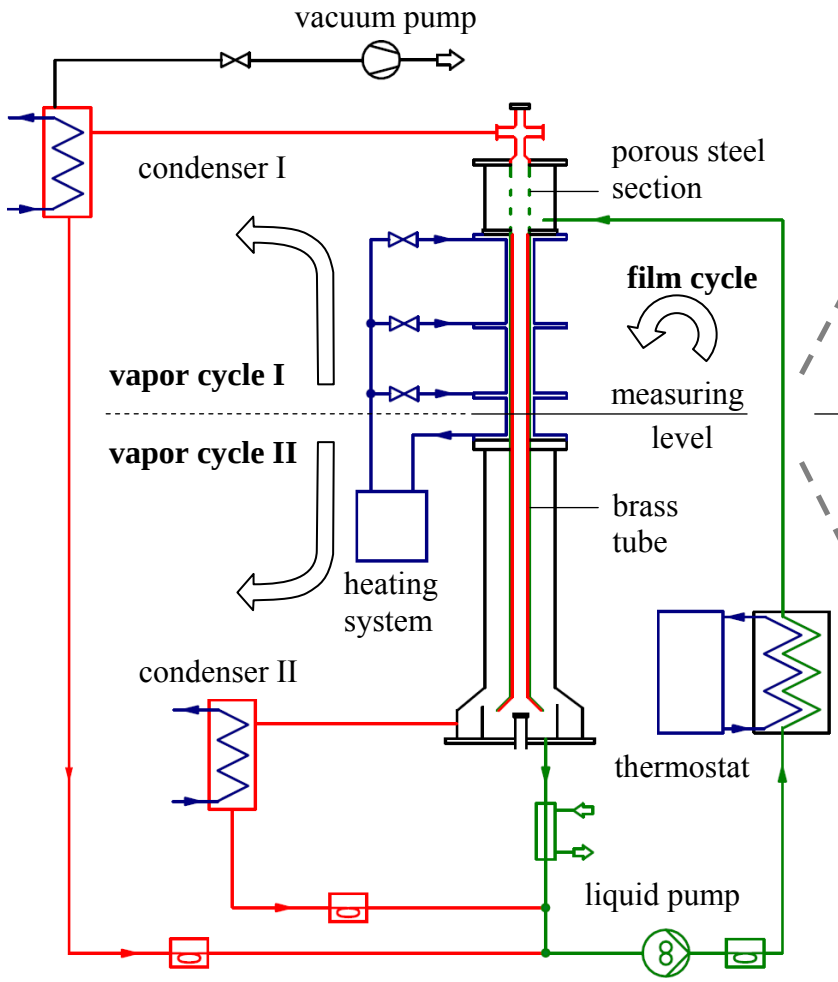

Figure 3. Schematic drawing of the test plant

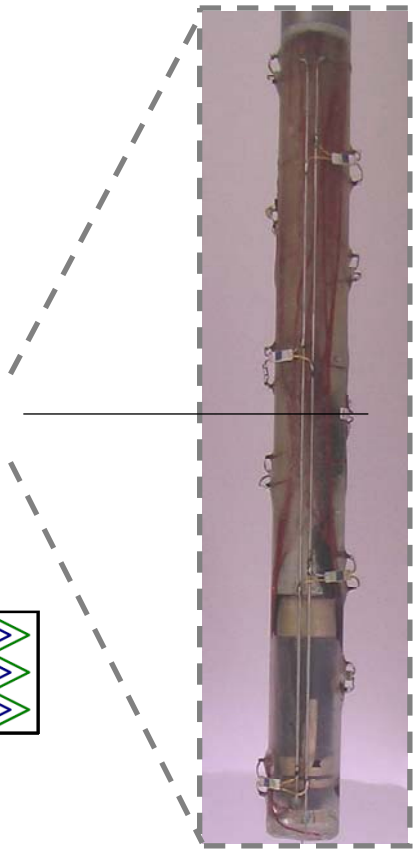

Figure 4. Measuring probe

Using a very fine condenser setting the ratio between the two vapor flow rates (upward and downward) can be controlled in a specific way for shifting the level of zero velocity (vapor) exactly to the heat transfer measuring level. This vapor flow condition is comparable to experiments outside a tube where the vapor volume is big enough to be considered at rest.

For identification of the zero-velocity point a special measuring probe has been designed, installed and tested inside the tube, see Fig. 4. It consists of 8 micro resistance thermometers (PT 1000) mounted at equal distances of 20 mm and situated along the tube axis being centered in the measuring level. These resistance thermometers are self heated, and they are cooled by the vapor flow, see [8]. The resulting temperature distribution along the tube axis directly corresponds to the vapor velocity and the location of maximum temperature is obtained at the zero-velocity level. By measuring this temperature distribution the condenser settings were aligned until the vapor stagnation zone is situated in the measuring level.

The particular mass flow rates were measured after liquification by means of Coriolis flow meters with an accuracy of about ± 0.15% on the measured value. Before entering the porous steel section the liquid temperature is controlled by a thermostat.

RESULTS AND DISCUSSION

Evaluation of data

The film Re number in the measuring level has been evaluated from the liquid mass flow rate corrected for the liquid evaporated above the measuring level.

$$\mathrm{Re}_{\mathrm{film}} = \dot{m}_{\mathrm{liq}} / (\pi\, d_{\mathrm{inside}}\, \mu_{\mathrm{liq}}) \qquad (4)$$

Measured heat transfer coefficients are expressed as the Nu number (accuracy ± 5.04%)

$$\mathrm{Nu} = \frac{h\,(\nu_{\mathrm{liq}}^2 / g)^{1/3}}{\lambda_{\mathrm{liq}}} \quad \text{with} \quad h = \dot{q}_{\mathrm{wall,inside}} / \Delta T_{\mathrm{film}} \qquad (5), (6)$$

The heat transfer coefficients (condensation and evaporation) typically exceed those predicted by Nusselt's theory by a certain amount due to wave formation and turbulence. The improvement in the range of laminar-wavy film flow is usually expressed by the wave factor F_{wave} relating the measured heat transfer coefficients to those predicted by Nusselts's theory [6]:

$$F_{\mathrm{wave}} = \frac{\mathrm{Nu}_{\mathrm{exp.}}}{\mathrm{Nu}_{\mathrm{laminar,Nusselt\,[6]}}} \qquad (7)$$

Further the Pr and Ka numbers are evaluated with the temperature-sensitive liquid properties due to

$$\mathrm{Pr}_{\mathrm{liq}} = \frac{c_{\mathrm{p,liq}}\, \mu_{\mathrm{liq}}}{\lambda_{\mathrm{liq}}} \text{ and } \mathrm{Ka} = \frac{\mu_{\mathrm{liq}}^4\, \rho_{\mathrm{liq}}}{\sigma_{\mathrm{liq}}^3\, g} \qquad (8), (9)$$

The liquid properties are taken at a reference temperature

$$T_{\mathrm{ref}} = T_{\mathrm{wall,inside}} - f_{\mathrm{ref}}\,(T_{\mathrm{wall,inside}} - T_{\mathrm{vap}}) \qquad (10)$$

with f_{ref} = 0.25 for the viscosities and f_{ref} = 0.5 for all other. As exception for $\mathrm{Pr}_{\mathrm{liq,\ freesurface}}$ the properties are taken at vapor temperature with f_{ref} = 1. Extended experiments have been carried out at zero-velocity conditions. Local heat transfer coefficients have been measured for falling film evaporation of isopropanol covering film Reynolds numbers up to 100, inner wall heat flux up to 12,500 Wm^{-2}, and vapor temperatures ranging from 8.5 °C to 36 °C.

Reynolds number effects

The results are plotted in Fig. 5 in terms of F_{wave} versus Re number. Various heat-flux classes ranging from 2,000 ± 500 Wm^{-2} to 12,500 ± 500 Wm^{-2} are represented by a variety of symbols (there is one exception for 6,550 Wm^{-2} with only ± 150 Wm^{-2} as the interval). In general, the wave factor F_{wave} is found to increase along with the Re number. This is sketched in Fig. 5 by the yellow trend line interconnecting data points at 6,550 Wm^{-2} and t_{vap} = 36 °C.
Five characteristic Re number ranges are found with limits as indicated in Fig. 5 by vertical yellow lines:

(a) Re < 2.5: F_{wave} is nearly constant (obtained for heat fluxes 7.500 - 9.500 Wm^{-2});

(b) 2.5 < Re < 4: The wave factor starts to rise moderately;

(c) 4 < Re < 25: The increase becomes stronger …

(d) 25 < Re < 70: … and weaker again …

(e) Re > 70: … and finally a re-intensification is obtained with a significantly stronger slope of the yellow curve.

The various Re number ranges correspond to respective ranges for the wavy-film flow characteristics: Only occasional, so-called "very small" and first small waves (both two-dimensional circled) are found in (a) as reported in Gross et al. [7]. Range (b) represents transition to two-dimensional waves with rising mightiness, (c), characterized by increasing wave frequency and heat transfer enhancement, whereby a fluid transition from two to two-dimensional-inclined and further on to three dimensional wave shape is found. Range (d) with fully three-dimensional waves brings first indications for the transition to local turbulence with further increased frequency showing, however, only moderate additional enhancement of heat transfer which finally is further increased at about Re > 40 with the transition to developed turbulence in range (e).

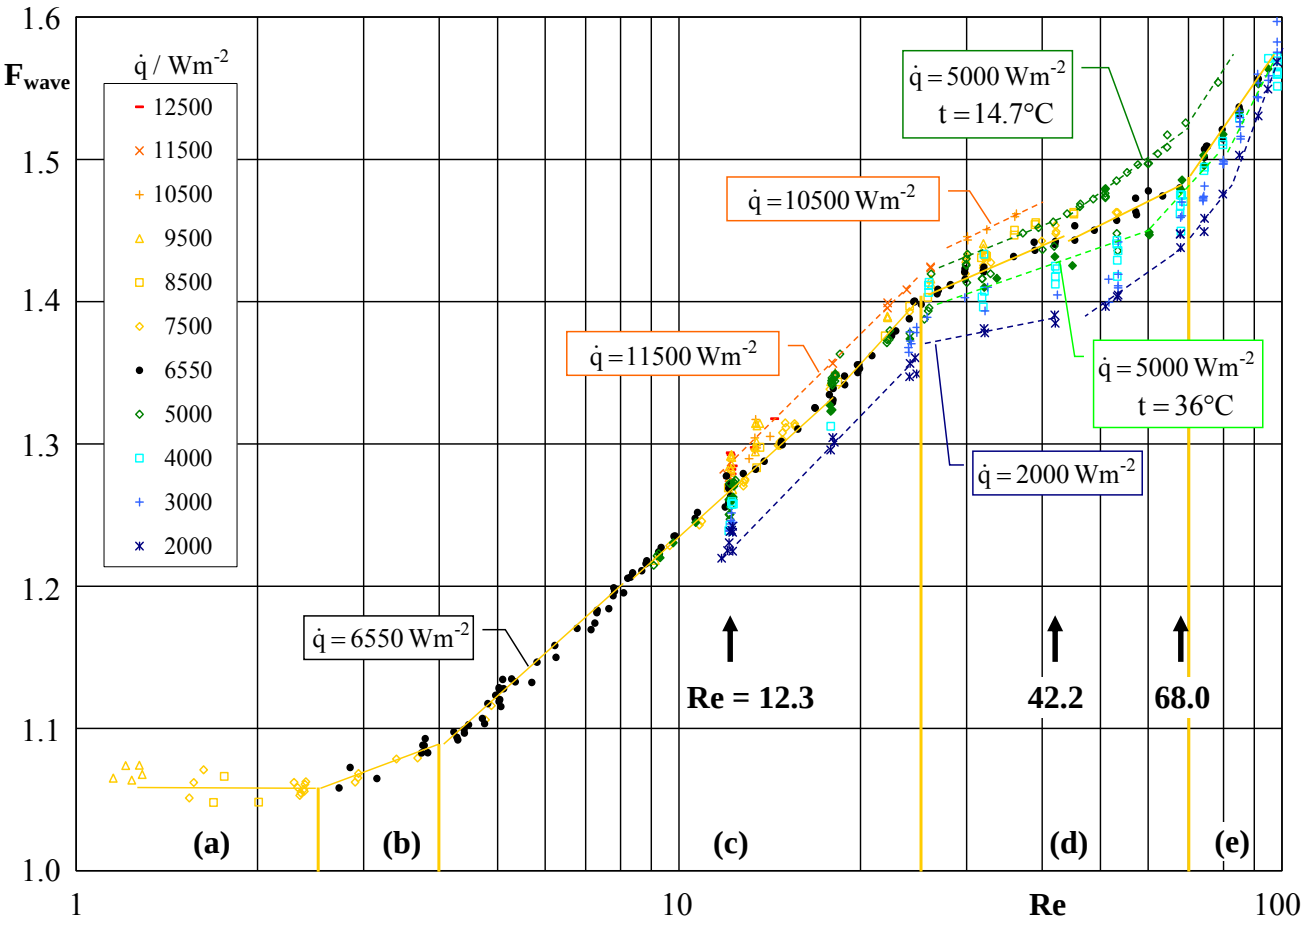

Figure 5. Wave factor vs. Re number (evaporation heat transfer data)

This general Re number effect on F_{wave} is found to be superposed by a certain influence of the wall heat flux. This is clearly seen in Fig. 5 for range (c) showing some increase of F_{wave} when the heat flux is raised from 2,000 Wm^{-2} to 11,500 Wm^{-2}. This influence seems to by even stronger in range (d), i.e. in presence of developing turbulence. Here an additional temperature effect becomes visible showing a decrease of F_{wave} when the temperature is raised from 14.7 °C to 36 °C (as measured for 5,000 Wm^{-2}). This strange behavior asks for analysis and clarification.

Heat flux and temperature effects

Three different Re numbers have been selected. They represent the ranges of two-dimensional waves (Re = 12.3), the begin of transition from three-dimensional waves to local turbulence (Re = 42.2), and finally transition to developed turbulence (Re = 68.0).

The Nu number versus heat flux plot, Fig. 6, shows characteristic rising curves for each of the selected Re numbers with a weak superposed vapor-temperature effect as already seen in Fig. 5. Both the temperature effect and the heat flux effect (i.e. temperature-difference effect) are caused by respective thermophysical property variations in the evaporating liquid film.

A vapor temperature decrease results in an increase of the Kapitza number caused by the combined effects of surface tension, liquid density and viscosity variations. An intensification of the wave activity is observed, see Gross et al. [7], and subsequently the Nusselt number is forced to rise.

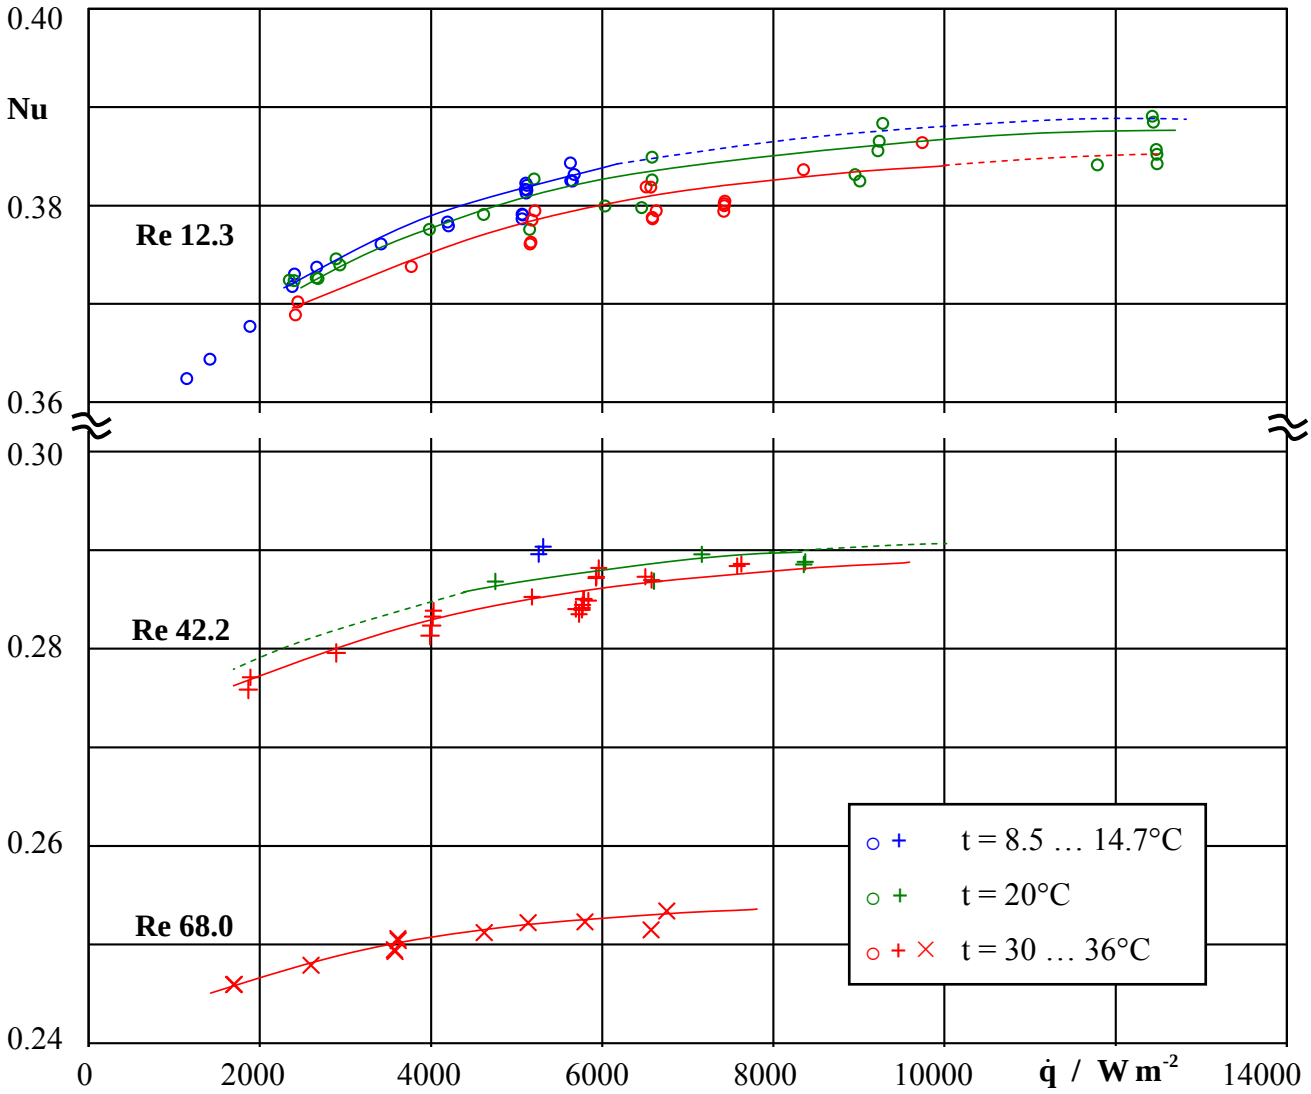

Figure 6. Nu number vs. heat flux

Increasing heat flux at a constant vapor temperature brings proportionally increasing temperature differences across the evaporating liquid film. The latter one becomes increasingly superheated next to the wall surface. The following effects have to been taken into account:

- Superheated liquid is in a metastable thermodynamic state with the latent chance for the formation of vapor bubbles. If the excess temperature is large enough, transition to nucleate boiling is obtained with strongly increased heat transfer coefficients on one side and an increasing danger of dry-patch formation on the other. These phenomena are outside the scope of the present investigation which is pure related to evaporation from the falling film surface.

- Evaporating films show characteristic temperature profiles with the gradient orthogonal to the wall surface and respective variations of the temperature-dependent thermophysical properties. The heat transfer experiments have been evaluated by taking mean values of the properties, equation (10), ignoring their variations across the liquid film. The liquid viscosity as the most sensitive property exhibits increasingly big differences between the wall surface (where it is low) and the vapor-side surface (where it is large) when the heat flux is being raised.

This phenomenon is not generally new. Heat flux effects on single-phase convection heat transfer in tubes has already been studied by Sieder and Tate [10] who introduced $(\mu_{liq} / \mu_{liq,\ wall})^{0.14}$. This concept has been modified by M.A. Mikheev and by V.V. Yakovlev in the 1950's for turbulent flow situations, and based on their suggestion Hufschmidt et al. [11] found $(Pr_{liq} / Pr_{liq\ ,wall})^{0.11}$ as an optimized correction term which finally is suggested in the VDI Wärmeatlas [12] for both laminar and turbulent internal convection. This concept will now be applied to consideration of heat flux effects on falling film evaporation heat transfer.

Correlation

All experimental heat transfer data, in terms of F_{wave} , have been correlated with Re and Ka numbers using the following power law equation:

$$F_{wave} = C\ Re^{a}\ Ka^{b} \left(\frac{Pr_{liq,\ freesurface}}{Pr_{liq,wall}} \right)^{0.11} \qquad (11)$$

This has been done separately for the ranges (b) to (d), see table 1. In (a) the wave factor has been obtained to be constant at about $F_{wave} = 1.06$. For the fully turbulent liquid film in range (e), the enhancement factor concept based on Nusselt's solution looses its sense.

Table 1
Results of data correlation following equation (11)

Range	Re number range	Constant	Re number exponent a	Ka number exponent b
(b)	2.5 < Re < 4	1.040	0.0467	0.0021
(c)	4 < Re < 25	1.096	0.1450	0.0126
(d)	25 < Re < 70	1.217	0.0593	0.0036

The strongest Re and Ka number effects are clearly found in range (c), i.e. for the developed two-dimensional wavy film flow situation with continuous transition to two-dimensional-inclined and further to three dimensional wave shape.

The remaining deviations between correlated and experimental data are plotted in Figs. 7 and 8 versus Re and Ka number respectively. The correlation proves to be extremely good with deviations typically within ± 3%. This is, of course, due to the limited width of the data set regarding Re number and also Ka number ranges. It is not the intension of this article to provide correlations for design engineers. This will be done in future after completing the data base by measurements with further liquids like ethanol, water and others. The basic intension of this presentation is a

comparison of the characteristics in the various Re number ranges, and also a comparison with the earlier condensation results as reported in equations (1) to (3).

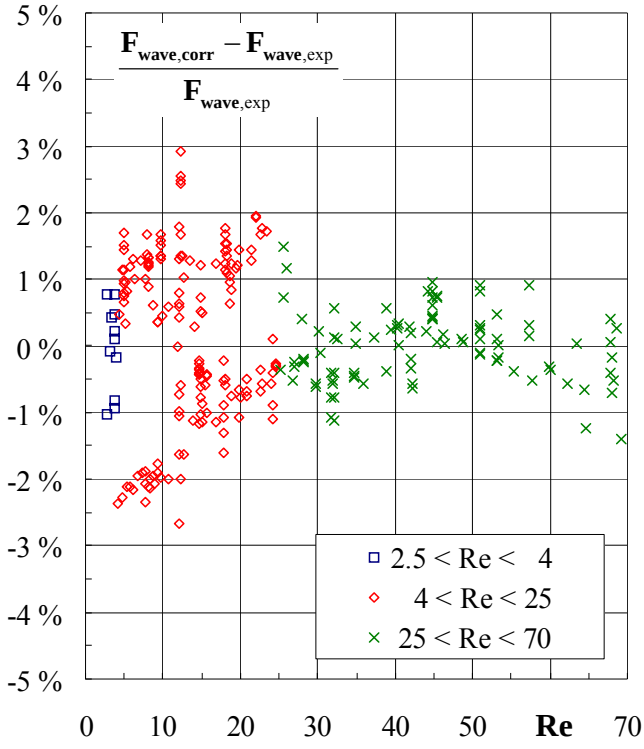

Figure 7. Deviation of correlation vs. Re

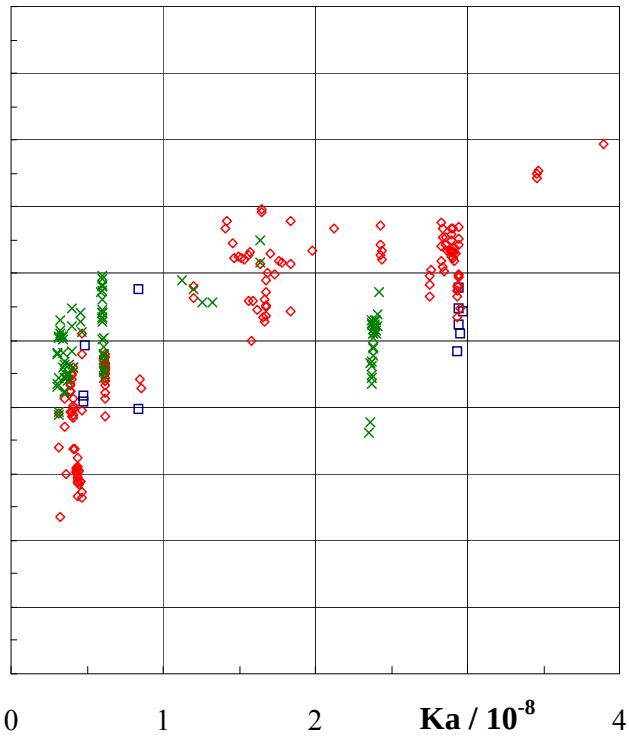

Figure 8. Deviation of correlation vs. Ka

Comparison with the literature

The open literature contains only a few references regarding the heat flux effect. For conditions without bubble formation in the superheated liquid film, only a fistful of earlier studies is found.

Struve [13] and Elle [14] investigated falling film evaporation heat transfer of refrigerant R11 outside a vertical tube. No heat flux effect has been found by them below the limit of first bubble formation.

Shah and Darby [15] studied surfactant effects on evaporation heat transfer in a liquid film flowing downward a vertical flat plate. Among many other findings they obtained results for the limiting case of pure water at Re numbers in the range of developing turbulence. There are clear signs of heat transfer promotion for increasing heat flux which is found to be moderate in case of surface evaporation. Beyond the onset of bubble nucleation, at about $\Delta t = 5$ K, the heat flux effect becomes much stronger.

Alhusseini et al. [16] measured mean heat transfer coefficients for evaporation of water and propylene glycol outside a vertical tube and they provided the following correlation valid for the laminar-wavy region:

$$Nu = 2.65\,Re^{0,175}\;Ka^{0.0563} \tag{12}$$

which may be rewritten for the wave factor as

$$F_{wave,Alhusseini\,et\,al[16]} \propto Re^{0,175}\;Ka^{0.0563} \tag{13}$$

Both the Re and Ka number effects are obviously much stronger than in the present investigations.

Weise and Scholl [17] present falling film evaporation results for liquids in the high Prandtl number range with Pr_{liq} = 40 to 130. Overall heat transfer measurements have been carried out with the heat flux, i.e. the driving overall temperature difference, as one of the parameters. Only a few of the results are found for the laminar range with no significant heat flux effects. In the turbulent range, however, there is a heat transfer enhancement in the order of 20 % when the driving temperature difference is increased from Δt = 10 K to 20 K. This effect has been found for Pr = 40 and 58 and it seems to vanish for larger Prandtl numbers, i.e. $Pr \geq 78$.

CONCLUSION

For isopropanol, the authors' local heat transfer measurements of falling film evaporation have been evaluated at zero shear stress inside a vertical tube with systematic variations of Re number, heat flux and vapor temperature. Basically the new results verify the earlier condensation heat transfer results. Nevertheless, a deviation in the range of transition from three-dimensional wave shape to turbulence (Re = 25 to 70) was found. Heat flux effects have been detected and correlated. Thereby the ratio of Pr numbers at vapor temperature and wall temperature, as known from pipe flow correlations, have been used. Prospective investigation with other fluids will follow to verify the presented effects.

ACKNOWLEDGMENT

The authors like to thank Alexander Köhler, Tobias Nell, Nick Trümmel and Volkmar Wörner for their contributions. The support by the Deutsche Forschungsgemeinschaft (DFG) is greatly appreciated.

ABSTRACT. An upward isothermal co-current air-water flow in a vertical pipe (52 mm inner diameter) has been experimental investigated. Local measurements of void fraction, interfacial area concentration (IAC), interfacial velocity and Sauter mean diameter were measured using a four sensor conductivity probe. Liquid velocity and turbulence intensity were measured using Laser Doppler Anemometry (LDA). Different air-water flow configurations was investigated for a liquid flow rate ranged from 0.491 m/s to 3 m/s and a void fraction up to 25 % .For each two-phase flow configuration twenty five radial position and three axial locations were measured by the conductivity probe methodology, and several radial profiles was measured with LDA at different axial positions..

Keywords: *double sensor conductivity probe, LDA, Interfacial Area Concentration, two-phase flow structure*

INTRODUCTION

One of the most important key in the two-phase flow is the existence of multidimensional interfaces between both phases. The correct behaviour prediction of this interfaces, and its quantification is one of the frontiers in the theoretical and experimental studies of this kind of flow, and up to now, there is not an effective technique and methodology for the multidimensional interface characterization in two-phase flow measurement [1] . Then, experimental works play a very important role in the development of new theoretical models and it is essential for design, analysis and behaviour analysis of existing and futures scenarios. In this work a detailed experiments are performed in order to have a good data base about the main parameters in two-phase flow characterization in upward co-flow in vertical pipes.

The basic structure of a two-phase flow can be characterized by three fundamental parameters. These are the void fraction, Sauter mean diameter (for bubbly flow mainly) and interfacial area concentration (IAC) [2]. The void fraction expresses the phase distribution and it is a required parameter for hydrodynamic and thermal design in various industrial processes. On the other hand, the interfacial area describes available area for the interfacial transfer of mass, momentum and energy, and it is a required parameter for a two-fluid model formulation. Various transfer mechanisms between phases depend on the two-phase interfacial structures. Therefore, an accurate knowledge of these parameters is necessary for any two-phase flow analyses.

The void fraction measurement is not so complicated using intrusive methods like conductivity probes with only two sensors. But IAC, defined by the quantity of interface between both phases, measured in area units per each unit of mixture volume, is quite complex itself, and with a large difficulties to be

E-mail address: schiva@emc.uji.es

measured. [3] defined the local time-averaged IAC at a fixed position in space derived on the basis of velocities measurements according to the expression:

$$\bar{a}^t = \frac{1}{\Omega}\sum_l \frac{1}{|\vec{V}_{il}\cdot\hat{n}_{il}|} \qquad (1)$$

That definition opens the door to measure the interfacial area using the velocity of the interphase , if it is measured with enough detail together its vector components. The theoretical fundaments for this technique was originally proposed by Kataoka [4], and during the last fifteen years numerous researcher have used and improved that technique using intrusive probes of two, four and five sensors. In this work we have used four-sensor probes in order to characterize the two-phase flow parameters. The double–sensor sensor conductivity probe technique is useful for 1D flow when spherical bubble can be assumed, which could be easily supposed in flows trough vertical pipes with relative small diameter and with gas moderated flow. The IAC and interface velocity can be calculated using the distance between the probe tips, but a calibration factor, based in a Mote-Carlo methodology, is proposed to relate the real magnitude to that measured from the experimental signal. It is necessary to introduce a calibration factor, based on statistical methods, to be able to take on account the possible deviation from the vertical direction and the presence of missing bubbles, bubbles that produces bad signals or bubble that only produce a signal in only one of the tips. Interfacial velocity, void fraction, Sauter mean diameter and IAC were measured using double-sensor probe. Also in this work, we include a detailed liquid velocity and turbulence intensity measurements using LDA which it is not usual in other research works where it is measured using hot-wire anemometer (HWA) . LDA is a not intrusive method and it give a more precise results and easier to interpret than HWA when bubbles are present in a liquid flow. Accurate magnitude information about liquid is basic for a good results interpretation.When spherical bubbles can not be assumed, it is necessary to introduce a four-sensor conductivity probe to perform the measurements, since no hypotesis for the bubble shape is necessary in the mathematical formulation to calculate the local interfacial area concentration.

EXPERIMENTAL FACILITY AND INSTRUMENTATION

The experimental work was performed using a thermo-hydraulic loop placed at the Energy Engineering Institute in Polytechnic University of Valencia (Spain). The loop is schematically illustrated in Figure 1. It consists of a test section, a round transparent tube made by Plexiglas with constant section, an upper plenum and a lower plenum where air and water are mixed. The test section has a 52 mm inner diameter and a length of 3340 mm. The water was circulated by two centrifugal pumps controlled by a frequency controller.

The air was supply by a compressor, and it was introduced to the test section through a porous sinter element with a average pore size of 10 mm installed below the mix chamber. The air and water temperature was kept constant during the test assay. The air mass flow rate was measured with a thermal mass flow meter and controller (Bronkhorst ® , EL-FLOW model), liquid flow rate with a Electromagnetic flow meter (Badger Meter ®), and the pressure with a precision pressure transmitter, DRUCK ® PTX 600 series.(INF position: range [0..1] bar, MED, SUP position range [0..250] mbar (Prec. 0.5% F.S.)

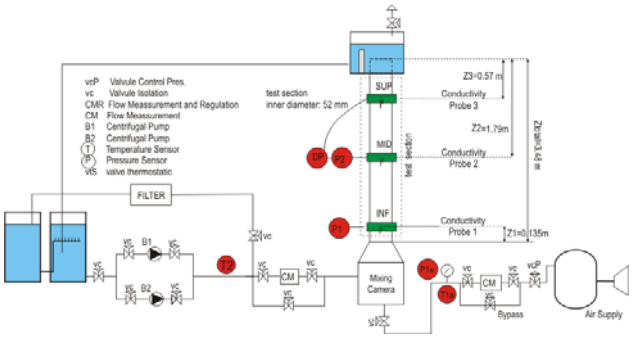

Figure 1. PUMA Facility scheme

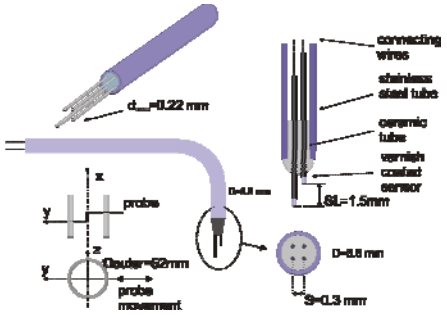

Figure 2. Schematic diagram of four sensor conductivity probe

The LDA equipment consists of a 0.5W Ar+ Ominichrome laser, Dantec Fiberflow beam separator, Dantec FVA 58N40 processor and a PC using the software Floware for data acquisition. A lens of 0.125 m focal length was used and the system was operated in backscattering mode. The vertical component was determined with green (λ=514.5 nm) beams and the horizontal component with blue (λ=488 nm) beams. A preshift frequency of 500 kHz was used. The flow was seeded with hollow particles which were neutrally buoyant with a 10 □m mean size (Dantec HGS-10); therefore, only the liquid velocity was measured [7]. The time series obtained were 60 seconds long. The LDA system provides the liquid phase velocity moments. However, a number of data-processing steps are required before calculating the velocity moments. Firstly, the multiple validation, i.e. the multiple detection of the burst caused by a single particle, was handled by first rejecting velocity realizations with $V_i - \overline{V_i} > 4\sigma$ (σ is the standard deviation of the signal, $\overline{V_i}$ a single velocity realization and the averaged velocity over the measurement time). Then, the bursts which follow other bursts within a 1 ms interval were removed. Finally, the velocity bias, i.e. higher velocities over-representation, was corrected using the so-called 2D+ weighting: inversely weighting the data with the velocity [8]. Since only two components are known, the magnitude of the third component is estimated from the variance of the second component: the weighting factor w is,

$$w = 1/\sqrt{V_x^2 + V_z^2 + (d_m / l_m)^2 \overline{V_z'^2}} \qquad (2)$$

with dm/lm as the diameter-to-length ratio of the ellipsoidal measurement volume. The use of only two components is justified since the magnitude of the vertical and lateral fluctuations will be close, and the influence of the third component is slight since d_m/l_m is also small. In this way, pairs of vertical and lateral velocity realizations, which have arrival times inside coincidence windows with a length of 200 μs, are searched. More technical details about the data processing can be found elsewhere [9],[10].

Sensor conductivity probe methodology

The four- sensor probe is basically a phase identifier. It consists of two sensors made of stainless steel, coated with gold, with a diameter of 0.22 mm. The vertical distance between both tips was about 1.5 mm . Each sensor is insulated using a insulating varnish except its tips. If the probe is connected to a power supply with a fixed voltage, due to the large difference in conductivity between the liquid phase and the gas phase, the impedance signal acquired rises sharply when a bubble passes through one of the sensor tips, obtaining a more or less square signal. With a suitable signal processing methodology is possible extract precise information from that raw signal.

From the time lag, between the impedance signals of the front and back tips, we can know the time that needs the front of the bubble to travel from one tip to the other that is far away a distance, S. Then a measurable value of the bubble velocity, Vm, can be easily obtained. If the bubble moves with its velocity vector parallel to the conductivity probe orientation then the measurable value Vm of the velocity match the true value of the bubble speed. However, as the bubble velocity fluctuates in response to the turbulence of the liquid phase then the bubble's lateral motion along with the finite value of the distance between both tips of the probe, and the bubble curvature can cause problems in the measurement of the true value of the bubble velocity. To quantify this difference it is possible to define a calibration factor as the ratio between the mean value and the measured value of the bubble including the missing bubbles. The most common model used are: Kataoka statistical model, Wu statistical model or Hibiki statistical model.

In this work we have chosen the methodology carried out by Muñoz-Cobo et al. [5] to determine the calibration factor. In his study the effects of bubble motions, and probe spacing have been included. The value measured is related to the local bubble interface velocity in the surface normal direction. The probability density function of each variable is identified with the suitable coordinate transformation. Two theoretical calibration factors are defined to relate the mean measurable parameter to the interfacial area concentrations obtained and the measured bubbles, including the missed bubbles. These calibration factors have been obtained through analytical and numerical method, using a Monte Carlo approach. The results of these calculations show that the total interfacial area correction factor is very close to 2, and depends very weakly on the velocity fluctuation, and the relative distance between tips. For the velocity calibration factor, the Monte-Carlo results show that for moderate values of the relative bubble velocity fluctuation and values of the relative distance between tips not too small, the correction velocity factor for the bubble sensor conductivity probe is close to unity.

EXPERIMENT RESULTS AND CONCLUSIONS

The flow conditions have been chosen measuring the superficial liquid and air velocity and the average void fraction on z/D=56 in each condition. All the conditions (Table 1) are in the bubbly flow regime, and only in the highest void fractions appears some large cups, near the transition . For each liquid velocity conditions we have at least five gas conditions from 5 % to up 25% . That void fraction was measured by a pressure sensors at z/D=56. For the probe sensors, two different configurations were used, as it can see in Figure 5 and 6, in order to study the best configuration, mainly near the wall. Details about the experiments and the facility can be found in [11]

The bubble diameter at the inlet depends on the gas flow and liquid flow, for a pressure and a bubble generator system given. The initial diameter was not controlled in this experiment, we only measure it. With liquid velocities at the inlet below 2 m/s the turbulence does not produce bubble

disintegration, then the initial bubble determinates the developing profile. The bubble diameter at the inlet was in the range [2–4] mm, Figure 4, file 1, and by pressure reduction along the flow direction, the bubble diameter change increasing its diameter, Figure 4, file 2. For jf = 0.5 , G05 (20%) and G06 (25 %) conditions large cup bubble were detected.

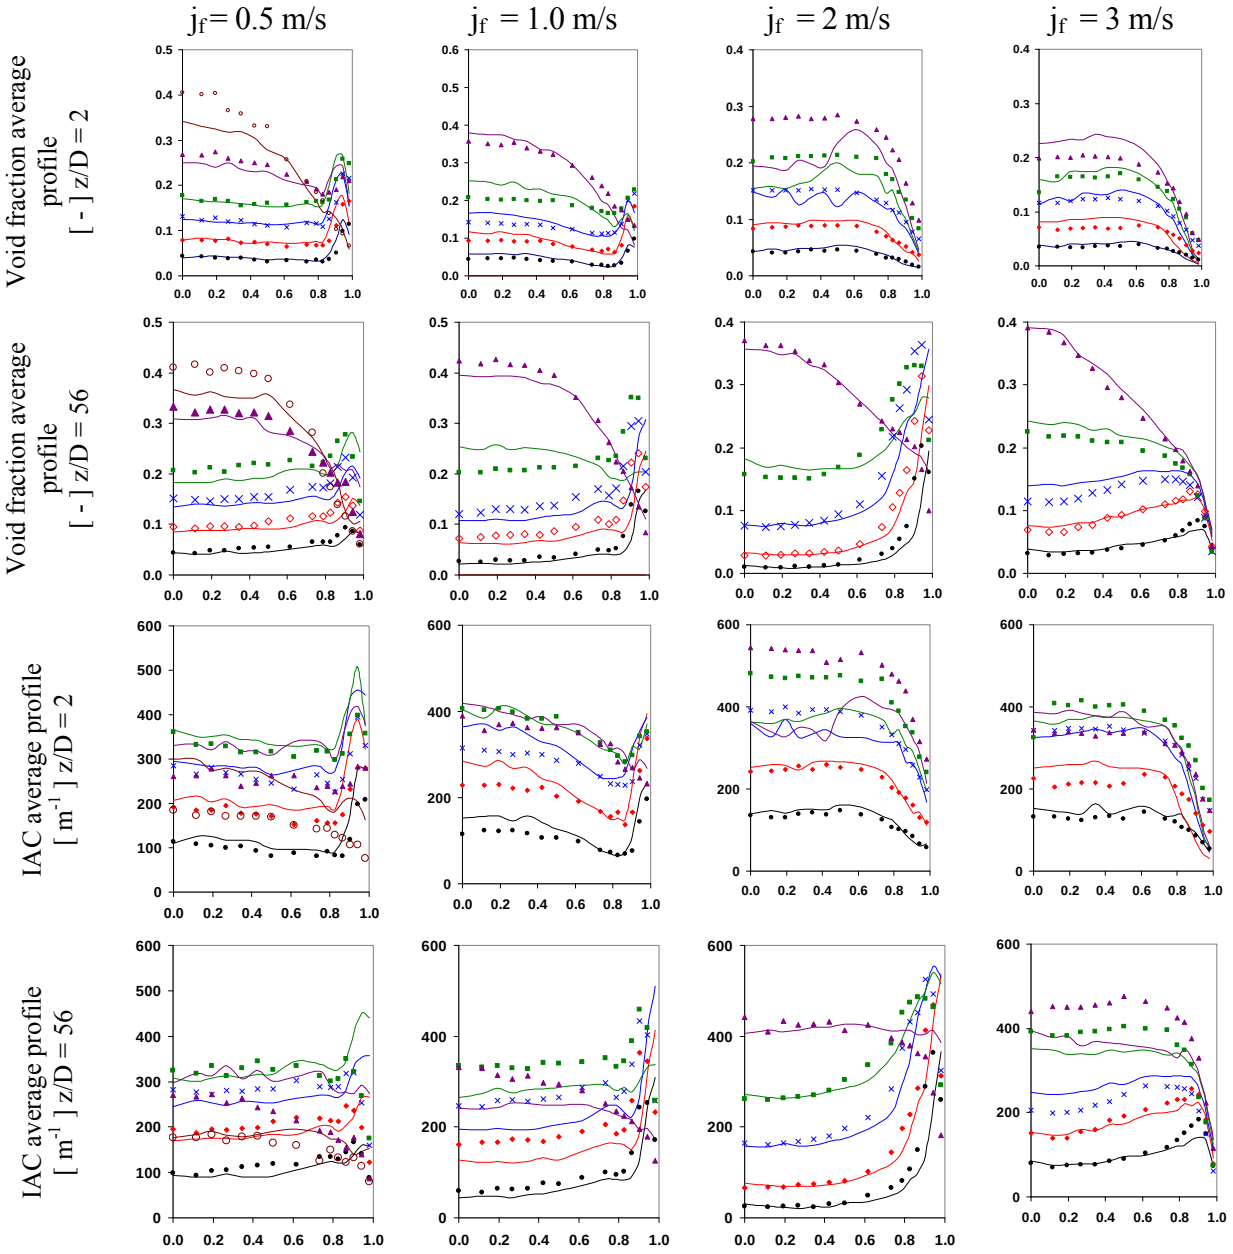

Figure 3. Results: Average profile (r/R) for IAC and void fraction for two axial position. Solid symbol correspond to F0A probe configuration, and without symbol for F0.. The legend for the graphs are as follow: Black (●) G01, Red (◊) G02, Blue (X) G03, Green (■) G04, Violet (▲) G05, light Violet (○) G06

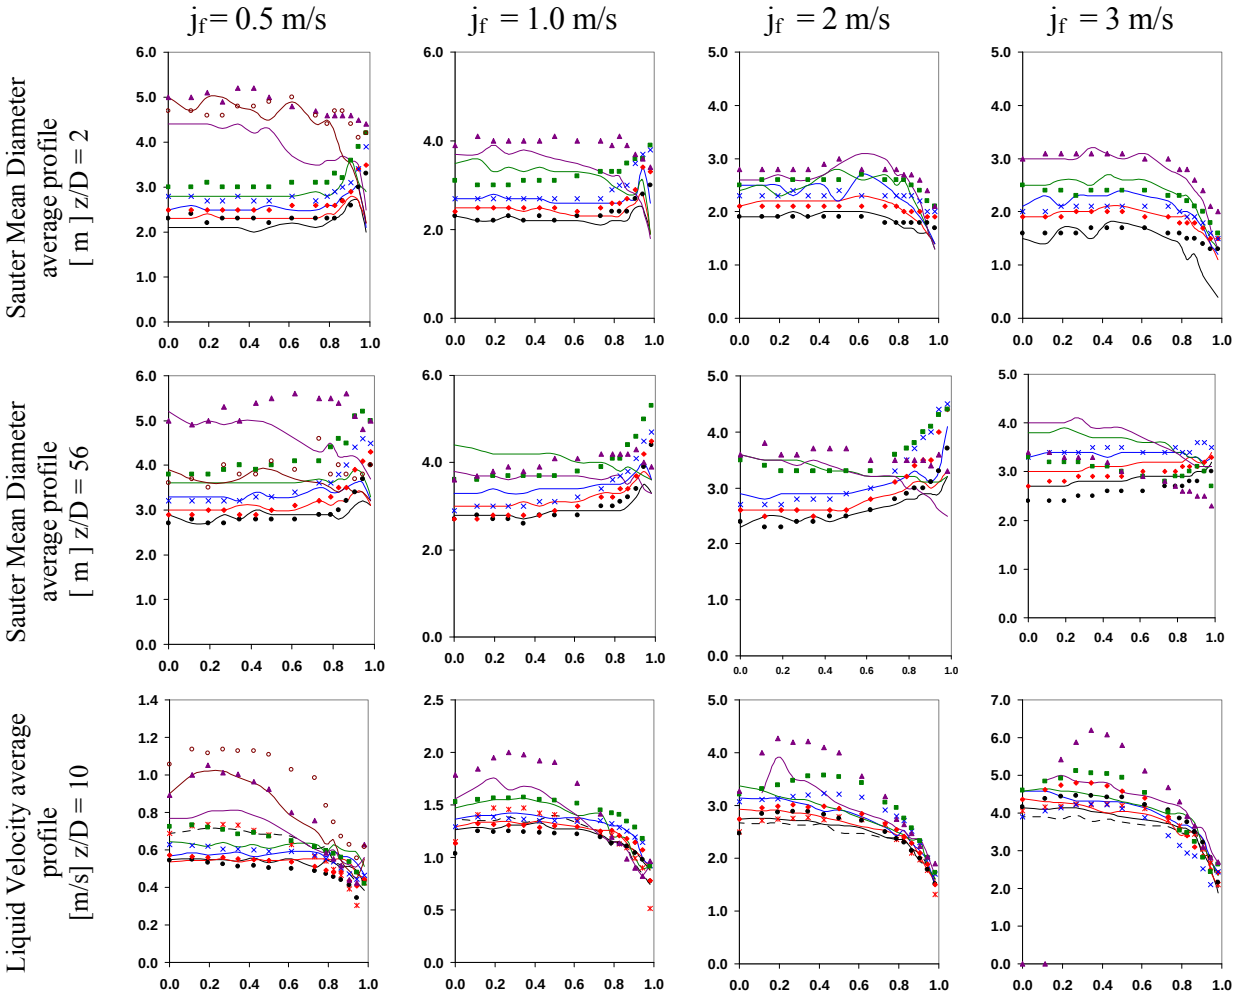
The radial distribution of the bubble, gas phase, depends on the diameter, and the liquid velocity gradient. Small bubbles tend to move toward the wall , while large bubble migrate preferable to the center. This lateral movement is determinate by the lift force, and its sign change as function of the bubble diameter. We must consider other later force, the wall lubrication force, which acts to drive the bubble away from the wall, but its effect decreases very fast. The balance, from those two forces, produces the peak near the wall. Figure 3, file 1 and 2, shows the void fraction behaviour. We can observe the three typical profiles, wall-peak, transitional and core-peak. For, F01, F02 and

F03, j_f = [0.5 – 2] m/s the void fraction show a wall-peak profile for G01,G02 and G03, typically [0-15%]. The local void fraction profile have a typical evolution of the pressure reduction, it match with lack of bubble break-up o coalescence due to the reduced liquid velocity and the moderated void fraction. The peaks in the void fraction profile match quite good with the peaks position described in the literature, the peaks were located more or less at one bubble diameter from the wall. For jf = 2 m/s and 3 m/s at lower position no wall-peak profile was observed for void fraction , perhaps, the development zone at the entrance produces bubble migration toward the center, since the bubble diameter is small. For G04 (20%), the profile has an evolution to transitional shape, due, mainly, to the tendency to migrate toward the channel center by the large bubble, and only shows wall-peak for jf=0.5 and 1 m/s at z/D=2. For jf=2 m/s and 3 m/s at z/D=2 the void fraction has a transitional profile for all the void fraction concentration. The core-peak profile appears when large quantity of gas is injected to the system and large bubbles appears (Figure 4, file 1 and 2) , migrating toward the center of the tube. For void fraction average largest than 20% a core-peak profile appears, mainly in the upper part of the section.

Since, in the cases without cups, the Sauter diameters are quite uniform, Figure 4, file 1 and 2, in all the profile, the IAC profile (Figure 3, file 3 and 4) shows a similar behaviour of its respective void fraction profile. Special attention needs the F01 case, jf=0.5 m/s , when large cups appears in G05 and G06 cases, since although a core-peak is showed in its void fraction profile, the IAC have a flat profile. It could be explained by the minor IAC were cup are presents.



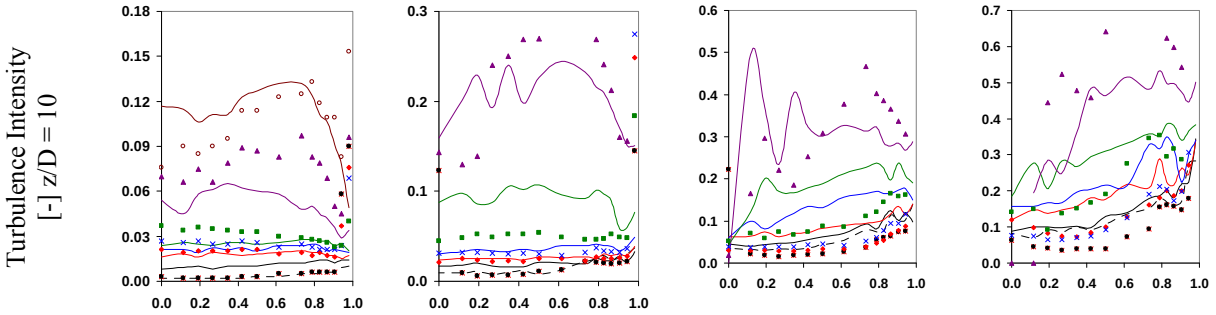


Figure 4. Results: Average profile (r/R) for Sauter Mean Diameter for two axial position, Velocity and Turbulence intensity for liquid phase at z/D = 10. Solid symbol correspond to F0A probe configuration, and without symbol for F0.. The legend for the graphs are as follow: Red (X) G00, Black (●) G01, Red (◊) G02, Blue (X) G03, Green (■) G04, Violet (▲) G05, light Violet (○) G06

The liquid velocity (Figure 4, file 3) and its turbulence intensity (Figure 4, file 4) were measured using LDA. In each figure, a red line is included, that line shows the single phase behaviour. For each liquid velocity a velocity profile was measured for single phase condition, where only liquid flows through the test section. The liquid flow rate calculated from the velocity profile was compared to the liquid flow rate measured with the flowmeter with very good results. The liquid velocity profile , in general, is more flatted when bubbles appear, but this effect is quickly saturated when the quantity of bubble increase, but when the liquid velocity increases, $\geq$ 1 m/s, the liquid profile is not largely affected by the bubbles, and the shape of the profile in single phase is maintained. The cups produce an increase in the liquid velocity, with a more pronounced core peak profile, , i.e. Figure 7, file 3, for void fraction largest than 20%

In general, the wall-peak profile in the turbulence intensity can be explained by the large gradient of the velocity and shear stress distribution near the wall, mainly in the lower part of the test section, where the flow is developing. In the center part of the pipe the turbulence is quite constant and lower than near the wall. It could explain why the bubbles are not disintegrated in the center of the pipe. When caps appear, the turbulences is enhanced (void fraction > 20%). It is interesting to comment that in certain flow conditions, as it was pointed out by Serizawa and Kataoka [11], locally, bubbles can reduce the turbulence intensity, when the liquid velocity is equal or bigger than 1 m/s. That could explain the turbulence intensity behaviour of G01, as you can see at Figure 4, file 4, for jf > 1 m/s.

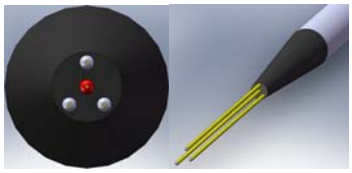

Figure 5.- Probe Configuration F0X

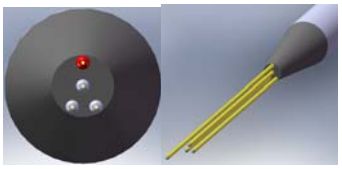

Figure 6.- Probe Configuration F0A

Both geometrical configurations give good and very similar results. The F0X configuration gives better results in position very close to the wall, with more robust physical sense. The second configuration, F0A, gives the best results when we need detect large bubbles or the velocity of the liquid is high. More experimental work and a detailed redesign are been done in order to give more answers about the election of the suitable design.

CONCLUSIONS

As it is showed in the paper, the results maintain a good agreement with those published by authors like Hibiki [6] and co-workers, with a very good prediction of the peaks in the profiles and its tendencies. The liquid velocity and its turbulence intensity were measured using LDA, with more accurate results. Then, the experimental methodology developed to build the four-sensor conductivity probe and to process the data set obtained, give good and repeatable results about the two-phase flow parameters. This methodology could be considered a suitable tool to study two-phase flow sceneries together the use of LDA to measure the liquid magnitudes.

EFFECT OF SURFACTANTS ON BOILING PHENOMENA

A.T.Pise*[1], A.R. Acharya[1] and I. I. Momin[1]
[1] Department of Mechanical Engg. Govt. College of Engineering. Karad M.S. 415124, India

ABSTRACT. The heat transfer in boiling can be enhanced by adding small amount of additive in fluid. Presence of small amount of additive in the fluid changes the physical behavior of the boiling phenomenon. These surfactants change thermo-physical properties of the fluid. Experiments on pool boiling were carried in presence of the surfactant in pure water. Ammonium Chloride NH_4Cl, Sodium Lauryl Sulphate SLS, Hydroxyethyl Cellulose HEC-H and Betel Nut served as test surfactants and added separately in water with varying concentration. The results of surfactants namely SLS, HEC-H and betal nut in pure water showed the heat transfer enhancement up to 500ppm and NH_4Cl up to 2800ppm concentration, above this range no enhancement was observed. Enhancement was more for SLS as compared to other surfactants. Also the trend of boiling curves in presence of these surfactants in the water, shifted towards the lower temperature difference side. Presence of Betel nut (Areca Catechu) in water showed the value of critical heat flux low as compared to other surfactants. Also the kinetics of vapor bubble in pool boiling phenomena for pure water with and without surfactants were observed in terms of bubble nucleation, growth and their departure.

Keywords: *Surfactant, Boiling, additive, Surface Tension, Bubble behavior Flow Visualization.*

INTRODUCTION

There is a general need to increase the heat transfer rate in pool boiling applications for saving the energy required to phase change. Now lots of efforts are taking place to save the energy from different applications due to energy crisis and global warming. Hence the main motive is to reduce the energy i.e. increase the heat transfer in pool boiling. Researchers found enhancement techniques in heat transfer for the boiling. The addition of surfactant as additive in the solution is the cost effective technique and simple to handle. Some of the researchers had conducted the experiments on pool boiling enhancement-using additives.

Hetstroni and his group [1,2] in their study of pool boiling on horizontal stainless steel tube inside a transparent glass vessel observed the bubble behaviors. They observed that boiling in surfactant solution when compared with that in pure water was more vigorous and more activation of nucleation sites in clustered mode. For the boiling curve, wall temperature of the heated tube decreased with an increase in the concentration of the alkyl polyglucosides. Bubble form in Habon-G solution was very much smaller than those in water and surface becomes covered with them faster. Kotchaphakdee et al., [3] studied the effects of Polyacrylamide, PA and Hydroxyethyl Cellulose, (HEC) solute concentrations ranged from 62 to 500 ppm liquids in water boiled at atmospheric pressure on a

horizontal steam heated chrome-plated surface. They observed that amount of polymers in water increases nucleate boiling heat flux. PA leads to significantly improved heat transfer coefficient over the entire range of excess temperature. The peak heat flux is considerably higher than for water. Klein et al., [4] investigated the effects of APG surfactant solution flows through a micro-channel heat sink in which heat generated due to electronic components were removed. Surfactants mixed solution-boiling phenomena were also found to stabilize the maximum and average surface temperatures for a wide range of applied heat fluxes. Further effort invested on revealing proper surfactant additives and performing experiments of surfactant solutions flowing through a various micro-channel heat-sink configurations. Urquiola, et al., [5] did the boiling experiments with pure water and surfactant solutions of SDS on horizontal heating surface. Surfactant behavior was studied in terms of static contact angle directly related with the surface conditions, rather than the surface tension value. Higher contact angle leads the boiling curve of a specific liquid or solution to show better heat transfer characteristics. Wen and Wang [6] observed the effects of surface wettability on nucleate pool boiling heat transfer for Sodium Dodecyl Sulphate (SDS) and Triton (X-100) surfactant in water. They found that both SDS and Triton X-100 could increase boiling heat transfer coefficient. Also the boiling phenomena is mainly depends on thermo physical properties of fluid that are density, surface tension and kinematic viscosity. The addition of small amount of surfactant does not affect the density of solution but it slightly increases the viscosity and measure reduction in surface tension if surfactant is polymeric. Number of researchers measured the surface tension data with and without surfactants in water, [2,8] which shows with increase in surfactant concentration surface tension decreases.

After the extensive literature reviewed some of the conclusions are contradictory. Selection of the additive and its optimum quantity. Whether it mix or not? The mechanism of enhancement is not yet properly understood, but a reduction in surface tension changes the boiling behavior. Better understanding of this process is needed. So in this work, the effect of surfactants in pool boiling for enhancement of heat transfer is experimentally investigated. Ammonium Chloride NH_4Cl, Sodium Lauryl Sulphate SLS, Hydroxyethyl Cellulose HEC-H and Betel Nut served as test surfactants and added in water with varying concentration in search of to find optimum quantity. The overall aim of this work is to understand the phenomenon of nucleate pool boiling of water with and without surfactants, as it is very complex in nature.

EXPERIMENTAL METHOD

Experimental setup

The apparatus as for experimental studies on pool boiling is shown in Figure1. It consists of cylindrical glass container housing, the test heater and the heating coil for the initial heating of the water. The heater coil is directly connected to the mains (Heater R1) and the test heater (Nichrome wire) is connected also to mains via a dimmerstat. An ammeter (range 0-10A) is connected in series while the voltmeter across it to read the current and voltage. Voltage selector switch is used to select the voltage range 50/100V. These controls are placed inside the control panel.

Test Procedure

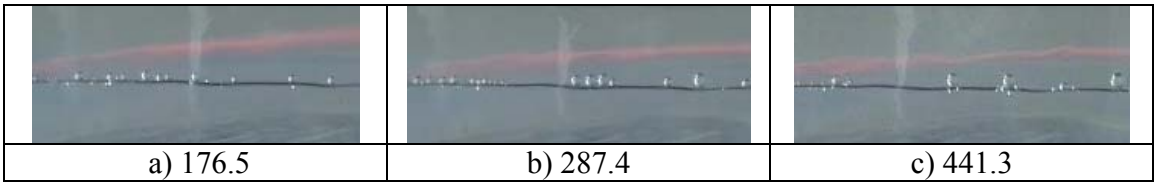
The glass container was filled with 2.5 liters of water and it kept on a stand, which is fixed on a wooden platform. The temperature of bulk water i.e. saturation temperature of water was measured using mercury thermometer with least count of 0.5^{o}C Cr-Al k-type thermocouple. It is connected to nichrome heater wire to measure the temperature of wire using digital temperature scanner having least count 0.1^{0}C. The kinetics of boiling (bubble nucleation, growth and departure) i.e. bubble behavior with and without surfactants in water was recorded by Handy camera (800X) video recording. Each experiment was repeated three times to maintain the repeatability.

RESULTS & DISCUSSION

The extensive experimentation of pool boiling was carried for pure water with and without surfactants of varying concentrations namely SLS, HEC-H, NH_4Cl and Betel nut. From the obtained experimental data results are plotted in terms of boiling curve as a heat flux vs. heater excess temperature. Also the some images of kinetics of boiling (bubble nucleation, growth and departure) i.e. bubble behavior for water and water with surfactants were recorded by Sony Handy camera (800X). Comparative studies of results of surfactant were broadly discussed into two categorize as boiling behavior and boiling curves.

Boiling Behavior

The kinetics of vapor bubble in pool boiling phenomena for pure water with and without surfactants was observed in terms of bubble nucleation, growth and departure the evolution of vapor bubble. The growth of bubble is one of the parameters determining the intensity of the heat transfer from a heated surface. All the pool boiling experiments were carried out under atmospheric pressure. The phenomenon of foaming, often observed during boiling in the presence of surfactant in water. The foam formed on the surface of the solution and its height increased with the heat flux. The bubble behavior was recorded at 24 frames per second by the video camera and recording was done for varying the concentration of the surfactants and heat flux. The typical stages of bubble growth analyzed for this study are shown in Figs. 2–4.



a) 176.5	b) 287.4	c) 441.3

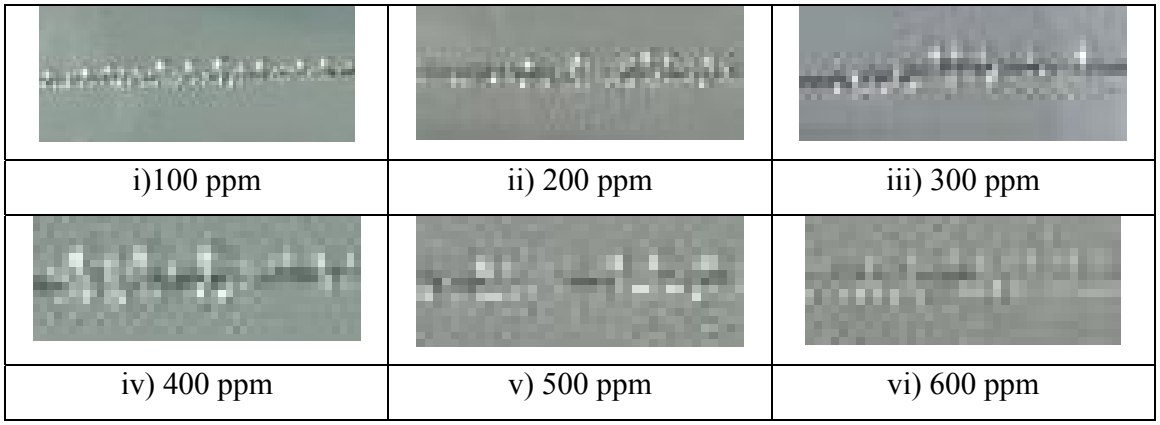
Figure 2. Images of boiling of pure water for heat fluxes (kW/m^2): a) 176.5 b) 287.4 c) 441.3

Figure 2 (a-c) show typical images of deionized water boiling on the nichrome wire at heat fluxes 176.5, 287.4 and 441.3 kW/m^2 respectively. Population of bubbles was observed in the vicinity of the heated wire. The bubble dynamics for water were seen to depend on heat flux, similar to well-known boiling visualization data. After the onset of nucleate boiling, the regime of single bubbles occurred close to the heated wall (Figure 2a). As the heat flux increased, bubble coalescence takes place (Figure 2b). This phenomenon was more pronounced at heat flux 441.3 kW/m^2 (Figure 2c). For pure water, the average bubble size was observed to slightly increase with increasing heat flux. The bubbles have an irregular shape at all values of heat flux. Same heat fluxes with SLS, HECH-H of 400 ppm and NH_4Cl of 1200 ppm in pure water was observed and the images of 400ppm with SLS are shown in Fig. 3(a-c).

a) 176.5;	b) 287.4;	c) 441.3

Figure 3. Images boiling of 400 ppm SLS in water for heat fluxes (kW/m^2): a) 176.5; b) 287.4; c) 441.3

The SLS additive reduces significantly the tendency of coalescence between vapor bubbles. Here too, there is a weak tendency toward increasing the average diameter as heat flux increased. In this case, the shape of bubbles is closer to spherical than for pure water. It presents cluster of small bubbles, which rise from the cavity. The bubbles are adjacent to each other and the cluster neck is not observed. Effect of the surfactant concentration on the boiling phenomena was also recorded at the 300 kW/m^2. Surfactant concentrations were varied from 100 to 600 ppm for the SLS, HEC-H and betal nut and 200 to 2800 ppm NH_4Cl in water.



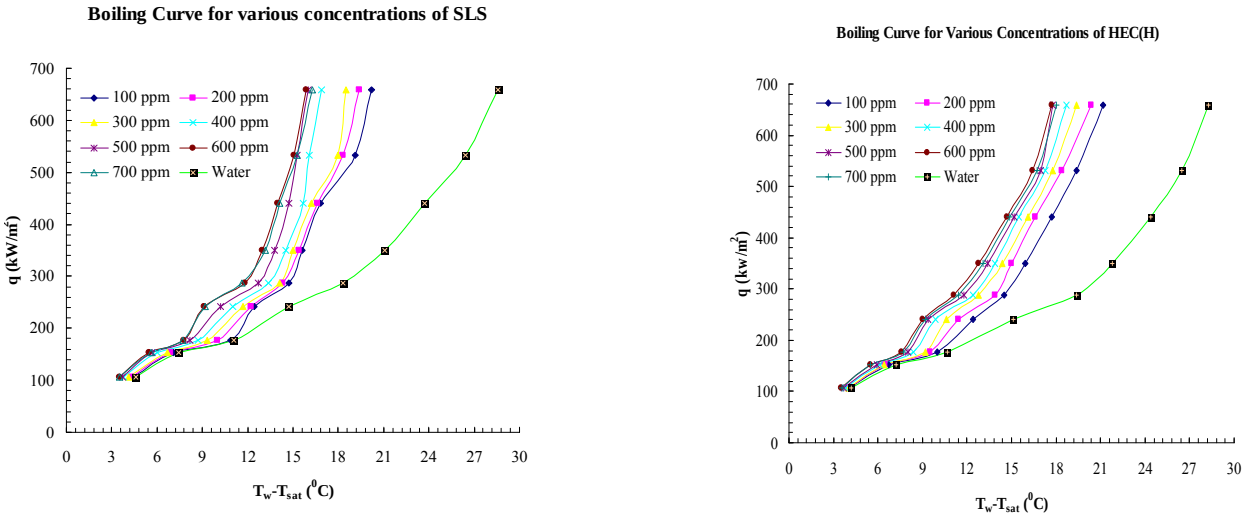
i)100 ppm	ii) 200 ppm	iii) 300 ppm
iv) 400 ppm	v) 500 ppm	vi) 600 ppm

Figure 4. Photographs of 100-600 ppm SLS in water for heat flux 300 kW/m^2

Figure 4 show the boiling images of SLS water having concentrations 100–600 ppm at heat flux 300 kW/m^2. It was observed that with increased in heat flux i.e. temperature, bubble size also increased and detaching time of the bubble was less as compared to pure water. Diameter of bubble in surfactant solution is smaller as compared to water. Bubbles form a blanket over the wire, which could not observed in pure water. This might be due to addition of SLS in water, decreases the surface tension of solution and hence the forces acting on bubbles are smaller and detach rapidly from the surface. Also surfactant activates the number of nucleation sites on the same wire. The time between detaching bubbles from wire and reaching the bubble up to free surface is measured in Windows Movie Maker and the distance between wire and free surface was measured using Adobe Photoshop 7.0 software. The same procedure was repeated in three times for each concentration and average velocity was calculated. The results show that the velocity of bubble slightly increased with varying concentrations from 100 to 600 ppm. This might be due to addition of surfactant, surface tension force decreases and hence resistance to bubble motion is also decreases [2,8]. Similar boiling phenomena were observed HEC-H, NH_4Cl and betel nut used as surfactant. The phenomenon of foaming was observed after 1200-ppm concentration for NH_4Cl and velocity of bubbles are slightly increased with varying concentrations from 200 to 3000 ppm. Up to 800ppm NH_4Cl in the water the boiling behavior quite similar to that of water.

Boiling Curves

The saturated pool boiling curves are plotted with varying concentrations of surfactant in pure water as a function of the heat flux q (kW/m^2) vs. the heater excess temperature (T_w-T_{sat}) ^{0}C (Figs.5-6). Figure (a) show the surface temperature of the heated nichrome wire decreased monotonically with an increase in the concentration of the SLS solution up to 500 ppm, also noted that the effect of surfactant additives on nucleate boiling heat transfer slightly decreases or almost constant, when the concentration of SLS in water solution was higher than 500 ppm. The analogues data on the decrease in the heat transfer for 1060 ppm Habon-G solution also reported by Hetsroni et al [2].

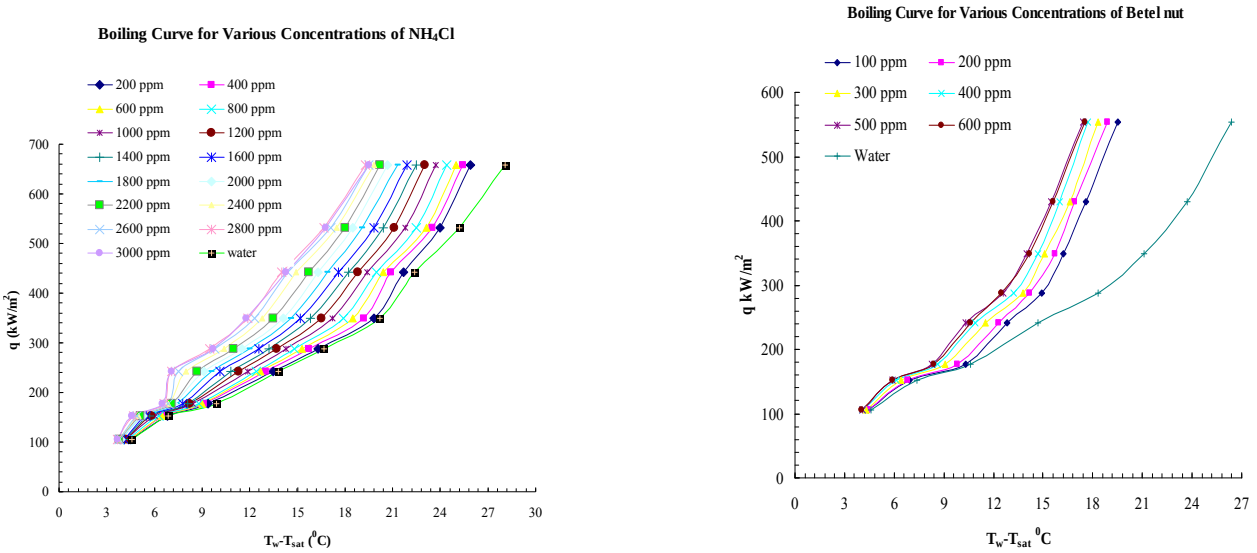


a) SLS **b) HEC-H**

Figure 5. Pool boiling curves of pure water with SLS & HEC-H

The effect of SLS additives on nucleate boiling heat transfer slightly decreases, when the concentration of SLS solution is higher than 500 ppm. Figure 6(b) the saturated pool boiling curves of water with varying concentrations of HEC-H. HEC-H is the polymeric surfactant with viscous in nature. An increase in concentration of HEC-H in pure water increases the viscosity with significantly decreases the surface tension [8]. The general effect of increasing concentration of HEC-H additive in pure water is to increase the heat transfer. The similar effect of concentrations was observed as that of

the SLS. Upto 500-ppm heat transfer increased above that there is slightly decreased in heat transfer and cross over of the curve towards right for 600 ppm at heat flux 152 kW/m^2. Similarly check the effects of NH_4Cl as a surfactant in pure water are also checked. The surface temperature of the heated nichrome wire decreased monotonically with an increased in the concentration of the NH_4Cl solution up to 2800 ppm, also noted that the effect of surfactant additives on nucleate boiling heat transfer slightly decreased, when the concentration of NH_4Cl solution is higher than 2800 ppm. Figure 6(a) shows the boiling curve for various concentrations of NH_4Cl in water.



(a) NH_4Cl **(b) Betel Nut**

Figure 6. Pool boiling curves of pure water with NH_4Cl & Betel Nut

The effects of varying concentrations of Betel nut in the water were studied. It was observed that increase in concentrations up to 500 ppm the heat transfer rate increased. The power required to reach the critical heat flux is low as compared to other surfactant solutions means heat required to reach the maximum heat flux is low but use of betel nut has some limitations that, it adversely affects the solution properties and its less solubility in water. The excess betel nut was floating. Also changes the solution color with remains red marks left on the glass surface. Figure 6(b) shows boiling curve for varying concentrations of Betel nut in water. The general effect of increasing concentration of Betel nut additive is to increase the heat transfer up to 500 ppm, above that heat transfer is constant. Similarly the heat transfer coefficient increased as the heat flux and concentration are increased, except when the concentration is higher than 500 ppm.

CONCLUSION

From the experimental results of this study the following major conclusions are drawn. The bubbles formed in water with surfactant solutions are much smaller than pure water and they covered the surface of wire faster. Presences of the surfactant reduce the boiling excess temperature ΔExcess it results the boiling curves shifted to the left side and promotes activation of nucleation sites in a clustered mode. For pure water average bubble size was observed to slightly increase with increasing heat flux. Up to 800-ppm ammonium chloride NH_4Cl in the water the boiling behavior quite similar to that of water. This might be the slight reduction in surface tension up to 800 ppm and due to its higher solubility limit in the water. The addition of small amount of anionic surfactant Sodium Lauryl Sulphate SLS and polymeric surfactant Hydroxyethyl Cellulose HEC-H in water makes the boiling behavior quite different from that of pure water. It might be that reduction in surface tension results in

a decrease of energy required creating a bubble. All the surfactant showed the heat transfer coefficient was increased up to solubility limit of the surfactant in water. The addition of the surfactant beyond the solubility limit was almost constant or slightly decreases the heat transfer coefficient. Presence of surfactant in water increases average bubble velocity.

AN EXPERIMENTAL AND NUMERICAL INVESTIGATION OF A COMBUSTOR OPERATING IN THE FLAMELESS OXIDATION REGIME

A. Rebola, M. Costa* and P. J. Coelho
Mechanical Engineering Department, Instituto Superior Técnico, Technical University of Lisbon, Avenida Rovisco Pais, 1049-001 Lisboa, Portugal

ABSTRACT. Flameless oxidation is a combustion regime that may allow a significant reduction of the NO_x emissions without compromising the combustion efficiency. The present study investigates this combustion regime both experimentally and computationally. The experiments have been performed in a small-scale combustor, fired with methane, and include flue-gas measurements for various combustor operating conditions that allowed for the quantification of the dependence of the NO_x emissions and combustion efficiency on the stoichiometry, thermal input and inlet temperature of the combustion air. Subsequently, detailed measurements of local mean gas species concentrations and local mean gas temperatures for one representative combustor operating condition have also been performed. In the parallel modeling work, a computer code was employed to predict the temperature and species concentration fields. The experimental data revealed that NO_x emissions are always low regardless of the combustor operating conditions. The prediction of the temperature and major species concentration is in satisfactory agreement with the measurements, except in the near burner region, where the predicted temperature rise is too steep in comparison with the experimental data.

Keywords: *flameless oxidation, pollutant emissions, combustion efficiency*

INTRODUCTION

Flameless oxidation is a combustion regime where the reactants are highly diluted with hot combustion products causing the reaction to occur in a distributed reaction zone with a reduced temperature maximum and low O_2 partial pressure. In this regime, distinct flame fronts, as they occur in typical lean premixed or diffusion flames, are replaced by a volume type flame mode. As a consequence, the temperature distribution is nearly uniform and the NO_x emissions are very low. The reduction of the aero-acoustic fluctuations and the extended stability limits are additional benefits of this combustion regime. This technology has received various names, namely flameless oxidation (FLOX) [1], moderate and intense low oxygen dilution (MILD) combustion [2] and colorless distributed combustion (CDC) [3], with a number studies revealing the success of this technology as a NO_x control technique.

Related experimental studies include those of references [1-9], among others. Wünning and Wünning [1] and Plessing et al. [5] presented data from recuperative furnaces operating under flameless oxidation conditions and showed that the temperature increase in the near burner region was rather smooth and that the thermal NO formation was largely suppressed owing to the nonexistence of temperature maxima. Plessing et al. [5] concluded that under flameless oxidation conditions combustion takes place in a regime similar to that of a well-stirred reactor, where no

ignition and quenching events occur, which explains the low level of the combustion noise associated with this combustion regime. Dally et al. [6] studied the effects of the fuel dilution on the flameless oxidation structure in a recuperative furnace, for a variety of fuel mixtures. The results showed that the fuel stream dilution with inert gases helps to establish flameless oxidation conditions and to reduce NO_x emissions. Weber et al. [4] and Flamme [7] reported data from semi-industrial furnaces operating under flameless oxidation conditions. Weber et al. [4] observed that the furnace operated under conditions resembling a well-stirred reactor, and almost all furnace volume was filled with combustion products containing 2-3% of O_2, with high and uniform radiative heat fluxes, while Flamme [7] showed the capacity of achieving low NO_x emissions using this technology even with high preheated air levels. Recently, Weber et al. [2] demonstrated the potential of the technology for the combustion of liquid and solid fuels, and Flamme [8] and Schieper et al. [9], among others, evaluated its potential in gas turbine combustion chambers.

Related numerical studies include those of references [10-16], among others. Coelho and Peters [10] carried out numerical simulations of a flameless oxidation burner from a recuperative furnace. The numerical simulation was based on the Reynolds averaged Navier-Stokes (RANS) equations and the turbulence-chemistry interaction was accounted for by means of the non-premixed flamelet–PDF approach. The NO_x emission was calculated by the Eulerian Particle Flamelet Model (EPFM) in a post-processing step. They argued that the steady flamelet library was unable to correctly describe the formation of NO_x, since this is a chemically slow process, which is sensitive to transient effects, while the unsteady flamelet model was able to predict the correct order of magnitude of the NO_x emissions. Mancini et al. [11, 12] presented numerical simulations of a laboratory burner. The standard k-ε turbulence model was used together with three combustion sub-models: the eddy-breakup model (EBU) with a two-step reaction scheme, the eddy-dissipation concept model (EDC) with chemical equilibrium and the mixture fraction/PDF model with equilibrium tables. The uniformity of the temperature and O_2 fields was reproduced correctly, but the combustion models, which provided similar predictions, could not describe the chemistry and the temperature field in the fuel jet region.

Christo and Dally [13] performed simulations of high temperature and highly diluted turbulent reacting jets using three variants of the k-ε model (standard, renormalization group and realizable). The combustion/turbulence interaction was simulated using the conserved scalar approach along with an assumed PDF and equilibrium tables, the non premixed flamelet model, the eddy dissipation (EDM) and the EDC with skeletal and detailed chemical kinetics. They concluded that the standard k-ε turbulent model with a modified dissipation equation constant ($C_{\varepsilon 1}$) provides the best agreement with the experimental data, and the EDC model with skeletal and detailed chemistry performs better when compared to the conserved scalar models like PDF and flamelet models. Paul and Mukunda [14] presented numerical simulations of a flameless combustion test facility using the EDC model, a skeletal chemical reaction mechanism and including an extinction model based on the Da number. The predictions of this model compared well with the experimental results. Very recently, Duwig et al. [15] presented numerical simulations of a flameless oxidation combustor using the LES (Large Eddy Simulation) technique and a combustion model based on a tabulation technique proposed by Duwig and Fuchs [16] that includes detailed chemical kinetics based on the stirred reactor approach.

In spite of the studies above, the present knowledge on the theoretical foundations of flameless oxidation phenomena is still limited. In particular, there is a lack of detailed experimental data available to provide increased insight into the underlying physics, and there is no consensus about which combustion models are able to simulate accurately this combustion mode. The present article is aimed at contributing to overcome these shortcomings, by providing new experimental data and employing two different partially premixed combustion models. Both models combine a steady laminar flamelet approach for diffusion flames with another approach for premixed flames.

EXPERIMENTAL

Figure 1 shows schematically the combustor used in this study. The combustion chamber is a cylinder with a diameter of 150 mm and a length of 300 mm. The burner is placed at the top end of the combustion chamber and the exhaust of the burned gases is made by the bottom end through a convergent nozzle with a length of 50 mm and an angle of 35º. Along the length of the combustion chamber there are 5 ports, each with a diameter of 20 mm, which allow for the introduction of probes inside the combustion chamber. The chamber is equipped with electrical elements that allow preheating the combustor walls up to ≈ 900 ºC. Two thermocouples installed in the combustion chamber (Fig. 1) are used to monitor the wall temperatures and to evaluate the temperature gradients along the combustor. The burner consists of a central gas gun and a combustion air supply in a conventional double concentric configuration. The combustion air is preheated by an electrical system that allows inlet temperatures up to 750 ºC. The sampling of gases for the measurement of local mean O_2, CO, CO_2, unburned hydrocarbons (HC) and NO_x concentrations was achieved using a stainless steel water-cooled probe. The analytical instrumentation included a magnetic pressure analyzer for O_2 measurements, non dispersive infrared gas analyzer for CO_2 and CO measurements, a flame ionization detector for HC measurements and a chemiluminescent analyzer for NO_x measurements. Local mean temperature measurements were obtained using uncoated 76 μm diameter fine wire platinum/platinum: 13% rhodium thermocouples. The analog outputs of the analyzers and of the thermocouple were transmitted via A/D boards to a computer where the signals were processed and the mean values computed. Flue-gas data were obtained using the same procedures.

MATHEMATICAL MODEL

The mathematical model is based on the numerical solution of the Favre-averaged governing equations for mass, momentum and energy and on transport equations related to the turbulence and combustion models. The standard k-ε model was used to model the turbulence, the thermal radiation was taken into account using the discrete ordinates method and the radiative properties of the participating medium are modelled by the weighted-sum-of-grey gases model. Combustion models for diffusion flames employed in the past have revealed difficulties in modeling flameless oxidation phenomena, since the fuel mixes and reacts with a mixture of air and recirculated combustion products, rather than with pure air, as in conventional diffusion flames. In an attempt to describe this process, two different combustion models, hereafter referred to as models A and B, were employed. Both of them assume that the reactants are partially premixed and combine the steady laminar flamelet model for diffusion flames with a model for premixed flames. In the steady laminar flamelet model, the balance equations for the species mass fractions and temperature in the mixture fraction space were solved assuming unity Lewis number for all species. The turbulent effects were accounted for by integrating the laminar values over the mixture fraction space using an assumed beta PDF. The mean mass fractions of the species are stored in a library as a function of the mean mixture fraction, its variance and the scalar dissipation rate. Model A is a partial premixed turbulent combustion model based on the solution of a transport equation for a non-reacting scalar variable G, which represents the normal distance to the flame front. This G-equation may be derived from the local kinematics relation between the propagation velocity of a flame front in the unburnt mixture and the local flow velocity [17]. The model B is based on the premixed model presented in [18] and involves the solution of a transport equation for the reaction progress variable.

RESULTS AND DISCUSSION

The experiments performed in the small-scale combustor (Fig. 1), fired with methane, included initially flue-gas measurements for various combustor operating conditions as summarized in Table 1. They encompass various experimental flames which quantify the effects of the excess air

coefficient (tests 1 to 9), thermal input (tests 10 to 14) and combustion air inlet temperature (tests 15 to 18) on NO_x emissions and combustion efficiency from the present combustor. Subsequently, detailed measurements of local mean gas species concentrations of O_2, CO_2, CO, HC and NO_x and local mean gas temperatures for one representative combustor operating condition (test 10 in Table 1) have also been performed.

Flue gas measurements

Figure 2 shows the effect of the excess air coefficient (λ) on CO and NO_x emissions. It is seen that NO_x emissions are extremely low, as expected for flameless oxidation conditions, even near stoichiometry with a relatively high level of air preheating. The CO emissions are also extremely low, in particular for small values of λ. For values of $\lambda > 2$, however, the CO emissions become important. This is because an increase in λ causes a reduction in the temperature inside the combustor, as typified by the temperature of the exhaust gases displayed in Table 1, which slows down the reaction rate and hence increases the level of CO emissions.

Figure 3 shows the effect of thermal input and air inlet temperature on NO_x and CO emissions. Both NO_x and CO emissions are extremely low regardless of the thermal input. This suggests that the thermal density in the combustor does not affect the combustion performance provided the combustor wall temperature is kept constant. Fig. 3 also reveals that above 500 ºC the inlet air temperature has no significant effect on NO_x emissions. The reduction of the air inlet temperature reduces the temperatures inside the combustion chamber. This slows down the reaction rate which causes CO emissions to increase. Moreover, the reduction of the air inlet temperature causes a decrease in the air injection velocities which may affect the mixing process and thus CO emissions.

Figure 4 shows the effect of λ and $T_{in}/T_{wall} \times R_m$ on NO_x emissions and combustion efficiency, R_m

being the ratio of the inlet fuel to inlet air momentum fluxes. It should be noted that the data presented in both graphs of Fig. 5 include all the experimental conditions shown in Table 1. Combustion efficiency is here defined as $\varepsilon = 100\times\left[1-10109\times(EI_{CO}/\Delta h_c)-EI_{HC}/1000\right]$, where the emissions are expressed as emissions index (EI) and Δh_c is the lower heating value expressed in J/kg. The results show that increasing λ beyond ≈ 1.6 causes a reduction in ε. Large values of λ reduce the temperature inside the combustor, which in turn decreases the reaction rate, increases the CO emissions and penalizes the combustion efficiency. In addition, the parameter $T_{in}/T_{wall} \times R_m$ appears to correlate well with ε. This suggests that R_m affects the mixing process in the combustor and thereby the combustion efficiency.

In-flame data: measurements and modeling

The present calculations were carried out using a collocated, two-dimensional axisymmetric, non-uniform grid. The grid has a higher density in the region near the burner exit and in the vicinity of the centreline. In the inlet boundaries the radial velocity component at the burner exit was taken as zero, and the axial velocity was calculated from the fuel and air mass flow rates, respectively. The inlet turbulent kinetic energy, $\tilde{k}_{in}$, was estimated by assuming that the turbulence intensity is 10%.

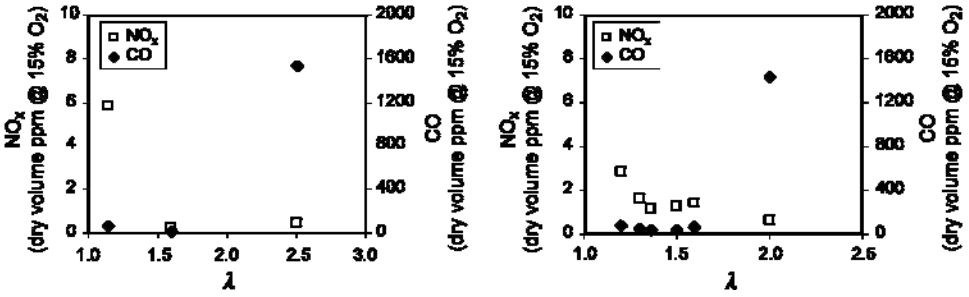

Figure 2. Effect of λ on CO and NO_x emissions. Left: tests 7 to 9; right: tests 1 to 6.

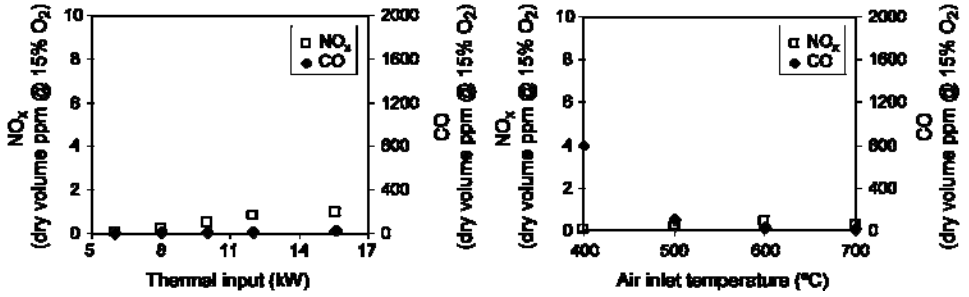

Figure 3. Effect of thermal input (left) and air inlet temperature (right) on NO_x and CO emissions.

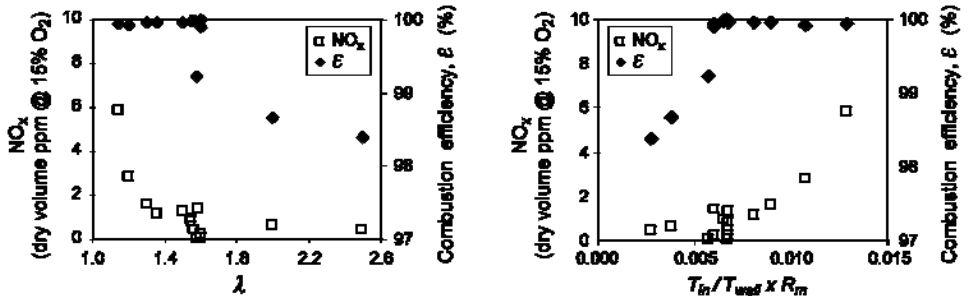

Figure 4. Effect of λ (left) and $T_{in}/T_{wall} \times R_m$ (right) on NO_x emissions and combustion efficiency.

The inlet values of the dissipation rate of the turbulent kinetic energy were determined from $\tilde{\varepsilon}_{in} = 0.169\,\tilde{k}_{in}^{1.5}/l$. The mixing length, l, was taken as the hydraulic radius of the fuel and air injector. The wall temperature was predefined and considered equal to the measured value and the wall emissivity was taken as 0.7. The commercial software COSILAB was used to compute the laminar flame velocity for different degrees of premixing and temperatures of the unburnt mixture. The laminar flame velocity computed is stored in a library as a function of the mean mixture fraction and the unburnt temperature. The values of temperature and mixture fraction upstream of the flame front were used to interpolate the laminar flame velocity and calculate the turbulent flame velocity.

Figure 5 shows the axial profiles of predicted temperature and O_2 and CO_2 mole fractions together with the measurements for test 10, while Figs. 6 and 7 show the radial profiles of temperature and O_2 also for test 10. The experimental data reveal that the temperature field inside the combustor is relatively uniform. The axial temperature profile is smooth and the radial profiles do not present the pronounced gradients typical of those encountered in conventional flames. The maximum measured temperature exceeds a little 1400 ºC in a small region of the combustor which explains the low NO_x emissions measured in the flue gases. As expected, the CO_2 molar fraction profiles present qualitatively the same trends as those of the temperature, being the O_2 molar fraction profiles complementary of those of the CO_2 and relatively uniform, except in the region where mixing is intense.

The predictions of both models are similar and, in general are in fair agreement with the experimental data, except in the near burner region where important differences between the computational results and the experimental data occur. Both models predict a moderate evolution of the temperature downstream of the burner. However, after this initial zone the models predict a strong gradient of the temperature and species concentrations, which is not supported by the experiments. In the computational domain, where the variable G is lower than zero, the molar fraction of the species and the temperature change only due to the mixing process between the combustion air, the recirculated products and the fuel. After this initial region, the variable G becomes greater than zero, and outside the thin layer that represents the turbulent flame thickness, the model becomes identical to the flamelet model for diffusion flames. This explains the predicted strong rise of the temperature and of the molar fraction of CO_2 and the reduction of the O_2 concentration. This is also valid for model B, *i.e.*, after the initial region of the combustor, where the variable c has values between zero and one, the model is identical to the flamelet model for diffusion flames. A possible source of inaccuracy common to both models may be the calculation of the laminar flame velocity, which does not account for the presence of the recirculation combustion products in the flame front. So, the laminar flame velocity computed by COSILAB and used in both models is likely to over predict the real value of the flame velocity in the conditions of the flameless oxidation regime. The same limitation affects the laminar flamelet data used to build the library of the chemicals species.

CONCLUSIONS

The main conclusions of this study are as follows:

- The flue gas data reveal that NO_x emissions are always low regardless of the combustor operating conditions. The CO emissions, and thus the combustion efficiency, are however strongly affected by the excess air level.
- The in-flame data disclose that the temperature field inside the combustor is relatively uniform, without the pronounced gradients typical of those encountered in conventional flames. The major species mole fraction profiles present, however, a less pronounced uniformity.
- The prediction of the temperature and major species mole fractions are in satisfactory agreement with the measurements, except in the near burner region, where the predicted rise in temperature and CO_2 mole fraction are too steep in comparison with the experimental data. The reduction of the O_2 concentration downstream of the fuel ignition is also over predicted.

EXPERIMENTAL POOL BOILING INVESTIGATIONS OF VERTICAL COALESCENCE FOR FC-72 ON SILICON FROM AN ISOLATED ARTIFICIAL CAVITY

ABSTRACT. In this study bubble growth from an isolated artificial cavity micro-fabricated on a horizontal 380 µm thick silicon wafer was investigated. The horizontally oriented boiling surface was heated by a thin resistance heater integrated on the rear of the silicon test section. The temperature was measured using an integrated micro-sensor situated on the boiling surface with the artificial cavity located in its geometrical centre. A resistive track was used as the sensor, which when calibrated, exhibited a near-linear behaviour with increasing temperature. To conduct pool boiling experiments the test section was immersed in degassed fluorinert FC-72. Bubble nucleation, growth and detachment at different pressures were observed using high-speed imaging. Coalescence was observed at the boundary between the isolated bubble and interference regimes. The occurrence of vertical coalescence was found to be more frequent, with increasing wall superheat and decreasing pressure.
The equivalent sphere volumes of two bubbles before and after coalescence were evaluated from area measurements. It was observed that the second nucleated bubble is always smaller than its predecessor. The vapour generation appears not to stop during coalescence as the volume of the merged bubble was typically 5-18% larger than the sum of the bubble volumes just before coalescence.

INTRODUCTION

Nucleate boiling heat transfer remains as a potential cooling solution for high-performance micro-processors. Despite the intensive research over the last decades, a comprehensive understanding of many aspects and mechanisms is still not available. One of these aspects is vertical coalescence. In general, coalescence is a hydrodynamic direct interaction between bubbles, as they collide and hence merge into one larger bubble.
Zuber [1] separated nucleate boiling into two regions, the regime of isolated bubbles and the region of interference. The isolated bubble regime in nucleate pool boiling has been discussed in many publications [2]. In this regime, bubbles are produced intermittently and do not interfere with each other. When the wall superheat increases, the waiting time between the nucleation of a new bubble and the departure of the previous bubble, grown from the same site, becomes shorter. If a certain critical temperature is reached, succeeding bubbles merge to form a mushroom-like bubble. This merger can also involve pairs consisting of a large bubble followed by a small one departing from

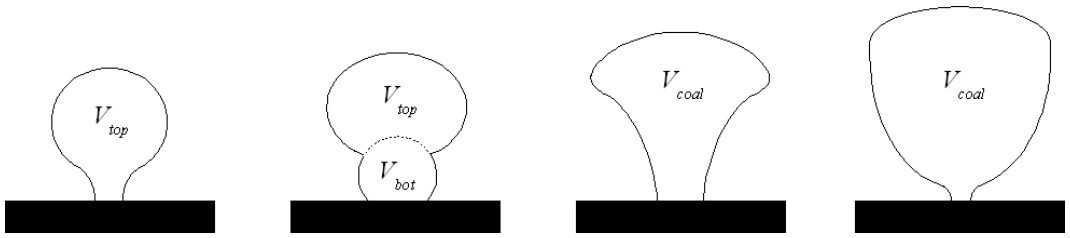

Figure 1. Vertical coalescence of two succeeding bubbles from an artificial nucleation site. The bubble with the volume V_{top} merges with the bubble with the volume V_{bot} to form a bubble of the volume V_{coal}.

the same nucleation site. This is known as the region of interference; bubbles interfere with each other and form continuous vapour columns and patches.

Buyevich and Webbon [3] investigated the limit of the isolated bubble regime. They identified four contributing mechanisms that lead to this limit, a) the upward flow of the rising bubble which obstructs the downward flow of liquid required to compensate for the vapour removal from the wall, b) lateral coalescence of bubbles from several nucleation sites to form large bubbles and extended vapour patches on the surface, c) longitudinal coalescence close to the wall, which results in the departure of dissimilar sized bubble pairs as mentioned before, d) longitudinal coalescence in the bulk, which leads to the formation of vapour columns. Buyevich and Webbon identified the last case as the most important effect for the termination of the isolated bubble region, as it can lead to the boiling crisis and trigger the critical heat flux.

Zhang and Shoji [4] classified 3 types of coalescence, i.e. vertical, horizontal and declining coalescence. Vertical coalescence occurs when during its growth phase a bubble touches the previously departed bubble, which is then drawn into and pulled away from the hot surface as illustrated in Figure 1.

Horizontal coalescence happens between two or more adjacent growing bubbles, which merge to form one large bubble. The merger of a growing bubble with an already departed bubble from an adjacent nucleation site is called declining coalescence. Zhang and Shoji concluded that bubble coalescence near the heated wall promotes growing bubbles to depart from the nucleation site. However, because vertical coalescence can occur for single and adjacent multiple nucleation sites, only horizontal and declining coalescence were thoroughly analysed. Although vertical coalescence is mentioned in several publications, this type of bubble interaction is usually not given much attention in the boiling heat transfer literature.

The bubbles in this study are growing from one isolated artificial cavity acting as nucleation site, allowing control of the location of the active site. Artificial cavities are widely used in boiling heat transfer research and mainly manufactured using microfabrication. Vapour or gas trapped in a cavity acts as a nucleus for the growth of a bubble. Bankoff [5] formulated the first criterion for pre-existing nuclei. This paper focuses on vertical coalescence occurring during nucleate pool boiling in the region of interference from an isolated artificial cavity. Coalescence is a hydrodynamic direct interaction between bubbles, as they collide and hence merge into one larger bubble. This is only of interest when occurring close to the heated surface, because away from the surface the impact on the boiling heat transfer is small [6].

EXPERIMENTAL SETUP

The working fluid was fluorinert FC-72, which is widely used for boiling experiments due to its non-toxicity, non-flammability and its low boiling temperature (T_{sat} = 57.15 °C at p = 1 bar). Its good dielectric properties make it possible to immerse the bare electrical connections to the 380 µm thick

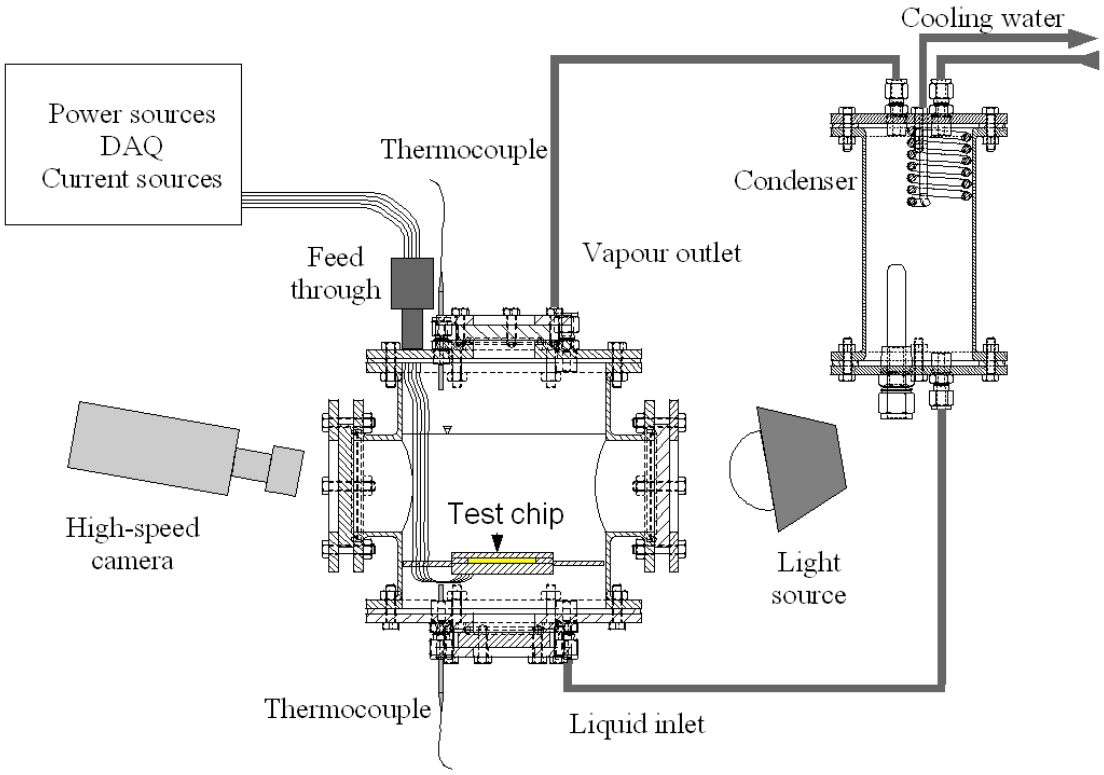

Figure 2. Experimental setup including the main parts boiling chamber with test section, condenser, high-speed camera and backlight source.

silicon test section into the liquid. Electrical connections from the silicon chip are made through an air-tight feed-through in the wall of the stainless steel boiling chamber to provide the interconnect to the DAQ, the power supply for the integrated resistance heater and the constant current sources for the integrated micro-sensors. The chamber has four windows for optical access to the test section as shown in Figure 2. The wall temperature of the chamber is controlled by two silicone heater pads wrapped around the chamber. Four heater elements at the bottom of the chamber are used for degassing and bringing the liquid to the set temperature. Two thermocouples inside the chamber measure the temperature of the liquid and the vapour. If they indicate the same temperature, the saturation pressure has been reached and saturated boiling is taking place. The pressure in the chamber is measured by a calibrated pressure transducer with measurement error smaller than 0.2%. Boiling can be maintained at any pressure between 0.5 and 3 bar by adjusting the condenser cooling water flow with a valve and the temperature with a heating bath.

An isolated cylindrical artificial cavity with a mouth diameter of 10±0.5 µm and a depth of 80±5 µm was micro-fabricated on the top surface of the silicon test section. A Ti/Ni micro-sensor with a square shape covering an area of 0.84 mm x 0.84 mm was deposited around the artificial cavity. The silicon chip was held in place and, except for the actual boiling surface, insulated with a frame made of PEEK, which has similar thermal properties to PTFE. Spring probes were used, in order to ensure a good electrical contact between the integrated heater and sensor on the chip and the wires. The resistance of the sensor was calibrated using a standard thermometer and exhibits a near linear behaviour with temperature.

After the boiling liquid is thoroughly degassed and the set pressure reached, boiling from the artificial cavity is initiated with the resistance heater integrated on the rear of the silicon wafer. Bubble growth is observed with a high-speed camera and a backlight source positioned on the opposite side. The temperature readings from the micro-sensor are simultaneously acquired through a trigger. Synchronisation is necessary to correlate measurements to video recordings and will be

essential to link small changes in local wall temperatures to the bubble dynamics in future studies. In this paper the sensors are used to measure the time averaged wall surface temperature in the immediate vicinity of the nucleation site for the duration of recording. The limit of error is 0.5 K for all wall superheat measurements and the standard deviation is within the error. However, no error bars are indicated in the plots in order to improve legibility. The heat flux was measured with a voltage and current meter and has an error of ±1%.

Figure 4. Average frequency of nucleation with increasing wall superheat for a) 0.5 bar, b) 0.75 bar and c) 1 bar.

EXPERIMENTAL RESULTS AND DISCUSSION

The lowest possible wall superheat is limited by the internal temperature of the nucleus, which must equal the saturation temperature for the pressure of the vapour phase in order for the nucleus not to shrink. It is calculated from the Laplace equation:

$$p_g - p_l = \frac{2\sigma}{r_b} \tag{1}$$

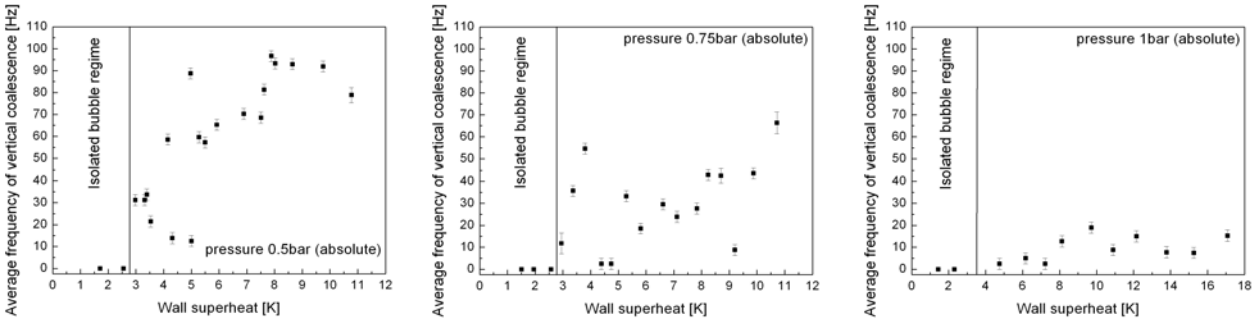
where p_g is the vapour pressure, p_l the pressure of the liquid, σ the surface tension and r_b the nucleus curvature radius which equals the cavity mouth diameter r_c. For 0.5 bar, 0.75 bar and 1 bar the minimum temperature differences are 1.98 K, 1.29 K and 0.94 K.

The average frequency of nucleated bubbles and vertical coalescence from an isolated single cavity were measured using high-speed images for absolute pressures of 0.5 bar, 0.75 bar and 1 bar with increasing wall temperature superheat. Figure 3 presents a sequence of bubble growth at 0.5 bar absolute pressure and a wall superheat of 7.9 K (applied heat flux 4.8 kW/m^2) with camera set to 1000 fps. Bubble nucleation occurs at 0 ms and for the first 11 ms the bubble growth follows the common behaviour of a single bubble. At 11 ms a second bubble nucleates from the same artificial cavity and within 3 ms completely merges with the previously departed upper bubble. At 15 ms a third bubble nucleates, but does not coalesce with its predecessor during growth. The occasionally visible widening of the bubble base is due to reflection of the bubble on the silicon surface.

Figure 4 shows the average nucleation frequency with increasing wall superheat for the above three pressures. With increasing pressure the number of nucleations per second decreases. With increasing wall superheat this number of nucleations initially increases sharply and seems to level off, with this behaviour being more pronounced for the 0.5 bar pressure case. The results for 0.75 bar are rather scattered and for 1 bar the initial increase is less noticeable.

Figure 5 presents the average frequency of vertical coalescence for the same three pressures with increasing wall superheat. Lowering the pressure or increasing the wall superheat increases the occurrence of coalescence. The average frequency of bubble nucleation corresponds to an increase in the average frequency of vertical coalescence, as coalescence tends to reduce the bubble growth time. Bubbles are pulled away from the surface at much smaller size and this increases the number of nucleations for the same time period but increases the total growth time of the two bubbles only by a few milliseconds.

Figure 6 compares the average frequency of vertical coalescence with the number of nucleations (*VC*/*Nu*). At 0.5 bar approximately 50% of the bubbles coalesce for higher wall superheats. The



a) b) c)

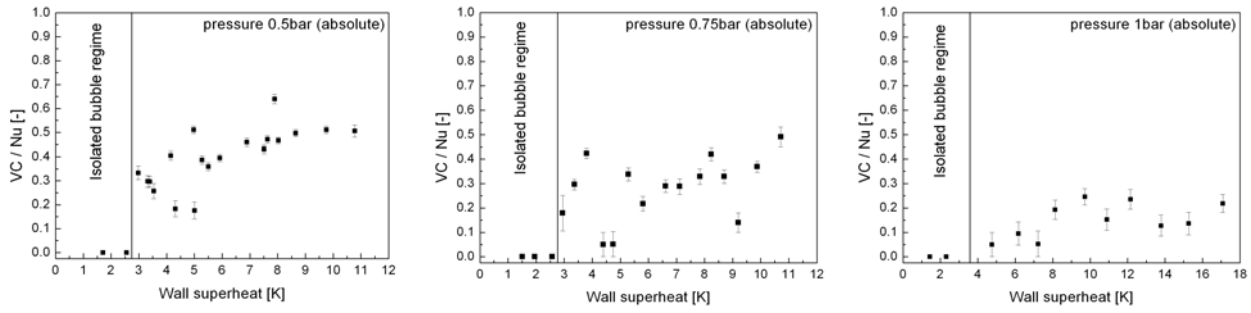
Figure 5. Average frequency of vertical coalescence with increasing wall superheat for a) 0.5 bar, b) 0.75 bar and c) 1 bar.

ratio remains at this level even with increasing wall superheats. A possible explanation for this behaviour might be the fact that vertical coalescence most commonly appears only in pairs, i.e. only very rarely does a third bubble coalesce with already vertically coalesced bubbles. As the pressure increases, the ratio between vertical coalescence and nucleations decreases. For 1bar the maximum ratio is around 0.2 for high wall superheats. This means that around three bubbles depart as single bubbles before vertical coalescence occurs between the two that follow. Measurements for 0.75 bar tend to lie in between the results for the lower and higher pressure.

Following the above observations the volumes of ten bubble pairs immediately before and after coalescence are presented. The pressure was 0.5 bar with a wall superheat of 7.9 K (applied heat flux 4.8 kW/m^2). Bubble vapour volumes were estimated from high speed image sequences and Figure 7 presents an example sequence. The original images were processed with the software PCO Picture Viewer and a suitable threshold helped to identify the bubble area. The program then solved the equation:

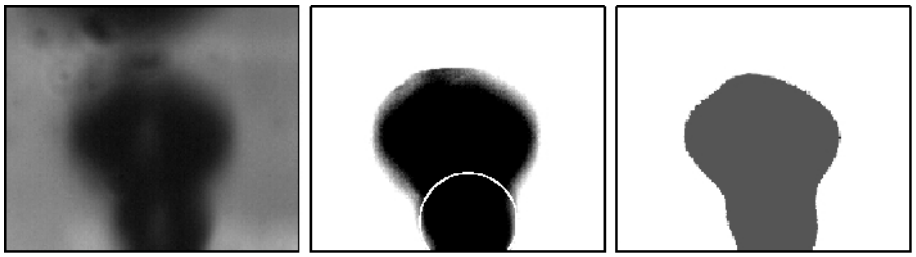
$$V = \pi \int_0^y r_b(y)^2 dy \tag{2}$$

where $r_b(y)$ is the bubble radius depending on the vertical position. The volume was scaled with a reference image loaded into the software. The measurement error was estimated to be ±0.005mm for the bubble radius. Due to the invisibility of the intersection between the top and bottom bubble the shape of the bottom bubble was assumed to be spherical. Since small single bubbles have a small Eötvös or Bond number, gravitational effects are negligible and the shape is near spherical.



a) b) c)

Figure 6. Ratio of the average frequency of vertical coalescence and bubble nucleation with increasing wall superheat for a) 0.5bar, b) 0.75bar and c) 1bar.



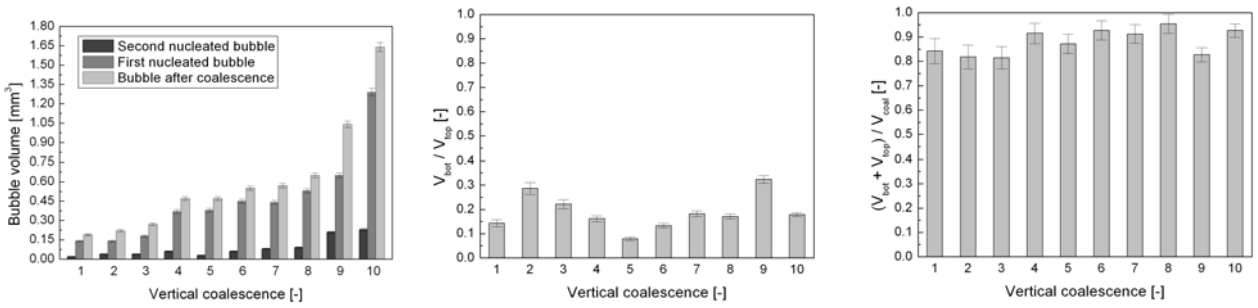
a) b) c)

Figure 7. a) Original image during bubble growth with vertical coalescence. b) Processed picture with the assumed shape of the bottom bubble indicated. c) Area measured with PCO Picture Viewer software. From this area the volume of revolution is calculated.

Figure 8 a) shows the results with the systematic measurement error indicated. The newly nucleated bubble (bottom bubble) is always smaller than the previously departed one (top bubble) and the total volume immediately after coalescence is larger than the sum of volumes before the coalescence. Figure 8 b) shows the ratio between the volume of the bottom bubble V_{bot} and the top bubble V_{top} with error bars indicating the propagated systematic measurement error. The volume of bottom bubble never exceeds one third of the volume of the top one. The smallest bottom bubble compared to its top one is 10 times smaller than its predecessor. Figure 8 c) illustrates the ratio between the sum of the volumes of the two bubbles $V_{bot}+V_{top}$ immediately before coalescence and the total volume V_{coal} just after (1ms). After coalescence the total volume is 5-18% larger than before. This suggests that the process of coalescence causes a brief increase in heat transfer to the liquid-vapour interface. This might occur at the base of the second bubble, or by heat transfer from a thin superheated liquid layer trapped between the bubbles, or by rapid motion close to the line of coalescence.

CONCLUSIONS

Bubble growth from an isolated artificial cavity at the end of the isolated bubble regime and the beginning of the regime of interference, where vertical coalescence appears, has been experimentally investigated. The phenomenon of vertical coalescence was visualised and quantified using high-speed imaging. Further studies of longer sequences at different wall superheats and pressures of 0.5 bar, 0.75 bar and 1 bar revealed the dependence of vertical coalescence on these properties.



a) b) c)

Figure 8. a) Bubble volume immediately before coalescence and the total volume after for 10 pairs of bubbles. b) Ratio between the volume of the newly nucleated bubble (bottom bubble) and the previously departed bubble (top bubble) for the same 10 bubble pairs. c) Ratio of the total volume of the top and bottom immediately before coalescence and the volume of the coalesced bubble.

With increasing wall superheat bubble growth changes from the isolated bubble regime into the regime of interference. The average frequency of bubble nucleation and vertical coalescence increased with the wall superheat. Decreasing the pressure, increases the average frequency of vertical coalescence and therefore subsequently the average frequency of nucleated bubbles from the artificial cavity. At 0.5 bar every two nucleated bubble pairs merge into one for high wall superheats. At 1 bar up to three single bubbles depart from the artificial cavity, before two coalesce.
The equivalent volume of a sphere was calculated for ten pairs of bubbles immediately before and after they coalesced. The second nucleating bubble is always smaller than its departed predecessor. During coalescence the vapour volume still increases, as the merged bubble is between 5 and 18% larger than the summarised volumes of the two bubbles before coalescence.

EXPERIMENTAL STUDY OF HEAT TRANSFER INSIDE A HYDROGEN COMBUSTION ENGINE: MEASUREMENTS UNDER MOTORED CONDITIONS

J. Demuynck*, M. De Paepe, H. Huisseune, C. T'Joen, S. Verhelst
Ghent University, Gent, Belgium

ABSTRACT. This paper presents the first stages of an experimental study of heat transfer inside a hydrogen combustion engine. A heat transfer model for hydrogen engines is under development and measurements are carried out for validation. The current paper describes heat transfer measurements in the cylinder under motored conditions. Transient heat flux is evaluated at the cylinder head and liner with a commercially available sensor. The influence of the compression ratio and measuring position is investigated. Results show that the peak of the heat flux trace rises with increasing compression ratio. The position of the peak remains the same for all the compression ratios. The heat flux is negative during the intake and differs from position to position because of differences in the local air flow field. The flux varies less in the compression and expansion stroke but a large cyclic variation is present in that part of the cycle.

INTRODUCTION

Hydrogen-fuelled internal combustion engines are attractive as they offer the potential of near-zero noxious emissions, high efficiency and zero greenhouse gas emissions. Computer simulation of the performance enables a cheap and fast optimization of engine settings for operation on hydrogen. A quasi-dimensional simulation model, the GUEST-code (Ghent University Engine Simulation Tool), has been developed by Verhelst and Sierens [1]. Up until now the GUEST-code has simulated power output and efficiency of hydrogen engines with good accuracy. The simulation tool has been validated for varying mixture richness, ignition timing and compression ratio.

In a next step emission calculations will be added to the GUEST-code. In hydrogen engines NO_x emissions occur at high loads. It is important to describe the heat transfer from the burning gases to the cylinder walls in a sub-model in order to calculate the maximum gas temperature which influences the NO_x emissions. Several models exist but they have been developed for fossil fuels and are cited to be inaccurate for hydrogen engines [2, 3]. The maximum possible heat transfer in an engine operating on hydrogen is expected to be higher than in a hydrocarbon-fuelled one. The shorter quenching distance of hydrogen leads to a thinner thermal boundary layer, the higher flame speed causes an intensified convection and hydrogen has a higher thermal conductivity. A new model for the heat transfer in hydrogen engines is under development and measurements inside an engine are carried out for validation.

A stepwise investigation of the heat transfer inside a cylinder is performed in order to fully understand the process and all the effects which take part in it. First of all measurements under motored operation are investigated to decouple the flow and turbulence from combustion. The

Reynolds and Nusselt number should be the same under motored and fired operation according to Nijeweme [4], so it is interesting to look at the heat transfer without having combustion. The stepwise investigation also allows an exploration of the possibilities of the heat flux sensor. In this paper a sensor is mounted in a CFR-engine (CFR: Cooperative Fuel Research) and measurement results under motored conditions are discussed. The flow field inside this type of engine (modified for optical access) has been investigated by Namazian [5] with Schlieren visualisation techniques. The flow field inside the CFR engine can be summarized as follows. It takes a while after IVO for the gases to enter during the intake stroke. A shrouded intake valve induces a counter clockwise swirl and a vortex flow is created in the top left and right hand corners of the cylinder (see Figure 1). This vortex is present through the intake process, persist during compression and still influences the flow field during expansion. Again it takes a while after valve opening before the gases start to move during the exhaust stroke.

EXPERIMENTAL EQUIPMENT

Test engine. Heat transfer is measured in the cylinder of a CFR-engine. This single cylinder engine has a variable compression ratio (ε) and a constant rotation speed of 600 rpm. The cylinder liner and head are one piece so it is difficult to install sensors. However, four holes with an M18 thread are available in the cylinder head for sensor mounting (see Figure 1). One hole is lost in case of fired operation because of the spark plug. The geometrical properties and valve timing of the engine are summarised in Table 1. The intake valve is shrouded and induces a swirl as mentioned above.

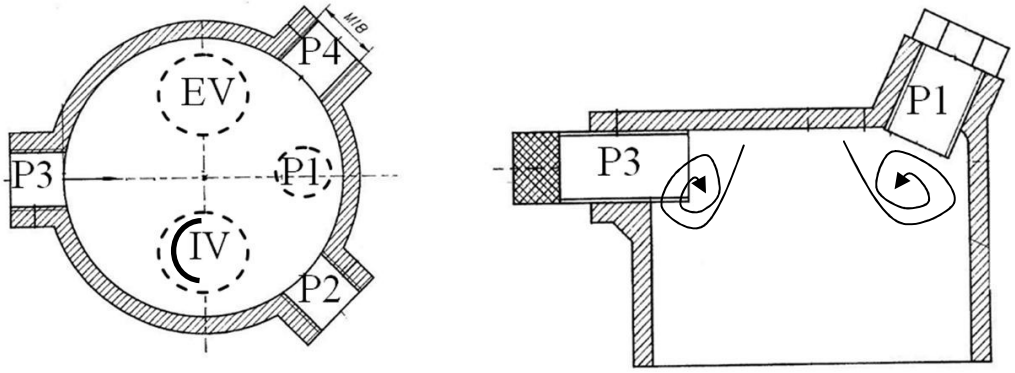

Figure 1. Top and side view of the CFR-engine, P1-P4: sensor positions, IV: shrouded intake valve, EV: exhaust valve

Table 1
Geometrical Properties and Valve Timing of the CFR-engine

Bore	82.55 mm
Stroke	114.2 mm
Connecting rod length	254 mm
Stroke volume	611.7 cm³
Intake valve opening (IVO)	17 °ca ATDC (After Top Dead Centre)
Intake valve closing (IVC)	26 °ca ABDC (After Bottom Dead Centre)
Exhaust valve opening (EVO)	32 °ca BBDC (Before Bottom Dead Centre)
Exhaust valve closing (EVC)	6 °ca ATDC

Heat transfer sensor. The sensor used for heat transfer measurements in the engine is a custom-made HFM-7 E/L (Heat Flux Microsensor) from Vatell Corporation [6]. The sensor has two signal outputs. Firstly an HFS-channel (Heat Flux Sensor) which is the voltage of a thermopile proportional to the heat flux, secondly an RTS-signal (Resistance Temperature Sensing) which is the resistance of a platinum RTD (Resistance Temperature Detector) proportional to the temperature of the substrate of the thermopile. Figure 2 shows the head of the sensor with the thermopile in the centre (diamond shape) and the RTD in a loop around it.

The basic principle of a heat flux sensor is to measure the temperature gradient over a layer with known thermal properties. The thermopile however measures the heat flux over a thin layer (in the order of 1 µm) so the temperature gradient is very small and one thermocouple pair would result in an immeasurable signal. That is why several thermocouple pairs are connected in series to give a measurable signal output which is in the order of 150 µV for 1 W/cm² in the case of the HFM (see Figure 3, TL&TH: temperatures at each side of the layer, A&B: the two different metals of the thermocouples). The temperature measured with the RTD is used to correct the HFS signal because the thermal properties of the sensor substrate are temperature dependent.

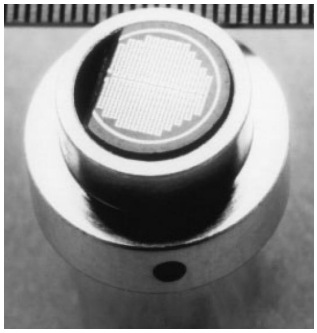

Figure 2. HFM-7 E/L sensor

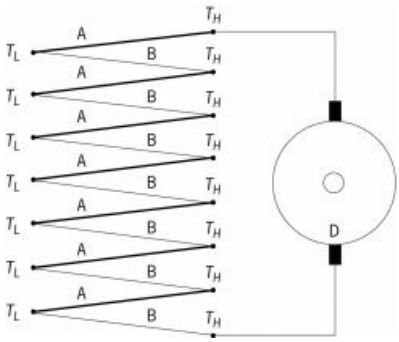

Figure 3. Construction of a thermopile

The HFS and RTS signal are sent to an AMP-6 amplifier from Vatell Corp. It sends a current of 100 µA through the RTD and measures the corresponding voltage drop. The two signals are amplified with a selectable gain. The sensor is calibrated by Vatell Corp. and the calibration coefficients make it possible to calculate the heat flux and sensor temperature out of the two measured voltage signals. At the beginning of each measurement the HFS and RTS signal have to be zeroed at zero heat flux and a known temperature.

Other sensors and data acquisition. Two pressure transducers are mounted, one in the intake manifold and one in the cylinder. The transducer in the intake manifold is of the piezoresistive type and the one in the cylinder of the piezoelectric type. An encoder is mounted on the crankshaft in order to sample the measured signals at certain degrees crank angle (°ca). A 12-bit Keithley data acquisition card collects the data of the four channels every 0.1 °ca.

MEASUREMENTS

Test conditions. The commercially available film type heat flux sensor is mounted in the CFR-engine in four different positions (P1-P4) as shown in Figure 1. The pressure transducer is mounted in P2 or P4. Measurements under motored conditions at 600 rpm are executed, investigating the influence of the compression ratio and the measuring position on the heat flux. The compression ratio is varied from 6 to 15 during measurements in P1 and heat flux is measured in the four positions for ε equal to 10. Only air is sucked into the engine. The heat flux and pressure traces are averaged over 20 cycles (unless it is mentioned otherwise).

Results and discussion. Heat flux is positive when heat is transferred from the walls to the gases and negative when the gases cool the wall. If the heat transfer is negative and the flux trace decreases, an enhancement in heat transfer occurs. So an observed decreasing in the heat flux trace will be described as an improved heat transfer. Heat flux is plotted on the left vertical axis and pressure on the right one if they are given in one figure.

The heat flux traces at P1 for varying compression ratio are shown from Figure 4 to Figure 6. In Figure 4 it can be seen that during intake the heat flux is negative so heat is flowing from the wall to the air which is colder. The heat transfer increases for increasing ε because the wall temperature rises and there is a bigger temperature difference between the air and the wall. The heat flux starts to decrease at an earlier degree crank angle for increasing ε because there is a larger difference between the inlet and cylinder pressure so air enters the cylinder more rapidly.

The peak of the heat flux trace during compression increases with increasing ε (see Figure 5) because of rising gas temperature, the average heat flux trace peaks a little bit before TDC for every ε. The flux decreases more for higher ε at the end of the expansion stroke, except for ε=12. It will be investigated with more measurements around this compression ratio whether this is a measuring error or an anomaly. The trend for lower and higher compression ratios may differ from those around ε=12 because of contradictory effects.

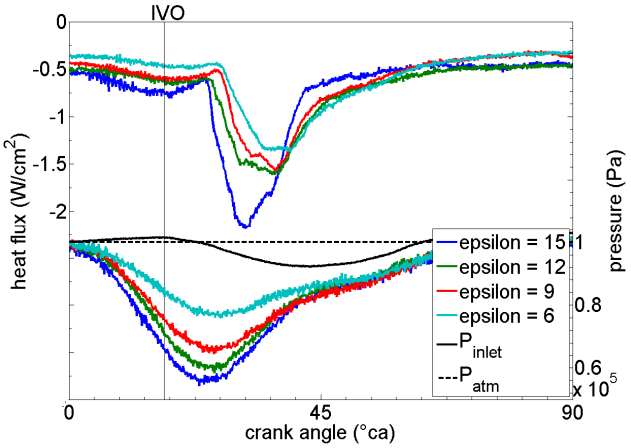

Figure 4. Heat flux and pressure (cylinder and inlet) for varying compression ratio at P1 during intake stroke

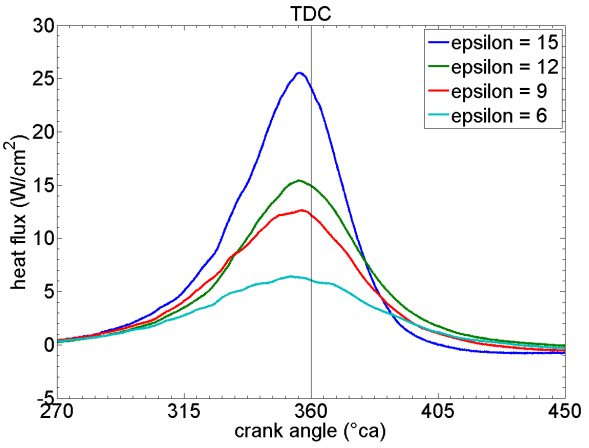

Figure 5. Heat flux for varying compression ratio at P1 during the compression and expansion stroke

Figure 6 shows the heat flux and cylinder pressure during the exhaust process. It appears that the cylinder pressure is lower than atmospheric pressure at EVO so air from the exhaust manifold flows into the cylinder. The pressure rises because of the inflowing air and the actual exhaust process starts a while after BDC which causes the heat flux to level off. The heat transfer (negative again) increases before BDC with increasing compression ratio, but again ε=12 is an exception.

No consistent difference can be found between the four measuring positions during the compression and expansion stroke. Certain measurements show equal heat fluxes for varying measuring positions (see Figure 7). Others show differences, but these are never consistent. The reason is shown in Figure 8. The cyclic variation of the heat flux during the compression and expansion stroke is higher as one might expect under motored conditions. The difference between the peak of the mean and the maximum flux trace is around 10 W/cm², which is 67% of the mean peak value. This cyclic variation is not present during the intake and the exhaust stroke.

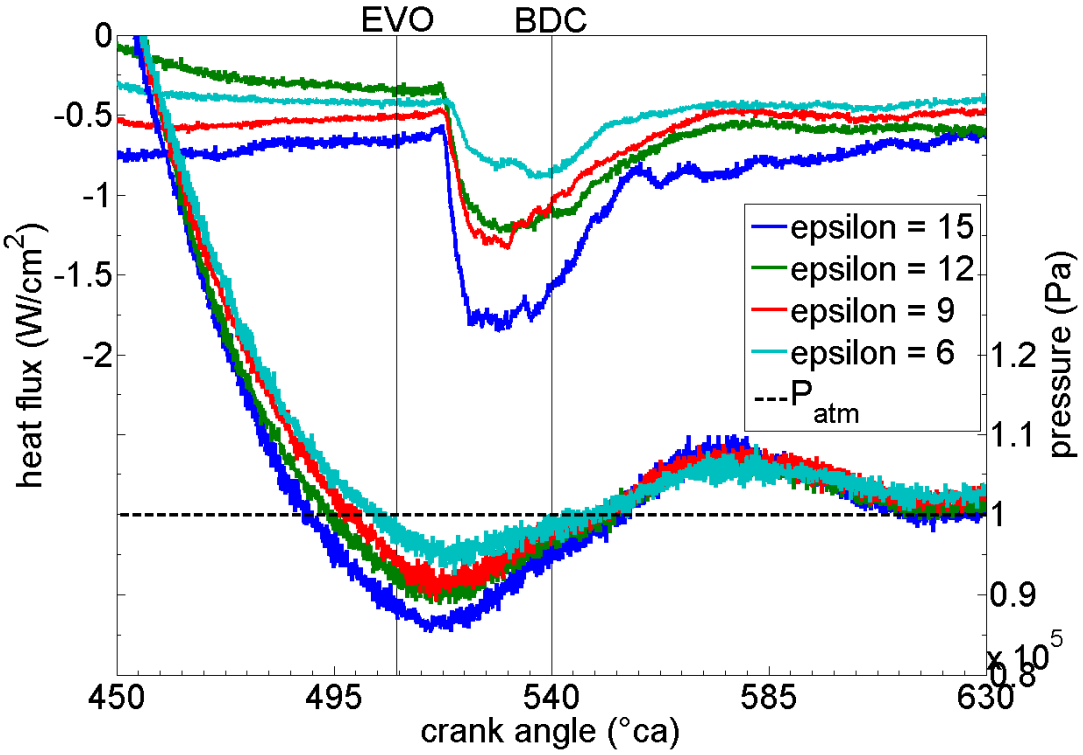

Figure 6. Heat flux and cylinder pressure for varying compression ratio at P1 during the exhaust process

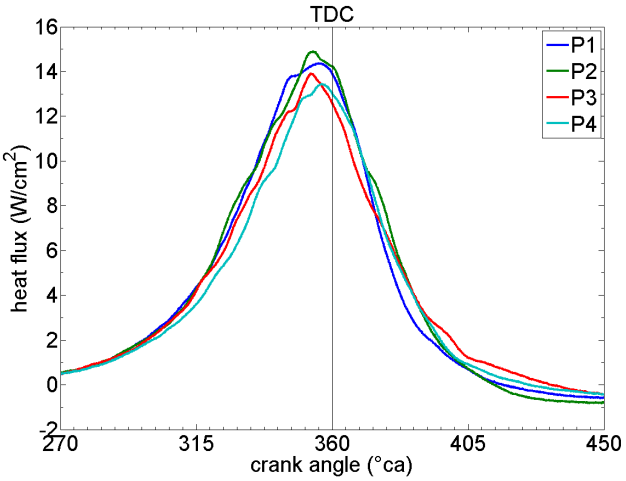

Figure 7. Heat flux for varying measuring position during the compression and expansion stroke (ε=10)

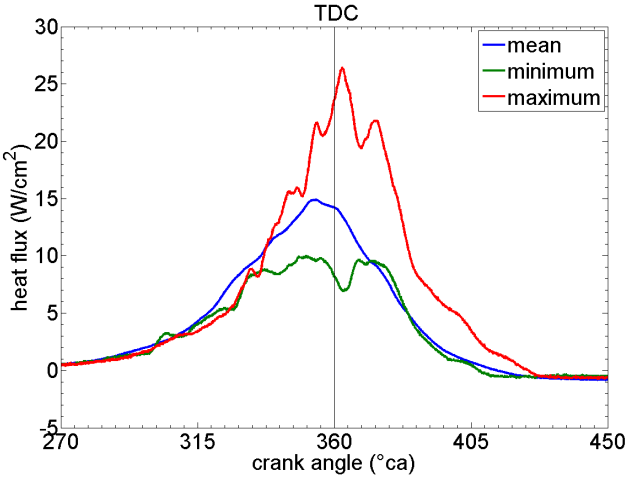

Figure 8. Cyclic variation of heat flux at P2 (ε=10)

This indicates that turbulence and gas motion (with a large cyclic variation) influence the heat flux trace during compression. The temperature and the amount of mass of air entering or exiting the engine do not fluctuate much over cycles and have to be the driving forces of the heat transfer in the intake and exhaust process. The heat flux traces in Figure 9 support this idea. A throttle in the intake manifold is stepwise closed to create extra turbulence. At first the heat flux rises during compression. When the gas temperature decreases too much because of lower cylinder pressure (throttle is almost closed and causes a strong expansion of the inflowing air so cylinder pressure at IVC is beneath atmospheric pressure), the heat flux starts to decrease again.

Two important differences can be seen in the heat flux traces (negative again) during the exhaust stroke (Figure 10). It takes a while for the incoming exhaust air to reach P2 which lies furthermost away from the exhaust valve, so the heat transfer augments at a later degree crank angle than at the other positions. Less air reaches P3 so the minimum in the heat flux trace is less deep. The heat flux remains constant a little bit after BDC when the actual exhaust process occurs.

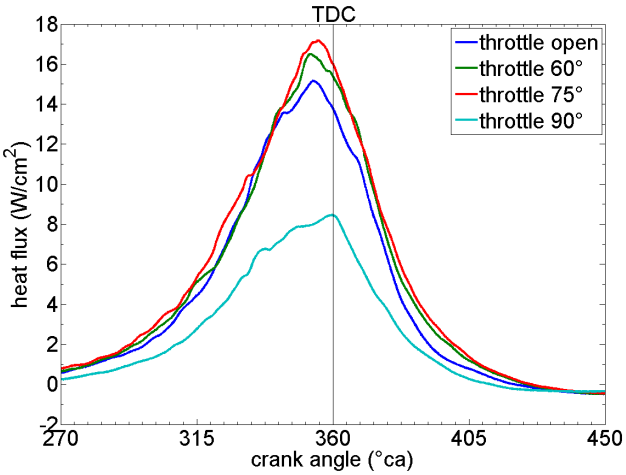

Figure 9. Heat flux for varying throttle opening during the compression and expansion stroke at P1 (ε=10)

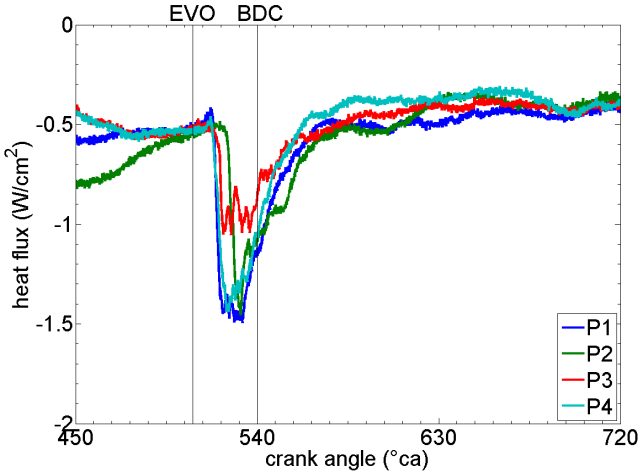

Figure 10. Heat flux for varying position at P1 during the exhaust stroke (ε=10)

There is more variation in heat transfer from position to position during the intake process. A bigger temperature difference between wall and gas, more inflowing air and a shrouded intake valve are the causes for this pronounced variation. The shroud opens in the direction of P1 as drawn in Figure 1 so a counter clockwise swirl is induced. First the existence of the swirl will be demonstrated. Then a general description of the heat flux traces in the four positions will be given starting at IVO going to IVC. The heat flux traces are negative again, so a decrease actually means an increase in heat transfer.

The existence of this swirl can be seen in Figure 11 if one only focuses on the heat flux traces at P2 and P4. The heat transfer at P4 starts to increase at a later degree crank angle than at P2 because it takes a while for the swirl to reach P2. The minimum in the flux trace at P4 is less deep because the incoming air warms up in its way towards P4. The second drop in the heat flux trace at P2 (starting around 48 °ca) can also be found with a delay at P4 (starting around 80 °ca). The drop at P4 is less profound again. The heat transfer at P3 and P1 starts to increase simultaneously with the one at P2. The minimum at P1 is less deep than at P2 so more fresh air reaches P2. Strangely the heat transfer at P3 increases at the same time as at P2 (but less profound) because one should expect no air reaching P3 because of the shrouded intake valve. Two reasons could explain this phenomenon. Firstly a little bit of air could flow at the left side of the shroud in the direction of P3. Secondly a general change in gas speed following the start of the intake process could cause an enhancement in heat transfer without fresh air reaching P3.

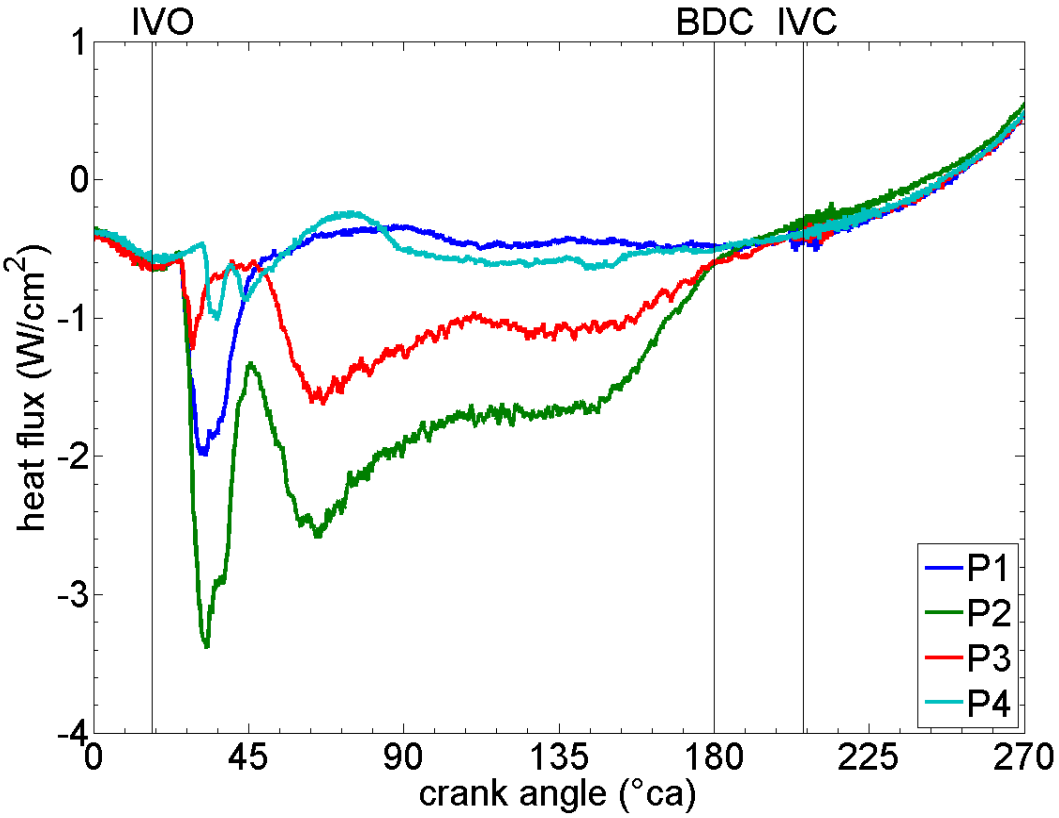

Figure 11. Heat flux for varying measuring position during the intake stroke (ε=10)

Now a general overview of the heat flux traces in Figure 11 will be given starting around IVO. Before the heat transfer at P1, P2 and P3 increases around 8 °ca after IVO, they decrease a little bit because gas speed is dropping after EVC. This counters the effect of dropping cylinder pressure and gas temperature which create a bigger temperature difference between the gas and the wall, hence an increase in heat transfer. After 10 °ca the heat transfer at P1 and P2 drops again because the rising cylinder pressure starts to increase the gas temperature in the cylinder (see the pressure traces in Figure 4). The heat transfer at P3 drops earlier. Only the heat transfer at P4 then increases again around 40 °ca. Perhaps the swirl coming from P2 has just reached P4 causing this augmentation which could mean the first increase at 33 °ca is caused by the possible general change in gas speed (mentioned above) reaching P4.

The transfer at P2 and P3 increases again around 48 °ca. This could be caused by the pressure wave in the intake manifold which increases the mass flow rate at that moment. This increase occurs simultaneously again at P2 and P3 (less profound). One could imagine the swirl travelling around the entire cylinder causing the increase in the heat transfer at P2, but this should then be visible earlier at P3. The heat flux at P1 remains constant after 48 °ca because of the vortex in the top right hand corner of the combustion chamber as mentioned above. The heat transfer reduces again because of lowering gas speed and rising cylinder pressure and temperature. The levelling off at P2 and P3 from 110 °ca until 150 °ca can be explained by the pressure wave in the intake manifold which causes a second increase in the mass flow rate of the incoming air.

CONCLUSIONS

Heat transfer measurements have been carried out in an engine under motored operation as a first part of the stepwise research on heat transfer in a hydrogen engine. The influence of the compression ratio and measuring position is investigated with following conclusions:

- The heat transfer augments with increasing compression ratio. A bigger temperature difference between wall and gas is the cause of this enhancement during the intake and exhaust stroke. The heat transfer starts to increase earlier with increasing compression ratio because of a bigger pressure difference between intake or exhaust manifold and cylinder. The increasing gas temperature is the cause of the increasing heat transfer during the compression and expansion stroke.
- The trend around ε=12 could be different and this will be investigated with extra measurements.
- The heat transfer varies along the cylinder wall surface during the intake and the exhaust stroke. The delay between the heat flux trace at P2 and P4 shows the effect of the shrouded intake valve. No significant difference in heat transfer for varying measuring position can be seen during the compression and expansion stroke.
- Cyclic variation in turbulence causes a large cyclic variation in the heat flux around TDC during the compression and expansion stroke.

HOW TO ESTIMATE THE HEAT TRANSFER DUE TO DROPLETS IMPINGING ONTO A HOT SLAB?

F. Lelong[1,2], M. Gradeck[1,*], A. Ouattara[1], D. Maillet[1], N. Seiler[2]

Abstract: The present work achieved in collaboration between LEMTA (Laboratoire d'Energétique et de Mécanique Théorique et Appliquée) and IRSN (Institut de Radioprotection et de Sûreté Nucléaire) aims at accurately characterizing the heat flux removed by single droplet (50-300µm diameter) impinging onto a hot surface. As the interaction between the droplet and the wall is very fast (a few of ms), the experimental set-up to measure the heat flux during the resident time of the droplet at the wall has been carefully designed. The heat flux due to the droplet impingement is estimated using a semi-analytical inverse heat conduction model. The resolution of the inverse heat conduction problem (IHCP) is based on an analytical solution of the direct problem. The unsteady heat equation is double transformed in the Laplace-Hankel space. As the transform temperature can be expressed as a linear function of the transform heat flux, a least square method can be used to estimate the heat flux. The goal of this paper is to described the experimental method for measuring this cooling flux.

INTRODUCTION

Liquid cooling is unavoidable in applications where the required power dissipation must be very important. Possible liquid cooling technologies include single-phase boiling, immersion flow boiling, jet impingement cooling, spray cooling. This study is concerned with the safety of nuclear pressurized water reactor (PWR). During a LOCA (Loss of Coolant Accident, basic designed accident for PWR), a pipe rupture in the primary circuit could lead to an important rise of the fuel rod temperature because of the water vaporization in the nuclear core reactor. This is followed by the thermal mechanical swelling of the clad and consequently by the rupture of the fuel clad, Fig.1. The reflooding phase is initiated by water injection after the activation of security system. During this phase, liquid water is injected into the reactor core in order to cool down the fuel rod heated by the nuclear residual power. This water, rising along the rods, is instantaneously vaporized because of the very high wall temperature. The important amount of vaporized water leads to create a high vapor flow, which pulls up and drags some water droplets above the quenching front. As one of the safety issues is the coolability of the fuel assemblies in the blockage regions, the capacity of the generated mist flow to cool down the fuel blockage region must be accurately evaluated. Thus, it is necessary to characterize the mist flow in these zones and its effect on the heat transfers to be able to predict the transient of the nuclear core during a LOCA. Up to now, no measurement of heat transfer for single droplet impinging a hot wall has been experienced. These experiments are now performed at LEMTA located in Nancy (France). An experimental program, with droplet and wall

characteristics (velocity, diameter and temperature) in agreement the LOCA conditions, is performed.

LITTERATURE SURVEY

The estimation of the heat transfer removed from the wall by the impinging droplets is thus one part of the work devoted to LOCA safety studies. A lot of experimental studies of droplets impacting onto a heated surface are extensively reported in the literature. When a droplet interacts with a hot wall, the impact regime is determined by two important dimensionless parameters : the Weber number $We = \frac{\rho_L D_d u^2}{\sigma}$ which is the ratio of the impact inertial force to the surface tension force and the dimensionless temperature $T^* = \frac{T_w - T_{sat}}{T_{Leid} - T_{sat}}$. So, depending on these two parameters, the droplet would either rebound without disintegration (perfect bouncing regime), partially rebound (bouncing regime with secondary atomization), or splash on the wall after the impact (splashing regime). As the temperature of the fuel rod is much higher than the Leidenfrost temperature, the expected impact regime will be the bouncing one. Some models of heat transfer are reported in the literature. Andreani et al. [1] proposed a correlation for the estimation of the heat flux, q_{DC}, between a single droplet that impinges a hot wall in the case of the Leidenfrost regime. They assumed that only a few part of the droplet evaporates, thus the heat flux removed at the wall by the direct contact of the droplet is known if the effectiveness ε of the heat exchange can be estimated. The effectiveness ε is the ratio between the energy E_{DC} exchanged during direct contact of the droplet and the hot wall and the energy necessary to completely evaporates this droplet :

$$\varepsilon = \frac{E_{DC}}{\rho_L h_{LV} V_d} \text{ and } Q_{DC} = \frac{\varepsilon}{\Delta t_C} \rho_L h_{LV} V_d \quad (1)$$

Guo et al. [2] estimated the heat transfer due to the contact of droplets bouncing on the wall using the following equation. This one has been established by solving mass, momentum and energy equations in the vapour cushion beneath the flatten droplets above the hot wall in the Leidenfrost regime :

$$Q_{DC} = \dot{m}_d (T_w - T_{sat}) \left[\frac{18 \lambda_V{}^3 \Delta t_C{}^3 \rho_V \Delta h_V u_d}{D_d{}^5 \rho_L{}^3 \mu_v (T_w - T_{sat})} \right]^{0.25} \quad (2)$$

Correlations of post-dry out heat transfer have been compared with experimental data of Evans [3] and Gotulla [4]. The agreement seemed to be good. In a recent review, Mishima [5] concluded that : "*However, direct droplet-wall contact and vapor-wall radiation have significant contributions to*

the wall superheat and to the vapor superheat. Ignoring any of these two heat transfer processes will result in unacceptable errors".

A simple calculation using (1) or (2) shows that, considering only one droplet impinging on a hot wall, the value of Q_{DC} is very small (about one hundred mW) and thus is difficult to measure. In what follows, we describe the experimental method, which has been developed to measure such low cooling fluxes.

EXPERIMENTAL SET-UP

The experimental set-up has been designed in order to be able to make a full energy balance of the droplet-wall interaction, Figure 2. A thin nickel Slab (1) is heated thanks to an electromagnetic device (not represented here). When the temperature of the wall has reached a value much over the Leidenfrost temperature, the heating is stopped and the slab is cooled down by a controlled monodisperse droplet stream. At the same time, the temperature field on the rear face of the nickel disk is measured using an infrared camera (2). The monodisperse droplet stream is generated with a home-made device (3) ; the available droplets have a diameter ranging between 80 and 200μm and their velocities are close to 2-5 m.s^{-1}. Velocities, temperatures and diameters will be measured thanks to the lacer-induced fluorescence technique [6] and interferometry set-up. Since the interaction between the droplet and the wall is very short (a few of ms [7]), the estimation of the resident time of the droplet at the wall can be accurately measured from picture recorded thanks to a high speed camera (4). An example of droplet stream impinging onto the hot slab is given in Fig. 3.

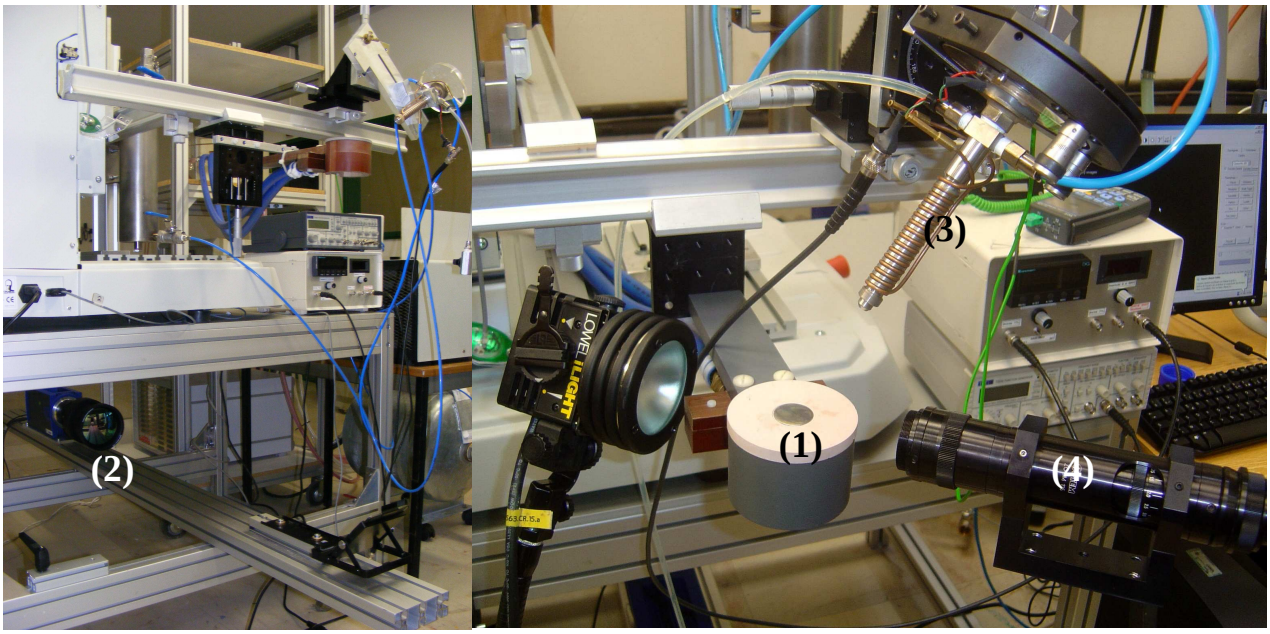

Figure 2 : experimental device

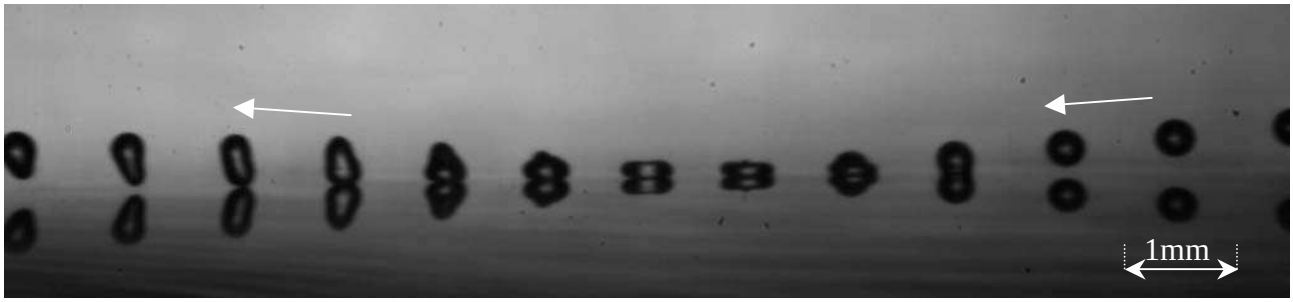

Figure 3 : example of 300 µm droplet stream impinging onto the slab (T_w > 300°C)

As mentioned before, the heat flux is estimated using an inverse heat conduction problem through the rear face temperature profile, measured thanks to the infrared camera. In the following parts, this estimation and this inverse model will be exposed.

HEAT FLUX ESTIMATION – INVERSE MODEL

Solution of the direct heat transfer problem

One consider the internal transient conduction within a finite circular disk whose radius is *R*=25mm and thickness *e*=500µm. Assuming constant thermophysical properties, the basic set of equations are thus the followings, assuming constant thermophysical properties :

$$\frac{\partial^2 T}{\partial r^2}+\frac{1}{r}\frac{\partial T}{\partial r}+\frac{\partial^2 T}{\partial z^2}=\frac{1}{a}\frac{\partial T}{\partial t} \tag{3}$$

$$T=T_\infty \text{ at } t=0\ ;\ \lambda_{NI}\left.\frac{\partial T}{\partial z}\right|_{z=0}=h_{SUP}^{EQ}(T-T_\infty)+q_{DC}(r,t) \tag{3a}$$

$$-\lambda_{NI}\left.\frac{\partial T}{\partial z}\right|_{z=e}=h_{INF}^{EQ}(T-T_\infty)\ ;\ -\lambda_{NI}\left.\frac{\partial T}{\partial r}\right|_{r=R}=0 \tag{3b}$$

Laplace (⁻) and Hankel (~) transforms are performed so that equation (1a) can be solved :

$$\frac{\partial \tilde{\bar{\theta}}_n^2}{\partial z}-(\alpha_n^2+\frac{p}{a})\,\tilde{\bar{\theta}}_n=0 \quad \text{with } \theta=T-T_\infty \tag{4}$$

with *p*, the Laplace parameter, $\alpha_n=\frac{u_n}{R}$ and u_n solutions of $J_1(u_n)=0$

Finally, the quadrupole method [8] yields a linear relationship between the rear face temperature (*z* = *e*) and the cooling heat flux (z = 0) :

$$\tilde{\bar{\theta}}_n=\tilde{Z}_n(p+a\alpha_n^2)\,\tilde{\bar{q}}_n \tag{5}$$

where: $\bar{Z}(p)=\dfrac{1}{((h_{SUP}^{EQ}+h_{INF}^{EQ})\cosh(e\sqrt{p/a})+\dfrac{h_{SUP}^{EQ}h_{INF}^{EQ}}{\lambda_{NI}\sqrt{p/a}}\sinh(e\sqrt{p/a})+\lambda_{NI}(\sqrt{p/a})\sinh(e\sqrt{p/a}))}$

Laplace inversion of equation (2) makes a convolution product appears:

$$\tilde{\theta}_n(t)=\int_0^t e^{-a\alpha_n^2(t-t')}\tilde{Z}_n(t-t')\,\tilde{q}_n(t')\,dt' \tag{6}$$

Finally, the real temperature in time-space domain is obtained through the following relation :

$$\theta(r,e,t)=\frac{2}{R^2}\sum_{n=0}^{\infty}\tilde{\theta}_n(e,t)\frac{J_0(\alpha_n r)}{J_0^2(\alpha_n R)} \tag{7}$$

Inverse heat transfer problem

Inverse Heat conduction Problem (IHCP) is a specific estimation technique that consists in using discrete temperature measurements inside a solid or at one of its external wall in order to recover a time and/or space boundary condition (in our case the distribution of cooling flux at the droplet impact). This estimation problem is not well-posed, which means that low magnitude perturbation in the temperature measurement (noisy temperature) can generate large deviations on the estimated wall heat flux. This is due to the discrete features of measurements while the information that is looked for is a continuous function of time and/or space. Different regularization techniques such as the least square method (used in this paper) have been designed to overcome this effect and to efficiently stabilize the inversion algorithm. In our case, it can be easily solved because the solution of the direct heat transfer problem is known (see equations 5 and 6).

Equation (6) which is expressed in Hankel domain (~) is the starting point of the inverse heat conduction problem ; the integral form in that equation (6) can be expressed using a truncature :

$$\tilde{\theta}_n(t_k) = \sum_{j=1}^{k} e^{-a\alpha_n^2 (k-j)\Delta t}\ \tilde{Z}_n((k-j)\Delta t)\,\tilde{q}_n(t_j)\,\Delta t = \sum_{l=1}^{k} S_{kj}\ \tilde{q}_n(t_j) \tag{8}$$

where Δt is the time step of the infrared camera or a multiple and $t_k = k\,\Delta t$, $t_l = l\,\Delta t$.

The harmonics of heat flux (noted '^') can be thus estimated using a least square method. In our case, a Gauss-Markov estimator was used to estimate the temperature in the hankel domain to take into account a non uniform noise variance (ie the input temperature field is obtained from a conversion and averaging of the initial field from Cartesian to cylindrical frame) :

$$\tilde{\theta}_n = (X_n^t\,\Omega X_n)^{-1}\,\Omega X_n^t\,\theta \ \text{ with } \ \Omega = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & . & 0 & 0 \\ 0 & 0 & . & 0 \\ 0 & 0 & 0 & \sigma_{k\max}^2 \end{bmatrix} \tag{9}$$

$$\text{with } \ X_{ln} = \frac{2}{R^2}\frac{J_0(\alpha_n\, r_l)}{J_0^2(\alpha_n R)}$$

$$\tilde{\theta}_n = \begin{bmatrix} \tilde{\theta}_n(t_1) \\ . \\ . \\ \tilde{\theta}_n(t_{k_{\max}}) \end{bmatrix} = \mathrm{S}_k^n\,\tilde{\mathrm{q}}_n = \begin{bmatrix} S_{11}^n & 0 & 0 & 0 \\ . & . & 0 & 0 \\ . & . & . & 0 \\ S_{k_{\max}1}^n & . & . & S_{k_{\max}\,k_{\max}}^n \end{bmatrix} \begin{bmatrix} \tilde{q}_n(t_1) \\ . \\ . \\ \tilde{q}_n(t_{k\max}) \end{bmatrix} \tag{10}$$

$$\hat{\tilde{q}}_n = (S_n^t\,S_n)^{-1}\,S_n^t\,\hat{\tilde{\theta}}_n \tag{11}$$

The return to time-space domain yields:

$$q_{DC}(r,t_k) = \frac{2}{R^2}\sum_{n=0}^{n_{\max}} \frac{J_0(\alpha_n\, r)}{J_0^2(\alpha_n\, R)}\,\hat{\tilde{q}}_n(t_k) \tag{12}$$

Heat flux estimation from real temperature data

The temperature *T(x,y,t)* obtained from the infrared camera is available in a Cartesian reference frame while the input data *T(r,t)* of the model must be known in a cylindrical reference frame. Thus, it requires the conversion and the averaging of the initial Cartesian temperature field in order to obtain the input data. As a consequence, we can not access to the real heat flux $q_{DC}(x,y,t)$ but only to an averaged heat flux $q_{DC}(r,t)$. So, *the first step* of the inversion procedure is to obtain the input temperature by averaging the initial field. In *a second step*, the Hankel transform (~) of the temperature $\tilde{\theta}_n$ will be estimated using a Gauss-Markov estimator (equation 9) because the temperature distribution *T(r,t)* shall be subject to a non uniform noise variance. Then, the harmonics of heat flux (in the Hankel domain) can be estimated using the equation (12). As the cooling flux is very weak, we must consider all the heat loss by conduction, convection and radiation.

PRELIMINARY RESULTS

The previous inverse model has been tested with some data obtained from simulations of the direct problem. Indeed, these tests are necessary to calibrate the robustness of our model. Dewitte [9] gave a relation which help us to estimate the efficiency of the droplet evaporation (about 2.5% for a 100 µm droplet diameter of water impinging a hot slab with u=2m/s, T_d=20°C and We=7). This low value is due to the fact that the interaction time Δt_C is very short, typically about 1ms for a 100µm droplet diameter and that the incoming droplet evolves in an environment being saturated in vapour by the preceding droplets. All the input data are given in the table 1. Q_{DC} is estimated using (1) and we assumed that the droplet does not slip on the surface and impinges at $r = 0$ so that the heat flux $q_{DC}(r,t)$ of each incoming droplet is expressed as :

$$q_{DC}(r,t) = \frac{Q_{DC}}{S\Delta t_C}\left[H(r) - H(r - \frac{D_d}{2})\right]\left[H(t) - H(t - \Delta t_C)\right] \tag{13}$$

where H is the Heaviside function.

Table 1
Input data for the direct simulations

Q_{DC} (mJ)	$S.10^8$ (m²)	Δt_C (ms)	h_{LV} (kJ/kg)	ε
0.0295	7.85	0.198	2258	0.025

T_d (°C)	h_{SUP}^{EQ} (W/m².K)	h_{INF}^{EQ} (W/m².K)	λ (W/m.K)	a (m²/s)
20	68	55	90.9	$2.3\ 10^{-5}$

A white noise (variance about 0.8°C) is added to the calculated temperature field in order to test a near experimental condition. Indeed, as we used an infrared camera, the signal on each sensor pixel will be noised. The inversion has been made with a number of harmonic n_{max}=20 and is compared to the input heat flux on the figure 4. This shows that the inversion is still possible even if the measured temperature field is noised. All the losses are estimated from the temperature field which relaxes naturally. In figure 5, we show the initial temperature field in the Cartesian frame and compare the average temperature distribution *T(r,t)* with the reconstructed field using n_{max} Hankel harmonics. In this example, we considered n_{max}=60.

CONCLUSIONS

In this preliminary work, we described the experimental method to measure cooling flux due to single droplet impacting onto a hot slab. As these fluxes are very low, the model must take into account all the unavoidable losses when we experienced droplet impacts. For the moment, it is not possible to obtain a better estimation than the average cooling flux removed by the impact of drops. For better resolution, a new inverse model could be developed in the initial Cartesian frame but the experimental data of the average of this flux is sufficient to check and/or derive correlations used in simulations of LOCA transients.

EXPERIMENTAL STUDIES ON THERMAL CONDUCTIVITY OF POLYMER SOLUTIONS AS A FUNCTION ON SHEARING RATE AND THEIR RHEOLOGICAL PROPERTIES

L. Broniarz-Press*, K. Pralat[2]

[1]Poznan University of Technology, Department of Chemical Engineering and Equipment, Poznan, Poland
[2]Higher Vocational State School of President Stanislaw Wojciechowski, Polytechnic Institute, Kalisz, Poland

ABSTRACT. In the present paper the results of the experimental studies directed to the correlation between the non-Newtonian fluids rheological behaviour and thermal conductivity taking into account shear rate effect, have been presented. In the experimental tests 3 Newtonian liquids (water, drive oil, aqueous solution of glycerol) as well as 18 aqueous solutions of polymers (non-elastic shear thinning fluids), have been used. It was confirmed that the thermal conductivity k of Newtonian liquids at $T = \text{const}$ is independent of shear rate. For the non-Newtonian aqueous solutions studied the effect of shear rate is evident and should be taken into account in all design practices. The thermal conductivity increases linearly with shear rate increase.

Keywords: *thermal conductivity, power-law fluids, shear effect, temperature effect*

INTRODUCTION

Many important industrial fluids, which are non-Newtonian or rheologically complex in their flow characteristics are often used in the chemical processes and food industries, as well as in many other practical applications. For the unavailability of another literature data in previous works on non-Newtonian fluid heat transfer the thermal conductivity was accepted to be identical with that one in the clear solvent. It was essentially a rough approximation that existed long. Additionally, it must be emphasized that until now the kinetic-molecular theory for liquids does not exist, and the relationships proposed for thermal conductivity in Newtonian liquids are empirical and very different in their form.

Of the significance is the fact that in non-Newtonian fluids the most experimental studies on thermal conductivities were performed under static conditions [1, 2]. Bellet, Sengelin and Thirriot [1] have determined the volume specific heat at constant pressure and thermal conductivity using an analytical identification method (Figure 1). Authors showed that the volume specific heat is independent of shear rate. In both, carboxymethylcellulose sodium salt solution (Na-CMC RC 197) and Carbopol 960 aqueous solutions in the range of temperature $293 \le T \le 333$ K thermal conductivity increased with increasing of temperature and decreased with an increase of polymer concentration in a solution. Lee, Cho and Hartnett [2] have tested the aqueous solutions of polyethylene oxide, polyacrylamide, carboxymethylcellulose sodium salt, Carbopol 960 and Attagel 40 (specialty attapulgite product, fine-milled grade, thickener of waterborne systems) in the range

of concentrations changed from 100 to 10,000 w.ppm under static conditions. As a result they stated an increase of thermal conductivity when the concentration of the polymer in a solution increased, thus indicating the contrary effect in reference to the study presented above [1].

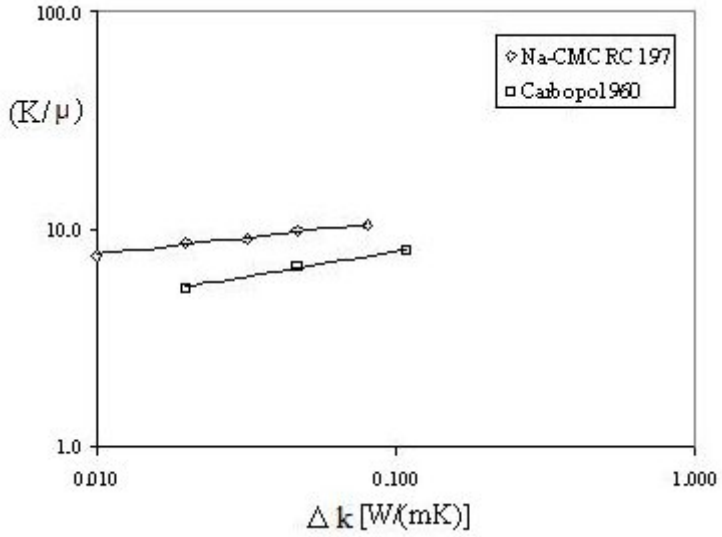

Figure 1. Change of thermal conductivity in non-Newtonian polymer aqueous solutions [1]

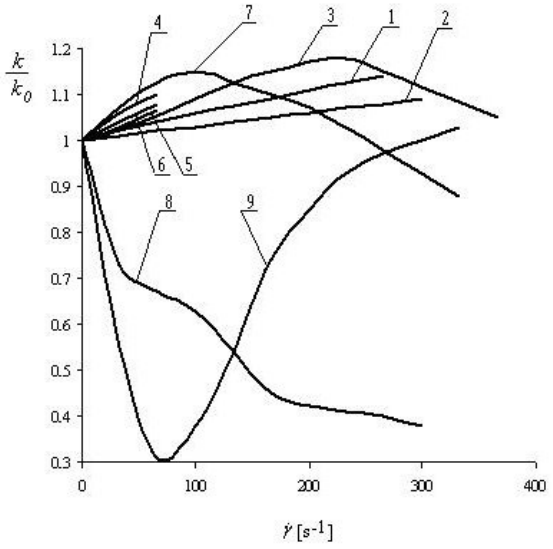

Figure 2. Comparison of the shear rate dependent thermal conductivity of non-Newtonian fluids resulted from literature [10]:
1 – Cocci and Picot [3], Dow 200, T = 288,7K; 2 – Cocci and Picot [3], Dow 200, T = 327K; 3 – Chitrangad and Picot [4], Dow 200, T = 298K; 4 – Chaliche *et al*. [8], Na-CMC, 8%, T = 298K; 5 – Loulou *et al*. [7], Carbopol, 0.1%, T = 298K; 6 – Loulou *et al*. [7], Carbopol, 0.2%, T = 298K; 7 – Picot *et al*. [5], polyethylene melt, T = 423K; 8 – Wallace *et al*. [6], low molecular weight polyethylene melt, T = 433K; 9 – Wallace *et al*. [6], high molecular weight polyethylene melt, T = 433K

The measurements of non-Newtonian fluid thermal conductivity should be made when the fluid is in a motion. Only few previous works studying the effect of shear rate on thermal conductivity in non-Newtonian polymer solutions have been found, whereas their results are contradictory [3-13] The exemplary graphs of the shear rate dependent thermal conductivity of non-Newtonian fluids resulted from these studies are presented in Figure 2.

Shin [14] has presented theoretical study where the empirical linear model for shear rate dependent thermal conductivity was adopted (Figure 3). The model can be formulated as follows:

$$k = k_0 + \left(\dot{\gamma} - \dot{\gamma}_0 \right) tg\alpha \tag{1}$$

where k_0 represents the stationary thermal conductivity of fluid, and $\dot{\gamma}_0$ indicates the bound of the linear region below of which the thermal conductivity seems to be invariable and independent of shear rate.

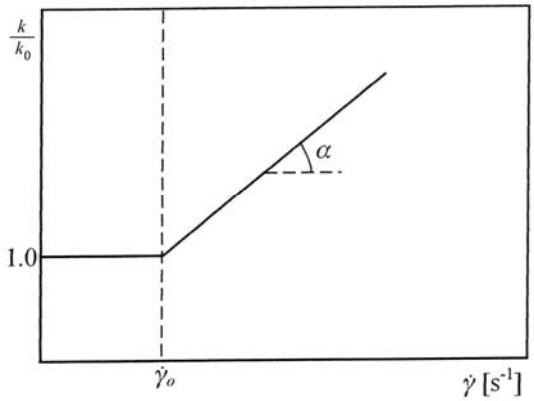

Figure 3. Theoretical model of thermal conductivity for non-Newtonian fluids [9]

The present study is concerned with determination of viscous properties of chosen non-Newtonian liquids with a view to correlate the viscous and thermal properties of these fluids. In the fluids studied the thermal conductivity was measured both, in static and dynamic conditions, over a shear rate range where the viscous properties significantly vary with shear rate.

EXPERIMENTAL SET-UP

To measure the heat conductivity the new experimental installation was designed (Figure 4) which permitted to determine thermal conductivity for power-law fluids basing on the rheometric technique and very accurate temperature measurement on outer cylinder. The main parts of the system were two coaxial cylinders while the inner cylinder is mounted as stationary and the outer cylinder is rotating. Cylinders made of steel chosen as the one permitted to use in food technology are of the following dimensions: outer cylinder with inner diameter 72 mm and inner cylinder with outer diameter 69 mm. The test fluid was located in the annular gap of 1.5 mm between two cylinders. The inner cylinder included the resistance sensors and the heater, which was designed and realized especially for experiment. The heater consisted of three sections: main and two guards (Figure 5). Three calibrated sensors were used to measure the surface temperature of the inner cylinder. The resistance sensors were positioned in the middle of the test section, and uniformly distributed at 120° interval. Analogically, three sensors were mounted in the surface of the outer cylinder. The novel element of experimental setup to measure the temperature of the outer cylinder consists of two parts as integrated circuits: transmitter and receiver. Transmitter was mounted on the outer cylinder. Receiver was connected with measurer which indicated temperature on the rotating cylinder. This innovatory element of temperature measurement of the outer cylinder based on wireless communication. Transmitter, changed sensors resistance signal into light signal, which was transmitted from diode. The receive diode, changed light signal into voltage signal, which was registered on measurer.

a) b)

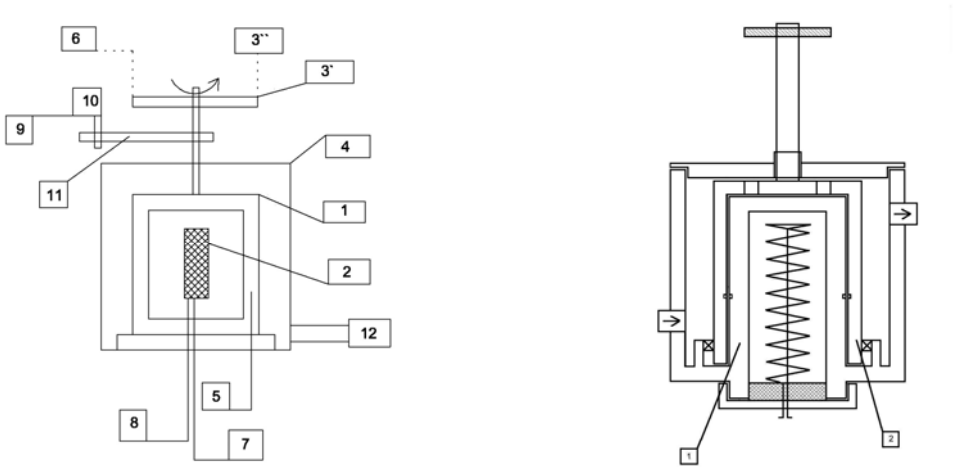

Figure 4. Scheme of the experimental set-up (a) and coaxial cylinders used (b):
1 – coaxial cylinders, 2 – heater, 3 – integrated circuit to measure temperature of outer cylinder, 4 – water jacket, 5 – meter to measure temperature of inner cylinder , 6 – tachometer, 7 – power supply, 8 – ammeter/voltmeter, 9 – motor speed controller, 10 – motor, 11 – rotating mechanism, 12 – water bath

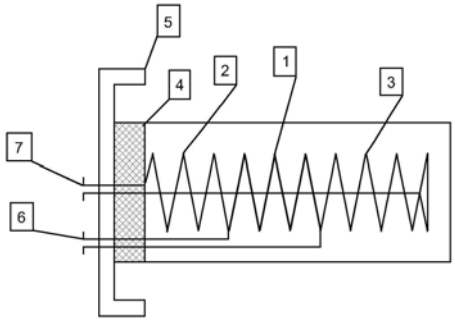

Figure 5. The novel heater mounted in the inner cylinder:
1 – main heater, 2,3 – two guards heaters, 4 – isolation, 5 – cover, 6,7 – wires

The two guard-heaters are controlled in such a way to maintain uniform axial temperature in the central, main-heater region. The latter heat flux is virtually in the radial direction only. The guard heaters will prevent end effects and heat losses.

Provided that Fourier`s law of conduction is applicable, the apparatus is operated at steady state, the shear rate variation across the gap is negligible, and the thermal conductivity of the liquid in the gap is considered to be independent of temperature, the following equation is used to calculate the thermal conductivity:

$$k = \frac{Q \ \ln\left(\frac{d_o}{d_i}\right)}{2\,\pi\, L\, \Delta T} \tag{2}$$

where Q was calculated from the measurements of current and voltage through the main heater:

$$Q = I \ V \tag{3}$$

EXPERIMENTAL RESULTS

The liquids tested were water, glycerol (50%) and petrol as Newtonian fluids, and aqueous solutions of: carboxymethylcellulose sodium salt (delivered by Aldrich Company, of the molecular masses 250,000 and 700,000 and of the polyelectrolyte concentrations in solutions ranged from 1,000 to 5,000 w.ppm) and high-molecular polyacrylamide $M \approx (2 \div 4) \cdot 10^6$ (kg kmol^{-1}) (Rokrysol WF1, delivered by Rokita S.A.), partially hydrolyzed polyacrylamide $M \approx (2 \div 4) \cdot 10^6$ (kg kmol^{-1}) (Rokrysol WF2, delivered by Rokita S.A.) as well as their mixtures as non-Newtonian fluids. All polymer solutions used were non-elastic power-law fluids:

$$\tau = K \dot{\gamma}^{n} \tag{4}$$

Experiments were performed at temperatures changed in the range from 299 K to 315 K. The shear rate range studied was $0 \le \dot{\gamma} \le 750\,(\mathrm{s}^{-1})$.

It was confirmed that thermal conductivity of Newtonian liquids at constant temperature is independent of shear rate. On the ground of experimental studies the relationships $k = f(T)$ for analyzed model Newtonian fluids were found (Table 1).

Table 1
Newtonian liquids used

Name	ρ (kg m^{-3})	$\mu \times 10^3$ (Pa·s)	Authors' experimental data correlations
diesel oil	844.0 ÷ 849.2	2.76 ÷ 3.53	$k = 33.5 \cdot T^{-0.803}$
water	991.5 ÷ 996.8	0.630 ÷ 0.900	$k = 1.11 \cdot 10^{-5} T^{1.91}$
aqueous solution of glycerol (50 %)	1116 ÷ 1125	2.06 ÷ 5.30	$k = 1.57 \cdot 10^{-7} T^{2.6}$

For all non-Newtonian solutions used thermal conductivity values obtained in static conditions increase with the temperature increase. The maximal values were obtained for aqueous solutions of carboxymethylcellulose sodium salt of the averaged molar mass M = 700,000 (kg kmol^{-1}).

In Figures 6 and 7 the experimental relationships of thermal conductivity vs. shear rate for the inelastic non-Newtonian solutions studied are presented. The evident increase of the thermal conductivity compared to water in all polymer solutions used has been observed. The thermal conductivity at a higher temperature at a certain shear rate is greater than at a lower temperature. The temperature effect is significant, and the increase in thermal conductivity at higher temperatures with respect to shear rate is larger than at lower temperatures. The general trends of the curves are similar in all graphs. The solution of the lowest concentration (1,000 w.ppm) has a greater change in thermal conductivity with shear rate in comparison with the solution of the highest concentration (5,000 w.ppm). The generalized relationship has the form:

$$k = a_o + a_1 \cdot \dot{\gamma} + a_2 \cdot T + a_3 \cdot \dot{\gamma} \cdot T \tag{5}$$

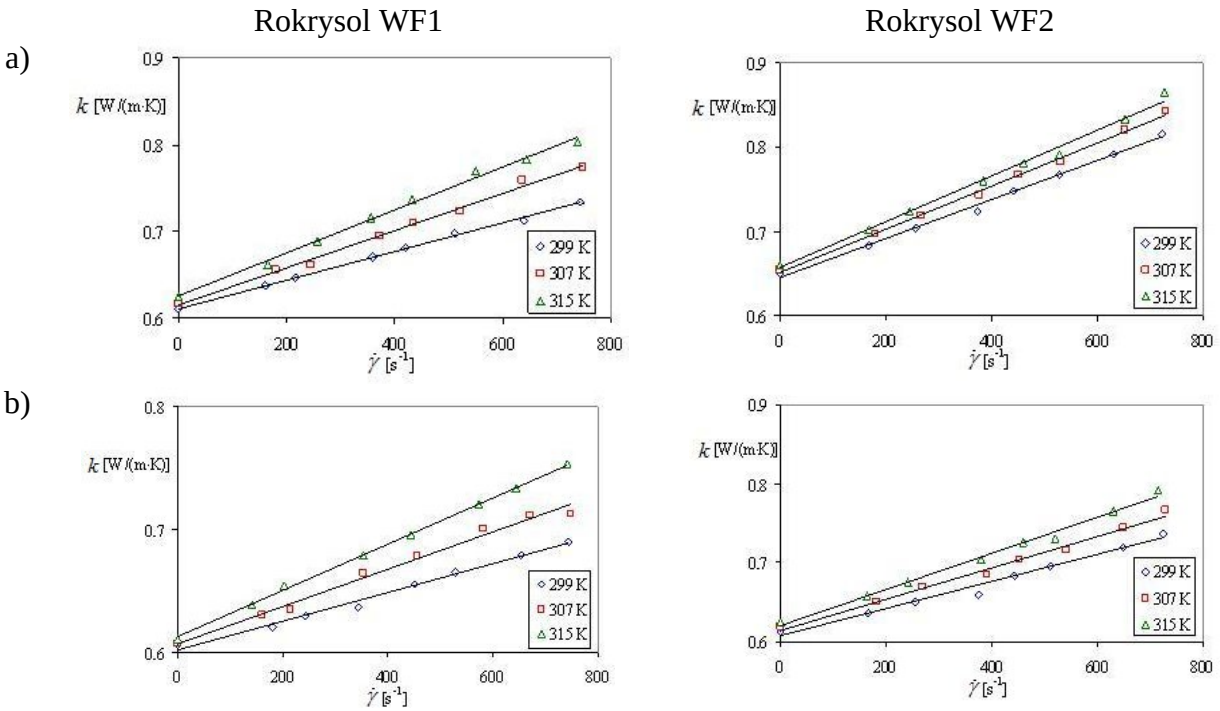

Figure 7. Thermal conductivity coefficient k vs. shear rate $\dot{\gamma}$ for polyacrylamide solutions of concentrations of:
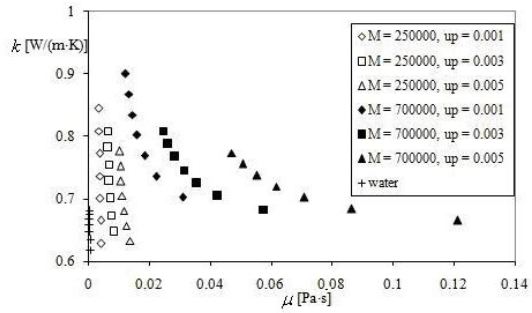
a) u_p = 0.001 (kg p kg^{-1}), b) u_p = 0.005 (kg p kg^{-1})

The increase of the polymer concentration in a solution caused the decrease of the thermal conductivity k. The increase of the molar mass or hydrolyzation degree of a polymer caused the

increase in the values of k. The maximal values of $k = 0.992$ (W m^{-1} K^{-1}) were obtained for the solution of mixture III (Na-CMC$_{700,000}$: $u_p = 0.001$ (kg p kg^{-1}) and Rokrysol WF1: $u_p = 0.005$ (kg p kg^{-1})) at temperature of 315 K and shear rate of $\dot{\gamma} = 750$ (s^{-1}). Additionally the existing of the critical values of shear rate $\dot{\gamma}_o$ below of whose the thermal conductivity for non-Newtonian fluids was independent of shear velocity and equal to the static one, has been observed. The increase of the shear rate at the values greater than $\dot{\gamma}_0$ caused the effect of the shear rate on thermal conductivity, related to the Shin [9] suggestion. The critical values of shear velocity increase with the polymer concentration in a solution.

a)



b)

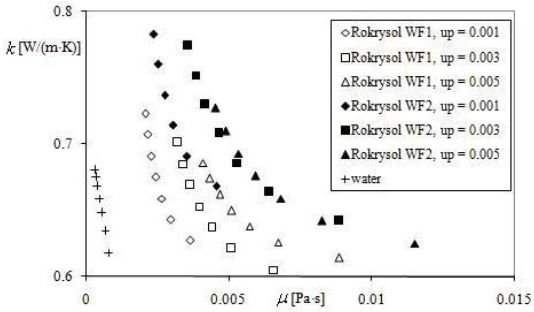


Figure 8. Comparison of the non-Newtonian viscosity effect on heat conductivity coefficient values at temperature 299 K:
a) aqueous solutions of carboxymethylcellulose sodium salt, b) aqueous solutions of high-molecular polyacrylamide

Next, basing on thermal conductivity and rheological measurements the effect of the non-Newtonian viscosity μ on thermal conductivity, has been determined. It has been shown that the relation of k vs. μ depends considerably on molecular mass of the polymer studied and temperature (Figure 8). It seems evident that thermal conductivity decreases when the Newtonian or non-Newtonian viscosity increases. It was affirmed that for all liquids used the relationship of thermal conductivity vs. viscosity can be well approximated by the third degree multinomial function of the form as follows:

$$k = C_0 - C_1 \cdot \mu + C_2 \cdot \mu^2 - C_3 \cdot \mu^3 \tag{6}$$

In the final step of the experimental data elaboration the special attempt was undertaken to express the relationship between the ratio of non-Newtonian viscosity to heat conductivity coefficient and rheological parameters of polymer solutions used. Basing on thermal conductivity vs. shear rate and viscosity vs. shear rate correlations, we proposed new formula for all non-Newtonian fluids:

$$\frac{\mu}{k} = 2.095 \cdot K^{0.95} \cdot \dot{\gamma}^{0.881 \cdot n - 1.021} \tag{7}$$

valid at $n \in (0.51, 0.98)$ and $K \in (0.003, 1.140)$ (Pa·s^n).

CONCLUSIONS

The effect of temperature, shear rate, molecular mass of polymer present in non-Newtonian solution and its concentration on thermal conductivity, has been observed. The increase of the molar mass or

hydrolyzation degree of a polymer caused the increase in the values of *k*. The increase in concentration of polymer in an aqueous solutions caused the decrease in values of thermal conductivity *k*. It has been stated that the values of thermal conductivity for aqueous solutions of polymers as well as their mixtures increase linearly with the increase of both, shear velocity $\dot{\gamma}$ and temperature. Additionally the existing of the critical values of shear velocity $\dot{\gamma}_o$ below of whose the values of thermal conductivity for non-Newtonian fluids were independent of shear velocity and equal to the static ones, has been observed. The increase of the shear velocity at the values greater than $\dot{\gamma}_o$ caused the effect of the shear velocity on thermal conductivity, related to the Shin's suggestion. For all liquid systems tested (Newtonian and non-elastic shear thinning) the decrease of the thermal conductivity with the increase of liquid viscosity was observed. The relationship between the ratio of non-Newtonian viscosity to thermal conductivity and rheological parameters of polymer solutions has been proposed.

A NOVEL EXPERIMENTAL SETUP FOR INVESTIGATION OF PERFECT MIXING AND PERFECT DISPLACEMENT SCAVENGING PROCESS IN A CAVITY

Adil Rasheed[1], Kausik Nandi, and A W Date[2,*]
[1]Ecole Polytechnique Federale de Lausanne, Switzerland
[2]Mechanical Engineering Dept., IIT Bombay, Mumbai-400076, India

ABSTRACT. In this paper, design of a novel experimental set-up for study of scavenging process in a rectangular cavity is described. The real scavenging process has two idealized extremes: (1) Scavenging by Perfect Mixing and (2) Scavenging by Perfect Displacement. In Two-Stroke Internal Combustion engines, the scavenging and the scavenged fluids are in gaseous state and, therefore, process visualization is not possible. In the present set-up, the scavenging fluid is water. The scavenged fluid is KMnO4 in the perfect mixing experiment whereas in the perfect displacement experiment, the scavenged fluid is Engine Oil. Transient measurements of scavenging process are made and illustrative results are presented.

Keywords: *Two Stroke IC Engine, Perfect Mixing Model, Perfect Displacement Model*

INTRODUCTION

Background

In Two-Stroke IC engines, the burnt charge in the engine-cylinder is driven out of the cylinder in two stages. At the end of the expansion stroke, as the piston approaches Bottom-Dead-Center (BDC) position, exhaust port opens and the low-density hot burnt gas is driven out by the higher pressure in the cylinder. As the piston moves further towards BDC, however, higher density fresh charge (fuel + air) is introduced through the inlet port while the exhaust port opens further. Ideally, the fresh charge should drive out the burnt charge in the cylinder completely as if the scavenged (burnt gas) and the scavenging (fresh charge) were immiscible. However, since both the fresh charge and the burnt gases are in gaseous state, fluid mixing takes place. As a result, during the scavenging transient, some of the fresh charge exits through the exhaust port as unburnt fuel while at the end of the scavenging process (when both the inlet and exhaust ports are closed due to upward movement of the piston towards Top-Dead-Center TDC) , some burnt gas remains in the engine-cylinder. The loss of fresh fuel through exhaust is associated with scavenging efficiency whereas the failure to remove all the burnt gas is associated with Trapping Efficiency. It is important to note that during the entire scavenging process (from exhaust port opening to closure of both the inlet and exhaust ports), the cylinder volume changes but, only by a very small amount. As such, the scavenging process may be idealized as a Constant-Volume process. The real process is extremely rapid and the cylinder interiors are inaccessible for direct measurements of concentration and temperature distributions. Also, flow visualization is not possible. As such, the scavenging process is idealized by two extremes: Perfect Mixing Model and Perfect Displacement Model [1]; the real process being a weighted combination of the two models. In more recent times, the entire engine-cycle is simulated by CFD [2]. Nonetheless, scavenging and trapping efficiencies can be estimated from exhaust-gas analysis.

In this paper, our aim is to mimic the two extremes of transient scavenging process in a Constant Volume cavity under iso-thermal conditions. Like in the real process, we use water as the scavenging fluid whose density is greater than or equal to the scavenged fluid. We employ KMnO4 (whose density is nearly equal to that of water) to mimic the perfect mixing model, water and KMnO4 being miscible in each other. In order to mimic the perfect displacement model, we employ Engine Oil (whose density is less than that of water). In both experiments, the processes are made visible and therefore filmed using a Handy Cam. Also, the amounts of fluids scavenged are measured as functions of time. Next section describes the experimental set-up and the procedure. The measured results are presented in the subsequent section. Finally, conclusions are reported in the end.

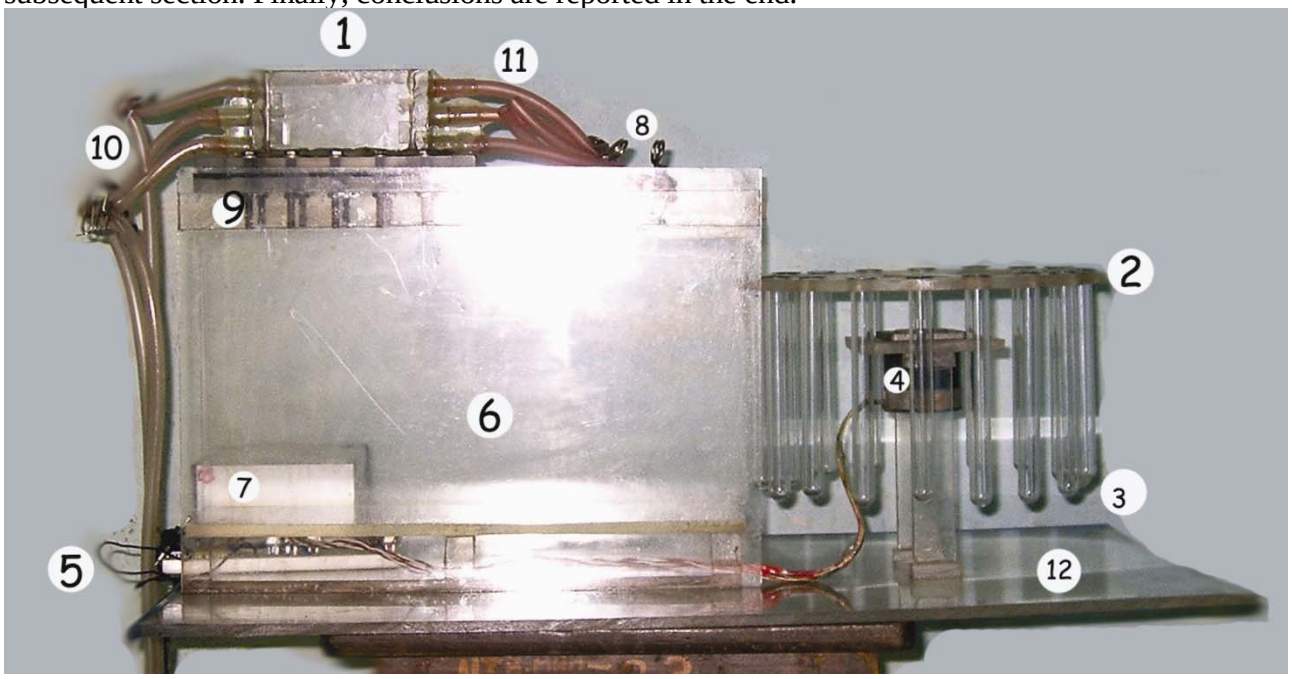

Figure 1: Experimental Setup

EXPERIMENTAL SET-UP AND PROCEDURE

The set-up (see Figure 1) consists of a 80 x 60 x 10 mm cavity (1) made from 8 mm thick Acrylic sheet. The cavity has 3 inlet and 3 outlet ports (10 and 11) of 5 x 10 mm (see Figure 2). The cavity is secured on a perspex mounting (6). Initially, the cavity is filled with a liquid to be scavenged with all ports closed. This liquid is driven out of the cavity by forcing water from a constant-head overhead tank (not shown) with a rubber tube connection to any one pre-selected inlet port. Both the inlet and the pre-selected outlet port are opened at the same instant. The discharge from the outlet port is intermittently collected in calibrated Test-Tubes (3) mounted on a horizontal 28 cm diameter rotating Wheel (2). The wheel is rotated by means of a Stepper Motor (4) at a pre-selected speed. The rotation of the motor (typically, 1.8 degree in one step) is controlled by Control Circuit PCB (5) (see Figure 3).

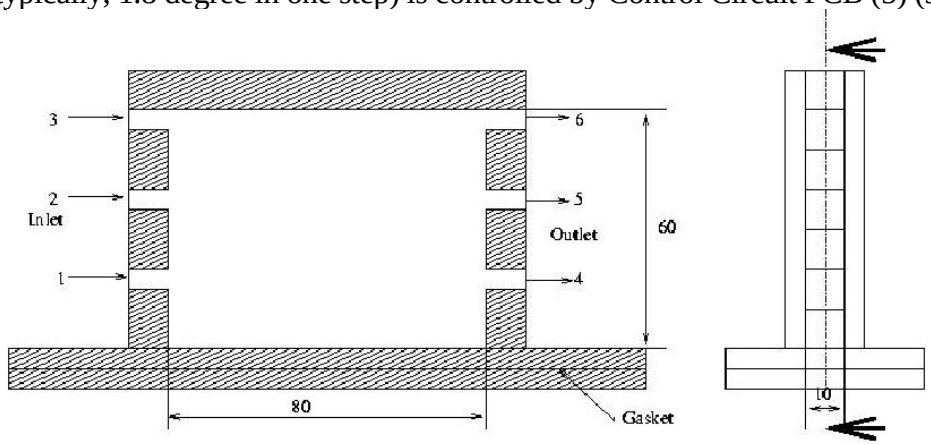

Figure 2: Schematic diagram of the test section

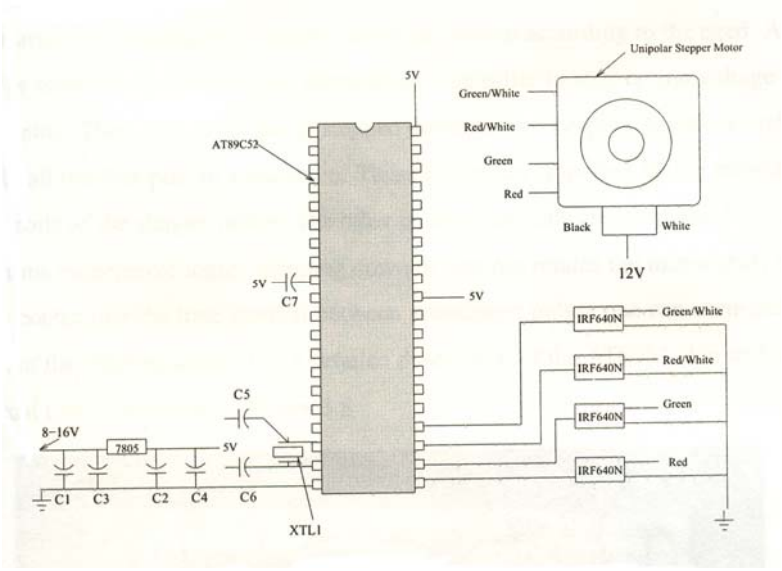

Figure 3: Schematic diagram of the electronic circuit

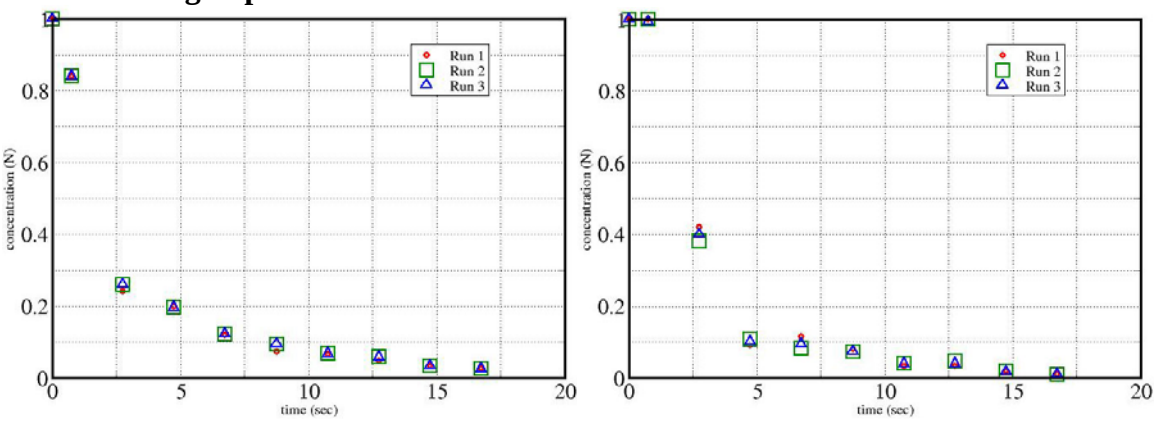
The supply voltage and current to the motor are regulated by Eliminator and Adaptor (7). In the Perfect Mixing experiment, the cavity is initially filled with 1 Normal KMnO4 solution. The scavenged liquid-mixture is collected in Test-Tubes at pre-set intermittency. The inlet port is kept open till the entire cavity is scavenged and is filled only with water and steady-state is established. In order to measure time-variation of the amount of liquid scavenged, at the end of the experiment, the collected mixture is titrated against Anhydrous Oxalic Acid in the presence of small amounts of Sulphuric Acid which acts as a catalyst. The mixture is also mildly heated before titration to speed-up the chemical reaction. In the Perfect Displacement experiment, the cavity is filled with a liquid (Engine Oil or Castor Oil) immiscible in water. In this experiment, a clear interface between water and the liquid is observed in the cavity. Depending on the water flow rate, the two-fluid cavity flow reaches either completely steady or periodically steady-state with some liquid entrapment in the cavity in both cases. In this case, the amount of scavenging is easily estimated because the two immiscible liquids naturally separate in the Test Tubes. Both experiments are repeated for different combinations of inlet-outlet port openings and different heads of water to change the scavenging water flow rates. The measured concentrations/volume fractions of the collected fluid are recorded as functions of time for a given flow rate of scavenging water. Concentration distributions and Interface evolutions are captured using a Handy Cam. Typical experimental results are presented in the next section.

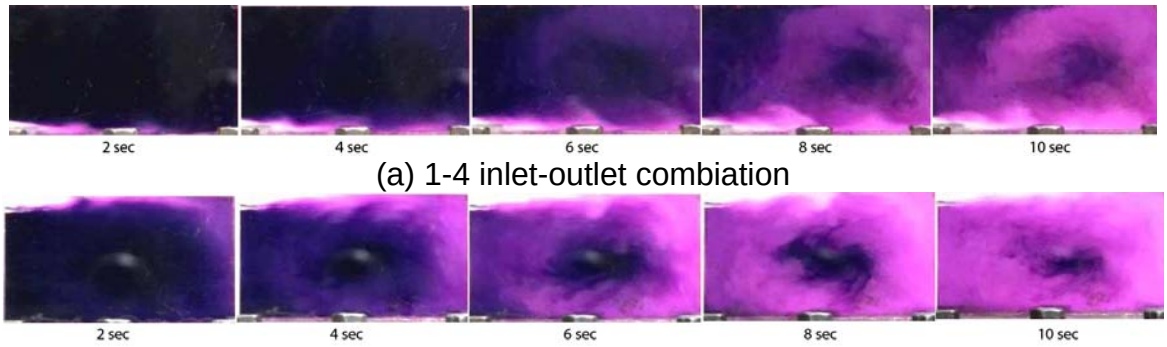
PRESENTATION OF RESULTS

Perfect Mixing Experiment



(a) (b)

Figure 4: Variation of $KMnO_4$ concentration with time for a) 1-4 configuration b) 3-4 configuration



(a) 1-4 inlet-outlet combiation

(b) 3-4 inlet-outlet combination

Figure 5 Snapshots of the test section at 2 sec time interval (Perfect Mixing case)

Initially, the cavity is filled with KMnO4 solution. Three runs Run1, Run2 and Run 3 (to ensure repeatability) are conducted corresponding to a volumetric flow rate of 20.43ml/sec. A given pair of Inlet and Outlet ports is opened simultaneously. The time-variations of the concentrations (of KMnO4) of the collected fluid are plotted for two combinations of inlet-outlet ports viz 1-4 and 3-4 in Figure 4. As is seen, in both cases and for all flow rates of injected water, after initial near-perfect-displacement, the concentrations decline and ultimately are reduced to zero because KMnO4 in the cavity is diffused out completely and only water remains in the cavity. Thus, scavenging is 100 %. Figure 5 gives a snapshot of the test section as a function of time. Figure 6 presents the scavenging time for six different combinations at different flow rates Q1, Q2 and Q3 corresponding to 20.43, 26.3 and 31ml/sec. Quite expectedly the scavenging time decreases with increasing flow rate for any inlet-outlet combination. Also one can see that the inline combination is the best for achieving lowest scavenging time.

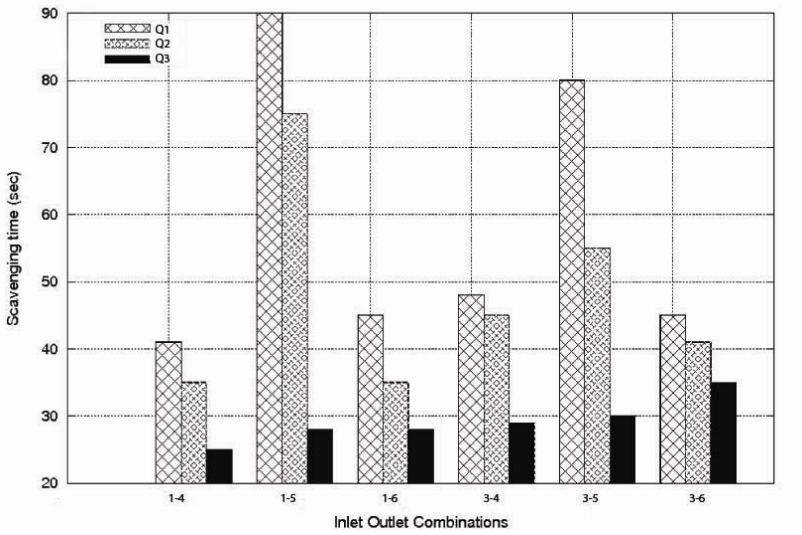


Figure 6: Scavenging time for different inlet-outlet combinations

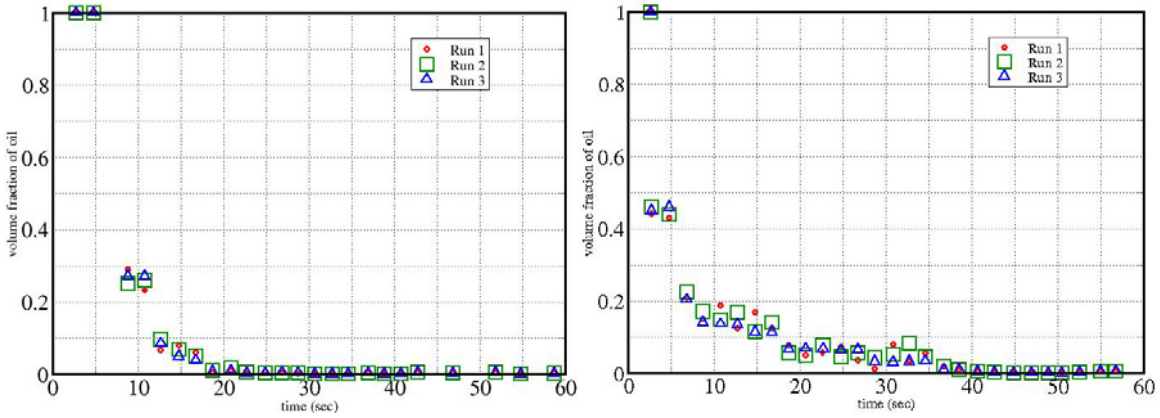
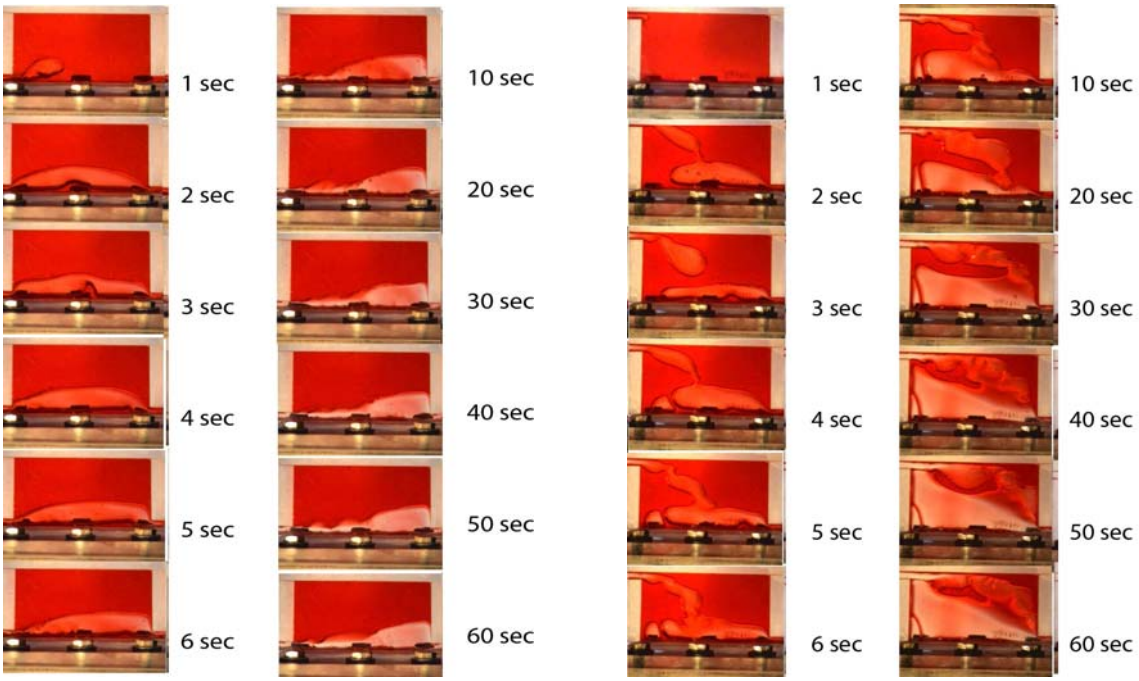
Perfect Displacement Experiment



(a) (b)

Figure 7: Variation of engine oil concentration with time for a) 1-4 configuration b) 3-4configuration



(a)1-4 (b) 3-4

Figure 8: Snapshot of the test section at different time (Perfect Displacement Case)

In this experiment, the cavity is initially filled with Engine oil which is displaced by injected water forming a clear interface. Figure 7 shows the time variations of volume fraction of oil in water collected in the test-tubes for the 1-4 and 3-4 port combinations. Three runs Run 1, Run 2 and Run 3 are conducted to ensure repeatability. The water flow rate is 8.33 ml/s in each of the 3 runs. It is seen that the volume fractions decrease with time but attain a steady finite value at large times. This suggests that scavenging is not complete. Figure 8 shows the snapshots of the test section at different times. It is seen that due to fluid circulations, the interface distorts; ultimately creating dead-zones at large times with trapped oil. For measuring the residual volume of oil two approaches are used. In the first approach the ejected volume in the test tubes are computed. This volume when subtracted from the volume of the test section gives the residual volume. In the second approach the residual volume was directly calculated using an image processing tool called GetData.

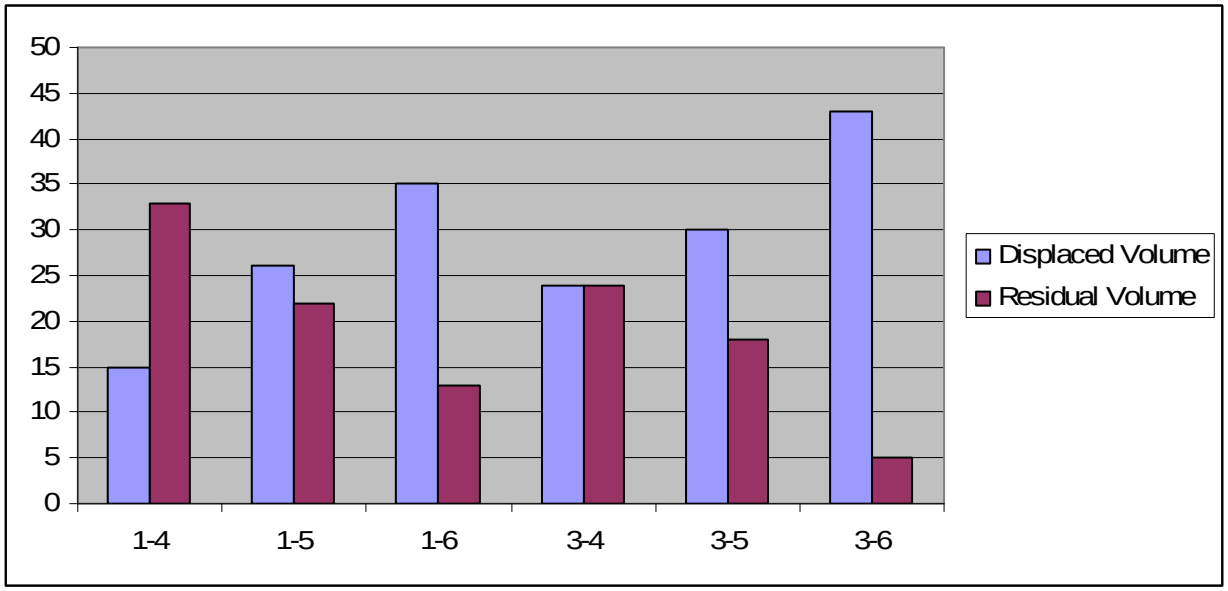


Figure 9: Displaced and Residual volume for a flow rate of 8.33ml/sec

In Figure 9 the displaced and residual volume of oil for different inlet-outlet combination is presented. It is clear from the figure that for any particular outlet increasing the height of inlet results in better scavenging as the displaced volume of oil increases. An interesting fact that comes to surface from the study is that the 1-4 combination which is best in the Perfect Mixing case turns out to be the worst in Perfect Displacement case. The reason for this is short circuit of the fresh charge through the exit port.

CONCLUSIONS

A novel experimental set-up is designed to capture essentials of Perfect Mixing and Perfect Displacement models of scavenging phenomena in two-stroke IC engines. Although, the density and viscosity of ratios of the burned and unburned gas mixture cannot be mimicked exactly, the experiment qualitatively shows features that can be used in design of cylinder interior (shape of cylinder head, for example) and relative locations of inlet and exhaust ports. A refined version of the experimental setup with sophisticated instrumentation can be used to generate high quality data set for validating CFD codes for both diffusion and interface tracking.

HEAT TRANSFER DURING HIGH TEMPERATURE OXIDATION OF MOLYBDENUM FILAMENT

S. Orlovskaya, F.Karimova, M. Shkoropado
Odessa Mechnikov's National University, Odessa, Ukraine

ABSTRACT**.** High temperature oxidation of molybdenum filaments was studied experimentally. The detailed investigation of filament heating by dc over the range 0.5A ÷ 7A was fulfilled by means of electrothermography and optical pyrometry. The conditions of stationary and non-stationary oxidation modes realization were established. The filaments temperature histories for a number of dc values were obtained. Heat transfer modelling results are in good agreement with the data obtained.

Keywords: *molybdenum, filament, oxidation, electrothermography, stationary, non-stationary*

INTRODUCTION

Refractory metals – molybdenum and tungsten are typically used in high temperature applications and their oxides have wide prospects in microelectronics, solar and green energy. So peculiarities of these metals high temperature oxidation are of great interest. In the present work we studied experimentally high temperature oxidation and heat transfer of molybdenum filaments heated electrically in air.

So called "hot filament" method now is used to produce diamond films, carbon nanotubes, but it is also promising method to produce high-quality metal-oxide films with a desired chemical composition [1]. We investigated molybdenum filaments heating by dc over the range 0.5A ÷ 7A by means of electrothermography and optical pyrometry. We defined heat transfer time characteristics and the conditions of stationary and non-stationary oxidation modes.

Computer-assisted electrothermography method consisted in programmed electric heating thin metal filament (with diameter in the range 100–300 mcm) and continuous registration its volt-ampere characteristic. Current value of the filament temperature was derived from the change of it's resistivity [2].

ELECTROTHERMOGRAPHY AND OPTICAL PYROMETRY

The experimental set-up included a reaction chamber provided with gas feed and pressure regulating system; electric power supply; ampere and volt meters; analog to digital converter, optical pyrometer, digital camera.

At first we defined experimentally the limits of stationary oxidation mode. We raised the heating current step by step and controlled temperature time behavior for every dc value. If the filament temperature approached some stationary value, i.e. the process became stabilized than we considered this dc value corresponding to some stationary oxidation mode. In so way we defined the upper limit of stationary oxidation mode existence. The minimum current value corresponding to non-stationary mode we named the current critical value I_{cr}.

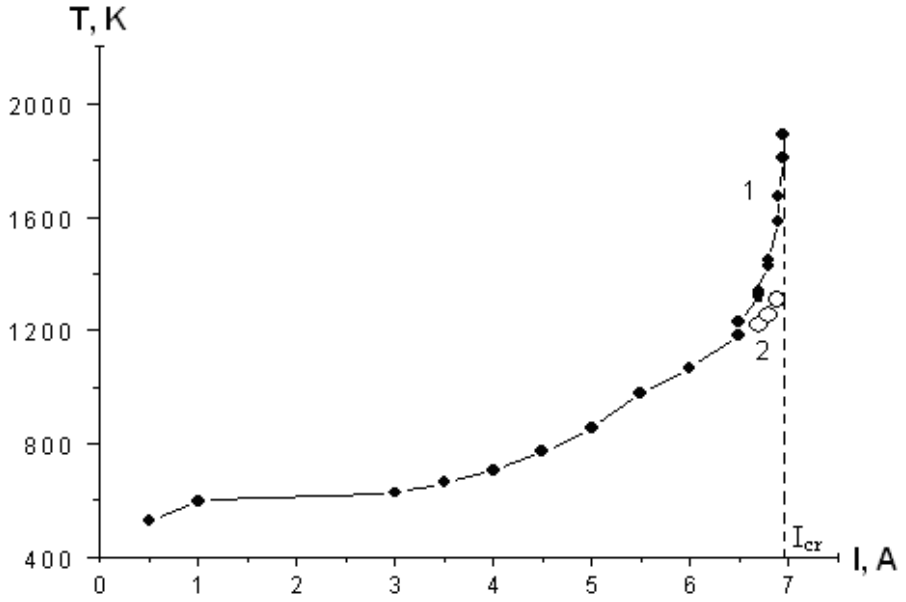

Fig. 1. Stationary filament temperature as function of heating current (d = $3 \cdot 10^{-4}$ m, L = 10^{-1} m): a) ♦–♦ the temperature defined by electrothermography; b) ○–○ the temperature in the central zone measured by optical pyrometer.

It depended on filament diameter, gaseous phase temperature and composition. On Figure 1 the experimental dependence of the filament stationary temperature on heating current is presented.

When heating current exceeded I_{cr} the accelerating oxidation due to oxide evaporation led to quick filament failure. The electrothermography gave us an averaged temperature value whereas during non-stationary oxidation the filament failure took place in the zone of maximum local temperature.

So we measured the temperature in the hottest zone by pyrometer with disappearing filament. In order to correlate the optical pyrometry temperature and the electrothermographical one we defined the temperature profile along the filament by use relative brightness pyrometry.

We took the pictures of hot filament by digital camera Canon 450D through narrow-band filter (λ=$0.77 \cdot 10^{-6}$ m). Than the images were processed using MATLAB 7.0. The temperature distribution was calculated by formula derived from Wien's law:

$$\frac{1}{T(x)} = \frac{1}{T_0} + \frac{\lambda}{C_2} \ln\left(\frac{S_0}{S(x)}\right) \tag{1}$$

here T_0 – the temperature measured by optical pyrometer in the filament centre; S_0 – the camera response in corresponding image pixel; $S(x)$– the response in the point x. We approximated the temperature profile near cold contacts by linear function.

The temperature profile along the filament was computed also numerically. Mathematical model of the heating process was based on solution of stationary heat transfer equation with account of the surface chemical reaction (every term of the equation is heat flux per unit filament length):

$$q_\lambda - q_\alpha - q_\varepsilon + q_{ch} + q_{DJ} = 0 \tag{2}$$

The first term of the equation (2) corresponds to heat flow to the filament ends:

$$q_\lambda = \lambda S \frac{d^2 T}{dx^2}$$

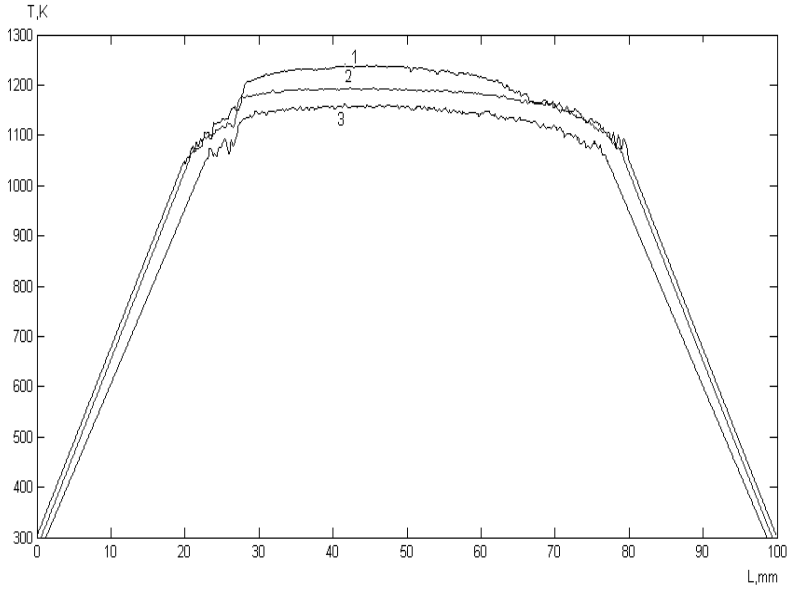

Figure 2. Temperature profile along the filament (d = $3 \cdot 10^{-4}$ m, L = 10^{-1} m):
1– I = 6.9 A, 2 – I = 6.8 A, 3 – I = 6.7 A, T_g = 293 K

The first term of the equation (2) corresponds to heat flow to the filament ends:

$$q_\lambda = \lambda S \frac{d^2 T}{dx^2}$$

The second term corresponds to convection heat loss:

$$q_\alpha = \alpha P\left(T - T_g\right),\ \alpha = \frac{\lambda_g Nu}{d}$$

Radiation heat loss is the next term:

$$q_\varepsilon = \varepsilon\sigma P\left(T^4 - T_g^4\right)$$

Oxidation reaction calorific effect equals

$$q_{ch} = QW_{O_2} P = Q\frac{k}{h} n_{O_2} \rho_g P$$

here

$$k = k_0 \exp\left(-\frac{E}{RT}\right) \quad n_{O_2,S} = n_{O_{2,\infty}}\left(1 + \frac{k}{h\beta}\right)^{-1} \quad \beta = \frac{NuD_{O_2}}{d}$$

where P – filament perimeter, k is oxidation reaction constant; k_0 – coefficient of reagents diffusion through oxide film; E – activation energy; h – oxide film thickness; ρ_g – air density; D_{O2}– oxygen diffusion coefficient; $n_{O_2,S}$ – oxygen relative mass concentration on the surface; $n_{O_{2,\infty}}$ – oxygen relative mass concentration at infinity; Q_a – heat of the reaction, T_g – gas temperature is supposed to be equal to one of the experimental chamber walls; α and β – heat and mass transfer coefficients.

The Joule heat equals:

$$q_{DJ} = \frac{I^2 \rho_0 \left(1 + \gamma\left(T - T_0\right)\right)}{S};$$

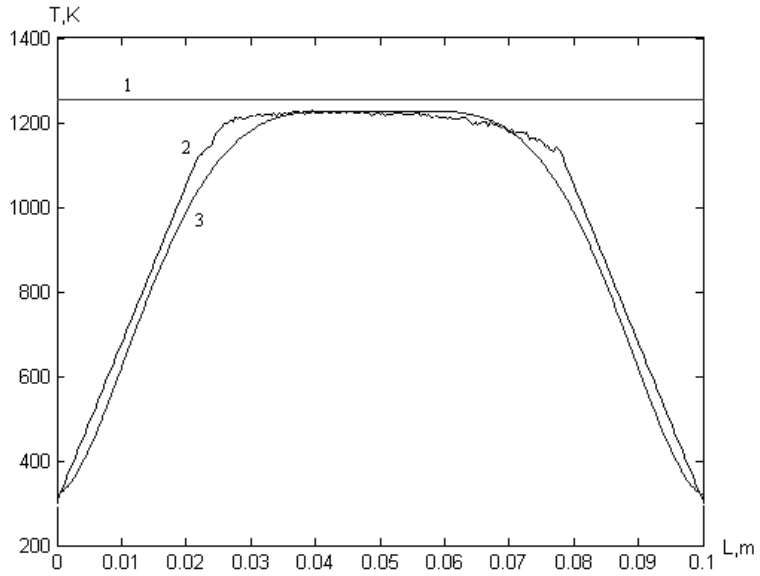

Figure 3. The temperature profiles: 1 – the electrothermography value; 2 – the experimental curve; 3 – the computed profile.

Figure 3 shows that the experimental curve T(x) computed by formula (1) is in a good agreement with the numerical solution of the equation (2), whereas the mean temperature defined by filament resistivity change is significantly higher. It is possible, that filament diameter change owing to metal oxidation resulted in significant error. So it is necessary to take into account the change of the filament conductive core diameter.

Non-stationary oxidation heat transfer was studied by use of electrothermography and optical pyrometry. Experimental thermogram (filament temperature history) is presented on Fig. 4. The thermogram allows identifying three successive stages of heat transfer during molybdenum filament high temperature oxidation.

After switching on the current the filament temperature quickly went up quasi-stationary value. At this stage of fast heating the filament temperature quickly increased due to Joule heat release. It is known that molybdenum is oxidation resistant up to 523 K. Further heating led to quick oxide film formation and growth. Initial oxide film consisted mainly of molybdenum dioxide and was rather dense. Usually the scale includes at least two layers: MoO_2 and MoO_3.

When the filament temperature attained trioxide melting point (point A) oxide scale began to melt. Molybdenum trioxide was highly volatile so oxidation and evaporation processes were parallel at the second stage – so called quasi-stationary oxidation stage, while the temperature increased relatively slowly at this stage.

When the the temperature in the filament centre attained the oxide boiling point (point B) the evaporation from the surface accelerated – at the third stage the scale practically didn't prevent from fast oxidation so the temperature increased sharply and went up to metal melting point (point C), corresponding to the filament failure.

In so way the oxide phase transitions were supposed to affect significantly molybdenum oxidation. Molybdenum oxide melting and boiling points defined the limits of high temperature oxidation succesive stages.

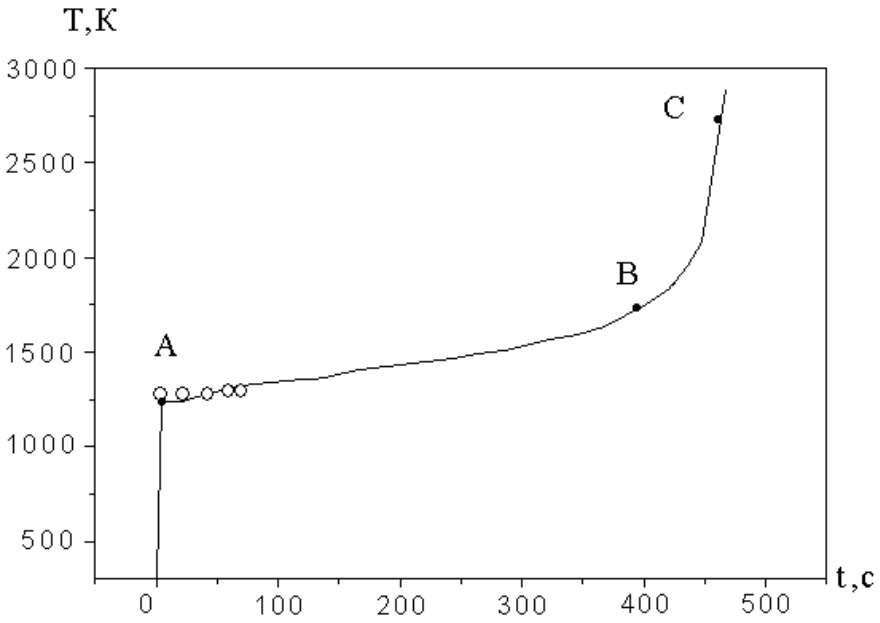

Figure 4. The molybdenum filament temperature history during non-stationary oxidation.

CONCLUSIONS

High temperature oxidation of molybdenum filaments in air was studied experimentally. It was shown that stationary oxidation mode realized when heating current was below some critical value.

The dependence of filament stationary temperature on heating current was found by means of electrothermography.

Temperature profile along the filament was found experimentally and numerically. The computed and experimental curves were in good agreement.

The temperature history was registered during non-stationary oxidation process. Three successive stages of the process were identified. It was shown that oxide melting point and boiling point delimited the succesive stages.

RECIRCULATION BEHAVIOR IN SUBSCALE GAS TURBINE COMBUSTOR

H. Moriai[1,2*], P. Wang[3], J. Hayashi[3], N. Nakatsuka[3], F. Akamatsu[3], R. Kurose[2], S. Komori[2]

ABSTRACT. Understanding internal flow field in combustors is very important to design and improve the low-NOx combustor for aircraft engines. The subscale (1/2) combustor model with swirl nozzle (air-blast nozzle) is newly fabricated, and the visualization and measurement of the internal flow in the combustor using PDA (Phase Doppler Anemometer) technique are conducted. The results show general feature of flow field in the combustor and effect of the air/fuel flow on the axial velocity and size distribution of the spray.

Keywords: *Gas Turbine Combustor, Spray Combustion, Swirl Flow, Recirculation Zone, PDA measurement*

INTRODUCTION

The aircraft gas-turbine combustor has to meet many requirements such as combustion efficiency, NOx/CO/UHC (Unburned Hydrocarbon) emission, combustor exit temperature profile, altitude relight capability, and blowout characteristics. To satisfy the combustion efficiency and emission requirements, air-blast swirl nozzle is commonly used. However, this type of nozzle sometimes causes problems associated with altitude relight capability and blowout performance [1]. Since these characteristics are closely related to the recirculation zones that work as flame holder of the combustor, it is very important to understand the relationship between the recirculation flow behaviour and swirler design in order to optimize the nozzle performance.

Figure 1 shows the general development cycle of the combustors (including the nozzle and the combustion liner). The precise predictions of the combustion behaviour and emission are so difficult that the cycle is generally repeated again and again to reach the spec requirements of the combustor. This means the try-and-error characteristics of the combustor development, in which quite a long time and high cost are needed. To reduce the development time and cost, CFD (Computational Fluid Dynamics) is strongly expected to be useful in the near future [2,3]. However, the reliability of the CFD has not been established yet, since the spray combustion in the aircraft gas-turbine combustors is a complex phenomenon in which swirling and recirculating flow, fuel jet breakup, evaporation, and chemical reactions and so on take place simultaneously and interact each other, and therefore the experimental data for the validation of the CFD are not enough.

The purpose of this study is, therefore, to provide the experimental data of the spray combustion in the aircraft gas-turbine combustors for the understanding of the spray combustion and the CFD validation. In this study, the fuel droplet velocity and size near the burner in the 1/2-scale combustor model are measured using PDA (Phase Doppler Anemometer).

EXPERIMENT

Figure 2 shows the PDA measurement system and the spray combustion combustor used in this study. The spray combustion combustor is a 1/2-scale combustor model with single burner (nozzle) and optical windows, and installed as a subscale combustor in the combustion test facility of Osaka University.

Test conditions are summarized in Table 1. The changed parameters are air flow rate and fuel flow rate. The measurements are conducted under atmospheric pressure condition (the measurements under the high pressure condition will be conducted in the near future). The PDA measurement points are shown in Figure 3. The nozzle has two swirlers (inner swirler and outer swirler) for spray atomization and recirculation zone that works as flame holder. In this figure, ● shows the measurement points at which the enough number of droplets are not detected, and ○ with numbers are the measurement points.

RESULTS & DISCUSSION

General Feature of Spray Flame

In Figure 3, it is found that the spray droplets do not exist in the centre of the spray cone. This is because the spray cone angle is very wide (strong swirl flow) and little spray droplets exist in the downstream direction. Another reason is that there exists a recirculation zone around the centre line right downstream of the nozzle but only burned gas (after vaporization, mixing and chemical reaction) in the downstream is recirculating to the upstream central region.

Figure 4 shows the direct photographs of spray flame for fuel-lean (equivalence ratio ϕ <1) and fuel-rich (equivalence ratio ϕ >1) combustion. Blue flame is observed in the fuel-lean condition and visualization and measurement are easier because little amount of soot generates on the quarts window surface. In the fuel-rich condition, on the other hand, luminous flame is observed and soot grows considerably on the window in short time.

Effect of Air Flow Rate

Figures 5 and 6 show the effect of air flow rate on the radial distribution of fuel droplet velocity *U* at two axial points from the nozzle exit of x = 6.8 mm and 15.8 mm. In the region close to the nozzle exit of x = 6.8 mm, very narrow recirculation zone exists and *U* increases with the air flow rate (almost in proportion to the air flow rate). In the downstream region of x = 15.8 mm, on the other hand, the recirculation zone gets wider (with wider cone width) and *U* becomes larger. The increase in *U* is mainly due to the thermal expansion of reacting flow.

Figures 7 and 8 show the effect of air flow rate on the radial distribution of fuel droplet size *D32* at x = 6.8 mm and 15.8 mm. It is found that *D32* decreases with the air flow rate. This is due to the fact that shear force for atomizing the fuel liquid becomes larger as the air flow rate increases.

Effect of Fuel Flow Rate

Figures 9 and 10 show the effects of fuel flow rate on the radial distributions of fuel droplet velocity *U* and size *D32* at x = 6.8 mm. Compared to the effect of the air flow rate, the effects of the fuel flow rate are found to be less on both *U* and *D32* in the measured region.

CONCLUSIONS

In this study, the subscale (1/2) combustor model of an aircraft gas-turbine combustor was newly fabricated for the laboratory-scale experiments. In addition, general feature of the spray combustion was visualized and the effects of the air and fuel flow rates on the fuel droplet velocity and size were investigated using PDA technique. It was found that the recirculation zone is formed in the central region close to the nozzle, and that the fuel droplet behaviour is strongly affected by the air flow rate but not by the fuel flow rate very much.

ABSTRACT. Calcium Sulfate ($CaSO_4$) deposit reduces heat exchange in heat transfer equipment which adversely affects the equipment performance and plant production. Experimental studies were conducted using Rotating Cylinder Electrode (RCE) equipment to study the effect of Calcium Sulfate ($CaSO_4$) scale deposition on coated carbon steel and titanium surfaces. In this study the rotational speed was varied from 100 to 2000 RPM to study the behavior of Calcium Sulfate ($CaSO_4$) accumulation on both materials. Based on the experimental results, Calcium Sulfate ($CaSO_4$) scale obtained in the present study was almost constant on coated carbon steel. However, it increased as speed increased for deposition observed on titanium material

INTRODUCTION

Fouling formation, and under deposit corrosion caused by scale deposits are major concerns for heat transfer equipment such as boilers, process fired heaters and heat exchangers in petroleum refineries, chemical and power plants. To mitigate corrosion and fouling, expensive corrosion-resistant alloys are used as construction materials for shell and tube heat exchangers. The use of titanium tubes in heat exchangers is a common practice now-a-days which has resulted in an exceptional increase of service life in many refinery heat exchangers. The copper based alloys such as Copper-Nickel (Cu-Ni) are the most effectiveness tube material used in desalination plants, however, due to seawater corrosion, the leak developed could cause serious problems. Titanium has been used either as original equipment or for retubing. Capital and maintenance costs of heat exchangers can be reduced considerably if inexpensive carbon steel tubes are coated with a low-cost, thermally conductive coating that provides corrosion resistance as well, equal to that of costly high-grade alloy materials. In aggressive environments, heat exchangers capital and maintenance costs are high due to the use of expensive corrosion resistance materials [1]. Heat exchanger fouling or deposition accumulation in general is a major economic problem accounting to 0.25 % of the total gross domestic product (GDP) in highly industrialized countries [2].

A methodology was developed earlier in laboratory by the use of Rotating Cylinder Electrode (RCE) to study scale build up on different metal surfaces. RCE is used to simulate conventional pipe flow [3]. The technique has some advantages over conventional flow loop test methods due to the ease of creating turbulent flow conditions and the simplicity in handling and operating the whole test

equipment. Although the boundary conditions in conventional flow loop and are different, scientists had successfully modelled the velocity affected corrosion mechanism. This was accomplished by equating the wall shear stresses in RCE to the pipe geometry under similar hydrodynamic conditions, for example turbulence, which resulted in identical mass transfer coefficients of both geometries [3]. In the present work the effect of solution hydrodynamics is studied at different rotational speeds (RPM) to obtain Calcium Sulfate ($CaSO_4$) scale deposition on coated carbon steel and titanium surfaces.

Fouling or deposit accumulation is a severe problem in heat transfer surfaces. Fouling is resulted from the accumulation of suspended particles in liquid or gas streams onto heat transfer surfaces [5]. Particles accumulation due to gravity is referred to as sedimentation. The suspended particles could include ambient pollutants such as sand, iron, and microbial organisms in cooling water.

It occurs when the process conditions lead to supersaturation of the dissolved inorganic salts on the heat transfer surfaces. These process conditions which lead to supersaturation involve evaporation beyond solubility limits, cooling/heating beyond solubility limits or mixing of the process stream. The industrial systems and operations in which the problem of precipitation fouling is significant are: Saline Desalination Plants, Geothermal Brine Systems, Cooling Water Systems, Steam Generation Systems and Potable Water Supply Systems. Some dissolved species show inverse solubility versus temperature behavior. In this case the substance tends to precipitate on a heated rather than a cooling surface as seen in cooling water application. Calcium Sulfate ($CaSO_4$) which is our main focus in this research study is one of the salts that exhibit this behavior. The driving force for crystallization is the chemical potential difference between the substances in the solution and deposit formed on the metal surface [5].

The effect of supersaturation, pH, Reynolds number and concentration of ions in the brine solution on the formation of silica scale in heat-exchanger tubes were discussed and also a silica deposition model was proposed by Neusen et al. [6]. Chemical reaction fouling includes deposits that are formed as a result of chemical reactions within the process fluid. Although heat exchanger surface doesn't act as reactant, it sometime behaves as a catalyst [7]. This type of fouling is commonly occurring in chemical process industries, refineries and dairy process.

Brian et al. [8]; investigated the use of titanium tubes in petroleum refining heat exchangers. The investigation was conducted on forty in-service heat exchangers. The investigation results revealed that the use of titanium tubes for heat exchangers resulted in an exceptional increase of service life in many refinery heat exchangers. The service life of the exchangers and plant production were improved by the use of titanium tubes. Scholl [9]; reported that capital costs of a typical heat exchanger can be reduced to 67% if polymer-coated carbon steel tubes, tube sheets, and headers are used in place of titanium tubes and titanium-clad plates. Scale deposit on coated surfaces is reduced tremendously compared with non-coated parts. Scale mitigation on heat transfer equipment improves equipment performance and reduces plants production losses.

Calcium Sulfate ($CaSO_4$) is considered to be one of the most commonly found scale in Arabian Gulf and Red Sea regions. Scale formation impacts heat transfer mechanism and affects equipment performance. The objective of this experimental work is to study the deposition of Calcium Sulfate ($CaSO_4$) scale on coated carbon steel and titanium surfaces

EXPERIMENTAL SET UP

The rotating cylinder equipment (RCE) used for conducting the experiments is shown in Figure 1 RCE consists of supersaturated solution tank, adjustable speed motor, Teflon-coated shaft, Teflon ring, specimen, Teflon cap, glass cell and hot water circulation bath. Coated carbon steel and titanium samples were fitted on the shaft that was attached to a rotating motor. The shaft holding the sample was completely immersed in double wall glass cell that contained supersaturated solution. The supersaturated, Calcium Sulfate ($CaSO_4$), solution was supplied to the glass cell from the tank. All the experiments were conducted at 60 ºC temperature and atmospheric pressure.

The solution tank which contained Calcium Chloride ($CaCl_2$) and Sodium Sulfate (Na_2SO_4) supersaturated solutions had a volume of four (4) litres. It was connected to the cylindrical double wall glass cell via ¼ inch (6.35 mm) tubing. The glass cell was 13.0 cm long with inner diameter of 3.4 cm. The supersaturated solution flowed to the glass cell at a rate of 1.0 to1.5 liter/hour. Overflow fluid was drained though an outlet ¼ inch (6.35 mm) tubing. Replenishment of the supersaturated solution in the tank was done when necessary by adding equal amount of $CaCl_2$ and Na_2SO_4 solutions. Continuous flow of the fresh solution to glass cell assured that the test specimen was exposed to a solution of constant composition. Motor speed was adjustable which enabled the sample rotation speed to be varied. The rotation speeds used in the experiments were varied from 100 to 2000 Revolution Per Minute (RPM).

At the beginning of each experiment, supersaturated solution was prepared and filled in supersaturated solution tank (1). Solution was allowed to flow to the glass cell (7) and heated to the required set temperature 60 °C, by circulating hot water. Hot water was circulated through the jacket surrounding the cylindrical glass cell. Water in glass cell was circulated by the use of constant temperature water-circulating bath arrangement (8) as shown in Figure 1. Each experiment was conducted at a certain rotational speed and preset solution temperature of 60 °C under atmospheric pressure. The duration selected for each experiment was six (6) hours.

When supersaturated solution reached to a temperature of 60 °C and the motor was set to the required rotational speed, test rig was ready to start. Before starting the experiment, each specimen (see Figure 2 and 3) was thoroughly cleaned with distilled water and acetone, weighed and mounted on the shaft of the rotating equipment. The shaft was immersed in the glass cell and the test started. At the end of each experiment the specimen was rinsed with water and carefully removed from the shaft. It was dried in the oven for two (2) hours. The oven temperature was set at 70 °C. Then, the test sample was re-weighed to determine the mass of scale gained by the specimen.

Before starting the next experiment the glass cell and solution tank were soaked overnight with dilute acid (HCl) then thoroughly cleaned with normal tap water followed by cleaning with distilled water.

Figure 2. Photograph of Coated Carbon Steel Samples

Figure 3. Photograph of Titanium Samples

DATA REDUCTION AND UNCERTAINTY ANALYSIS

The weight gained (W_g) by the specimen was resulted from the weight difference of specimen after the test and its initial weight before the test. The deposition rate (D_r) is calculated as the weight gained (W_g) of the scaled specimen in grams (g) divided by the surface area of the specimen in square meter (m^2), and the experiment time in hour (hr). The deposition rate (D_r) therefore has units of g. m^{-2}. hr^{-1}.

Calcium Sulfate ($CaSO_4$) deposition rate on coated carbon steel and titanium samples was calculated by the following reduction equation.

$$D_r = W_g * A_s^{-1} * t^{-1} \qquad (1)$$

Where;

D_r	Deposition rate ($g.m^{-2}.hr^{-1}$)
W_g	Weight gained by the specimen (g)
A_s	Surface area of the specimen [π*D*L] (m^2).

t Duration of the experiment work (hr).

The deposition rate uncertainty for Coated carbon steel was ± 8% and for Titanium was ±12 %

For each rotational speed, equivalent Reynolds numbers (Re) were calculated using the equation proposed by Gabe [3].

$$Re = R_1 \omega [(R_2-R_1)/\nu] \quad (2)$$

Where

Re	equivalent Reynolds number
R_1	radius of the rotating specimen (cm)
R_2	radius of the glass cell (cm)
ω	angular velocity of the rotating specimen (rad/sec)
ν	fluid kinematics viscosity (cm^2/s).

The Reynolds number uncertainty for coated carbon steel and Titanium ±4 %

RESULTS AND DISCUSSION

The following graphs are for titanium samples. Each graph shows three repetitions to compare the deposition accumulation at same Re (or rotational speed -RPM). These three tests are presented by Set 1, Set 2 and Set 3 respectively

Figures 4 and 5 show Calcium Sulfate ($CaSO_4$) deposition rates on the coated carbon steel and Titanium samples. For each rotation number, the experiment was performed three times to determine the deposition rate. In each experiment that was conducted a new sample was installed in the rotating shaft.

Figures 4 shows the behaviour of Calcium Sulfate ($CaSO_4$) deposition rates on the coated carbon steel samples. The deposition rate shows almost asymptotic line. It is an indication that mechanism of deposition and removal existing continuously regardless of the Reynolds number.

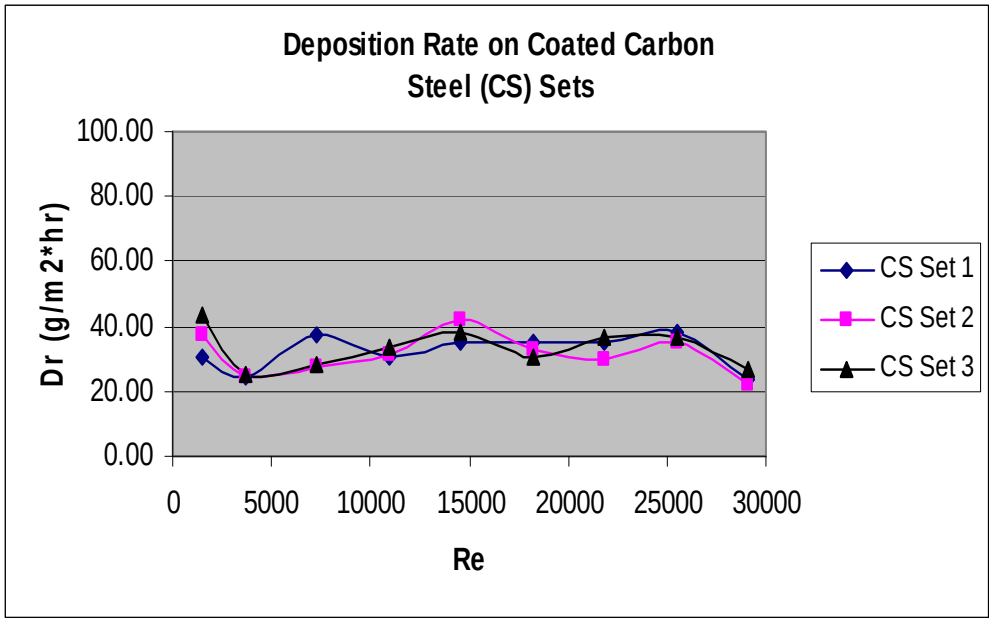

Figure 4. Deposition Rate on Coated Carbon Steel for Three Sets

Figure 5 shows the Calcium Sulfate ($CaSO_4$) deposition rate on Titanium samples. The deposition rate of Calcium Sulfate ($CaSO_4$) increases as the Reynolds number increases on titanium samples.

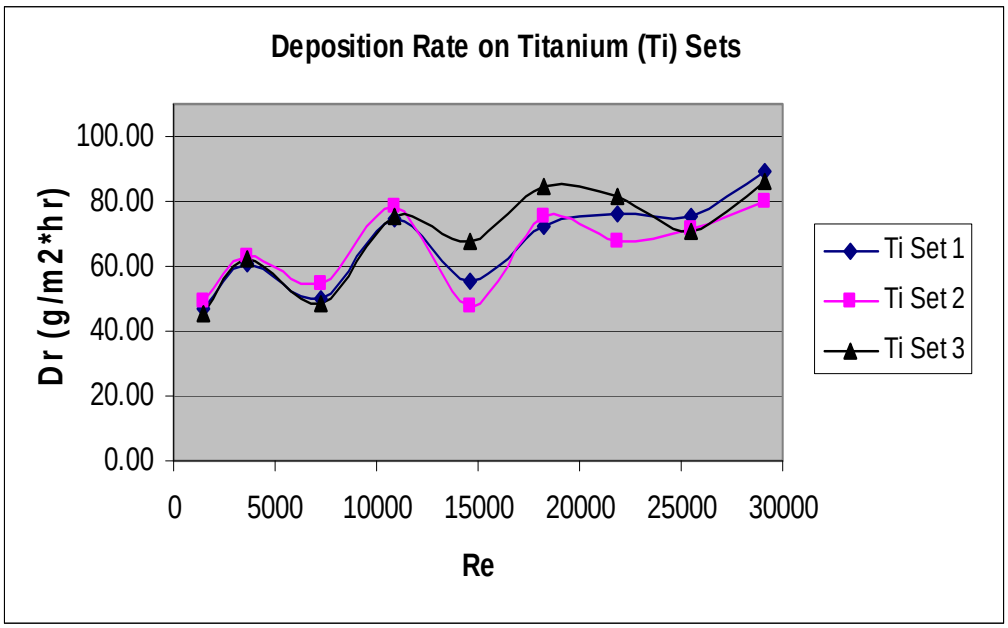

Figure 5. Deposition Rate on Titanium for Three Sets

Figure 6 shows the average deposition rate on Coated Carbon Steel and the Titanium samples. It can be seen that the deposition rate on the titanium samples are increasing proportionally to Reynolds number compared to coated carbon steel samples.

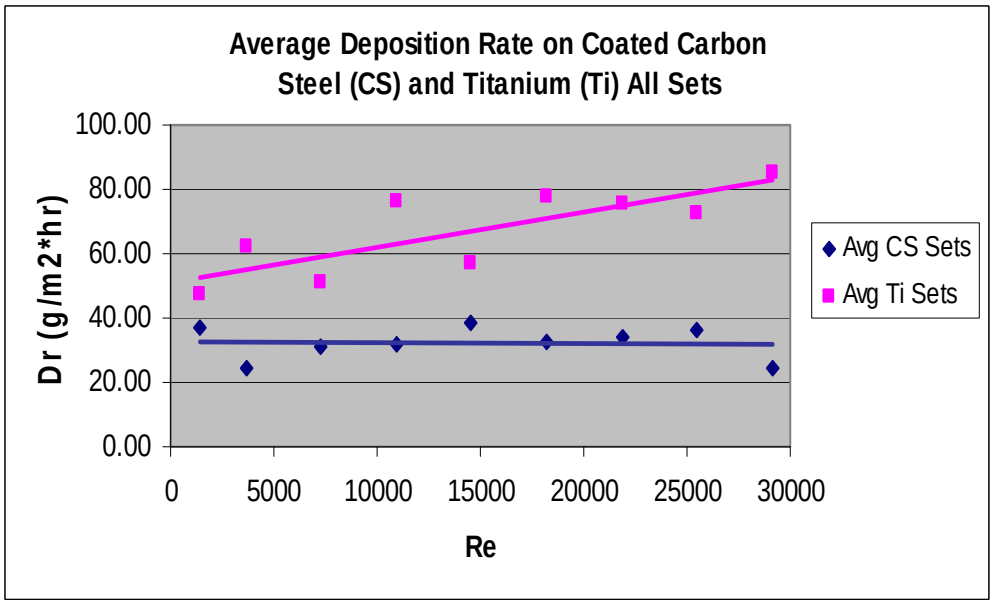

Figure 6. Average Deposition Rate on Coated Carbon Steel and Titanium Samples

According to the analysis done by Levich [11], the mass transfer coefficient should increase with the square root of Reynolds number - $(Re)^{0.5}$. For such case, the Log-Log plot should give a straight line with theoretical slope of 0.5. It is obvious from Figure 7 that the log-log plot of deposition rate

(D_r) versus Reynolds number shows a linear relationship,. a straight line with a slope of 0.45. This result is in close agreement with the theoretically predicted value of 0.5, obtained when the mass transfer coefficient is proportional to the square root of Reynolds. Hence, this shows that the process is diffusion controlled.

Based on the results presented in Figure 7, Coating on carbon steel samples reduced scale buildup and decelerated fouling accumulation on the external surfaces of the samples. However, in the case of titanium samples the scale growth was significantly more as the rotational speed was increased. Therefore, coated carbon steel samples showed better resistance to fouling and deposition compared to titanium samples

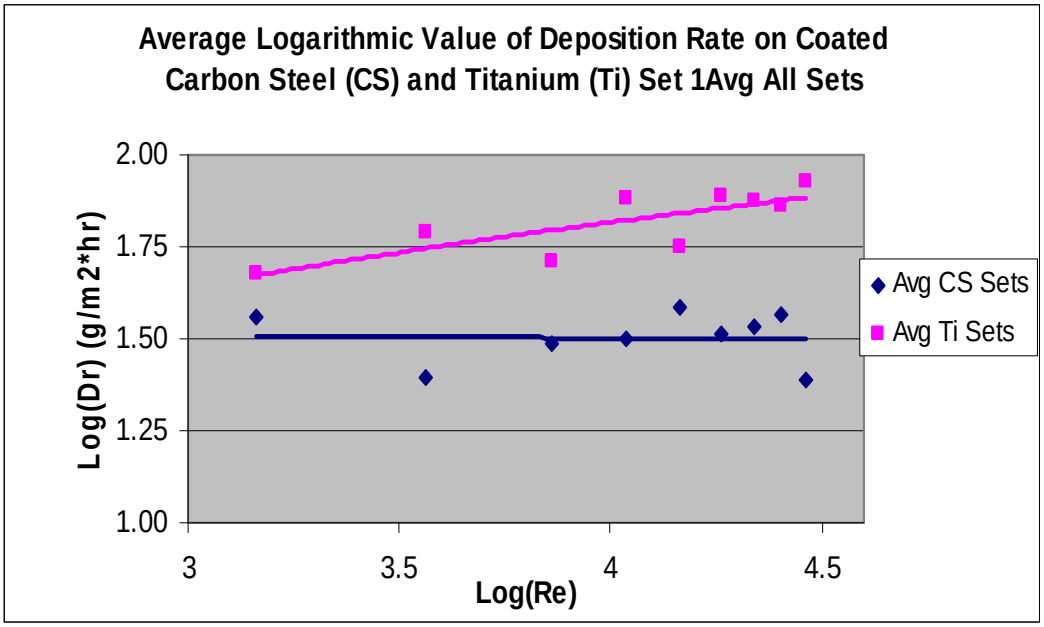

Figure 7. Average Logarithm (Deposition Rate) vs. Logarithm (Reynolds number)

CONCLUSION

Based on the results of the present experimental study, the following conclusions can be made:

- Scale buildup on the metal surfaces is proportional to the rotational speed. This is clear in case of titanium samples. As the rotational speed increased, the deposition rate increased which also was represented by more weight gained on the specimen surface.

- Another interesting point which was seen is the uniform distribution of Calcium Sulfate ($CaSO_4$) crystal on the metal surface. It was clearly seen that once a thin layer of scale is formed, the subsequent scale layer growth on it is much faster because of the readily available abundant nucleation sites as compared to the initially polished surface. Another perception could be that the scaled surface becomes sufficiently rough which promotes deposition process compared to the bare surface.

- The data analysis of Calcium Sulfate ($CaSO_4$) scale deposition rate showed that the rotational speed and the mixing of the solution have a strong influence on the rate of Calcium Sulfate deposition on coated carbon steel and titanium surfaces. The higher the speed of rotation the more scale crystals adhered to the metal surface. Deposition rate increased linearly with the square root of the Reynolds number, which showed that the process is diffusion controlled. It was noticed that, for both coated carbon steel and titanium

that were investigated, the deposition rate had clear linear relationship with the speed of rotation.

INVESTIGATION OF TWO-PHASE REFRIGERANT FLOW IN THE VERTICAL ACCUMULATOR OF A REFRIGERATOR

A. Celik[1,*], O. Unal[2], H. Kerpicci[1], I. Teke[2]
[1]Arcelik A.S., Istanbul, Turkey
[2]Yildiz Technical University, Istanbul, Turkey

ABSTRACT. This paper covers the transient two-phase isobutane (R-600a) refrigerant flow visualization and analyses, which were performed in the accumulator located after the fresh food evaporator of a two-compartment refrigerator. The inlet of the accumulator in such systems has very high refrigerant mass qualities between 0,9-1,0 during the on-cycle of the compressor. Effects of several system parameters have been taken into account during the experimental studies such as refrigerant mass flux and ambient temperature. High-speed camera pictures were taken to measure the liquid refrigerant droplet diameter and velocity for different test conditions. The refrigerant droplet size distribution and liquid refrigerant level increase inside the accumulator have been determined for different system parameters. Separation efficiency has been analysed based on force balance on the liquid droplet. Liquid refrigerant droplets ranging from 180µm-2000µm have been found in the experimental studies. Refrigerant mass flux has a profound effect on the liquid refrigerant diameter. Due to high variation in droplet diameter, calculated Sauter Mean Diameter (SMD) for the liquid droplets are found to be generally 32-50% higher than the calculated mean diameter of the droplets.

Keywords: *accumulator, two-phase flow, flow visualization, droplet distribution, high speed camera*

INTRODUCTION

Two-phase gas-liquid flows very often occur in industrial processes as well as in small capacity refrigeration systems. For instance, in household refrigeration systems, the refrigerant frequently leaves the specific heat exchanger named evaporator as in two-phase condition. There is a specific risk with these systems concerning the compressor. If two-phase flow occurs at the outlet of the evaporator, liquid phase of refrigerant will enter the suction line of the compressor in the refrigeration system without an accumulator. Slugging condition occurs when liquid refrigerant enters the suction line of the compressor. This is quite an important problem since the slugging condition may cause serious mechanical damage to the compressor. In most cases, an accumulator is installed vertically or horizontally between the evaporator and the compressor to prevent the occurrence of slugging condition. The basic function of the commonly used vertical accumulator is collecting the excess liquid phase refrigerant by gravity-driven separation of liquid-vapour mixture. Thus, the compressor is protected from damages caused by liquid refrigerant slugging.

Monnery and Svrcek (2000) established the separation efficiency of flare knock-out drums and determined the expected entrained liquid droplet diameter. Todd B. Jekel et al. (2001) reviewed the literature on the principles governing gravity-driven separation of liquid-vapour mixtures and

E-mail address: aydin.celik@arcelik.com

design methods for separators. They developed a model that predicts separator performance given operating requirements such as size or velocity and design droplet size. Sang-Joon Lee et al. (2003) investigated the flow structure inside the accumulator of a rotary compressor experimentally using a hybrid particle tracking velocimetry (PTV) velocity field measurement technique. C.M. Winkler and J. E. Peters (2002) determined the centerline droplet size in the header of a typical evaporator. They used a phase-doppler particle analyser to characterize the spray along the centerline of the header for 1, 2 and 3 g/s total mass flow rate. During the experiments the thermodynamic quality is varied in the header from 0 to 0,15. Cemil Inan et al. (2002) investigated the transient behaviour of a domestic refrigerator by an X-ray system. X-ray images were recorded by focusing to on the dryer, capillary exit, evaporator inlet, and accumulator regions specifically. They visualized the change in liquid level in the accumulator with R-134a refrigerant.

In this study, motion of droplets is visualized by Phantom v5.1 high-speed camera in order to understand dynamic and kinetic behaviour of liquid refrigerant droplets. Accumulator prototype is made of plexiglass for the flow visualization purposes. During the experimental study, ambient temperature is held at 25°C. Real time high-speed video images of the sight accumulator are taken during cyclic periods. The set of experiments are conducted to measure liquid refrigerant droplet diameter and velocity flowing with vapour phase.

THEORY AND MODELING

The droplet of any liquid in a vapour flow is under the influence of gravity, buoyancy and drag forces. The resulting net force on the droplet affects the velocity and separation of the droplet depending on the direction of the net force. The gravity force must be greater than the sum of buoyancy and drag forces in order to separate the droplet from the vapour flow. Figure 1 shows the forces acting on liquid droplet entrained in vapour flow.

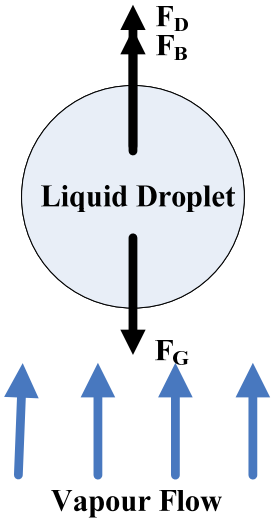

Figure 1. Forces on liquid droplet in vapour flow

According to Todd B. Jekel et al. (2001) [2], the forces acting on the liquid droplet and the force balance can be established by application of Newton's Law:

$$\sum_{i=1}^{n} \vec{F}_i(t) = m_d \vec{a}(t) \tag{1}$$

$$F_G = \rho_L V_d g \tag{2}$$

$$F_B = -\rho_V V_d g \tag{3}$$

$$F_D = -\rho_V U^2 C_D \frac{A_d}{2} \tag{4}$$

The signs in the above equations are given considering that the gravity force is always directed downward, the buoyancy force is opposite the gravity force and the direction of the drag force on the liquid is opposite to the gravity force.

When sizing the accumulator, SMD can be used for the force balance equations. According to ASTM E799-92, Kröger and Alkidas SMD is defined as [8]

$$d_{32} = \frac{\sum n d_d^{\,3}}{\sum n d_d^{\,2}} \tag{5}$$

The accumulator separation efficiency ηs describes the ability of an accumulator in separating the refrigerant phases. [6] Separation efficiency can be estimated as following

$$\eta s = \frac{\sum_{i=1}^{n} \rho_{l,i} d_{s,i}^{\,3}}{\sum_{i=1}^{n} \rho_{l,i} d_{s+e,i}^{\,3}} \tag{6}$$

EXPERIMENTAL SETUP

Tests were conducted with Phantom v5.1 high speed camera at 1000pps. The refrigerant droplet size distribution and liquid refrigerant level increase inside the accumulator have been determined for different system parameters. To capture minimum diameter of a liquid droplet, which is in the order of 50-100 µm, high magnification is required in the experimental setup. To achieve this, macro lens is used and an extension tube is mounted between the camera sensor and the macro lens. A cold light source and a boroscobe system are used for illumination of the test section to measure liquid refrigerant level in the accumulator. Temperature measurements are made with T-type thermocouples attached to different locations on the whole cooling circuit. ImageJ software is used for analyses of the liquid droplets. Minitab software is used for statistical analyses of the liquid droplets. Agilent 34970A acquisition system is used for temperature measurements. Accuracy of temperature measurement is ±0,25°C.

The original metallic accumulator in the refrigeration system of a refrigerator is replaced with a sight accumulator prototype made by plexiglass tubing capable of sustaining 6-10 bar pressure. Inlet and outlet pipes of the accumulator were kept in the system. The tube connections to the sight accumulator have been made by a unique epoxy designed for these type of low temperature, low pressure applications. The sight accumulator is placed vertically at the outlet of the fresh food evaporator, which is mounted in the insulation of the refrigerator through an opening. To determine droplets sizes, a ruler located near the accumulator prototype and glycol is applied to accumulator surface to prevent condensation. The visualisation section has a cover that is made of polyurethane to minimize heat gain when the flow is not being visualized. Figure 2 shows the experimental setup.

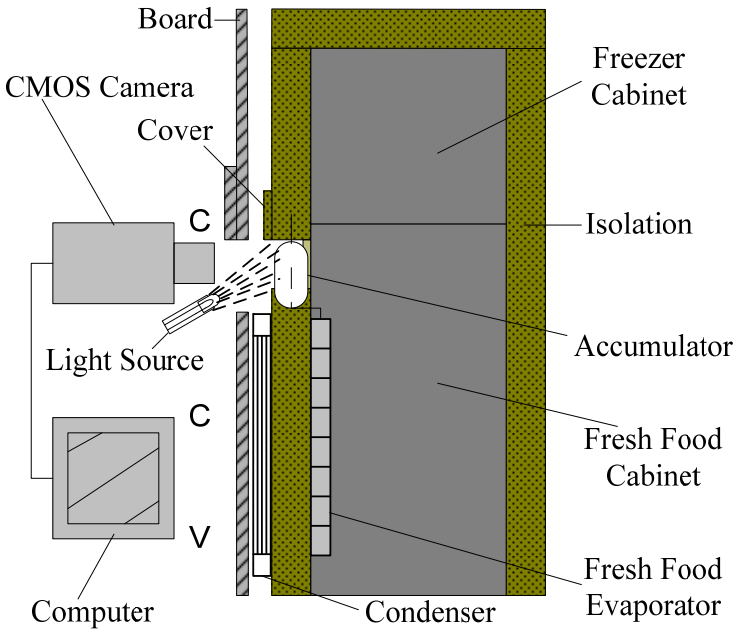

Figure 2. Experimental setup for liquid droplet visualisation

EXPERIMENTS

The refrigerator is placed in the conditioned room where ambient temperature is set to 25 ± 0,2°C. Temperature data collection has been synchronized with video recording by high-speed camera and boroscobe system. The high-speed videos are recorded at different times of on period of the refrigerator at 1000pps. For the real working conditions of the refrigerator, the droplet SMD was measured where the ambient temperature is 25°C by high-speed camera and analyzed with ImageJ. Figure 3 shows the real time captured picture and modified picture for the particle analysis with ImageJ.

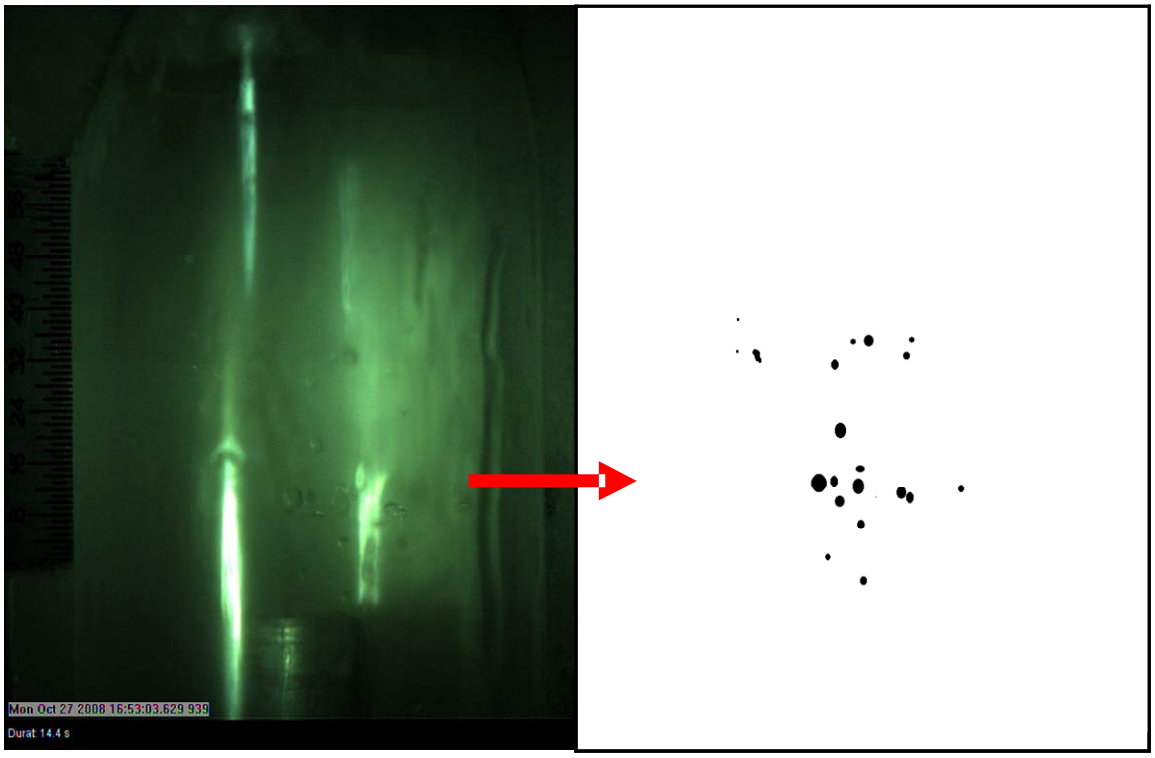

Figure 3. a) Real time captured picture b) Modified picture for particle analysis

Probability distribution and normal distribution of liquid droplet diameters are shown in Figure 4 and Figure 5 respectively. Liquid refrigerant droplets ranging from 180µm-2000µm have been found in the experimental studies. Entrained and separated droplets in vapour flow are visualized to determine the separation efficiency of the accumulator. The calculated separation efficiency (η_s) from Equation (6) for this droplet diameter distribution is 96,7%.

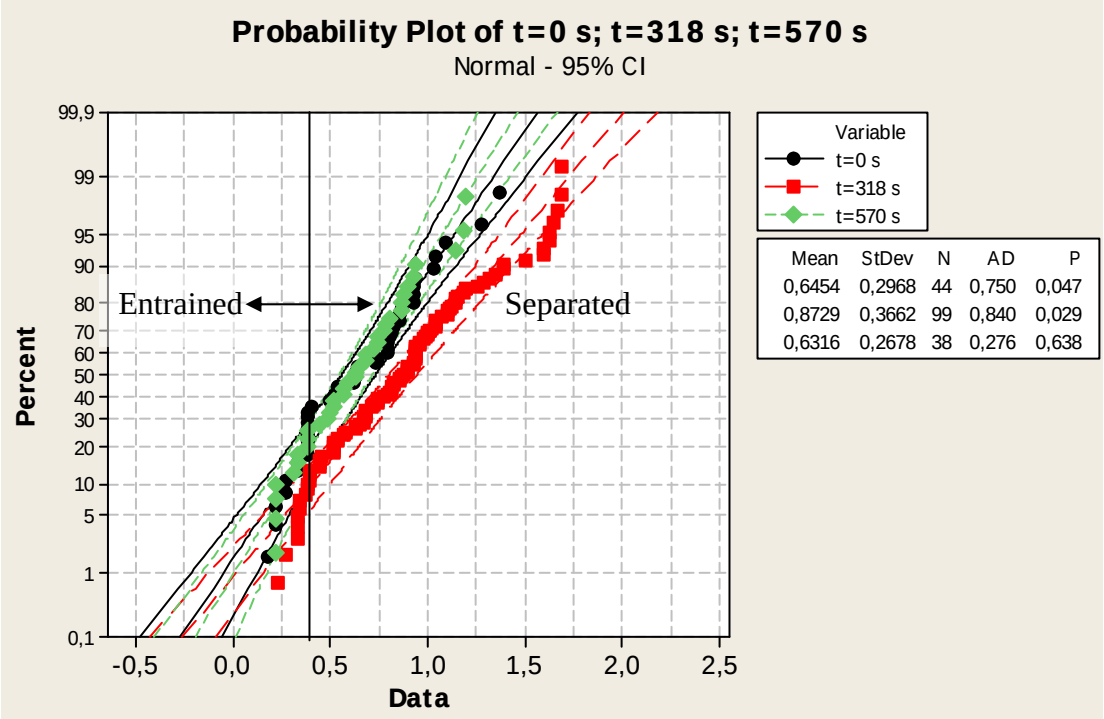

Figure 4. Probability distribution of liquid droplets

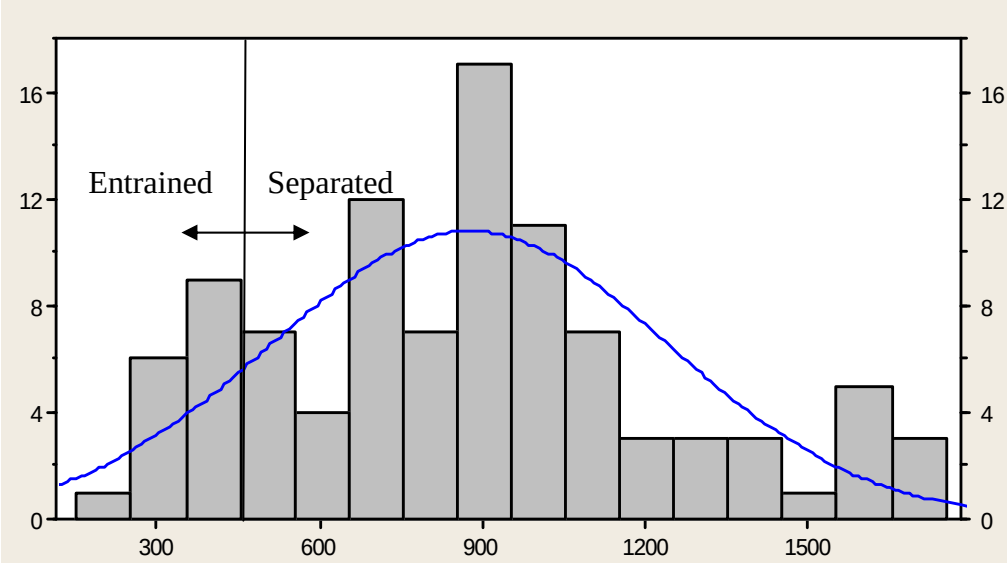

Figure 5. Normal distribution of liquid droplets

During the experiments, droplet size measurements are conducted at different total refrigerant mass fluxes on the time domain. Figure 6 shows the calculated mean diameter and SMD for the liquid droplets at different mass fluxes entering the accumulator. Due to high variation in droplet diameter, calculated SMD for the liquid droplets are found to be generally 32-50% higher than the calculated mean diameter of the droplets.

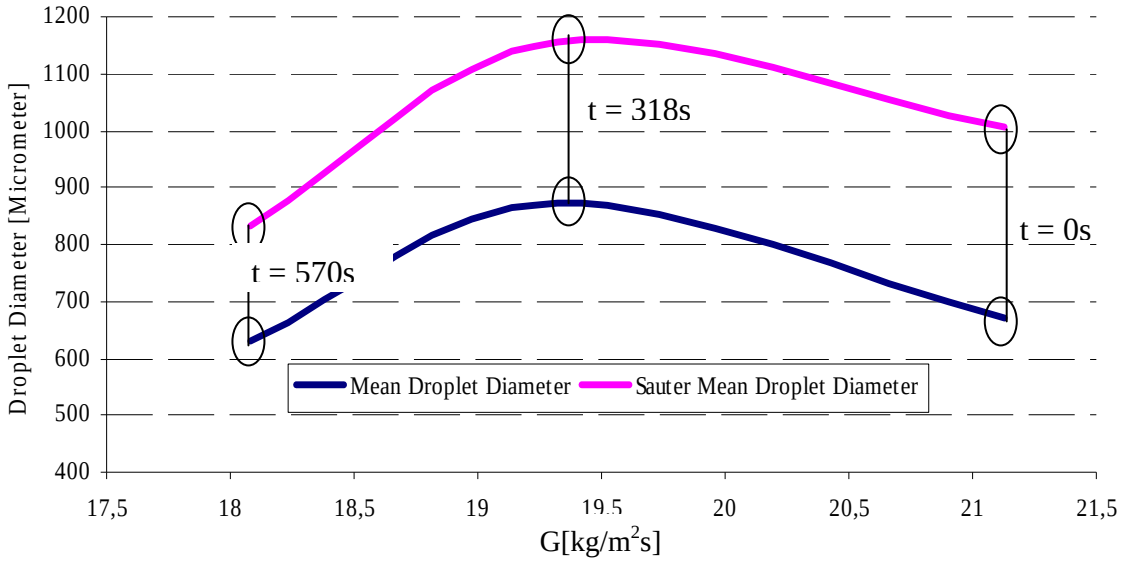

Figure 6. Mass flux versus mean droplet diameter and the SMD

Due to separation of liquid droplets from the vapour phase, continuous increase in the liquid level inside the accumulator has been observed. There are three important phases during on cycle of the refrigerator. First, the accumulator is filled up suddenly. This is due to high mass flux and low thermodynamic quality. Second, we observe a decrease in the liquid level due to partial evaporation of the stored liquid refrigerant. Third, increase in the liquid level with additional storage of liquid refrigerant due to low mass flux, but high thermodynamic quality. Figure 7 shows the change in the liquid level during the on period of the refrigerator.

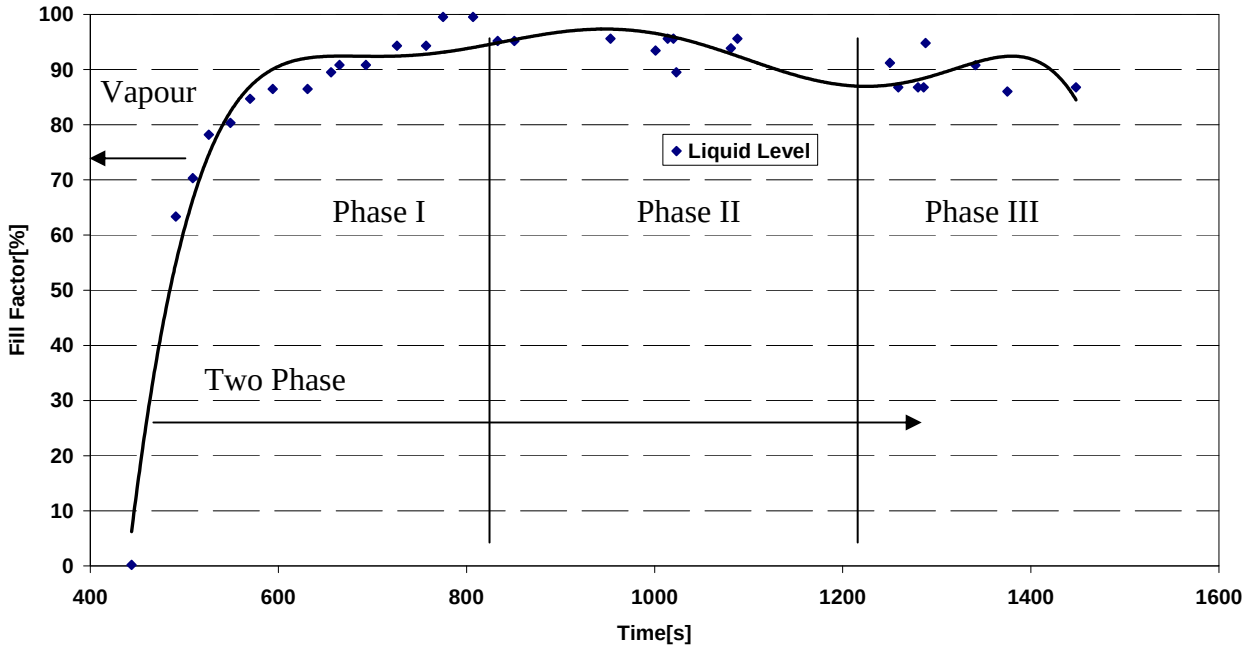

Figure 7. Change in the liquid refrigerant level during the on period of the refrigerator

The velocity, diameter and distance from the center of the accumulator inlet tube are measured instantaneously by the high speed camera. As shown in Figure 8, droplet velocity changes with the droplet diameter and the distance from the center of the accumulator inlet tube. It has been found that the velocity distribution of the liquid droplets also has a normal distribution along the axial direction. The positive and negative velocities indicate the entrained and the separated liquid droplets respectively.

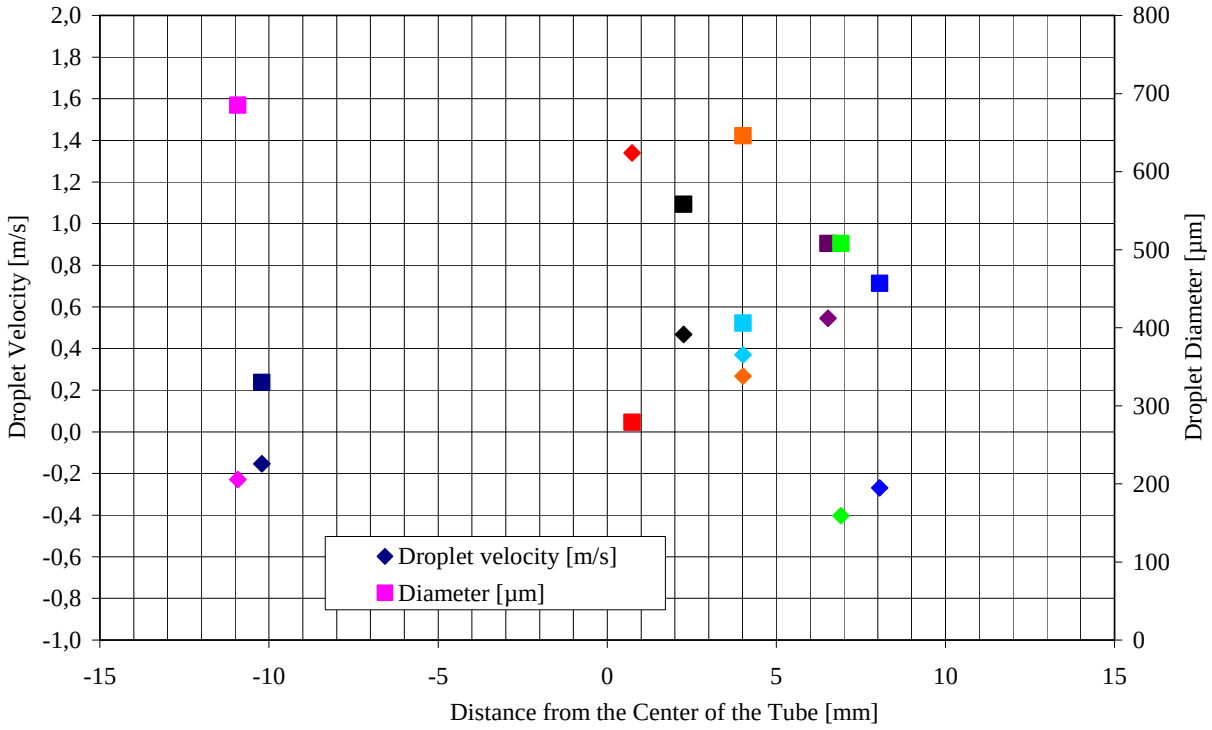

Figure 8. Velocity and diameter of liquid droplets in the accumulator

CONCLUSIONS

The transient two-phase isobutane (R-600a) refrigerant flow visualization and analyses in the accumulator provides important information on the flow characteristics. In this study, the refrigerant droplet size distribution and the increase of liquid refrigerant level inside the accumulator have been determined for different mass fluxes.

1. Liquid refrigerant droplets ranging from 180µm-2000µm have been found in the experimental studies.
2. Due to high variation in droplet diameter, calculated SMD for the liquid droplets are found to be generally 32-50% higher than the calculated mean diameter of the droplets.
3. Refrigerant total mass flux has a profound effect on the liquid droplet diameter.
4. Separation efficiency has been analysed based on force balance on the liquid droplet. The calculated separation efficiency (η_s) from Equation (6) for this droplet diameter distribution is 96,7%.
5. It has been found that droplet velocity changes with respect to the droplet diameter and the distance from the center of the accumulator inlet tube.
6. The velocity distribution of the liquid droplets also has a normal distribution along the axial direction.

ANALYSIS OF BOILING HEAT TRANSFER ON THE NON-ISOTHERMAL SURFACE COVERED WITH SELECTED WIRE MESH STRUCTURES

Ł.J. Orman[1,*], T. Orzechowski[2]
[1,2]Kielce University of Technology, Kielce, Poland

ABSTRACT. The paper presents the experimental results of distilled water and ethyl alcohol boiling heat transfer on the non – isothermal surface of a fin covered with wire mesh structures. The coating consists of 1, 2 and 3 layers of copper mesh whose wire diameter is 0.20 mm and mesh aperture 0.32 mm. The layers have been sintered to each other and to the copper fin in a reduction hydrogen atmosphere. The work covered the investigation into the impact of the number of mesh layers on heat flux, analysis of physical phenomena during the process and comparison of the results with selected heat transfer models. It has been concluded that the application of such porous structures enhances boiling heat transfer - the heat flux for mesh coated surfaces is several times higher comparing to the smooth surface. The thickest 3 – layer coating proves to be most favourable, especially at small superheats. For high superheats the heat flux approaches a certain limiting value, which seems to be caused by a capillary pumping crisis and the fact that a significant amount of vapour remains in the voids of the structure.

Keywords: *boiling, heat transfer enhancement, thermovision*

INTRODUCTION

Boiling heat transfer enables to dissipate significant heat fluxes at relatively small temperature differences. However, in order to further increase dissipated heat fluxes smooth surfaces of heat exchangers can be covered with some additional coatings: capillary porous, wire mesh and others. Such layers enhance boiling heat transfer comparing to smooth surfaces. Nevertheless, up to now it has not been possible to form a general model of heat transfer during boiling on such coatings, because the knowledge of physical fundamentals of the phenomenon is still insufficient.
Smirnov et al. [1] describe the boiling phenomenon in porous structures, which are modelled as arrays of microfins in which heat transfer under nucleate boiling regime occurs. The local heat transfer coefficients are determined considering hydraulic pressure loss of the counter flow of the vapour and liquid phase. A disadvantage of the model is a need to determine a constant that depends on the experiment conditions, sample properties and etc. A dependence of heat flux vs. superheat (defined as a difference between the wall and saturation temperatures) is given in the form of [2]:

$$q \sim \theta^m \tag{1}$$

where the contact m for mesh structures is nearly linear and in the range of $0.8 \div 1.0$.
In a semi – empirical model of Rao et al. [3] it is assumed that the pressure loss in the porous layer can be determined from the Darcy equation. A formula to calculate heat flux as a dependance of superheat, surface microgeometry and liquid physical properties is given. The model was verified

with experimental data of independent researchers for different flat surfaces and tubes covered with porous layers and good agreement was found.
A very simple and easy to use model to determine the heat flux was proposed by Nishikava et al. [4]. Heat is assumed to be transferred from the heating surface to the liquid by means of a 1-D heat conduction. The application of the model, however, might results in heat flux values well above the experimental data, as verified e.g. by Orzechowski et al. [5].
In order to propose a reliable model of boiling heat transfer it is necessary to properly conclude about the physical phenomena occurring in porous coatings. Brausch et al. [6] investigated water boiling on surfaces with 1, 3 and 5 layers of stainless steel mesh. Four kinds of mesh were used whose wire aperture ranged from 0.087 mm to 0.318 mm. It was observed that one layer of mesh improved heat transfer in comparison to the smooth surface at superheats up to 15 K, while at higher temperature differences the wire mesh made bubble removal from the structure more difficult, which resulted in the formation of a vapour film, which insulated the heating surface from the liquid. Franco et al. [7] made similar observations from the exerimental tests of pool boiling of the dielectric refrigerant R141b. The heating surface was covered with copper, aluminium, brass and stainless steel mesh structures. It was assessed that mesh layers of small aperture enhanced heat transfer comparing to the smooth surface for small heat fluxes. Higher values of heat flux in this case led to limiting heat transfer, which was due to an unfavourable effect of vapour dry out conditions and resulted in lowering the critical heat flux. However, contradictory conclusions can be drawn from the experimental investigations of Rannenberg et al. [8] focused on R11 and R113 boiling on surfaces covered with 2 – 9 layers of mesh, which generally showed no impact of the number of layers on heat transfer.
Boiling heat transfer measurements are widely conducted on experimental stands whose main element is an isothermal heating block. However, real heat exchanging surfaces are usually non-isothermal and in order to properly design heat exchangers there is a need to carry out experiments on real non – isothermal surfaces. Consequently, an experimental stand was constructed that enables to conduct measurements on such surfaces. An important element of the stand is a thermovision camera, which registers a thermal map of an object.
In the paper the mesh coatings were selected as enhancing coverings since they have a regular geometrical structure as opposed to some porous layers. Thus, there is a possibility to conclude about the impact of their geometry on heat flux and, basing on the results, draw conclusions regarding the physical phenomena inside the layers.

EXPERIMENTAL SET – UP

The main element of the experimental stand is a copper fin, which is part of the wall of a vessel (Figure 1). It is in contact with the boiling liquid on one side and with the air on the other. Heat is supplied to the base of the fin with an electric heater. A thermovision camera is used to observe the outer surface of the fin in order to determine temperature along its height. The measured temperature distribution is then used to determine local values of the heat transfer coefficient. An auxiliary heater is installed at the bottom of the vessel to maintain stable pool boiling regime. A detailed description of the apparatus and the research method has been given in [9].

The inner surface of the fin in contact with the boiling liquid was covered with copper wire mesh coatings of mesh aperture 0.32 mm and wire diameter 0.20 mm. Four kinds of surfaces were tested: surfaces with 1, 2 and 3 layers of mesh, while a smooth surface served as a reference surface. The meshes were sintered to each other and to the copper fin in reduction atmosphere of hydrogen. The applied technology ensures strong and large bonds between the elements. In this way a contact resistance is eliminated. The tests were conducted for distilled water and ethyl alcohol as boiling liquids at ambient pressure.

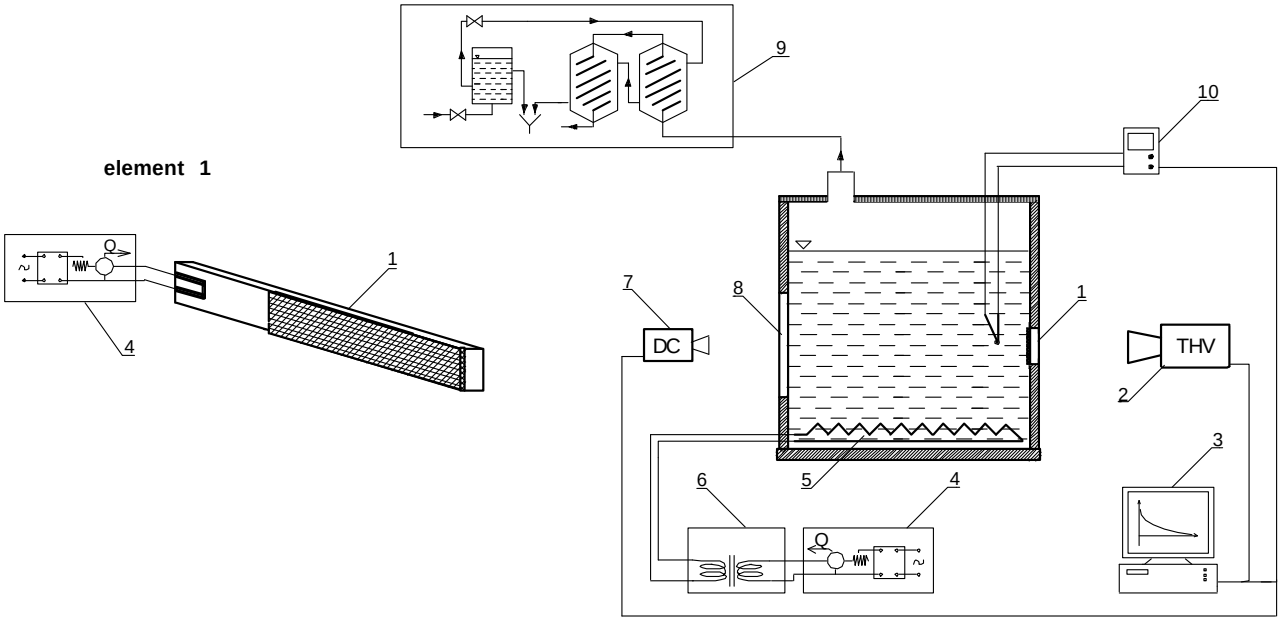

Figure 1. Schematic of the experimental set - up: 1 – copper fin, 2 – thermovision camera, 3 – data acquisition system, 4 – autotransformer, 5 – auxiliary heater, 6 – electrical current separation unit, 7 – digital camera, 8 – observation window, 9 – cooling and condensate retrieval unit, 10 – temperature measurement device [5]

RESULTS

The temperature distribution along the fin and its numerical differentiation enable to determine local values of the heat transfer coefficient according to the method presented in [9]. It has been assumed that the heat transfer coefficient between the fin and the liquid depends exponentially on superheat:

$$\alpha = a\,\theta^{n} \tag{2}$$

where a, n are constants, whose experimental determination leads to a formula for the boiling curve. Having considered (2) and the simplifing assumptions for 1-D heat conduction, a formula for temperature distribution along the fin is produced in the form of:

$$\frac{d^2\theta}{dx^2} = m^2\theta^{n+1} \tag{3}$$

which was analyzed by Ünal in [10].
After differentiation of (3) the superheat gradient in logarithmic coordinates is then calculated as:

$$\ln\left(\frac{d\theta}{dx}\right)^2 = \ln\left(\frac{2m^2}{n+2}\right) + (n+2)\ln\theta \tag{4}$$

where $n \neq 2$, while m^2 is defined as:

$$m^2 = \frac{a\,P}{\lambda F} \tag{5}$$

P and F are the circumference and surface area of the fin, respectively, while λ is the thermal conductivity of the fin's material. For fins of significant length, as in the analyzed case, no heat transfer at the tip can be assumed. In such a case an integration constant C in (4) equals 0.
Basing on the temperature distribution along the fin recorded with the infrared camera and its numerical differentiation the constants: a and n can be determined from (4), which is done applying the linear regression to research data. Consequently, it is possible to draw boiling curves as a function of heat transfer coefficient or heat flux and wall superheat using (2).
In order to more precisely determine the heat flux the results for ethyl alcohol have been analysed with a modified method, assuming the non - linear dependance for heat transfer coefficient [9]:

$$\alpha = a_1 + a_2\theta + a_3\theta^2 + a_4\theta^3 + \ldots \tag{6}$$

The infrared temperature measurements have been conducted with a long-wave (8 – 14 μm) thermovision camera VIGOcam v50 (Vigo System). The device is equipped with 22°x16° lens and a detector of 384x288 pixels whose thermal sensivity is 0.08 K at 30°C.
The measurement results have been presented in Figures 2a and 2b as heat flux vs. wall superheat for surfaces with 1, 2 and 3 layers of wire mesh. The porous layers have mesh aperture of 0.32 mm and wire diameter of 0.20 mm. The coating covers a surface of a copper fin of 4 mm thickness, 12 mm height and 90 mm length. For comparison the smooth surface test results for a bare surface are also given as in [11].

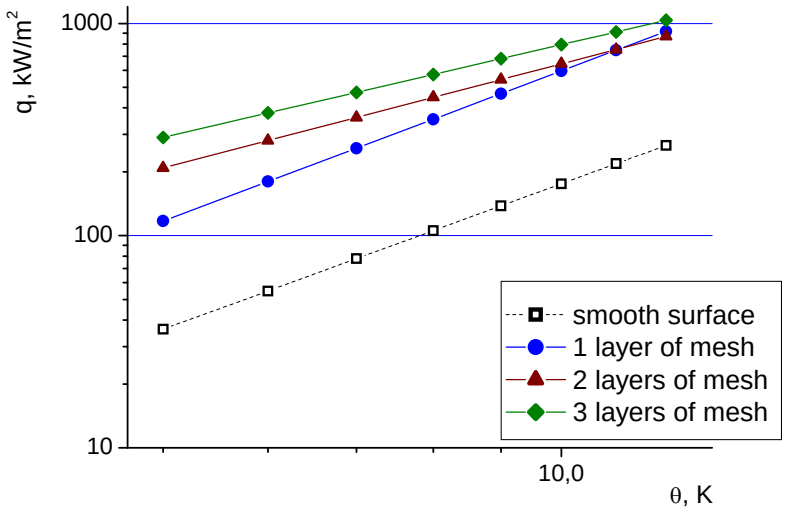

Figure 2a. Boiling curves for distilled water

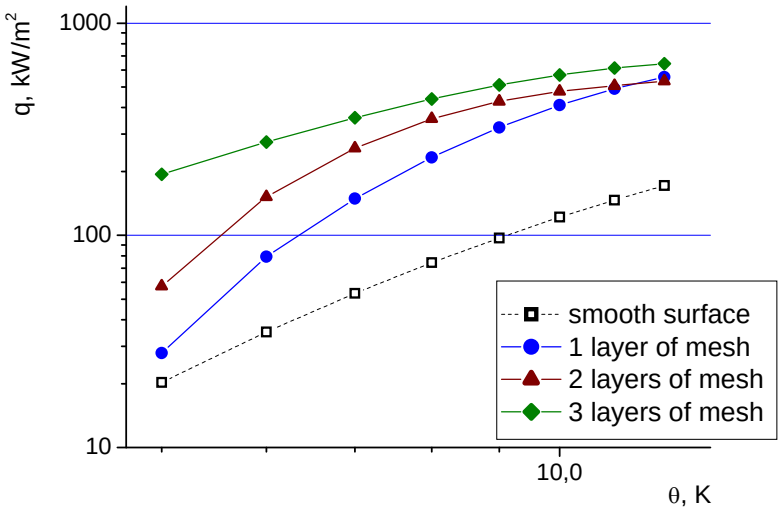

Figure 2b. Boiling curves for ethyl alcohol

As can be seen in the figures the porous coatings enhance boiling heat transfer comparing to the smooth reference surface. As the coating becomes higher (as more layers of mesh are applied – from 1 to 3) heat flux increases, which is most apparent for small superheats for both water and ethanol. For high superheats the heat flux approaches a certain value, which almost does not depend on the number of mesh layers. It seems to be caused by a crisis of capillary pumping and the fact that a significant amount of vapour remains in the interlayer's voids of the structure.
Figures 3a and b present a dependence of the enhancement factor expressed as a ratio of the heat flux for the surface with a microcoating (q_m) and for the smooth reference surface (q_s) as a function of the number of layers.

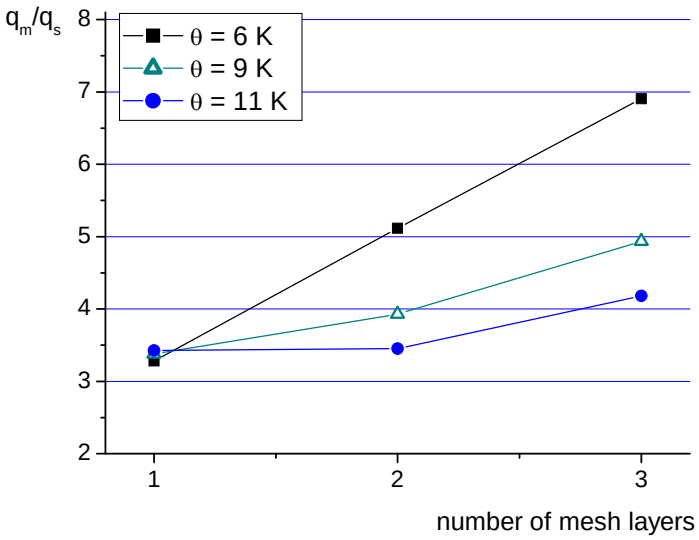

Figure 3a. Enhancement factor for distilled water

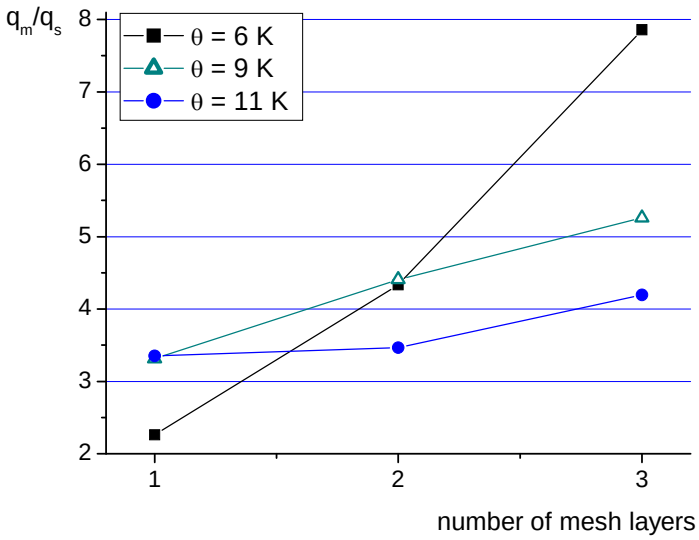

Figure 3b. Enhancement factor for ethyl alcohol

The analysis of Figures 3a and b reveals that the most significant impact of the application of the porous coatings is observed for small superheats. At the superheat of 6 K the heat flux for the surface with the 3 – layer mesh structure is almost 8 times higher for ethanol and 7 times higher for water in comparison to the smooth surface. It might be related to a higher active nucleation sites density. All the curves show a proportional dependence of the enhancement factor on the number of mesh layers, however, at high superheats this dependence is weakest, which might be caused by significant vapour flow resistance in such thick structures. It is worth noting that the results for the superheat of 11 K and the surfaces of 1 and 2 mesh layers are very similar to each other, while the 3 – layer coating performs much better. It might indicate that the transport of liquid into the structure by the side area of the sample is significantly improved for the thickest coating comparing to the other two structures, which might be verified by further visualisation studies.

Strong similarities between distilled water and ethyl alcohol results lead to a conclusion about the same mechanisms of heat transfer for both liquids. The enhancement factors for fully developed nucleate boiling (superheat of 11 K) have almost the same values for water and ethanol and they become more similar as superheat increases. It could indicate that in this regime coating properties have a dominant role.
In order to compare the present results with a model for boiling heat transfer obtained for isothermal surfaces the Smirnov model [1] has been selected. In this model the wire mesh structure is modelled as a system of regular microfins covered with a liquid film. The calculations are carried out according to the general formula:

$$q = C \sqrt[6]{\frac{r \sigma \lambda_l^3}{\nu_l}} (1-\varepsilon)^{\frac{5}{6}} \sqrt[3]{\lambda_{eff}} \left(\frac{\Delta T - \Delta T^*}{L_0} \right)^{\frac{5}{6}} \tag{7}$$

where L_0 is a structure parameter which depends on the mesh aperture and wire diameter, while ΔT - temperature differences.

The test results for a 2 – layer coating are compared with the calculation results in Figure 4. For both water and ethanol the congruity between the theoretical and experimental values is acceptable only for superheat of 5 K. Almost in the whole range of studied superheats the model

underestimates the experimental values, which might prove that it is unsuitable to successfully predict the heat flux for non – isothermal surfaces.

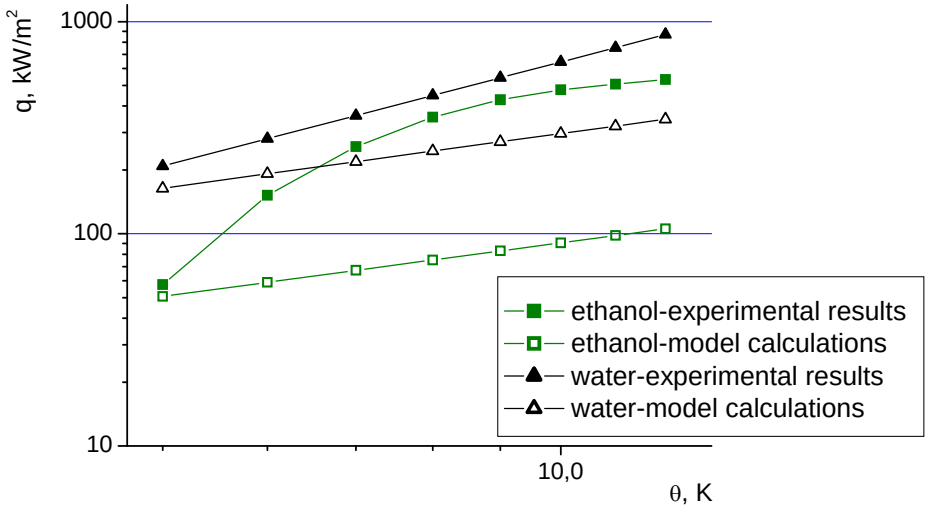

Figure 4. Comparison of the experimental data and calculation results according to the Smirnov model [1] in case of the 2 – layer coating

CONCLUSIONS

The application of porous structures enhances boiling heat transfer. The heat flux for surfaces with the investigated wire mesh structures is several times higher comparing to the smooth surface. The thickest 3 – layer coating proves to be most favourable, especially at small superheats. The present findings are congruous with the work of Kovalev et al. [12]. Moreover, as can be seen in Figure 2b, on the boiling curves for ethyl alcohol a region of significant increase in heat flux (for small superheats) is observed and than the curves become flatter, which is also described in [12] as a characteristic feature. However, the comparison of the results with the Smirnov model shows poor agreement. Consequently, there is a need to develop a correlation for the non – isothermal surfaces basing on the fundamental analysis of the boiling phenomenon in the porous coatings.
It is worth noting that for the tested mesh structures of mesh aperture of 0.32 mm, wire diameter of 0.20 mm and the number of layers from 1 to 3 heat flux increases as the coating becomes higher for supeheats up to 11 K. For high superheats the heat flux approaches a certain value, which seems to be caused by a capillary pumping crisis and the fact that a significant amount of vapour remains in the voids of the structure.

Nomenclature:
ε - porosity
σ - surface tension
C - constant
r - latent heat of vaporisation
eff - subscript of an effective value
l - subscript describing a liquid property

AN EXPERIMENTAL STUDY ON PRESSURE DROP OF INLET AND EXIT MANIFOLDS AND PORTS OF PLATE HEAT EXCHANGERS

C.-Y. Yang*, Y.-H. Lin and H.-T. Lo
Department of Mechanical Engineering
National Central University, Chung-Li, Taiwan

ABSTRACT. Precise pressure drop estimation is critical for an optimum plate heat exchanger design. Numerous studies have been conducted on the pressure drop within the plate passages but studies on pressure drop of flow through inlet/outlet ports are very limited. The present study is intending to derive a relation between the ports losses and the ports/core geometries. Four plate heat exchangers with various inlet/outlet port diameters and plate number were tested in the present study. The test results show that the port and manifold pressure drop predicted by Shah and Focke [1] is almost twice of the measure value for large plate number heat exchangers. The core friction coefficients for different pate number heat exchangers were also examined. There is a drastic difference between the heat exchangers with the same plate geometry but different plate number if the Shah and Focke [1] predicted manifold and port losses were used to evaluate core friction coefficients. However, while the measured manifold and port losses were used to evaluate core friction pressure drop and friction coefficients, the friction coefficients for both type heat exchangers agree very well with each other.

INTRODUCTION

Plate heat exchangers have been popularly used in industrial applications and air-conditioning systems for several decades. Owing to its complicate corrugate flow passages, the pressure drop in a plate heat exchanger is relatively higher than other type of heat exchangers. Precise pressure drop estimation is critical for an optimum plate heat exchanger design. The pressure drop in a plate heat exchanger consists of flow through inlet and exit manifolds and ports, flow through plate passages and the effects of elevation and momentum change. Numerous studies have been conducted on the pressure drop within the plate passages but studies on pressure drop of flow through inlet/outlet ports are very limited. In a well designer heat exchanger, the inlet/outlet ports pressure drop is kept below 10 % of the total pressure drop. Most of the designers applied a simplified correlation proposed by Shah and Focke [1], $\Delta p_p = 1.5\ G_p^2/2\rho$, to evaluate the manifold and ports pressure drop. However, for some high plates number exchangers, the ports pressure drop may exceed 40 % of the total pressure drop. The above Shah and Focke [1] correlation may course significant error on port pressure drop calculation.

The present study measured the pressure drop in inlet and exit ports and manifolds of plate heat exchangers directly by putting pressure probes into the manifolds of the heat exchangers. It is intending to derive the relation between the ports losses and the ports/core geometries.

EXPERIMENTAL SETUP AND DATA REDUCTION

Four plate heat exchangers with various inlet/outlet port diameters (16 and 28 mm) and plate number (10 and 60) were tested in the present study. All heat exchangers have the same flow passage height δ = 2 mm, passage width λ = 7 mm, chevron angle $\beta = 65^o$ and hydraulic diameter D_h = 4 mm. The cross section area for each port $A_p = \pi/4\ D_p^2$, each flow passage $A_{c1} = \delta(W - 4)$, total core $A_c = A_{c1}\ N/2$ and port/core cross section area ratio $\sigma = A_p/A_c$. Details dimensions of the plate heat exchangers tested are listed in Table 1. The relative geometric parameters are shown in Figure 1.

Table 1.
Dimensions of test heat exchangers (mm)

D16 x 10	16	10	194	80	200.96	152	760	0.264
D16 x 60	16	60	194	80	200.96	152	4560	0.044

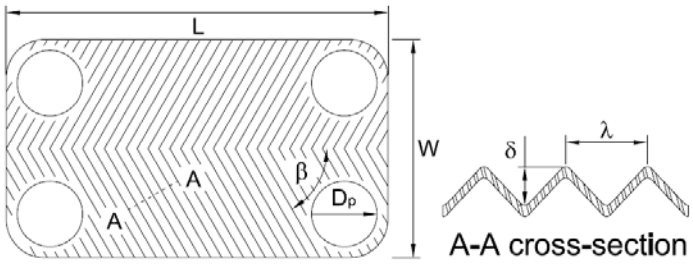

Figure 1. Geometric parameters of the heat exchangers

A schematic diagram of the test facility is shown in Figure 2. Water was pumped from the storage tank to the test section and return to the storage tank to complete a close loop by a variable speed centrifugal pump. A gear type flow meter was placed between the pump and the test section to measure the water flow rate. A RTD was installed near after the flow meter to measure the water temperature which is based for evaluating water properties. Three differential transducers were installed between the external inlet/outlet port, inlet port/upstream of the core inside the plate heat exchanger and outlet port/downstream of the core inside the plate heat exchanger to measure the total (Δp_t), inlet (Δp_i) and outlet (Δp_o) pressure drops respectively.

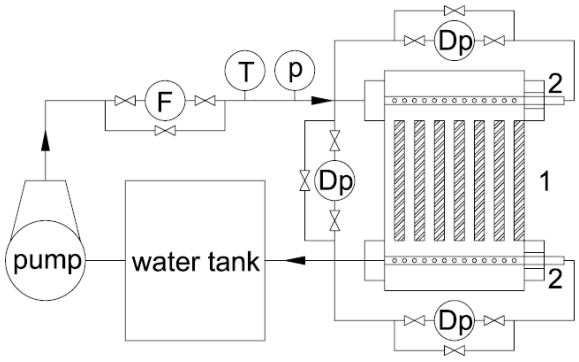

Figure 2. Schematic diagram of the test facility

As shown in Figure 3, the measured total pressure drop, Δp_t, consists of (a) pressure drop associated with the inlet and outlet external connecting parts for installing pressure transducer, Δp_{cni} and Δp_{cno}, (b) pressure drop associated with the inlet and outlet manifolds and ports inside the heat exchanger, Δp_{pi} and Δp_{po}, (c) frictional pressure drop within the core plate passages, Δp_f, and (d) pressure drop due to the elevation change. Since the test heat exchangers were placed horizontally, there is no elevation effect on the pressure drop measurement. The total measured pressure drop can be expressed as:

$$\Delta p_t = \Delta p_{cni} + \Delta p_{cno} + \Delta p_{pi} + \Delta p_{po} + \Delta p_f \quad (1)$$

Since the connecting parts losses, Δp_{cni} and Δp_{cno}, can be evaluated from the conventional correlations [2], the inlet and outlet ports losses, Δp_{pi} and Δp_{po}, can be obtained by direct subtracting the connecting losses from the measured inlet/outlet losses.

$$\Delta p_{pi} = \Delta p_i - \Delta p_{cni} \text{ and } \Delta p_{po} = \Delta p_o - \Delta p_{cno}$$

We may combine the ports and connecting parts losses as:

$$\Delta p_p = \Delta p_{pi} + \Delta p_{po} \text{ and } \Delta p_{cn} = \Delta p_{cni} + \Delta p_{cno}$$

The core friction coefficient, f, can be calculated as:

$$f = \frac{\Delta p_f D_h}{4L} \frac{2\rho}{G_c^{\ 2}} \tag{2}$$

where G_c is the mass velocity through the core area.

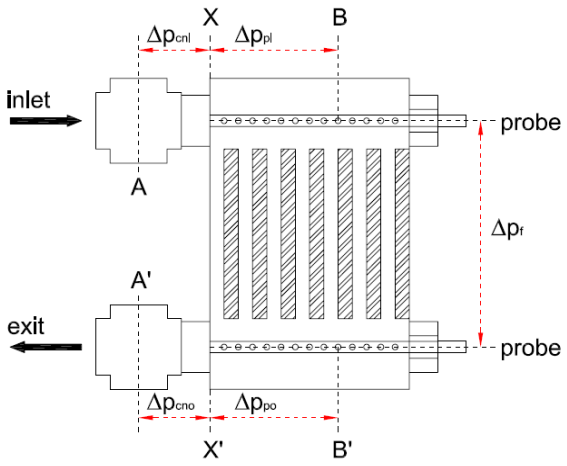

Figure 3. Schematic diagram of each pressure drop component

EXPERIMENTAL RESULTS AND DISCUSSIONS

Figure 4 shows each measured pressure drop components in the heat exchanger D28x10 which has larger port diameter and fewer plates. The manifold and port pressure drop predicted by Shah and Focke [1] is also sketched for comparison. The figure shows that the predicted value is slightly lower than the measured values. However, since the flow rate is low, the ports pressure drop is less than 10 % of the total pressure drop; the prediction discrepancy does not make significant error for core frictional pressure drop evaluation. The same experimental results for the heat exchanger D16x10 is shown in Figure 5. Since the port diameter of D16x10 is smaller than that of D28x10, the manifold and port pressure drop is higher than that of D28x10 and, therefore, the prediction discrepancy by Shah and Focke [1] is larger than D28x10.

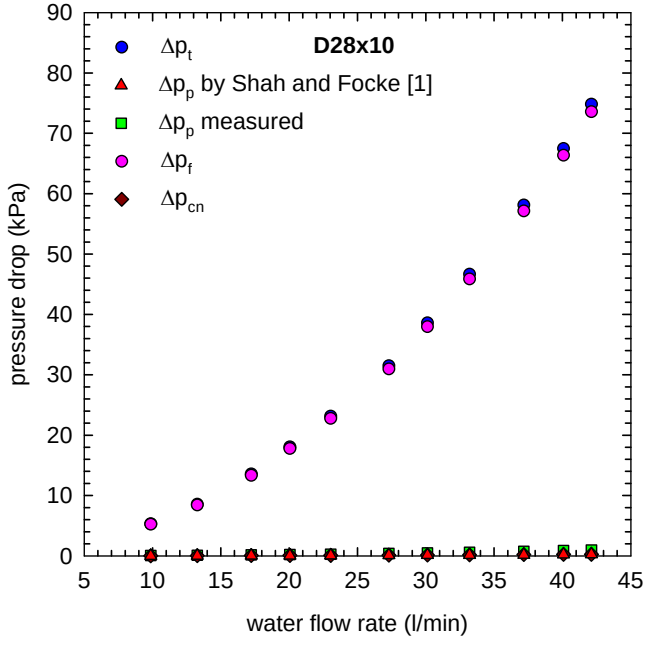

Figure 4. Measured and predicted pressure drops components of D28x10

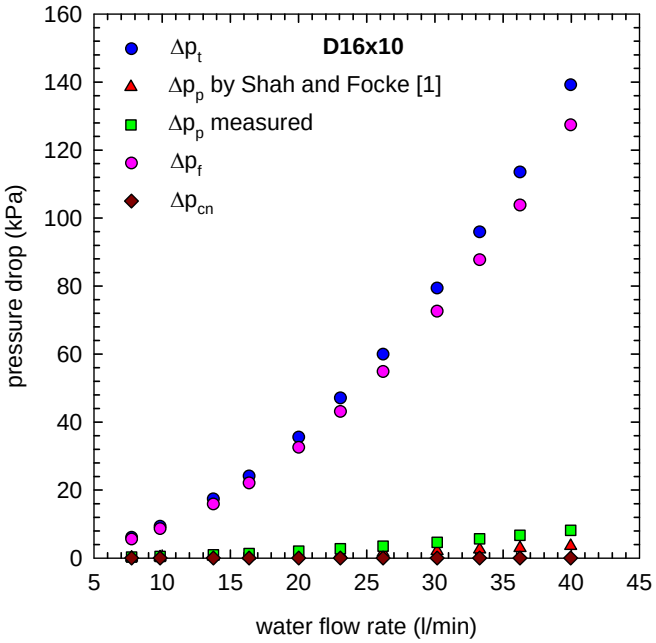

Figure 5. Measured and predicted pressure drops components of D16x10

As shown in Figures 6 and 7, for the larger plate number heat exchangers D28x60 and D16x60, the ratio of port and manifold pressure drop to the total pressure are larger than 10 %. Especially for the smaller port diameter heat exchanger D16x60, the pressure drop ratio is greater than 36 %. The port and manifold pressure drop predicted by Shah and Focke [1] is almost twice of the measure value. This causes a significant error for deriving friction coefficient. The discrepancy caused by the Shah and Focke [1] prediction is no longer negligible.

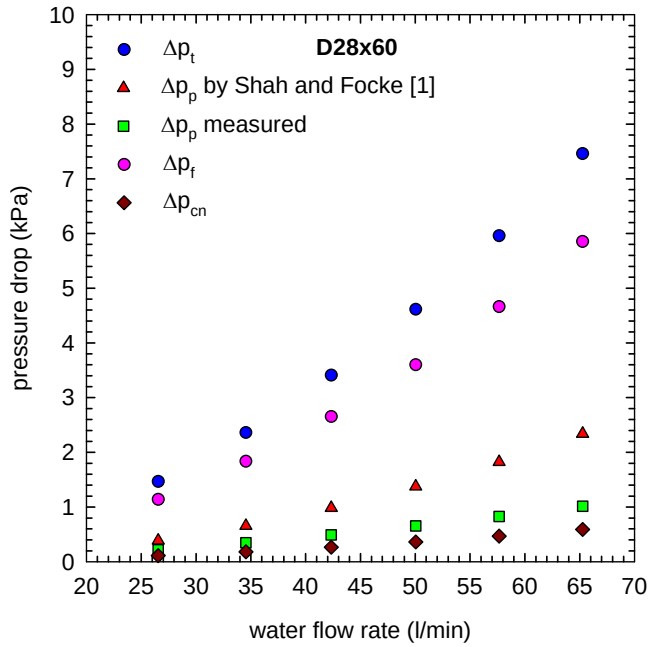

Figure 6. Measured and predicted pressure drops components of D28x60

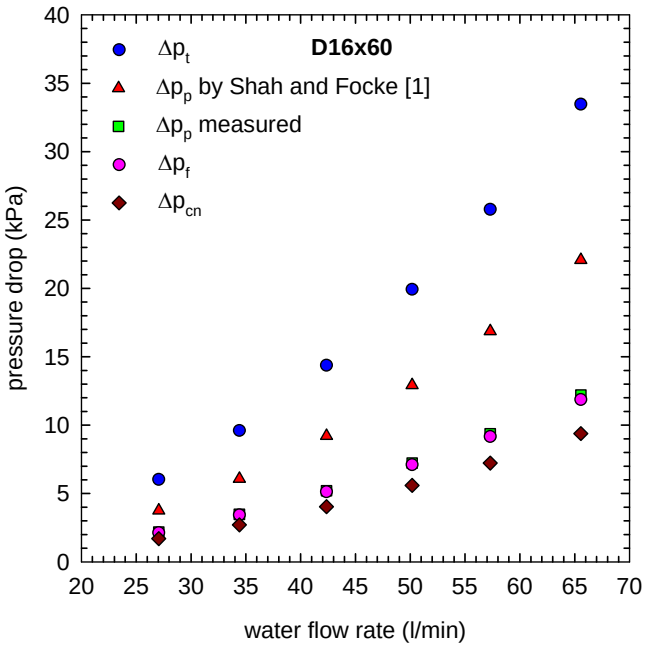

Figure 7. Measured and predicted pressure drops components of D16x60

For examining the correctness of the prediction port losses by Shah and Focke [1], the core friction coefficients based on the predicted and measured manifold and port losses were plotted in Figures 8 and 9. Figure 8 shows that if the Shah and Focke [1] predicted manifold and port losses were used in Equation (1) to evaluate core friction pressure drop and friction coefficients, there is a drastic difference between the heat exchangers with the same plate geometry but different plates number, especially for the smaller port heat exchangers (D16). This is not reasonable because the same plate geometries heat exchangers should have the same core friction coefficients. While the measured manifold and port losses were used in Equation (1) to evaluate core friction pressure drop and friction coefficients, Figure 9 shows that the friction coefficients for both type heat exchangers are agree very well with each other. This results shows that the Shah and Focke [1] correlation over predicted the port and manifold losses for high plate number heat exchangers.

Since the manifold and ports losses occur while the fluid flows through the sudden change of cross section area and direction from the ports to the core passage, they depend on the geometry of the inlet and outlet ports and core. It is expected that the manifold and port losses are in the form of conventional minor losses shown in Equation (3) and the loss coefficient, K_p, is a function of Reynolds number and port/core area ratio, $\sigma = A_p/A_c$.

$$\Delta p_p = \Delta p_{pi} + \Delta p_{po} = K_p \frac{G_p^{\,2}}{2\rho} \tag{3}$$

$$K_p = K_p\left(Re_{Dp}, \sigma\right) = C\sigma^n \, Re_{D_p}^{\,m} \tag{4}$$

Figure 10 shows that the loss coefficient K_p can be well correlated if the exponent of the area ratio, n = 0.5. More study for establishing accurate correlation is necessary for those kinds of plate heat exchangers.

CONCLUSIONS

Four plate heat exchangers with various inlet/outlet port diameters and plate number were tested in the present study. The test results show that the port and manifold pressure drop predicted by Shah and Focke [1] is almost twice of the measure value for large plate number heat exchangers. The discrepancy caused by the Shah and Focke [1] prediction is not negligible.

The previous test results were examined by plotting the core friction coefficients for different pate number heat exchangers. The Results show that if the Shah and Focke [1] predicted manifold and port losses were used to evaluate core friction coefficients, there is a drastic difference between the heat exchangers with the same plate geometry but different plates number, especially for the smaller port heat exchangers. However, while the measured manifold and port losses were used to evaluate core friction pressure drop and friction coefficients, the friction coefficients for both type heat exchangers agree very well with each other.

HEAT TRANSFER ENHANCEMENT FROM A CIRCULAR CYLINDER TO DISTILLED WATER BY ULTRASONIC WAVES: PRELIMINARY REMARKS

F. Baffigi, C. Bartoli *
Energetic Department "L.Poggi", University of Pisa, Via Diotisalvi 2, Italy

ABSTRACT. An experimental investigation was carried out to research the effects of ultrasonic waves on heat transfer, in subcooled boiling conditions, from a stainless steel horizontal cylinder, heated by Joule effect, to distilled water. Actually the acoustical streaming induces turbulence through the cinematic field and so an increase of the heat transfer coefficient. In this preliminary paper, the authors have studied the heat transfer enhancement for two-phase conditions. The dependence on such parameters as ultrasonic wave power, subcooled ΔT and convection heat flux is also examined. The aim of this paper is to find out the parameters that maximise the heat transfer coefficient. After our preliminary tests we had found that the maximum heat transfer coefficient increase occurs at the difference between the water saturation temperature and prefixed water temperature is higher, as also the ultrasonic generator power.

Keywords: *experimental methodologies, heat transfer enhancement, subcooled boiling, ultrasonic waves, cooling systems.*

INTRODUCTION

Since the 1960s the cooling effect induced by ultrasonic waves was investigated. Firstly R.M. Fand, in 1965, [1] reported the heat transfer data obtained in an experimental study to determine the influence of acoustic vibrations on solid-liquid interface process involved in the desalination of water. The heat transfer test section is a cylinder, 0.011 mm. O.D.. The tests were performed at constant bulk water temperature and frequency. The sound pressure level, measured by a calibrate hydrophone, varied from 0 to 10^5 Pa and the acoustic frequency was 6.5 kHz for all tests. The bulk water temperature was 300 K and the difference in temperature between the cylinder and bulk of water varied from 255.4 to 311 K. The maximum increase in the heat transfer coefficient, due to acoustically induced cavitation observed in these experiments, was 33%.
K.-A. Park and A.E. Bergles, in 1988, [3] undertook a study to confirm the effects of ultrasonic cooling of microelectronic components, in saturated boiling conditions, using R-113 as working fluid. They noticed that a degradation of low heat flux boiling occurred when the pool was saturated, but boiling was improved when the pool was subcooled. Burnout heat fluxes for saturated and subcooled conditions were slightly increased by an ultrasonic field.

In 1967, K.W. Li and J.D. Parker [2], had investigated the acoustical effects in free convection heat transfer to water. The heating surface consisted of a platinum wire ($2 \cdot 10^{-4}$ m. in diameter), immersed in water at the temperature of 302.6 K. Experimental results showed that the heat transfer rates were affected by the presence of sound waves in the vicinity of the wire. The sound frequency was set up at 20 kHz. The tests were carried out at a given temperature difference (ΔT = 288.7 and 299.7 K). It might be noticed that the influence of the acoustical field on free convection was greater at lower temperature difference. Moreover the heat transfer coefficient increased until a

E-mail address: c.bartoli@ing.unipi.it

certain level of sound, above which the heat transfer coefficient started to decrease. Actually the sound waves propagated through the water, induced a cavitation process in the water. As the sound pressure was greater than 53.4 kPa, this process due to the presence of the sound waves was significant.

In 1992 Y. Iida and K. Tsutsui [4] carried out a series of experiments to make clear systematically the effects of ultrasonic waves, at 28 kHz in frequency and 33.6 W in maximum power, on natural convention, nucleate boiling, and film boiling from a heated 0.2 mm diameter platinum wire to saturated water or ethyl alcohol. A distinctive augmentation effect on heat transfer was observed in both the natural convection and film boiling heat transfer regions. Though no effects were observed in nucleate boiling of water, a small effect was attained in low heat flux nucleate boiling of ethyl alcohol. An increase of about 20% in the maximum heat flux in both liquids was obtained by applying ultrasonic waves. The minimum heat flux point was raised at higher values of both the degree of superheat and the heat flux. Moreover it might be noticed that the heat transfer coefficients attained under ultrasonic waves were depended largely on the distance from the vibrating surface to the test position.

In 1993 S. Nomura and M. Nakagawa [5] explained the mechanism of heat transfer enhancement on a narrow surface by ultrasonic vibration, cavitation intensities and measured the heat transfer coefficients changing the width of the surface from 0.1 to 8 mm. It might be noticed that the heat transfer coefficient on a narrow surface without ultrasonic increased due to the heat conduction with decreasing width. Moreover, the authors found out that the ultrasonic waves induced at the same time cavitation and a perturbation of the dynamic field. They had measured the cavitation intensity, by measuring the erosion loss of the aluminium foil attached to the surface of a heater, and they could evaluated the contribution due to the only ultrasonic vibrations. The large-scale motions induced by acoustic streaming would be effective for cooling large heating surfaces, while the very-small motions induced by cavitation would be more effective for cooling small heating surfaces.

In 1997 S. Bonekamp and K. Bier [6] had been investigated the effect of ultrasound on pool boiling heat transfer to mixtures of the refrigerants R23 and R134a, in a wide range of heat flux and saturation pressure. The main result was that the enhancement of the heat transfer coefficient, which could be achieved by ultrasound, was much more pronounced than for pure substances.

In 1998 H. Yamashiro, H. Takamatsu and H. Honda [7] had studied experimentally the effect of ultrasonic vibration on the heat transfer during the rapid quenching of a thin horizontal wire in subcooled water. They had examined the parametric effects of the sound pressure and the frequency of ultrasonic vibration on the transient boiling curve and the first minimum heat flux point with a higher wall superheat.

H.-Y. Kim, Y.G. Kim and B.-H. Kang, in 2004 [8] reported the relationship between the flow behaviour induced by ultrasonic vibration and the consequent heat transfer enhancement in natural convection and pool boiling regimes. Experimental results showed that the effects of ultrasonic vibration on flow behaviour were vastly different depending on the heat transfer regime and the amount of dissolved gas. In natural convention and subcooled boiling regimes, behaviour of cavitation bubbles strongly affects the heat transfer enhancement. In saturated boiling, no cavitation occurs, thus the reduced bubble size at departure and acoustic streaming are major factors enhancing heat transfer rate. The highest enhancement ratio was obtained in natural convection regime, where the effect of ultrasonic vibration was manifested through violent motion of cavitation bubbles.

In 2004 B.-G. Loh and D.-R. Lee [9] found out that the cooling effect on the heat source had a correlation with the gap between the ultrasonic vibrator and heat source; the cooling effect was maximized when the gap corresponds to the multiple of half-wavelength of the ultrasonic wave and this effect was attributable to the resonance of the sound wave.

This introduction highlights that the scientific works about the cooling effect by ultrasonic waves aren't so clear, so the authors had been begun a systematic series of experimental tests, to try to understand the mechanism. Moreover, the aim of this work will be to find out the parameters that maximize the heat transfer coefficient from a circular cylinder to water. The first results are referred

to subcooled boiling conditions, because the heat transfer coefficient is higher than in single-phase conditions; in fact in saturated boiling [8] the effect of ultrasonic waves is negligible. Later on we could apply this basic research to the cooling of electronic components.

EXPERIMENTAL APPARATUS

The experimental set-up consisted of a rectangular stainless steel ultrasonic tank (300x230x200 mm^3). The ultrasonic waves generator worked at the frequency of 40 kHz (ν), with a combined transducer output from 200 to 400 W. An electrical resistance was put inside the tank, in order to heat the water. Cold water circulating into a copper coil (8-mm. O.D., 6-mm. I.D, length 2000-mm.), connected to an external refrigerator, was used to control the pool temperature. The heating element was a stainless steel horizontal cylinder (3-mm. O.D, 2-mm. I.D., length 192- mm.), immersed in water. The cylinder was heated by a direct current power supply (maximum value of current and voltage respectively 450 A and 20V).The experimental apparatus is shown in Figures 1 and 2. The test length, which was the distance between two voltage sensors, was 70 mm.. This two voltage sensors, made of 0.5-mm. diameter copper wires, were connected to a digital multimeter to measure the voltage drop across the test section. The amperage instead was measured by means of the voltage drop across a calibrated resistance. The cylinder axial temperature was measured by means of one sliding thermocouple. The results reported here refer to a test length, which was the central part of the heater, where the temperature is axially uniform to within ± 0.1 K. The water temperature near the heater, was measured by means of a thermocouple.

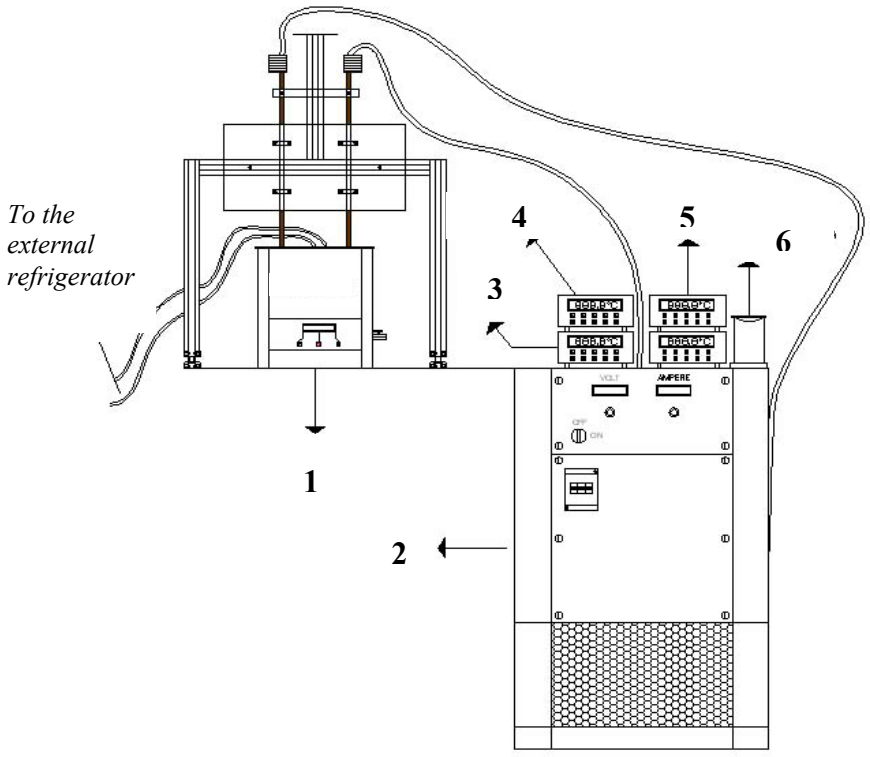

Figure 1. Experimental apparatus
(1. Ultrasonic generator; 2. DC power supply; 3, 4, 5.Digital multimeter; 6. Calibrated resistance)

PROCEDURE AND ANALYSIS OF UNCERTAINTY

The distilled water was set at the temperature of 338.15 K (ΔT_{sub} = 35 K) by the electrical resistance inside the tank. Then we supplied electrical power, $\dot{q}$, by the direct current power supply, varying from $80 \cdot 10^3$ W/m^2 to $160 \cdot 10^3$ W/m^2. The water remained at the same temperature by means

of the external cooling coil. When the steady state conditions had been reached, we activated the ultrasonic generator, and at first we changed the ultrasonic power, P_{gen}, from 200 to 400 W. Each parameters ($\dot{q}$ and P_{gen}) was been varied one by one.

(a) **(b)**

Figure 2. Experimental apparatus ((a) ultrasonic generator, (b) Stainless steel circular cylinder immersed in water inside the tank)

The circumferentially averaged external temperature of the heater was calculated, assuming cylindrical symmetry, after the circumferentially averaged internal temperature, the dissipated power, the thermal conductivity, and the thickness were known. The inner temperature (T_i) of the hollow cylinder is measured by a 0.5 mm in diameter T – type thermocouple. The external temperature (T_{wall}) is calculated through the Fourier equation as a function of the dissipated electric power per unit volume and of the hollow cylinder radii, as shown in equation (1):

$$T_{wall} = T_i + \frac{\dot{q}^*}{4 \cdot k} R_i^2 \cdot \left[1 + 2 \cdot \ln\left(\frac{R_e}{R_i}\right) - \left(\frac{R_e}{R_i}\right)^2 \right] \tag{1}$$

The flux per unit surface was been calculated by the equation (2):

$$\dot{q} = \frac{V \cdot I}{\pi \cdot De \cdot L} \tag{2}$$

Finally, we could calculate the heat transfer coefficient, by the Newton's equation, without and with the ultrasonic waves, as shown in equation (3):

$$\dot{q} = hA(T_{wall} - T_{H_2O}) \tag{3}$$

Radial conduction is assumed as being dominant. Indeed, investigations performed with a sliding thermocouple showed that the temperature variation along the test length of the cylinder didn't exceed the value of measurement uncertainties. Angular dependence, was not considered here, as an average value was sought. A thermocouple at the cylinder measured the water temperature. Uncertainty analysis has been carried out according to [10]. Uncertainty sources are reported in Table 1, while calculated values for q and ΔT are 4.2% and ±0.5 K respectively.

Table 1
Uncertainty Sources

Measured Quantity	Reference Value	Overall Uncertainty
Cylinder temperature	T_{wall}-T_{H2O}=60 K	0.5 K
Water bulk temperature	338.15 K	0.5K
Current	84 A	0.3%
Voltage	1.2 V	0.2%
Cylinder thickness	$0.5 \cdot 10^{-3}$ m	2%
Heater area	$6.6 \cdot 10^{-4}$ m^2	3.7%

DISCUSSION OF EXPERIMENTAL RESULTS

In this preliminary paper we had studied the subcooled boiling regime, because our aim was to find out the optimal conditions to maximize the heat transfer coefficient. Firstly we had tried some tests to investigate the ΔT_{sub} influence on the heat transfer coefficient (Table 2). These data were obtained at $\dot{q}$ =135·10^3 W/m^2, ν = 40 kHz and P_{gen}= 400W. The experimental results had shown that the optimal ΔT_{sub} is 35 K, at which one the h increase amounts to 53%. These data had highlighted that h increases with ΔT_{sub} increasing. For this reason we had chosen this value of subcooling for each next test.

Table 2
Trend of h without and with ultrasound waves versus ΔT_{sub}

ΔT_{sub}[K]	**h (without ultrasonic waves) [W/Km^2]**	**h (with ultrasonic waves) [W/Km^2]**	**Δh [%]**
35 K	2450	3750	53
25 K	2840	3510	24
20 K	3147	3347	6

Then we had investigated the P_{gen} influence on h. As shown in Table 3 we had found a trend monotonically of h versus P_{gen}. For this reason the next tests had been carried out at 400W.

Table 3
Trend of h without and with ultrasound waves versus P_{gen}

P_{gen} [W]	**h (without ultrasonic waves) [W/Km^2]**	**h (with ultrasonic waves) [W/Km^2]**	**Δh [%]**
200W	2091	2690	28.6
300W	2091	2675	28
400W	2091	2838	35

The data in Table 3 were obtained at ΔT_{sub} =35 K, $\dot{q}$ =84·10^3 W/m^2, ν = 40kHz.

In Figure 3 is shown the $\dot{q}$ trend versus the difference T_{wall}-T_{H2O} . The tests were carried out in the previous optimal conditions for ultrasonic generator power (P_{gen} = 400W) and ΔT_{sub}=35 K, with or without ultrasound waves. At the presence of ultrasound waves the trend of the experimental points is significantly horizontally translated: at the same heat flux we had found a decrease of the difference

T_{wall}-T_{H2O} from 25 to 10 K. This result showed that the ultrasound waves could be used to decrease the cylinder temperature and also could be applied for cooling electronics components.

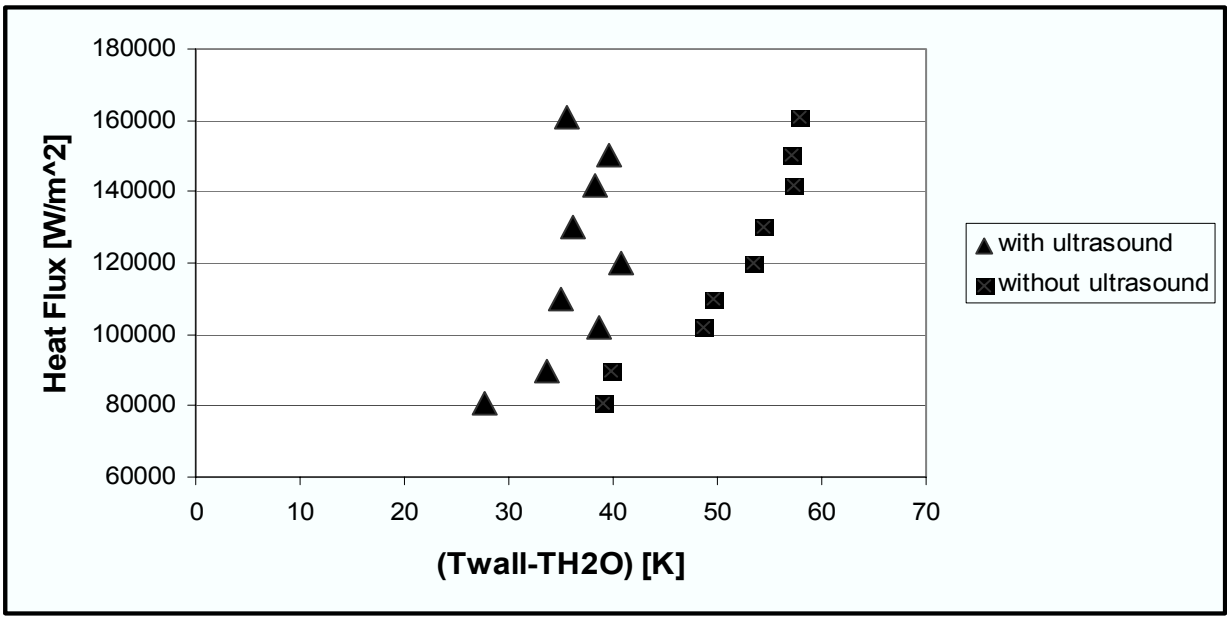

Figure 3. Trend of q versus (T_{wall}-T_{H2O}) at ΔT_{sub} =35 K, ν= 40 kHz and P_{gen} =400W

Figure 4 shows clearly that the presence of the ultrasound increases significantly the heat transfer coefficient, with the following parameters

1) ΔT_{sub} =35 K 2) ν =40kHz 3) P_{gen} = 400W.

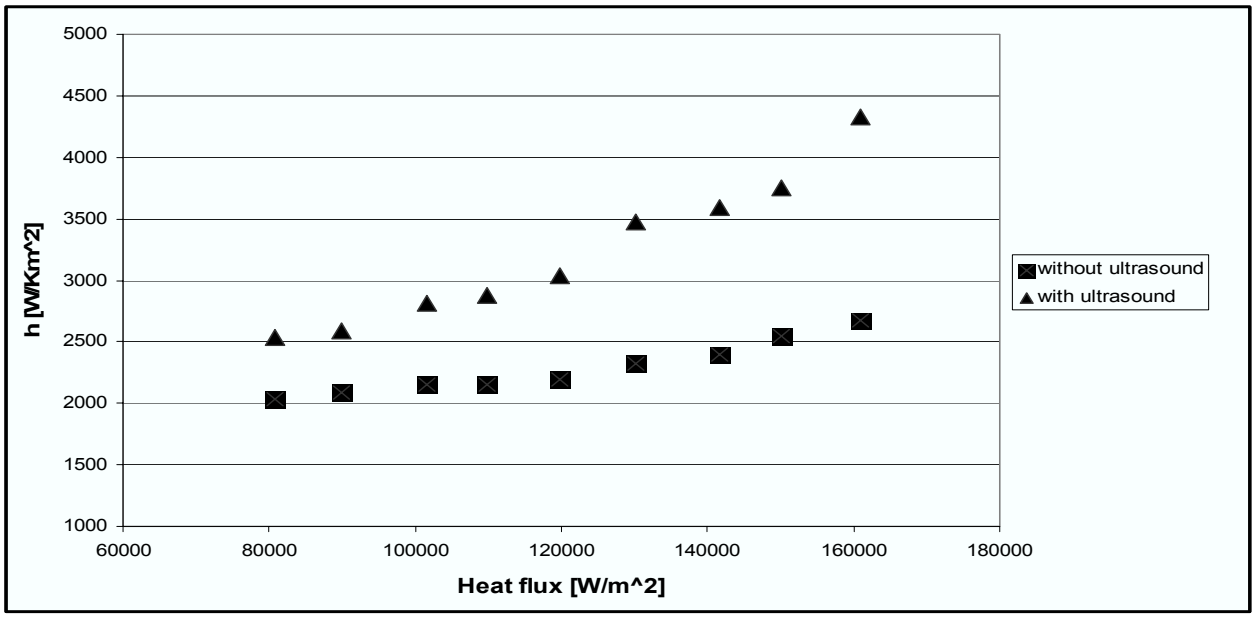

Figure 4. Trend of h versus at q (ΔT_{sub} =35 K, ν 40 kHz and P_{gen} = 400W)

In Table 4 we had summarized the data of figure 4.

Table 4

Trend of h without and with ultrasound waves versus $\dot{q}$

Heat flux [W/Km^2]	h (without ultrasonic waves) [W/Km^2]	h (with ultrasonic waves) [W/Km^2]	Δh [%]
$80 \cdot 10^3$	2032	2533	24
$90 \cdot 10^3$	2090	2585	23,7
$100 \cdot 10^3$	2151	2817	31
$110 \cdot 10^3$	2154	2876	33,5
$120 \cdot 10^3$	2192	3035	38
$130 \cdot 10^3$	2323	3477	50
$140 \cdot 10^3$	2398	3588	49,6
$150 \cdot 10^3$	2542	3757	48
$160 \cdot 10^3$	2678	4330	61,6

.

CONCLUSIONS

Afterwards we had been an exhaustive bibliography review, we had put right a new experimental research about ultrasonic waves. Our aim was to find out the parameters that maximize the heat transfer coefficient, in this case only in subcooled conditions. Each test had been carried out at the prefixed water temperature of 65 K and at the prefixed ultrasonic frequency, 40 kHz. After our preliminary tests we had found that the maximum h increase occurs at the difference between the water saturation temperature and prefixed water temperature is higher, as also the ultrasonic generator power. In this condition the presence of ultrasonic waves involves an h increase of about 53%, with heat flux of $135 \cdot 10^3$ W/m^2. In the future we firstly will complete the experimental study in subcooled regime, varying others different parameters, as the generator frequency and the gap between the cylinder and the bottom of the tank. Finally we will examine a narrow surface.

ACKNOWLEDGEMENTS

This work was supported by the NOVATEC S.r.l and his owner, Mr. Nello Franco, located in San Martino di Lupari (PD), which had donated to us the ultrasonic generator.

EXPERIMENTAL STUDY ON THE BRDF MEASUREMENT FOR SURFACE OF SOME MATERIALS

M. Xie*, X.C. Wang, H.H. Zhao, H.P. Tan
School of Energy Science and Engineering, Harbin Institute of Technology, 150001, China

ABSTRACT. Bidirectional Reflectance Distribution Function (BRDF) is a physical quantity that describes space reflection and scattering distribution characteristic of material surface. The concept of the BRDF defined by F.E.Nicodemus in 1970, is from the view of ray radiation and gets further development combined with the electromagnetic scattering theory of rough surface. Bidirectional Reflectance Distribution Function can describe the surface reflection and scattering characteristic of solid materials better, so considering the influence of material surface roughness, using lasers with band of 0.6328 μm, 1.34 μm and 3.39 μm, at different incident angles, we measured the BRDF of various materials including granite, aluminum plate, copper plate、aluminum foam, graphite fiber magnesium, carbon fiber (aluminum) through a self-built experiment table, by using the white standard plate made of polytetrafluoroethylene powder(approximate Lambert body) as a single sample for reference, and based on experimental data, we analyzed the reflection and scattering characteristic of the material surface.

Keywords: *BRDF, Reflection, Ray radiation, Characteristic*

INTRODUCTION

Bidirectional Reflectance Distribution Function (BRDF) is a physical quantity that describes space reflectance and scattering distribution characteristic of material surface. The concept of the BRDF defined by Nicodemus in 1970, is from the view of ray radiation [1] and gets further development combined with the electromagnetic scattering theory of rough surface. The BRDF can be used to evaluate reflection、absorption and scattering characteristic of varieties of material surfaces to the visible and infrared lights. So it can be used for telemetry or stealthy technology of the material surface and military target, and also be used for remote sensing measurement of satellites and other planets [2].

Considering that the BRDF influencing factors include material surface roughness, dielectric constant, incident angle and polarization etc, in this paper we used a self-built experiment table, according to a single reference method [3, 4, 5]—namely by using the white standard plate made of polytetrafluoroethylene powder(approximate Lambert body) as a single sample for reference, with band of 0.6328 μm, 1.34 μm and 3.39 μm, at different incident angles, considering the influence of material surface roughness at the same time, we measured the BRDF of various materials including granite, aluminum plate, copper plate, aluminum foam, graphite fiber magnesium, carbon fiber (aluminum), and based on experimental data, we analyzed the reflection and scattering characteristic of the material surface.

ANALYSIS OF INFLUENCE FACTORS

Surface roughness

With the increase of the measured material surface roughness, electromagnetic wave will change continuously from specular reflection to diffuse reflection, even cause shadowing and masking effect or polarization. So the experimental date of surface roughness is one of the major factors in this study.

Dielectric constant

When the measured material surface consist of different dielectric constant mediums, part of the energy projected to the underlying medium is scattered back again by inhomogeneous medium, the latter goes through the interface back to the upper medium [6]. The experimental samples of granite, aluminum plate, copper plate, aluminum foam, graphite fiber magnesium, carbon fiber (aluminum) selected in this paper all consist of opaque single medium, so dielectric constant is not considered.

Incident angle

Under the same condition of surface roughness, the factors below will change as a result of incident angle change: incident light flux, surface reflectivity and shadowing effect [4, 7]. If the sample used in the experiment is slightly roughness surface, then with incident angle increasing, there will be scattering peak in the corresponding specular reflection direction, the peak goes down with incident angle increasing, this is the result of interaction of three factors related to incident angle. As the surface is a bit gentle, the shadowing effect is not significant, the bidirectional shadowing functions in each incident angle is basically coincident, and there are a few differences only when the incident angle is very large. So incident intensity is decided mainly by the effective incident flux. As incident flux decreases with incident angle increasing, and specular scattering intensity goes lower and lower, so the change trend is contained in general effect under three factors above.

Polarization

The theoretical analysis shows that the surface roughness of the sample has an obvious effect on polarization: the bigger surface roughness, the more obvious polarization effect. Polarization scattering makes theoretical analysis more complex, it normally needs 4 Stokes parameter to describe polarization scattering fully; if the roughness surface described is random surface, then it needs one 4×4 Muller matrix, and all these parameter are functions of scattering field, which makes numerical calculation increase a lot [7]. So we only provided the experimental result of the BRDF in this paper, but did not do theoretical analysis on polarization effect.

EXPERIMENTAL PRINCIPLE

Classification and measurement of surface roughness

Classification of surface roughness. Material surface roughness, to a great extent, affects the reflection and scattering of light projected to the surface. Optics principle holds that surface rough or not is compared with incident wavelength. Here we give surface roughness condition divided by incident light wavelength λ and incident angle θ in optics aspect [8]:

Lubricous surface $$h < \frac{\lambda}{25\cos\theta} \quad (1)$$

Medium rough surface $$\frac{\lambda}{25\cos\theta} < h < \frac{\lambda}{8\cos\theta} \quad (2)$$

Rough surface $$h > \frac{\lambda}{8\cos\theta} \quad (3)$$

Where, h denotes relative height of two observation or measuring points on the surface.

As rough surface structure is random, we use surface height standard deviation σ_h instead of *h*, that is

$$\sigma_h = \sqrt{\frac{\sum_i^n f_i^2 - n(\mu)^2}{n-1}} \tag{4}$$

Where, *n* is measurement time, f_i is surface roughness is the *i*-th time measurement result, μ is the average of *n* times measurement.

The measurement of surface roughness. In this paper we adopt stylus tracing method to measure sample surface roughness, and use multi-parameter surface roughness inspection instrument [9]. The instrument uses a very small and fine diamond stylus (the arc radius of its contact is usually only 0.50mm), to touch the measured surface directly and do transverse move on the surface. When the stylus moves, its needle tip skates slightly over the measured surface(perpendicular to machining trace). As the measured surface is not smooth, the stylus will fluctuate vertically along with surface geometric shape, so we should change the signal of displacement, which gets from the stylus fluctuating vertical along with the measured surface tiny peak-valley, into electrical parameter, and amplify it, then do operation processing [9]. We choose 8 measurement points from every sample above to do measurement, 10 times every point. This paper gives only granite and aluminum foam surface roughness measurement curves (Figure 1 and 2). The measurement result substituted into formula (4), Table 1 shows the height standard deviation value σ_h of each material surface above.

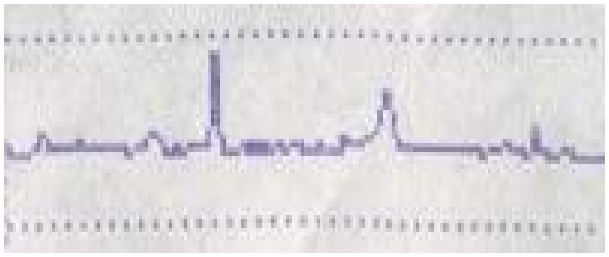

Figure 1. The curve of granite surface roughness (σ_h =0.280)

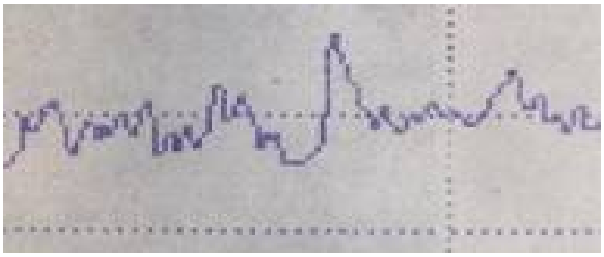

Figure 2. The curve of aluminum foam surface roughness (σ_h =0.374)

Table 1
The Height Standard Deviation Value σ_h of Each Material Surface Measuring Point

Sample	Granite	Aluminum plate	Copper plate	Aluminum foam	Graphite fiber magnesium	Graphite fiber aluminum	Carbon fiber (aluminum)
σ_h	0.280	0.305	0.133	0.374	0.367	0.381	0.352
Roughness	Medium rough surface		Lubricous surface	Rough surface			

The measurement of the BRDF

The principle of measurement. According to the concept of the BRDF and combining with rough surface electromagnetic scattering theory, we usually define the BRDF as [3, 4]:

$$f_r(\theta_i,\varphi_i,\theta_r,\varphi_r) = \frac{L_r(\theta_i,\varphi_i;\theta_r,\varphi_r)}{E_i(\theta_i,\varphi_i)} \tag{5}$$

Where, θ,φ denote the zenith and azimuth angle in spherical coordinates respectively, the subscripts *i, r* denote the incident light and reflection light respectively. $L_r(\theta_i,\varphi_i;\theta_r,\varphi_r)$ is the reflective brightness in the direction of (θ_r,φ_r), $E_i(\theta_i,\varphi_i)$ is the incident illuminance in the direction of (θ_i,φ_i). f_r ranges between $0 \sim \infty$, with dimension sr^{-1}.
Make the incident condition equal to the receiving, the reflective brightness of test sample could be obtained by voltage output of the receiving detector:

$$V_s = \tau_s \Re_s L_s A_s \cos\theta_s A_d \cos\theta_d / d_s^2 \tag{6}$$

Incident illuminance of test sample and standard board are equal to each other, Incident illuminance of standard board could be obtained by voltage output of receiving detector:

$$V_B = \tau_B \Re_B f_B E_B A_B \cos\theta_B A_d \cos\theta_d / d_B{}^2 \tag{7}$$

Where, s、B is the test sample and standard board, τ is the transmissivity of light, $\Re$ is the responsivity of detector, A_s, A_B is the area of test sample and standard board, A_d is the area of detector, θ_s,θ_B is the reflective zenith angle of test sample and standard board, θ_d is the incident zenith angle, d is the distance from detector to test sample, f_B is the BRDF quantity of standard board, so:

$$BRDF(f_s) = f_B \frac{V_s}{V_B} \frac{\tau_B \Re_B E_B A_B \cos\theta_B A_d \cos\theta_d / d_B{}^2}{\tau_s \Re_s E_s A_s \cos\theta_s A_d \cos\theta_d / d_s^2} \tag{8}$$

Where, $f_B = L_B / E_B$, choose parameters in the formula appropriately, $\tau, \Re, A, E, A_d \cos\theta_d / d_r{}^2$ are all constants, so the BRDF of test sample is expressed by the output voltage as:

$$BRDF_r(\theta_i,\varphi_i;\theta_r,\varphi_r) = f_B \frac{V_s}{V_B} \frac{\cos\theta_B}{\cos\theta_s} \tag{9}$$

The measurement system. The BRDF measurement system in this paper consists of optical debugging system、mechanical rotation system、heating system(not used in the experiment of this paper)and circuit receiving system. The lamp-house of testing system includes four wavelength lasers: visible light 0.6328μm, near-infrared 1.34μm, mid-infrared 3.39μm and mid/far-infrared 10.6μm. It completed multi-band measurements very well. Figure 3 shows measuring device system diagram.

The measurement method. The BRDF measurement can be divided into absolute and relative measurements [3]. The absolute measurement is carried out without any reference standard; while relative measurement is carried out by comparing the reference standard (reflectance known) with samples. The relative measurement can be divided into comparing measurement and single reference method. This experiment uses the single reference method, that is to say, firstly measures the voltage value of sample surface, and then measures the voltage value of standard white board surface (approximate Lambert body)(reflectance known) under the same geometric condition, finally obtains the BRDF value of sample by comparing the voltage of sample surface with standard white board.

Error analysis. We calibrate the error of the BRDF experimental table by a measurement method comparing three standard white boards with known reflectance, the measurement error can be controlled within 20% [10].

EXPERIMENTAL RESULTS AND DISCUSSION

In this paper, we carried out the measurement of the BRDF of the above materials with various bands at room temperature. Because of the limit of the space, we chiefly discussed partial experiment results with bands of 0.6328μm, 1.34μm and 3.39μm.

The measurement results of the BRDF with the band of 0.6328μm

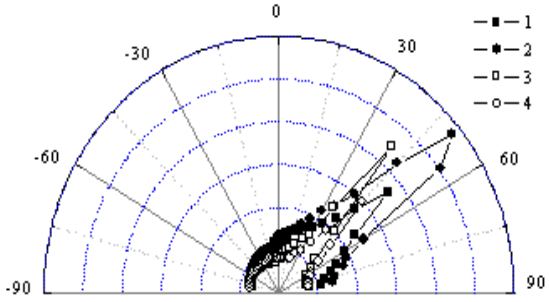

Figure 5. The BRDF distribution of the four composite surface ($\theta = 60^0, \varphi = 30^0$)

In this paper, we carried out the measurement of the BRDF of the above materials with the band of 0.6328μm and at different incident angle. Figure 4 shows the BRDF distribution of granite surface at the incident zenith angle of 35° [4]; Figure 5 shows the BRDF distribution of the four composites surface at incident zenith angle of $\theta = 60^0, \varphi = 30^0$. Case 1 in Figure 5 shows aluminum foam, case 2 shows aluminum-based graphite fiber, and case 3 shows magnesium-based graphite fiber, case 4 shows carbon fiber (aluminum).

Figure 6 shows the BRDF distribution of aluminum plate surface at the typical incident zenith angle; Figure 7 shows the BRDF distribution of copper plate surface with the band of 1.34μm as the incident angle change; Figure 8 shows the BRDF distribution of aluminum foam fiber surface at the typical incident zenith angle; Figure 9 shows the BRDF distribution of aluminum-based graphite fiber surface at the typical incident light zenith angle; Figure 10 shows the BRDF distribution of magnesium-based graphite fiber surface at the typical incident zenith angle; Figure 11 shows the BRDF distribution of carbon fiber (aluminum) surface at the typical incident zenith angle.

EXPERIMENTAL RESULT ANALYSIS

From Figure 4, we know that, with the band of visible light, the BRDF distribution of granite surface presents more concentrative mirror reflection component, though the surface is medium roughness, the granite is treated by water mill and polishing, mirror reflection effect appears at the incident angle of 35° [4]. However, the BRDF distribution of the four composites surface is more divergent at incident angle $\theta = 60^0, \varphi = 30^0$ than granite (as shown in Figure 5), that is because of the shadowing effect of rough surface. Besides, the BRDF value of the four composites surface is lower than granite evidently. After analysis, we consider that, the composite material surface mentioned above has obvious absorbency to the wavelength.

From Figure 6 and Figure 7, we know that, with the infrared band, copper plate surface is smoother than aluminum plate, the BRDF distribution of copper plate presents mirror reflection effect when the incidence angle has changed three times with the band of 1.34μm; while the BRDF distribution of aluminum plate shows scattering as the incidence angle and band change. Besides, the BRDF value of aluminum plate is lower than copper plate evidently, the same reason as granite.

From Figure 8 to Figure 11, we know that, with the infrared band, due to the rough surfaces, the whole presents scattering characteristic. The BRDF values of the four materials changed little as the azimuth angle increases when the incident angle is 0° , the corresponding zenith angle of the peak value is near 0° . The BRDF values of the four materials drive to diffuse reflection characteristic as the azimuth angle increases when the incident angle is 60° , the peak value has deviated from the direction of mirror reflection. At the same time, the whole reflects that, to different infrared bands, the BRDF distributions of aluminum foam fiber and graphite fiber adding metal are different. Besides, they have selectivity to the wavelength and the degree of reflection or scattering is different too.

CONCLUSION

An experimental investigation was conducted of the BRDF distribution of various material surfaces through a self-built experiment table by using single reference method. The results indicate that the influencing factors in BRDF distribution are surface roughness, incident wavelength and incident angle, it reflects the reflection and scattering characteristic of various material surfaces. Besides, other factors can also affect the reflection or scattering characteristic of material surface, including the shadowing and polarization effect、dielectric constant、surface temperature and material color and so on, which remain for further theoretical and experimental study.

ABSTRACT. The possible optimization of co-generation systems with combustion engines by the means of the ORC-Cycle for power generation from waste heat has been presented. The practical basis for this concept was the operational power and heat performance analysis of co-generation units with diesel engines using gaseous and liquid fuels (especially biogas installations). The key issue of the presented publication is simulation and thermodynamic analysis of the original concept with two-stage ORC process for waste heat utilisation as possible optimization measure. Due to process-related factors, the waste heat use in the exhaust gas heat exchanger and from the engine cooling system is performed at different temperature levels and is realised in the ORC cycle in two stages by the means of a micro-turbine and a screw engine. The special calculation procedure has been elaborated and the representative results are presented.
The next phase of the project will involve a practical analysis of the plant concept, e.g. the options regarding different expansion machines, regulation concepts, real losses, and other aspects.

Keywords: *waste heat use, combustion engines, ORC – two-stage process*

INTRODUCTION

One of the key challenges on the area of energy engineering is the system development for increasing the efficiency of primary energy conversion and use. From this perspective, low-and middle temperature heat as waste heat from various processes is becoming more and more "attractive" as a secondary energy source. The temperatures of the exhaust gas and other industrial processes and power plants are mostly less than 350°C – 400°C. Using conventional methods for waste heat recovery is in most instances technically and economically infeasible.
One of the typical examples is the utilisation of waste heat in the co-generation units with combustion engines, which was in many investigated installations non-optimal. A special case are biogas plants, where the heat use is often limited only to utilisation of thermal energy for the biogas generation process, while the remaining heat is either not used at all, or used only partially. In terms of total energy utilisation ratio, this situation is dissatisfactory and results primarily from the fact that there are no major consumers of thermal energy in the vicinity of biogas plants which would have a suitable and continuous requirement for thermal energy.

In these circumstances, optimising the biogas plants by converting the waste heat into electricity in an ORC (Organic Rankine Cycle) process at medium or low temperature is a relatively complicated and cost-intensive solution due to the investment involved, but one that leads directly to higher efficiency and, given the conditions described, is the only conceivable alternative. Since the ORC consumes virtually no additional fuel for the added power, emissions and pollutants would be decreased and according to the local demand, the ORC output heat could be further utilized for example to drive absorption chillers to supply cooling systems [1].

CONCEPT OF THE TWO-STAGE ORC CYCLE FOR HEAT RECOVERY IN CO-GENERATION SYSTEMS WITH COMBUSTION ENGINES

The presented concept evolves from own research activities about optimization measures of waste heat utilisation in biogas plants. Figure 1 shows a typical biogas installation with the two potential waste heat sources at middle and low temperature levels, it means the "exhaust gas heat exchanger" (EGHE) and the engine cooling "system heat exchanger" (SHE). In this example of the circuit diagram the both heat exchangers are in series connection.

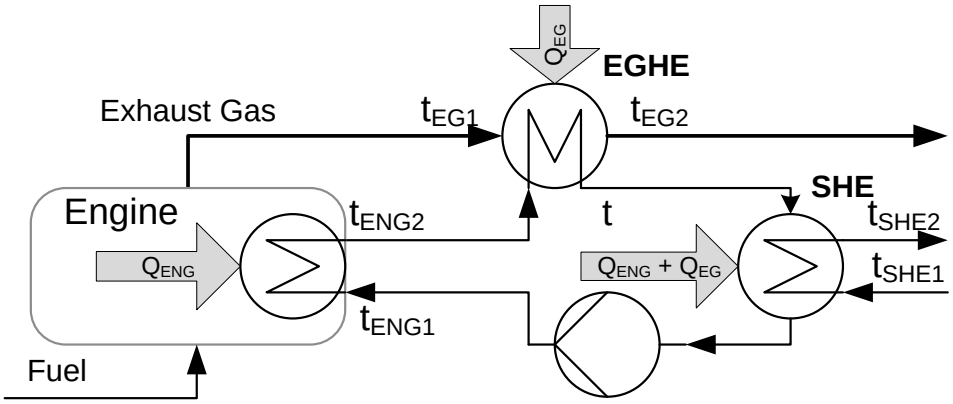

Figure. 1. Circuit diagram of a biogas installation (one of the possible typical variants)

As a result of the practical investigations and requirements a special procedure and program for the thermal operational analysis of the co-generation system with combustion engines were elaborated. Different variants of circuit diagrams, fuels and frame conditions can be taken into consideration by the means of the elaborated procedure. It is also possible to analyse the part load operation on the basis of the quasi-steady method. The possibilities and chosen results from this work were presented in other papers [2, 3] and are not matter here.

One of the analysed measures was the heat recovery by Organic Rankine Cycle. The efficiency of the ORC-Process and the total system depends (among other things) on finding an optimised working fluid [4] for biogas power plants with respect to properties and characteristics and on the working conditions connected to the temperature level of the waste heat. The following two diagrams show the representative results of the theoretical calculations of the investigated object [2, 3]. Figure 2 illustrates influence of the evaporating temperature, and Figure 3 – influence of the temperature difference by the heat recovery (an indicator of the irreversibility) on the efficiency of the ORC-Process. This was shown exemplarily for the chosen (partly environmentally unfriendly) refrigerants R 113, R 123, R 600, R 600a.

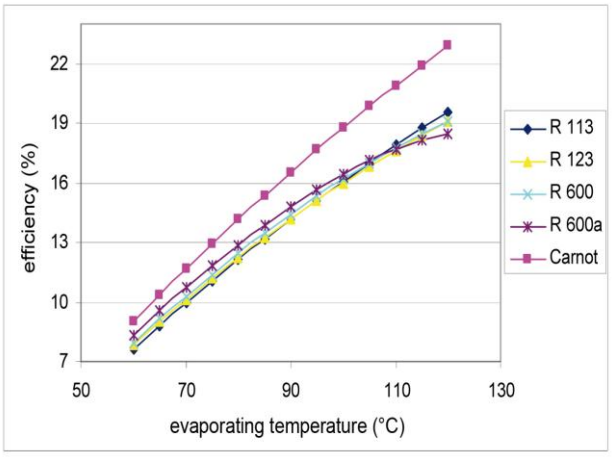

Figure. 2. Influence of the temperature difference by the heat recuperation on the efficiency of the Organic-Rankine-Cycle for different working fluids (theoretical calculation results).

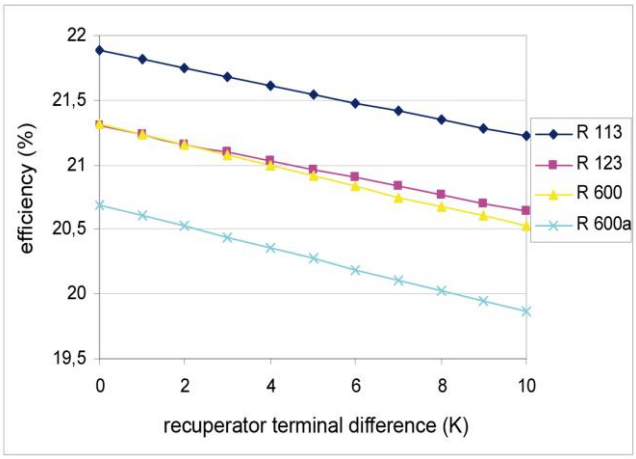

Figure. 3. Influence of the evaporation temperature on the efficiency of the Organic-Rankine-Cycle for different working fluids (theoretical calculation results).

An original concept of two-stage Organic Rankine Cycle [3,5] (shown in Figure 4) was elaborated, which arise from the practical experiences and requirements. The measurement results carried out from the real objects and characteristic of waste heat sources from co-generation systems with combustion engines were the basis for the proposed solution. The two temperature levels of heat input correspond to the heat transfer temperatures and ratios in the exhaust gas heat exchanger of a combustion engine - specifically a gas motor in a biogas plant - and in the cooling system of the engine. High-pressure expansion is carried out in a micro-turbine, and the residual expansion is coupled to expansion of the working fluid from the low-temperature heat input in a screw engine. In Fig. 5 the simplified view of the two-stage ORC process in the form of a T-s diagram is presented.

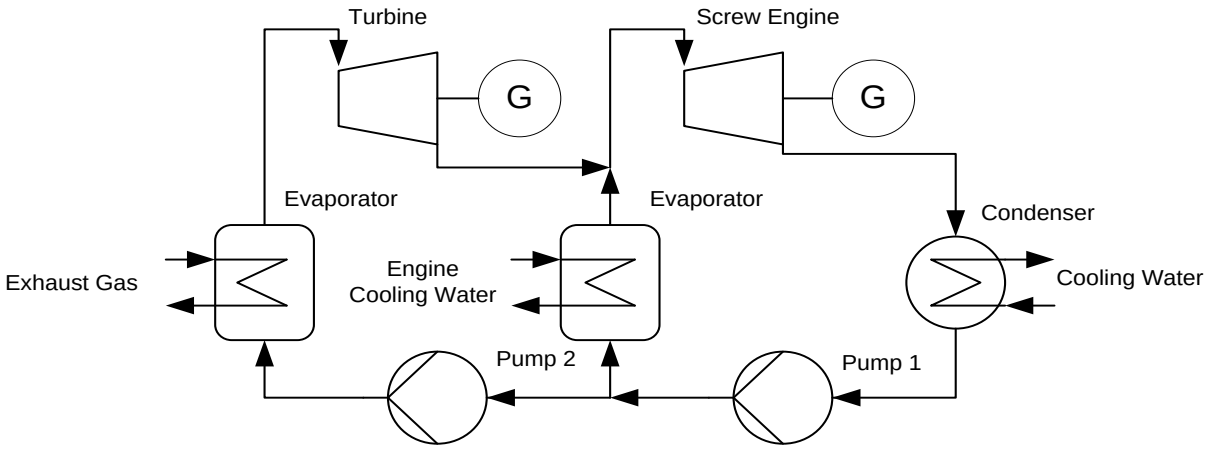

Figure. 4. Overall concept for a two-stage ORC plant

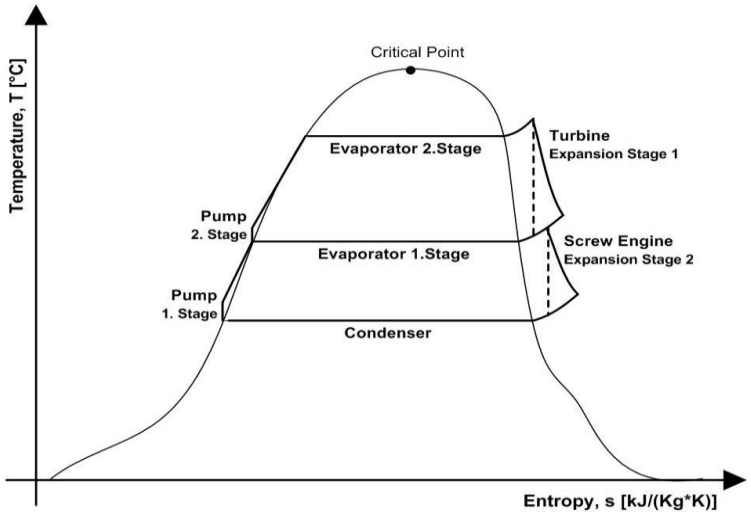

Figure. 5. Simplified view of the two-stage ORC process in the form of a T-s diagram

ANALYSIS OF THE TWO-STAGE ORC CONCEPT AND REPRESENTATIVE RESULTS

The concept was investigated theoretically by the means of the carried out calculations procedure and program and some chosen results of this analysis will be presented in this chapter.
An elaborated calculation procedure and program which is partly based on experience gathered by other researchers, e.g. [1, 6-10], is rather universal and which also matches the special requirements of the proposed plant concept was developed in order to conduct extensive arithmetic simulation, analysis and optimisation of the reference system [11]. The program consists of a database mainly containing the properties of different media, and a calculation and optimisation algorithm providing a range of options and possibilities. The calculation algorithm contains different switch variants (one- and two-stage, with and without regeneration) and permits simulation of the process for broad ranges of thermal parameters of the working fluid, and of the parameters of the available heat sources.
A large database containing the material properties of the working fluids is based on known media whose properties are generally available. In the course of the work carried out, no research on media (either theoretical or practical) was conducted, but the results of research work in this field, e.g. [4, 12] flowed into the optimisation measures being studied, of course.
The calculation method can also be applied in combination with a program for simulating the utilisation of exhaust heat from combustion engines [3]. In this way, it is possible to optimise the adaptation of the ORC process to the available heat source under both steady and quasi-steady operating conditions. In the quasi-steady method, operation of the engine under partial load conditions is simulated arithmetically in such a way that dynamic processes can also be taken into account.

Representative results obtained with the aid of the ORC calculation and simulation program developed are presented in the following, mainly in relation to the plant concept presented in the previous section and for pentafluoropropane R245–fa [13] as the selected working fluid.
In the first step, the influence of the internal efficiency of the two expansion machines on the total efficiency of the plant was examined. (The total efficiency of the plant, as shown in the following, ignores the work performed by the pump or pumps). Figure 6 summarises the representative findings that were obtained.

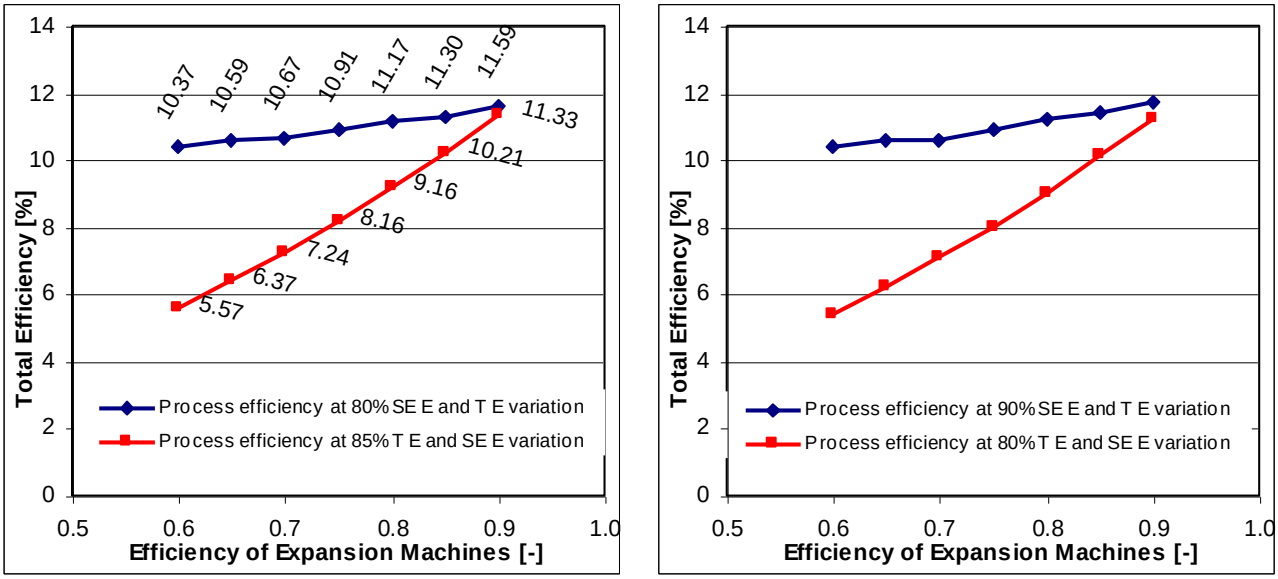

Figure 6. Influence of the internal efficiencies of the two expansion machines on the total efficiency of the ORC plant. (TE: turbine efficiency, SEE: screw engine efficiency)

In Fig. 6 the total efficiency of the ORC plant is shown as a function of the internal efficiency of the respective expansion machine used, with the efficiency of the other expansion machine assumed to be constant. In general terms, one can see from the gradients of the curves that the influence of the low-pressure stage is much greater than that of the high-pressure stage.

The selection of the intermediate pressure is also related to the total efficiency. Figure 7 shows the influence exerted on the total efficiency of the plant by the pressure upstream from the second expansion stage, based on the design parameters of the reference system, with the range of pressure variation corresponding to the options for technical realisation. It can be seen from the curve that the influence observed is relatively small in the parameter range that is technically feasible. Of course, this statement is specific to the plant and is dependent on the design parameters.

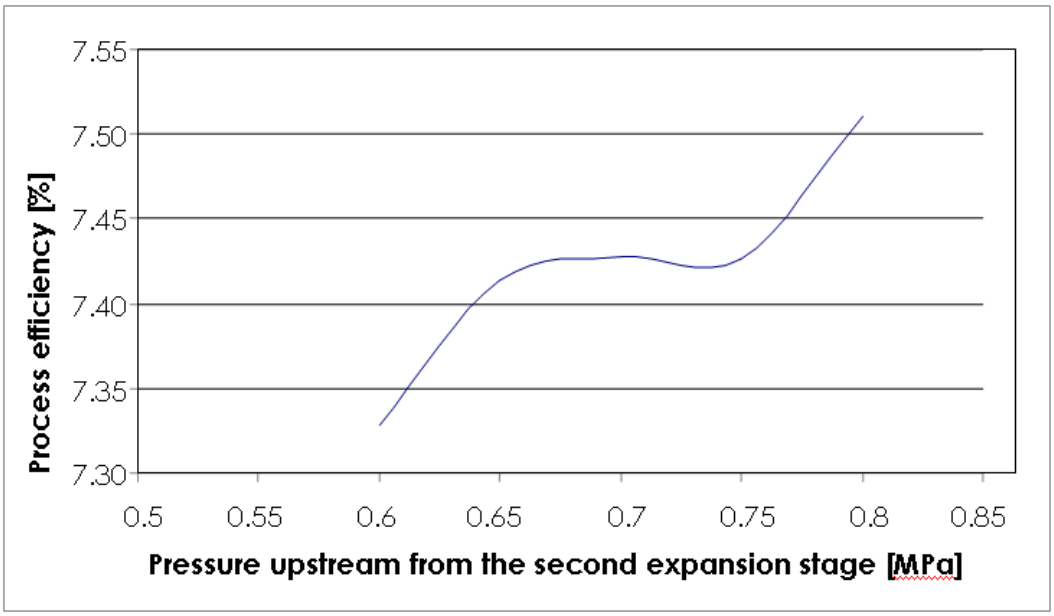

Figure 7. Influence of intermediate pressure on the total efficiency of the ORC plant

A standard question concerns, the influence of the condenser pressure on the efficiency of the plant, as illustrated in Fig. 8 for different initial pressures. As expected, lowering the condensation pressure (mainly achieved by reducing the temperature difference in the condenser) provides substantial optimisation potential. The irregularities found in the individual graphs result primarily from inaccuracies in determining the material properties, and from other sources of inaccuracy in the calculation method.

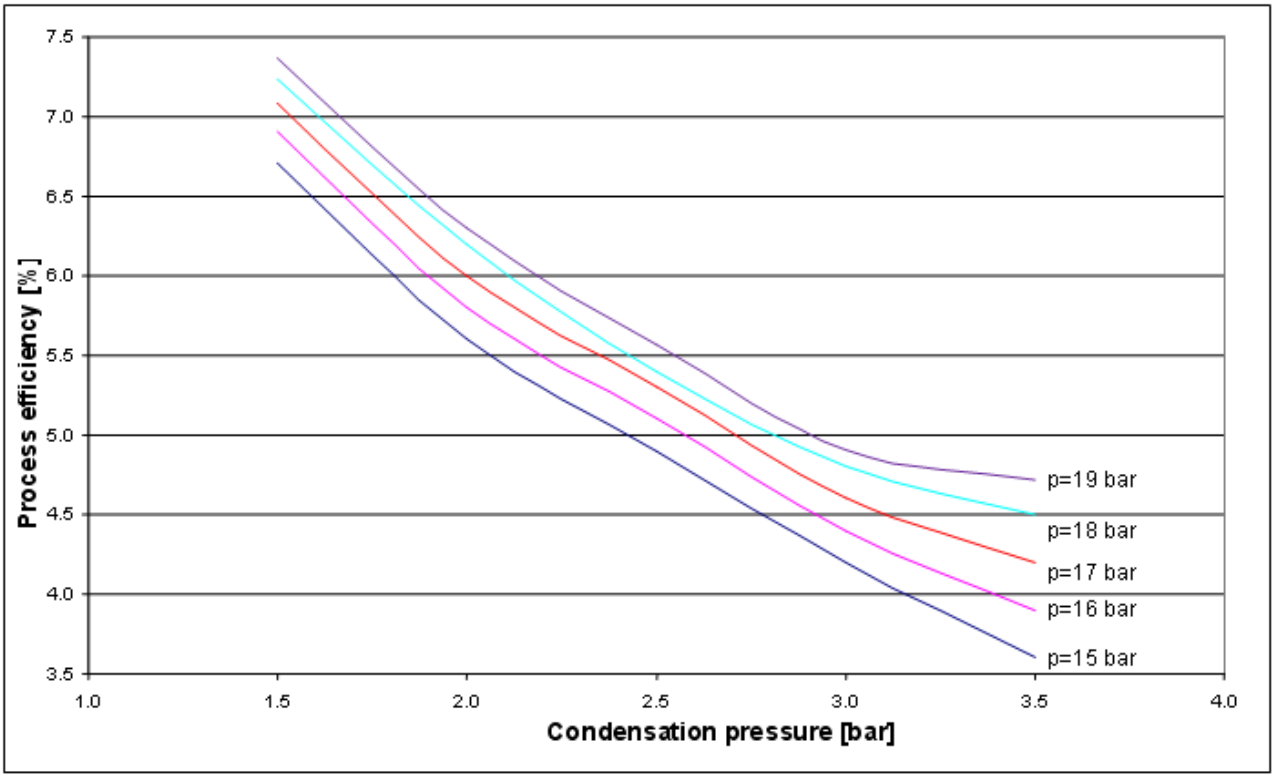

Figure 8. Change in total efficiency in relation to the pressure in the condenser

The influence of the initial pressure and of the level of superheating is relatively small, as can be seen in Fig. 9. Here, too, the irregularities in the curves are the result of inaccuracies in programming the characteristic values for the working fluids being used. This problem has a general impact on the accuracy of calculations. Depending on source, the material properties can be entered with a certain degree of precision, and the effects are particularly apparent in the range where two parameters (pressure and temperature) can vary, i.e. in the region of the superheated steam. However, with a more exact error propagation analysis it is possible to prove that the resultant errors are within a range that is acceptable for the technical calculations (less than one percent). Increasing the level of accuracy would require data sources that provide more precise details of the material properties.

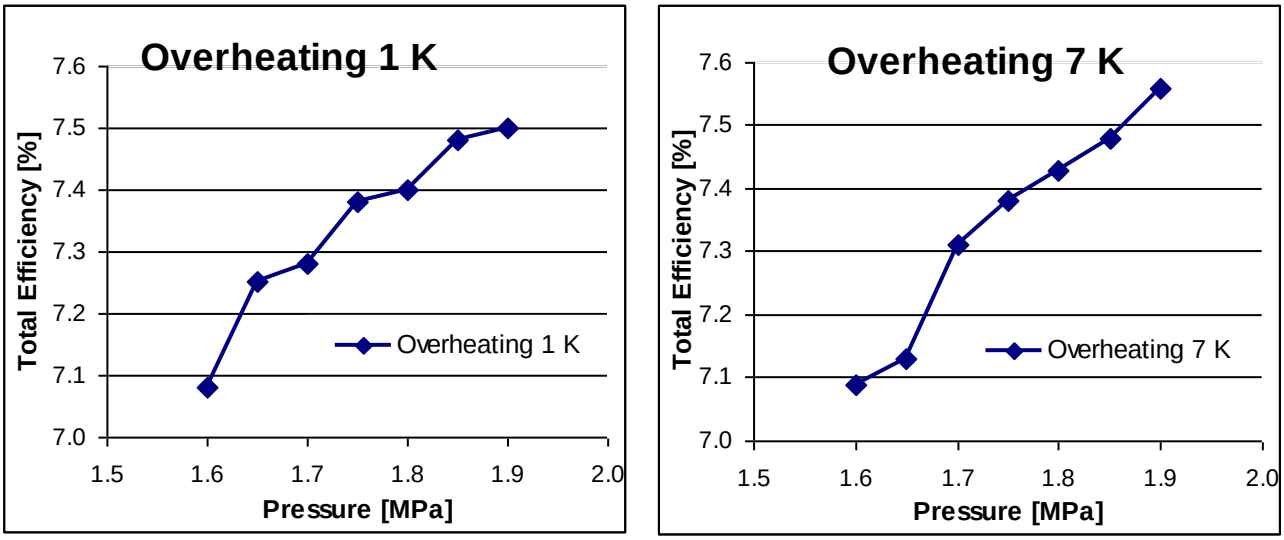

Figure 9. Total efficiency of the ORC plant as a function of initial pressure, for two different levels of steam superheating (1 K and 7 K)

The results presented in this section are intended to show, by way of example, the possibilities of the software developed, specifically in relation to the planned demonstration plant and the chosen working fluid. One important optimisation measure that has not been discussed here involves adapting the parameters of the ORC plant to the characteristics and temperature level of the available heat source.

CONCLUSIONS AND OUTLOOK

An original concept with a two stage ORC Cycle for waste heat utilisation from co-generation systems with combustion engines has been presented and analysed. The proposed solution results from the practical research work at the real objects, especially biogas installation with diesel engines. The special, innovative feature of the concept consists in adaptation of the two expansion stages to the characteristics of most biogas plants (two-stage heat input at different temperature levels). The expansion machines (small turbine and screw engine) should also be used in the realistic and optimal area of expansion ratios.

In the course of the work carried out, a calculation method and software were developed with which it was possible to analyse and optimise the two-stage plant system. The program and its procedures (including the database) are not limited solely to the plant in question, but are suitable in general for theoretical analysis of ORC processes. On the basis of the design parameters for the envisaged prototype plant, numerous simulations were carried out to investigate the complex interrelationships and influences at work. The influences of the thermal parameters in the key elements of the process and of the characteristics of the two expansion stages on die efficiency of the plant were analysed.

Simulation of the interaction between the two systems (the biogas plant and the ORC process) was also a part of the calculation procedure. With the present database of material properties, it is also possible to analyse the system efficiency with different working fluids for the specific applications in question. In the future the possible application of multicomponent working fluids [14] will be taken into consideration too.

The next step of the project will involve a practical part; it means the installation of the demonstration and test bench. First of all the application of the screw engine should be investigated practically. After that the total plant concept, regulation concepts, real losses, and other aspects will be researched and analysed.

MEASUREMENT OF TEMPERATURE TRANSIENTS IN THE SUCTION SYSTEM OF A RECIPROCATING COMPRESSOR

A. Morriesen, C. J. Deschamps*
Federal University of Santa Catarina, Florianopolis, Brazil

ABSTRACT. The present paper reports an experimental investigation of thermal transients in the suction chamber of a small reciprocating compressor, operating at 3600 rpm. Due to the small time scales associated with the phenomenon, a hot-wire system was employed to measure temperature and velocity transients. Results for valve displacement and pressure in the suction chamber were also obtained to complement the analysis. It has been observed a considerable increase in the gas temperature during the period in which the suction valve is closed. On the other hand, the results allowed identifying temperature transients correlated with pressure pulsation in the suction chamber.

Keywords: *thermal transients, anemometry, thermodynamics.*

INTRODUCTION

Figure 1 presents a schematic view of a reciprocating compressor and its indicator diagram for a typical cycle. When the piston moves downwards, it reaches a position where low pressure vapor is drawn in through the suction valve, which is opened automatically by the pressure difference between the cylinder and the suction chamber. The vapor keeps flowing in during the suction stroke as the piston moves towards the bottom dead center (BDC), filling the cylinder volume with vapor at suction pressure, p_s. The suction process is represented by curve A-C in the indicator diagram of Fig. 1b. After reaching the BDC, the piston starts to move in the opposite direction, the suction valve is closed, the vapor is trapped, and its pressure rises as the cylinder volume decreases. Eventually, the pressure reaches the pressure in the discharge chamber, p_d, and the discharge valve is forced to open. After the opening of the discharge valve, the piston keeps moving towards the top dead center (TDC), represented by point A. It should be noted that suction and discharge processes do not take place at constant pressure. This phenomenon is associated with the dynamics of the valves and the restriction imposed by the valve passage areas. This appears on the indicator diagram, with compression continuing after pressure p_d is reached and the same happening for the expansion stroke after pressure p_s.

In household refrigeration compressors, a significant portion of the energy losses is associated with refrigerant superheating along the suction path. This useless superheating provokes a reduction in volumetric efficiency and an increase in compression work per unit mass. A detailed thermal analysis of the suction system can lead to a considerable improvement in its performance, mainly through the reduction of gas superheating. However, a complete analysis of the involved phenomena requires also data for gas temperature transients. This is a very difficult task because the time scale of such variations is similar to that of compressor valves. Thermocouples are the most commonly used sensors in compressors but, nevertheless, their slow response time make them

* Corresponding author: Prof. C. J. Deschamps

E-mail address: deschamps@polo.ufsc.br

inappropriate for measurements of steep transients of gas temperature that occur in the suction system. This is a consequence of their thermal inertia, which can be substantially decreased with the adoption of micro-thermocouples.

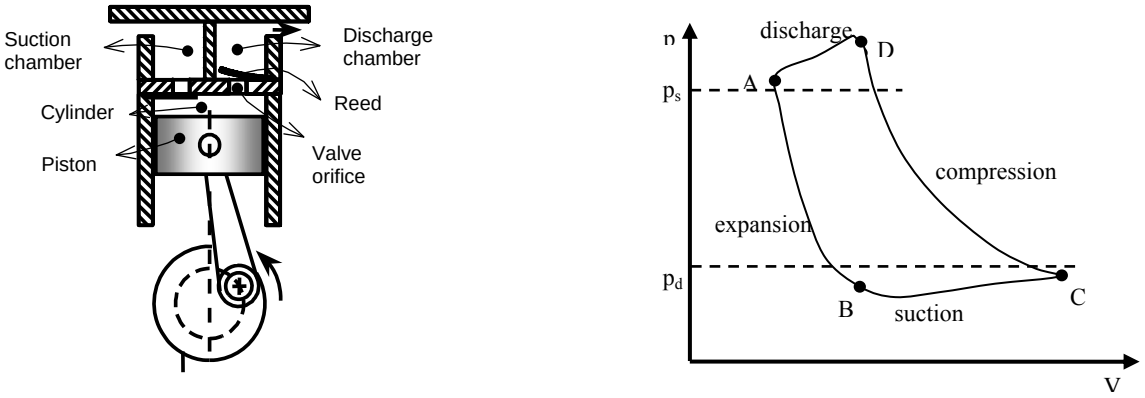

Figure 1. Dimensionless calibration curve and experimental obtained with argon.

Shiva Prasad [1] built a 12.7μm diameter chromel-constantan wire thermocouple especially designed for temperature measurements in a two stage, double acting, compressor running at approximately 900 rpm. He successfully measured the instantaneous temperature inside the cylinder, which suggested a large gas suction heating.

Experiments of flow in inlet manifolds of IC engine were conducted by Bauer *et al.* [2] with the purpose of analyzing heat exchange for different flow parameters. The instrumentation of the manifold was made with thermocouples, distributed in 5 positions along the manifold, and four heat flux sensors in each section. Next to the exit, the port was arranged to fit, alternatively, a hot-wire, a cold-wire and a heat flux sensor. The cold-wire probe calibration was made to allow temperature measurements up to 100°C, with a correction for thermal inertia using a fixed time constant of 2 ms, derived from energy balance and heat transfer correlations for the wire sensor. The authors concluded that the period in which the flow is stagnated contributes strongly to the total heat transfer to the fluid in the inlet manifold.

Zend and Assanis [3] analyzed heat transfer in inlet manifolds of IC engines, pointing out that during the operation cycle, the air flow inside the manifold is composed of two phases, associated with periods in which the admission valve is either open or closed. The authors developed a new correlation to characterize the transient nature of the flow.

In an experimental investigation of flow through inlet and discharge manifolds of diesel engines, Olczyk [4] identified that the main difficulties in measurements of temperature transient are related to the sensor time response and the signal interpretation. The experiments adopted thermocouples, hot-wires and cold-wires in an apparatus capable of generating pulsating flows with frequencies up to 180 Hz. A methodology was proposed to take into account thermal inertia in the measurements carried out with the cold-wire sensor, which does not require any information about its constructive parameters.

From the review given, it is clear that single point measurement techniques such as cold-wires and micro-thermocouples have been used to measure temperature transients in suction systems of IC engines, including the analysis of effects associated with thermal inertia. Yet, there is only one study dedicated to reciprocating compressors, considering a 900 rpm operation speed. In this paper, an experimental investigation of thermal transients is carried out in the suction chamber of a small

high speed reciprocating compressor, operating at 3600 rpm. Results for temperature, velocity, pressure in the suction chamber are used to analyse gas superhating.

EXPERIMENTAL SETUP AND PROCEDURE

A reciprocating compressor operating with R134a was selected for the analysis, being submitted to two operating conditions, represented by two pairs of evaporation and condensation temperatures: (-23.3ºC/54.4ºC) and (-35.0ºC/54.4ºC). The first condition defines the pressure in the suction and discharge lines as 1.149 bar and 14.71 bar, respectively. When the evaporation temperature is lowered to -35.0ºC, the suction pressure becomes equal to 0.6617 bar.

Measurements of pressure, valve displacement and crankshaft position

Piezoelectric pressure transducers were selected for the measurements in the suction chamber, due to their high response frequency, small size and reliability regarding the hostile conditions inside the compressor. To correlate the pressure measurement with the crank angle, a sensing winding was assembled to the crankcase to collect the signal emitted by a magnet fixed to the crankshaft. The instantaneous crankshaft position is calculated taking into account the compressor mechanism characteristics. Small sensing windings were also assembled into the valve plate seat to give the valve lift according to the crankshaft position.

Measurements of temperature and velocity

Measurements of temperature were conducted with a DANTEC anemometer system composed by a constant current module (90C20). Yet, for velocity measurements, a DANTEC mini-CTA system (54T30) was adopted. A single 5 μm diameter tungsten wire sensor (55P11) was employed for both velocity and temperature measurements. The sensor was calibrated for velocity measurements by using a DANTEC calibration unit (90H10), with a temperature sensor (55A76) being employed to register any significant variation during the process.

It should be mentioned that a number of aspects may affect measurements of velocity and temperature with anemometry sensors. For instance, Weiss *et al.* [5] has shown that the presence of oil droplets in the flow can increase the sensor diameter with running time, leading to a reduction of its frequency response. Such a contamination process requires testing and cleaning the wire steadily in order to keep a significant frequency response. This is particularly relevant in compressors because oil is always present in the suction system.

Calibration procedure

The calibration of a cold-wire sensor aims to establish a relationship between the temperature of the environment in which the sensor is inserted and the resulting tension read by the system; i.e. a relation between the temperature and the electric resistance of the sensor wire. In the present work, the calibration procedure for temperature consisted in placing the cold-wire sensor inside a cavity next to a thermistor. Then, by adjusting the power of a heater inside the cavity to different levels, the signal of both the sensor and the thermistor were registered, allowing a calibration curve to be obtained for the cold-wire sensor.

As far as the hot-wire sensor is concerned, the calibration was carried with a DANTEC calibration unit (90H10), in which the sensor is exposed to a range of flow velocities typically found in the suction chamber. A number of 20 different velocity levels was employed to adjust a calibration curve to express the velocity, U, as a function of the voltage indicated in the anemometry system, E. During the calibration procedure, pressure and temperature prevailing in the flow were also registered so as specify the fluid properties at each velocity level.

Tetrafluoroethane (R134a) is the working fluid of the compressor selected for the present study, which is a common choice for household refrigeration systems. Therefore, after the hot-wire sensor was calibrated in air, the resulting calibration curves were made dimensionless, by characterizing the fluid flow conditions through Reynolds and Prandtl numbers. There are a number of proposals for such dimensionless relationship in the literature [6]. Here, the relation proposed by Kramers [7],

$$Nu = A\,Pr^{a} + B\,Pr^{b}\,Re^{c}\,, \tag{1}$$

was chosen to express the dimensionless calibration curve. This correlation takes into account variations in fluid properties with temperature, which are evaluated at the film temperature rather than at the fluid temperature. Equation (1) is strictly valid only for hot-wire sensors with very high L/d ratios, where L and d are the length and diameter of the wire, respectively.

The coefficients and exponents A, B, a, b and c in equation (1) are adjusted for an adequate fit in relation to the experimental data. The adoption of this calibration curve requires that fluid properties (density, thermal conductivity, specific heat and viscosity) must be known for each measurement in the suction chamber. It was assumed that fluid properties could be evaluated from data of pressure and temperature acquired in the flow during the compressor operation.

Before proceeding to measurements in the compressor, the calibration curve obtained with air was validated through measurements of velocity in argon flow. To this extent the calibration unit was again used to specify different levels of velocity, following the aforementioned procedure. Figure 2 shows a comparison between the dimensionless calibration curve previously obtained for air and the new data acquired for argon. As can be seen, there is a good agreement between both results, with a maximum deviation of 2.2%. Therefore, the dimensionless curve was found to be also accurate for measurements in R134a.

Experimental procedure

A calorimeter facility was employed to investigate the compressor under the specified operating conditions. The uncertainties associated with measurements taken with the calorimeter are $\pm$ 3% for mass flow rate and power consumption. Further details of the experimental facility can be found in [8]. The compressor was tested three times for each operating condition.

The acquisition system is composed of a computer, a National Instruments converter analogue/digital (A/D), model 6071E, and a program for data acquisition and reduction, developed using LabView 6i [9].

As illustrated in Figure 3, the anemometry sensor was assembled at the entrance of the suction chamber, allowing measurements of velocity and temperature. A small tap hole (1 mm diameter) was used to connect the suction chamber to a larger orifice (7 mm diameter), in which the piezoelectric pressure transducer is mounted.

The first step in the experimental procedure is to submit the compressor to an adequate vacuum condition, in order to remove air, humidity and any other contaminant inside the system. Then, the system receives a charge of refrigerant and the flowmeter reading is set to zero. After the compressor is switched on, a period of approximately 6 hours is needed to establish a fully periodic operating condition because of compressor thermal inertia. When this condition is satisfied, data for energy consumption and mass flow rate are acquired during a period of 10 minutes. Finally, data for temperature, velocity and pressure in the suction chamber and displacement of suction valve are collected for 240 operation cycles of the compressor, allowing the evaluation of an average value for each quantity.

A total of 1000 measurements were acquired to properly characterize the compressor operation cycle. Since the compressor operates at a velocity of 3600 rpm, an acquisition rate of 60 kHz was needed. The 240,000 experimental data collected along 240 cycles were submitted to a statistical analysis, with ensemble average results being expressed as function of the crankshaft angle.

Measurements of velocity at the entrance of the suction chamber were used to allow a correction in the experimental data for temperature, associated with the sensor thermal inertia. The corresponding temperature and pressure in the suction chamber were also measured to specify physical properties. Then, based on the Nusselt number, *Nu*, for each crankshaft position an estimate for the time constant τ related to the sensor was obtained.

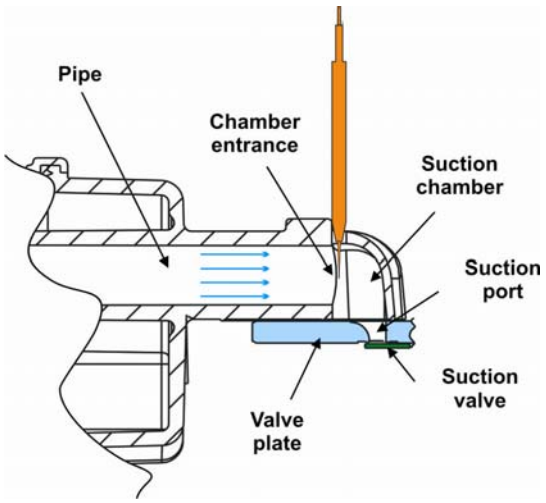

Figure 3. Detail of anemometry sensor assembly.

RESULTS AND DISCUSSIONS

Figure 4 shows results for temperature variation along the compressor cycle for the operating condition of -23.3°C/54.4°C, with and without correction for thermal inertia of the cold-wire sensor. It can be noticed some noise in the temperature data when the correction is applied to the sensor measurement. In this study, a smoothing process was adopted to remove such a noise, in which a discrete Fourier transform is initially applied to the temperature data. With the signal in the frequency domain, high frequencies are removed and then, via an inverse transform, the smoothed signal is finally corrected for thermal inertia.

As can be seen, the correction adopted for thermal inertia allows one to recover part of the temperature transient information lost in the measurement. For instance, the sensor was originally able to follow the temperature variation of 4.2°C/ms occurring in the cycle between 240° and 263°. Considering thermal inertia, a response of 4.9°C/ms is seen for the corrected data between 230° and 251°. Furthermore, the maximum value for temperature in the cycle is increased from 54.2°C to 54.9°C, with a shift of 12° in the crankshaft position.

In Figure 5, results for pressure, velocity and valve displacement are shown along the compressor cycle. It can be observed that the valve opening occurs at the angle of 230°, followed by a pressure drop and an increase in velocity, which reaches a maximum value of 32.2 m/s at the crankshaft angle of 264°. It is interesting to note that the points of maxima for velocity and valve displacement are not in

the same crankshaft position. Since the hot-wire sensor was installed at the entrance of the suction chamber, the distance the fluid has to flow before reaching the suction port contributes for a delay between the data for velocity and valve displacement. The other aspect taking part in this situation is valve dynamics, since inertia does not allow the valve to instantaneously respond to steep variations of velocity and pressure.

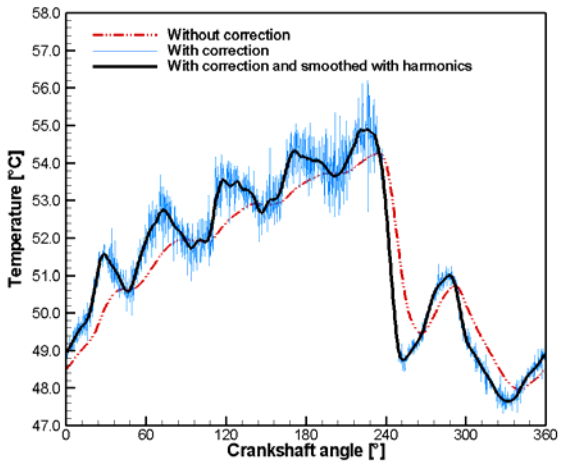

Figure 4. Correction in the temperature due to the sensor thermal inertia.

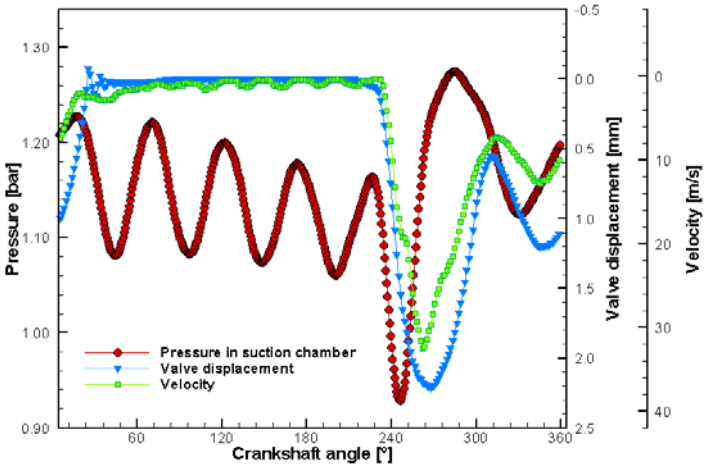

Figure 5. Measurements for temperature, pressure and velocity in the suction chamber.

Despite the difficulty originated by the two aforementioned aspects, it is clear that the velocity reaches its maximum value when the valve is fully open. It is also worthwhile noticing subtle variations in the velocity gradient around crankshaft positions 250° and 270°, probably due to perturbations in the flow. When the valve is closed, the sensor indicates the presence of velocity oscillations with amplitude of approximately 3 m/s. This phenomenon is associated with expansion and compression pressure waves traveling forward and backward in the duct that feeds the suction chamber. Naturally, the hot-wire sensor is insensitive to the velocity direction and, therefore, cannot detect an outflow condition in the suction chamber. Therefore, velocity magnitudes are always shown as positive.

Temperature variation in the suction chamber is due to heat transfer between the gas and the chamber walls, as well as pressure pulsation and interaction with the flow in the suction system. As can be seen in Figure 6 for the condition -23.3°C/54.4°C, pressure waves present during the suction process induce temperature oscillations. However, at the cycle positions 16, 28, 246 and 255°, within the period in which the valve is open, such variations are not perfectly in phase. The maximum and minimum temperature values in the suction chamber are equal to 54.8°C and 47.5 °C at the angles 227° and 331°, respectively. The temperature decrease observed when the valve opens can be attributed to the pressure drop to which the fluid in the suction chamber is submitted.

For the period in which the valve is closed, between 26° and 230°, there is an increase of approximately 3.5°C in the suction chamber temperature. Considering that such a time period corresponds to 9.4 ms, this temperature increase indicates a high intensity heat transfer between the gas and the chamber walls.

Figure 7 shows a comparison between results for temperature in the suction chamber obtained at two operation conditions: -23.3°C/54.4°C and -35°C/54.4°C. As can be noticed, the average cycle temperature is increased from 51.4°C to 57.3°C when the condition is changed to -35°C/54.4°C. Moreover, the temperature reduction observed when the valve opens is almost 1°C greater for this

condition. The other aspects already analyzed for the condition -23.3°C/54.4°C remains very similar in this new situation but, nevertheless, with a phase shift of 15° in the temperature and pressure oscillations.

It is interesting to observe the presence of two temperature oscillations during the period in which the valve is open for the condition -35°C/54.4°C. The first one occurs between the crankshaft positions of 280 and 330° and is linked to an increase of pressure in the suction chamber. On the other hand, the second oscillation can be attributed to heat transfer, since after the angle 330° the valve is almost closed and the fluid inside the chamber is virtually stagnated.

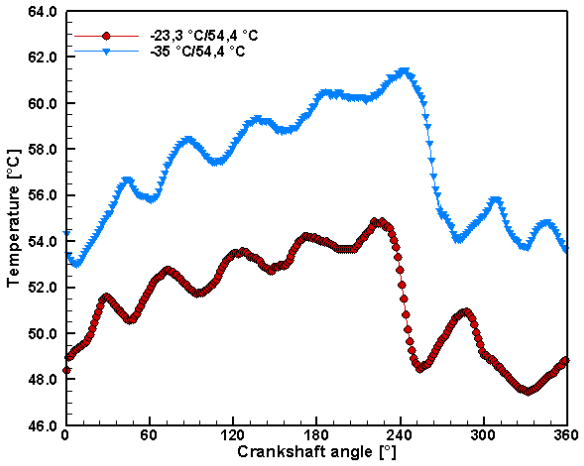

Figure 7. Temperature variation along the compressor cycle for two operating conditions.

CONCLUSIONS

An experimental setup was developed to investigate thermal transients in the suction chamber of high speed refrigeration compressors. To this extent, a hot-wire system with a 5μm diameter wire probe was adopted for temperature and velocity measurements. A calibration procedure was specially elaborated due to the impossibility of using the refrigerant as the working fluid. Additionally, corrections were made available to temperature measurements at each position of the compressor operation cycle, by estimating the sensor thermal inertia. Results for valve displacement and pressure pulsation in the suction chamber were also obtained to complement the analysis. Measurements indicated abrupt variations in all flow properties, strongly linked to the valve motion. When the valve is open, velocity reach levels of approximately 32 m/s, in comparison with 3 m/s when it is closed. It has been observed a considerable increase in the gas temperature during the period the suction valve is closed associated with heat transfer between the gas and the suction chamber walls.

PERFORMANCE, EMESSIONS, AND COMBUSTION DEPOSIT CHARACTERISTICS OF A DIECT INJECTION DIESEL ENGINE FUELED WITH WASTE SUNFLOWER OIL METHYL ESTER

Chris Steyn, Makame Mbarawa *
Department of Mechanical Engineering,
Tshwane University of Technology, Private Bag X680, Pretoria 0001, South Africa

ABSTRACT. In this study, performance, emission and combustion deposit (CD) characteristics of a direct injection (DI) diesel engine fuelled with the pure waste sunflower oil methyl ester (WSOME) and its blends at proportions of 30 %, and 70% (v/v) were investigated. The results showed the WSOME/blends presented better brake thermal efficiency than diesel fuel. This is due to the higher density and lower heating value of the WSOME than that of diesel fuel. Engine tests showed that the performance parameters of the WSOME/blends fuels did not differ greatly from those of diesel fuel. Slight power losses were experienced with the WSOME/blends fuels. This may be due to the lower heating value of the blends fuels. The engine operated on the WSOME100 and their blends resulted in higher NOx, HC, CO and lower exhaust smoke concentrations than the diesel fuel case. Further, it was found that the WSOME100 produced lowest fraction of carbon deposits as compared to diesel fuel and other WSOME blend fuels.

Keywords*: performance,; emission, combustion deposits, methyl ester, diesel engine*

INTRODUCTION

The rapid depleting of fossil fuels deposits, increasing global concern due to air pollution caused by internal combustion engines as well as escalating oil prices have catalysed efforts to look for alternative energy sources that are both renewable and environmentally friendly. In this respect, various investigations in many countries have been carried out to see the possibility of replacement of diesel fuel with oxygenated fuels such as biodiesel, ethanol etc. One of the oxygenated fuels that shows a great potential is biodiesel (BD). BD, an alternative fuel obtained from vegetable oils or animal fats, has a number of technical advantages over diesel fuel which include reduction of most exhaust emissions, improved lubricity and biodegradability, higher flash point, reduced toxicity, and renewable. In the case of viscosity, calorific value and cetane number, BD and diesel fuel show similar behaviour.

The raw material costs and limited availability of vegetable oil feedstocks are always critical issues for the BD production and are the major obstacles to its commercialization. The high costs of vegetable oils, which could be up to 75% of the total manufacturing costs, have led to the production costs of BD becoming approximately 1.5 times higher than diesel. The price of waste cooking oils (WCO) is still remains 2-3 times cheaper than the net vegetable oils, depending on the base stock, geographic area, variability in crop production from season to season, the price of the crude petroleum and other factors. Exploring ways to reduce the high cost of BD is of much interest in recent BD research, especially for those methods concentrating on minimizing the raw material

costs. One way to reduce the cost of BD is to use less expensive feedstock such as WCO from restaurants. WCO is a promising alternative to vegetable oil due to its reduced cost.

Although, there have been numerous studies on the performance and emission of the WCO based BD, there are limited studies in the literature concerning the comprehensive evaluation of BD from WCO as an alternative fuel for diesel engine. Hence, more detailed research is need. With this background, the present study is aimed in investigation the engine performance, emission and combustion deposit (CD) rate formation of a direct injection (DI) diesel engine fuelled with waste sunflower oil methyl ester (WSOME) and its blends.

EXPERIMENTAL SET-UP AND PROCEDURES

Experimental Equipment and performance and emission test procedures

Experiments were conducted on a four cylinders, four stroke, naturally aspirated, water cooled, direct injection Isuzu diesel engine with a bore of 93 mm, stroke of 92 mm and compression ratio of 18.4:1. The engine was directly coupled to an eddy current dynamometer using a flexible coupling and a stub shaft assembly. The maximum torque of the engine was 162 Nm at 2000 rpm and the rated power was 43 kW at 2800 rpm. No adjustment was made at the fuel injection timing, i.e**.** at 20^{o} before top dead centre (BTDC).

Testing was performed at maximum fuelling at different engine speeds to produce a power curve. This mode was performed at increasing speed starting at 1000 rpm, and incrementing in step of 200 rpm to 2800 rpm. The experimental procedures started with a preliminary investigation of the engine running on the pure diesel fuel in order to determine the engine's operating characteristics and exhaust emission levels, constituting the 'baseline' that is compared with the corresponding cases when the blended fuels were used. Before the significance of the performance and exhaust emissions results can be considered, it is important to establish if the engine operating conditions were reproduced consistently, as any deviation in operating conditions can have an overriding influence on performance and emissions. The reproducibility of the dynamometer speed control set points was generally within ± 5 rpm of the desired engine speed, while torque settings were generally achieved to within 1.5 %. All of the torque and power results were corrected using SABS 013-correction factor [1] to adjust for atmospheric variation. Exhaust gases: (CO (%), NO_X (ppm), HC (ppm) and CO_2 (%)) were measured on line by an Ultra-Tune gas analyser. The relative standard deviation of NOx, CO, HC and carbon dioxide (CO_2) concentrations was 1%, 3%, 3% and 0.3% respectively.

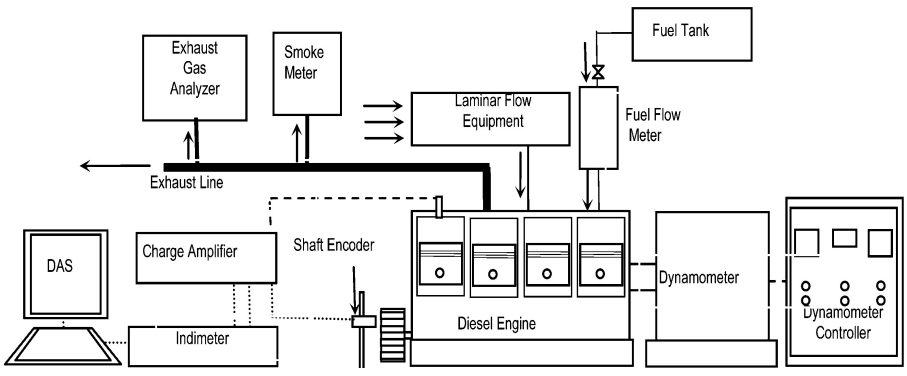

Figure 1. Schematic diagram of the experimental set-up

Combustion chamber deposits generation and analysis procedures

The same engine used in performance and emission testing was operated for 40 h under cycled conditions that approximated city-suburban driving conditions to generate CD from the test fuels.

The CD test cycle is shown in Table 2. At the end of each cycle, the engine was dismantled, visually inspected and rated according to the Coordinating Research Conical (CRC) test procedures [2].

After rating process, the deposit from each of the four combustion chamber region, cylinder head region and piston top region was scraped using gasket scraper and fine wire brush. The sample material from respective region of the four cylinders was then mixed together to form on large average sample for the respective region. After scraping, the cylinder head was washed using an organic solvent (acetone) assisted with sand paper and a wire brush for removing the remaining deposits. Then, compressed air was used to remove the loose carbon from cleaning areas. After that, cylinder head was assembled to the engine and used lubrication oil was discharged and refilled with new one before performing a new test.

Quantitative analysis of combustion deposit formation was carried out by weighting the scraped deposit samples from the test fuels. Then, the analytical analysis was characterised by using a scanning electronic microscopy (SEM) for morphology, X-Ray diffraction (XRD) for elemental composition and the nitrogen adsorption for surface area and pore size distribution. In addition, thermo-gravimetric analysis was carried out so that weight changes of combustion deposit could be measured qualitatively while being heated.

Biodiesel Preparation

In the present investigation, WSOME used was produced from sunflower WCO collected from different local restaurants. WSOME was prepared using alkali catalyzed method. Methanol (1:3 molar WCO: alcohol) was mixed with NaOH (1 wt. % of oil) added to the reactor containing oil. The reaction mixture was refluxed for 2-4 hrs. After completion of the reaction the material was transferred to separating funnel for separation and washing process. Although several blends with a wide composition spectrum were prepared by splash blending, the tests were carried out with WSOME30 (30% WSOME-70% diesel by volume), WSOME70 (70% WSOME-30% diesel by volume), WSOME100 (net WSOME). These blend ratios were chosen to see whether clear difference could be detected in their performance ability, emission and CD formation.

REUSLTS AND DISCUSION

Performance Parameters

The effect of the WSOME addition to the blends on the engine torque output for various speeds is shown in Figure 2a. The engine torque output of all test fuels increases as engine speed increases, reaches a maximum and then, as engine speed increases further, torque decreases. The torque decreases because the engine is unable to ingest a full charge of air at the higher speeds. This is due to the fact that as engine speed increases, there is less time for the engine cylinders to be filled with fresh air and expel exhaust gases. Comparison of engine torque between WSOME100, WSOME70, WSOME30 and diesel fuel generally shows reduction in torque that are approximately the same as the reduction in energy content of the blend relative to diesel fuel. It is shown that the maximum torque of 158 Nm was developed by the engine on the diesel fuel. The corresponding engine speed was 2400 rpm. The engine developed maximum torque of 156.1, 154.9 and 153.5 Nm at 2200 rpm when the engine was operated on WSOME30, WSOME70 and WSOME100 respectively. The lower specific heating value of WSOME is the reason for the reduction in torque.

Figure 2b shows the brake power output versus engine speeds for WSOME100, WSOME70, WSOME30 and diesel fuel. There is slightly difference between the brake power values developed by the test fuels. The increase in the amount of the WSOME in the blend fuels consistently shows a decreasing trend of the brake power output. This trend can be explained by the lower heating value of the WSOME-diesel blended fuels with increasing biodiesel concentration in the blends.

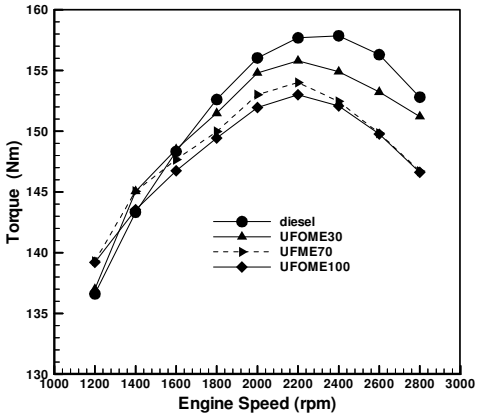

Figure 2a. Effects WSOME on engine toque

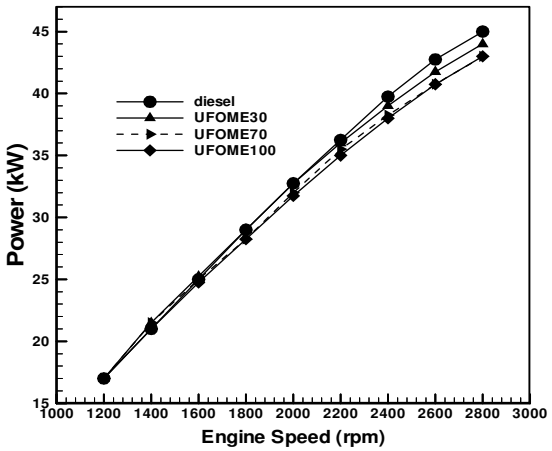

Figure 2b. Effects of the WSOME on engine power output

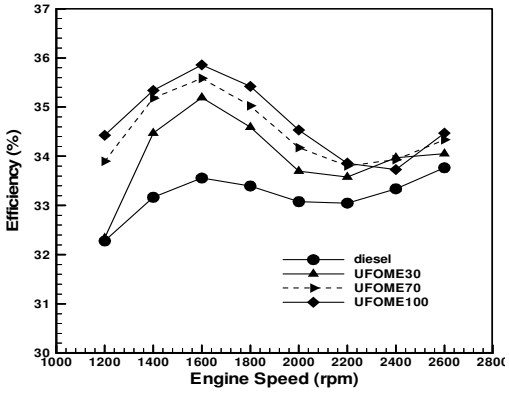
If different biodiesel fuel blends with different heating values are compared, their heating values decrease with the increase of biodiesel in the blend and for this reason; brake thermal efficiency is shown in Figure 3a instead of brake specific fuel consumption (BSFC). As shown in the figure, WSOME-diesel blends present better brake thermal efficiency than diesel fuel. These results concur with those obtained by Ramadhas et al. [3] who compared the performance of a diesel engine



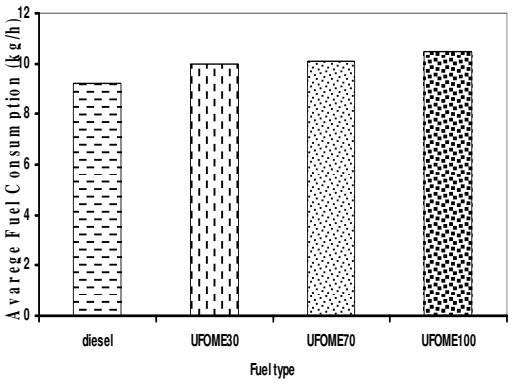


Figure 3a Effects of the WSOME on engine thermal efficiency

Figure 3b Effects of the WSOME on average fuel consumption

running on blends of diesel fuel and biodiesel derived from rubber seed oil. Elsewhere, Raheman and Phadatare [4] recorded a slightly different behaviour. The better engine performance with WSOME is probably due the oxygenated nature of WSOME, and also due to its higher viscosity and lower calorific value, which have a major bearing on spray formation and initial combustion. Figure 3b compares the average fuel consumption rates of the test fuels that were observed over the range of tested engine speeds. The diesel fuel had a slightly lower fuel consumption rate primarily because it had the largest heating value among the test fuels. In contrast, the WSOME100, which had the lowest heating value, had a slightly higher fuel-feeding rate to attain the maximum engine load required.

Regulated Gas Emissions

NOx as function of engine speed and percentage of WSOME is shown in Figure 4a. The results show that NOx increase gradually with the load and their values depend largely on the engine speed and the percentage of WSOME in the blend. The use of the WSOME100 and their blends resulted in quite considerably increased NOx emissions. This is due to the presence of fuel oxygen within the blend fuels. This observations are in line with many other biodiesel fuel emission studies (e.g. [5- 7]). Among the test fuels, WSOME70 produced the highest NOx for engine speed between 1400 and 2600 rpm while WSOME100 gave the highest NOx emissions at the engine speeds of 2800 rpm. As shown in Figure 4b, the engine running on WSOME and its blends showed higher HC concentration than those of diesel fuel. Among these fuels, WSOME70 produced the highest HC emissions while diesel fuel gave lowest HC emission for all engine speeds. Humke and Barsic [8] reported that the physical properties of fuel such as density and viscosity can have a greater influence on hydrocarbon emissions than its chemical properties. The viscosity of WSOME and its blends are higher than that of diesel fuel. High viscosity causes poor fuel atomization during the spray and may lead to higher fuel spray droplet sizes. As a result, the fuel spray for WSOME and its blends may not propagate deeper into the combustion chamber and gaseous hydrocarbons remain along the cylinder wall, the crevice volume and left unburned fuel [9].

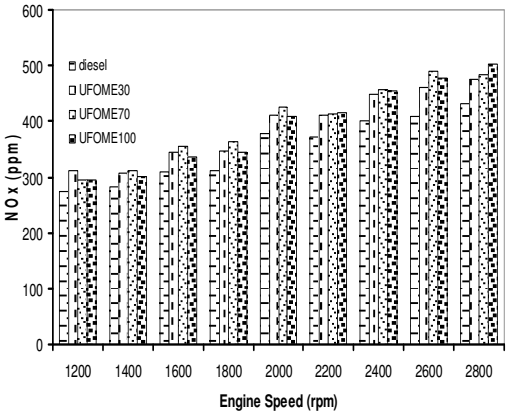

Fig 4a Effects of the WSOME on NO_X emissions

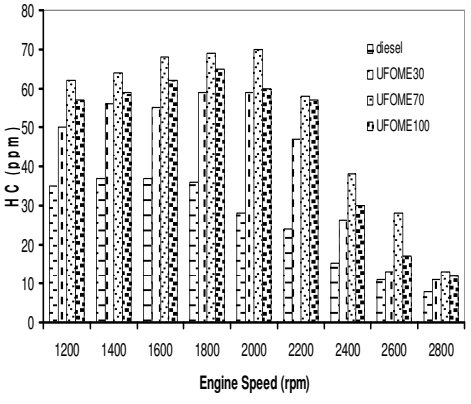

Fig 4b Effects of the WSOME on HC emissions

The CO emission in the exhaust gas indicates the lost chemical energy that is not fully utilized in the engine. Generally, CO emission depends on equivalence ratio, fuel type, atomization ratio, injection timing, engine load and speed. Figure 5a shows the changes in the CO emissions for different test fuels at different engine speeds. WSOME30 produced the highest CO emissions, while diesel fuel produced lowest CO emissions for all engine speeds. The CO emissions are found to be increasing with increase in engine speed to the maximum values at 2600 rpm and then decreases as the engine speed increases. Generally, the CO emission emitted by the blend fuels is higher than

that by the corresponding diesel fuel case. Relatively poor atomization and lower volatility of biodiesel compared to diesel oil is responsible for this trend.
Figure 5b shows that the CO_2 concentration increased with increasing engine speeds for all test fuels. WSOME30 produced the highest amount of CO_2 than other fuels for all engine speeds. The CO_2 emission from biofuel engines can be absorbed by plants for photosynthesis purposes, so that the CO_2 level in the atmosphere is kept in balance.

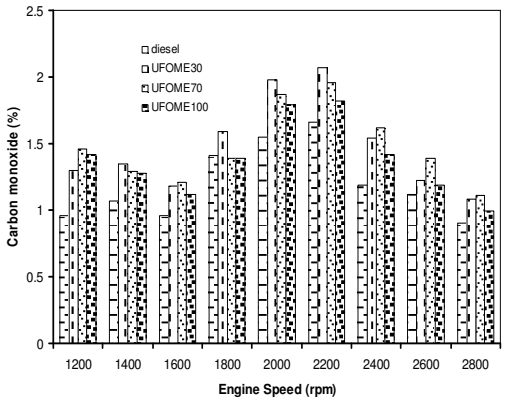

Fig 5a Effects of the WSOME on CO emissions

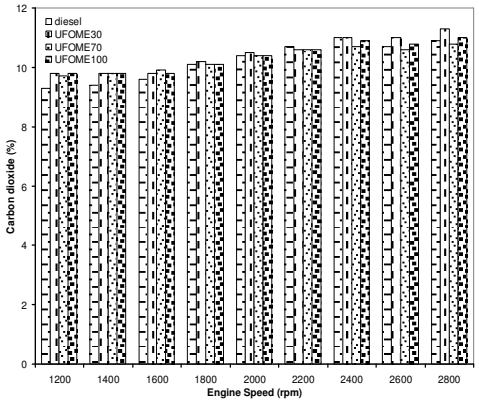

Fig 5b Effects of the WSOME on CO_2 emissions

Smoke opacity is a direct measure of smoke and soot. The exhaust smoke generated by different fuels depends on the engine load, engine speed, air turbulence velocity inside engine cylinder and the amount of oxygen content in the blend. As it is obvious from the Figure 8a, the exhaust smoke concentrations from the engine using WSOME100 were lower than the other test fuels for all engine speeds and WSOME blend fuels produced lower concentration than diesel fuel. The significant reduction in smoke emission for WSOME fuelled engine operation mode may be due to the oxygenated blends. Smoke is mainly produced in the diffusive combustion phase; the oxygenated fuel blends lead to an improvement in diffusive combustion for the biodiesel operation. These results are similar with the results obtained in previous studies [10, 11, 12, 13].

Combustion deposits formation

Figure 6 shows the CD build up in the cylinder head from the test fuels. It can be clearly seen that the CD for WSOME70 and WSOME100 operated engines are substantially lower than diesel-fuelled operated engine. The dark flat deposit is seen around the periphery of the cylinder head (Figure 5a). This area is where average temperatures are lower, promoting accelerated CD formation. WSOME blends produced less amount of CD compared with diesel fuel. Figure 7 also shows CD on piston top of the tested fuels. It can be clearly noticed that the CD formation for the WSOME- fuelled engines are substantially lower than diesel-fuelled engine.

Shown in Figure 8b are the CD weights on the cylinder head and piston tops of the test fuels. The differences in CD weights were found to be very small between diesel fuel and WSOME30. A reduction in CCD is observed with an increase in percentage of WSOME in the blend. WSOME70 and WSOME100 samples produced smaller amounts of CCD as compared to diesel fuel and WSOME30 samples. Lowest amount of deposits was recorded on WSOME100 fuelled engine. This may be due to more complete combustion resulted from the higher amount of oxygen in the WSOME. These results agree with those obtained by Agrawal et al. [14] who compared CD on cylinder head of biodiesel-fuelled engine after 512 h of engine operation.

Figure 9 presents scanning electron micrographs of diesel, WSOME30, WSOME70 and WSOME100 sample deposits. The diesel sample deposit is characterized by a relatively homogeneous appearance with plenty of tiny back particle materials (Figure 9a). These materials

become larger at the outer layer of combustion chamber suggesting agglomeration of small particle materials such as KCl which condensed on the surface of particles of more rich in silicates. WSOME-diesel blend

Figure 7 Carbon deposits on piston top after 40 h of engine operations

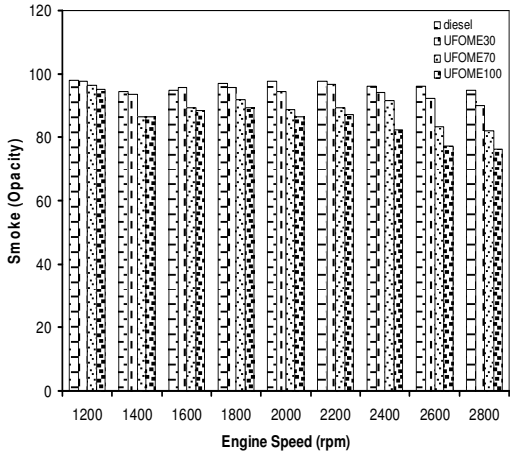

Figure 8a Effects of the WSOME on smoke

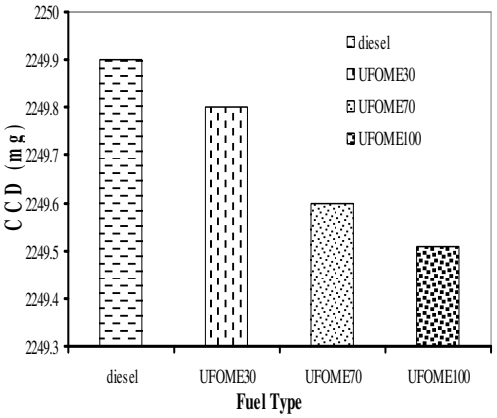

Figure 8b. Effects of fuel type on CD formation

WSOME resulted in more varied particle morphology (Figure 6c and 6d) with smaller particles, microspheres or agglomerates. WSOME and diesel have different portion of volatile and non-volatile matters. The non-volatile matter (carbon residue) in diesel is about 0.2% by mass, while in WSOME is approximately 0.36%. The larger amount of non-volatile matter in WSOME may cause the development of larger particles in WSOME30. On the other hand, the presence of oxygen in WSOME enables the reduction of soot particles in fuel rich regions. It was also observed that the deposits from diesel appear darker compared with WSOME-diesel blend deposits.

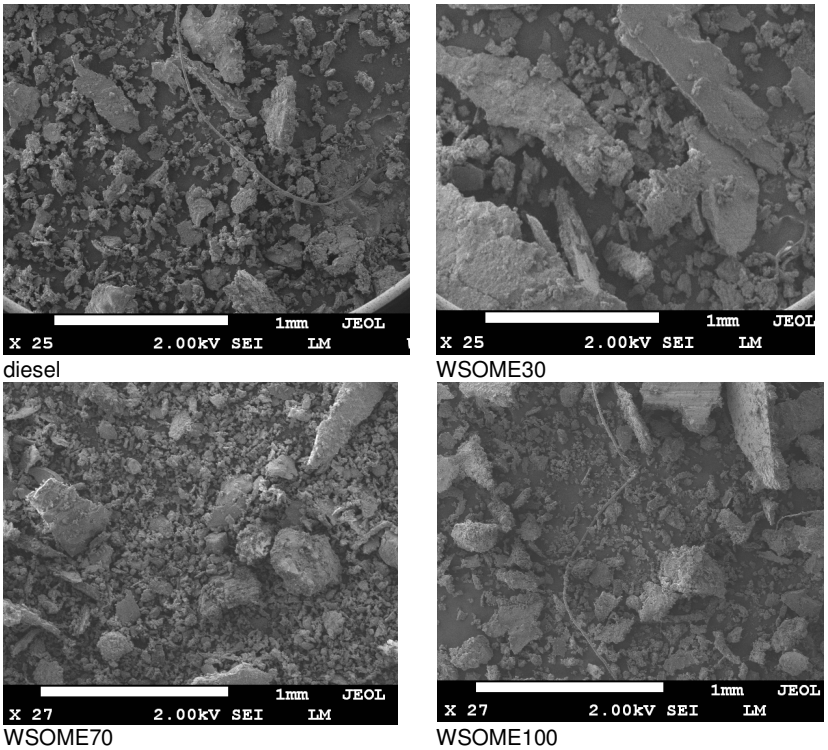

Figure 9. SEM micrograph of combustion chamber deposits for test fuels

CONCLUSIONS

The performance, emission and deposit characteristics of the diesel engine fuelled with the WSOME and its blends were investigated and the following conclusions can be drawn:

- WSOME/blends presented better brake thermal efficiency than diesel fuel. This is due to the higher density and lower heating value of the WSOME than that of diesel fuel. Increasing fuel density increases the energy content of the fuel brought into the engine at a given injector setting.
- Engine tests showed that the performance parameters of the WSOME/blends fuels did not differ greatly from those of diesel fuel. Slight power losses were experienced with the WSOME/blends fuels. This may be due to the lower heating value of the blends fuels.
- The engine operated on the WSOME100 and their blends resulted in higher NOx, HC, CO and lower exhaust smoke concentrations than the diesel fuel case.
- From the deposit characteristic results, it was found that the WSOME100 produced lowest fraction of carbon deposits as compared to diesel fuel and other WSOME blends fuels.

INTERFACIAL ENERGY AND ENERGY BALANCE IN WATER-IN-HEAVY-OIL EMULSIONS

V. Karcher, A. Bannwart*
State University of Campinas, Campinas-SP, Brazil

ABSTRACT. The aim of this study is to investigate the interfacial properties of water-in-oil (w/o) emulsions composed by water and a Brazilian heavy crude oil. For such purpose an experimental set-up was built in order to measure the different energy terms involved in the emulsification, including the interfacial energy of the emulsion being generated. Different w/o emulsions were prepared in a batch calorimeter by using a high-shear rotating homogenizer. Two experimental techniques were used, namely, the calorimetric method based on the energy balance for the emulsification and the standard method based on the measurement of the droplet size and distribution by means of a digital microscope. The uncertainties in the interfacial energy provided by both techniques were determined, in order to compare their feasibility. The main result is that the interfacial energy may be accurately determined from the drop size distribution and interfacial tension. The relative magnitudes of the different terms in the energy balance are established for the selected process.

INTRODUCTION

In the production operations for heavy crudes, water is commonly present within the oil phase as a finely dispersed phase. This situation may originate from the oil recovery method (e.g. water injection in the reservoir), presence of connate water inside the own reservoir [1, 2] and/or water injection in the production pipeline for friction reduction purposes. The turbulent shear associated with fluid flow within a pump, gas lift system and pipeline flow may cause the formation of water-in-oil emulsions (w/o). These remain stable for a long time, due the presence of naturally emulsifying agents in the crude oil phase, high oil viscosity and small droplet size. Thus, emulsion separation at surface facilities requires specific equipment which contribute to increase the production costs [2]. Besides, the viscosity of w/o emulsions is still higher than the viscosity of the heavy oil alone, with a typically non-Newtonian behavior [3, 4].

Oil-water emulsions can be encountered at many locations such as hydrocarbon reservoirs, well bores, pumps, production pipelines, surface facilities, refineries and at many stages during drilling, producing, transporting and processing of crude oils [2]. In oilfield, w/o emulsions are called 'regular', with drop sizes usually in the micron range. Oil-in-water emulsions (o/w) are termed 'inverse' or 'reverse'. In both cases their structure is complex and may include water-in-oil-in-water (w/o/w) or oil-in-water-in-oil (o/w/o) sub-systems [5].

It is well-known the influence of surfactant compounds naturally present in the crude oil itself on the stability of w/o emulsions. Crude oils, especially heavy oils, contain significant amounts of asphaltenes (high molecular weight polar components) and resins, both acting as natural emulsifiers

E-mail address: bannwart@dep.fem.unicamp.br

because of their active surface and structure-forming properties, which tend to accumulate at the interface and hence have pronounced effects on emulsion stabilization [5-7].
Interfacial properties of oil-water emulsions are strongly important to determine the mechanisms involved in their stability [6]. The process of emulsion generation, due to external forces such as shear, causes an increase in the total surface energy. However, there is a natural tendency for the coalescence of droplets to take place, which tends to reduce the total interfacial area and consequently the total surface energy [6, 7].
The dispersion of two immiscible fluids can be obtained by mechanical agitation. First, the interface is deformed and breaks up into many droplets under the action of shear or inertial forces in either laminar or turbulent flow. The droplet deformation is achieved if energy input creates a pressure differential of the same magnitude of Laplace pressure $2\sigma/R$ (where σ is the interface tension and R the radius of the droplet). This condition can be produced by intense agitation which requires a significant amount of energy [8]. However, it has been reported that only a small fraction of the energy input is spent in the increase of free energy of the interface [9, 10].
The intensity of agitation can be represented by the energy input per unit volume of mixture. For an emulsion prepared in an agitated vessel, not only the physical properties of the phases, but also the operational parameters affect the energy input. Earlier studies have investigated the behavior of the emulsion prepared mechanically in stirred vessels. Several correlations were proposed to determine the mean droplet size as a function of power input and operational parameters [10-13].
The objective of this study is to investigate the interfacial energy and the energy balance for w/o emulsions composed by distilled water and a heavy crude oil. Determination of the interfacial energy was based on the droplet size and distribution obtained by means of a digital microscope. An experimental set-up was built in order to measure the terms of the energy balance during the emulsion generation. The w/o emulsions were prepared in a calorimeter vessel in which a high-speed rotating impeller was inserted. The main result of this research is the determination of the relative magnitudes of the different terms in the energy balance during emulsification. The interfacial energy was compared with the energy provided by the impeller and the other terms of the energy balance.

EXPERIMENTAL SETUP AND PROCEDURE

The emulsions, composed by heavy crude oil (17 ºAPI) and distilled water, were prepared in water volume fractions of 0.1, 0.25 and 0.4 and stirrer speeds of 14000 and 22000 rpm. The total volume of the mixture (water and crude oil) was 90 cm³. Even for the water fraction of 0.4, coalescence was not observed in experiments.
Measured physicochemical properties of the crude oil are presented in Table 1. Measurements of surface/interfacial tension were carried out using an automatic tensiometer KSV Instruments, model Sigma 701. Oil-water interfacial tension was measured by the ring method and is provided in Table 2 at several controlled temperatures.
A specially designed calorimeter to determine the relative terms of the energy balance for the emulsification is shown in Figure 1. It consisted of a hermetically closed aluminum vessel of 100 cm³ capacity. The impeller of a homogenizer (IKA Ultra Turrax T18 Basic) was inserted into the vessel to disperse the fluids. A system of helicoidal fins of 1 mm in thickness with 5 mm pitch was machined externally to allow cooling of the stirred vessel by a water jacket. The ensemble was placed into a cylindrical 2 cm thick Teflon box to get good isolation.
The electric power input to the homogenizer was measured by means a wattmeter. The cooling water was supplied by a centrifugal pump, from a temperature controlled bath toward the calorimeter and returned to the same bath. Inlet (T_{inlet}) and outlet (T_{outlet}) temperatures of the coling jacket were recorded by using two platinum resistance temperature detectors (± 0.05 ºC). The internal temperature of the vessel ($T_{emulsion}$) was also recorded by a resistance temperature detector (± 2 ºC). The flow rate was controlled by valves and measured with a Coriolis mass flowmeter. All

the temperatures and water flow rate were collected and recorded by means of a LabView Signal Express data acquisition system (National Instruments). Thus the instantaneous heat transfer from the stirred vessel could be determined.

Table 1
Properties of Crude Oil

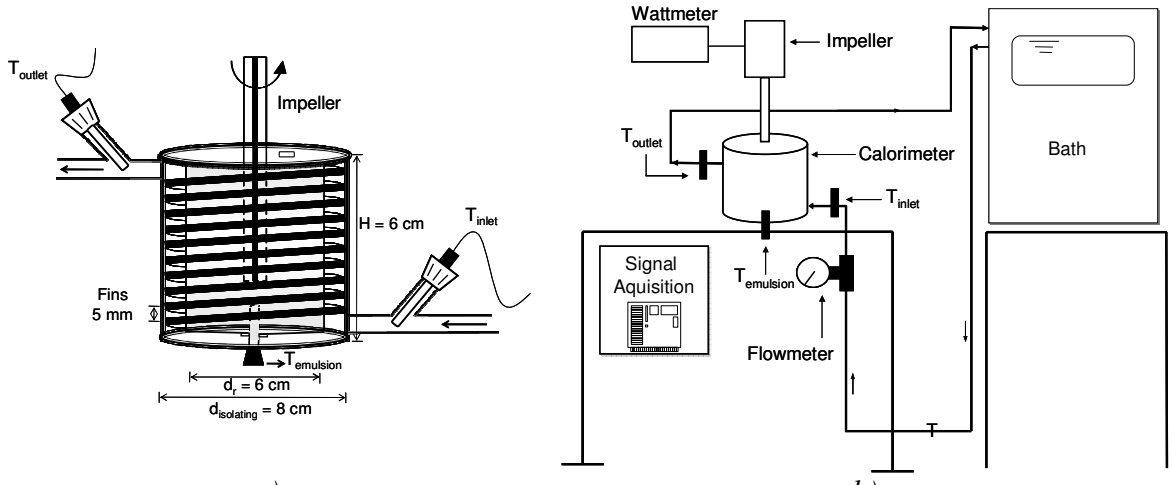
35	0.02632
45	0.02508



a) *b)*

Figure 1. *a)* Calorimeter and *b)* Experimental setup.

The experiments were performed at 25ºC in the beginning of the runs. Each run lasted approximately 12 minutes, which was far enough to homogenize the emulsion and attain a steady state operating condition. The uncertainty of experimental results depended, of course, on the accuracy of each instrument. To reduce the uncertainty in the cooling heat transfer, the water mass flow rate in the jacket was set to 300 g/min for all the experiments. Heat transfer uncertainties in the range of 5-8 % were obtained with this selection. The experiments were carried out in duplicates to ensure its repeatability.

Immediately after each emulsion generation experiment, six samples of the emulsion were withdrawn, placed between two slides and observed at the microscope (Coleman model NT 200 connected to a Sony 6.0 digital camera). A photograph was taken and analyzed in a laptop with specific image processing software (Image Tool) in order to measure the drop sizes.

INSTANTANEOUS ENERGY BALANCE

Considering the scheme of Figure2 the following energy balance can be formulated [14]:

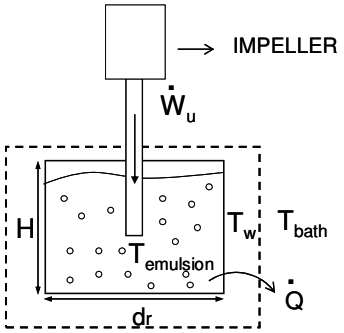


Figure 2. Schematic view of the emulsion generation experiment

$$\dot{W}_u = \dot{Q} + \left(\rho_1 \mathcal{V}_1 c_1 + \rho_2 \mathcal{V}_2 c_2 + m_{vessel} c_{vessel}\right) \frac{d\,T_{emulsion}}{d\,t} + \frac{d\left(u_i A_i\right)}{d\,t} + \frac{dE_k}{d\,t} \tag{1}$$

where $\dot{W}_u$ is the power transferred to the emulsion by the impeller; $\dot{Q}$ is the rate of heat transfer from the vessel, E_k the average kinetic energy of the emulsion (caused by the impeller), ρ_j is the density of phase (j = 1, 2 for oil and water respectively), $\mathcal{V}_j$ is the phase volume, c_j is the specific heat, m is the mass; $T_{emulsion}$ is the emulsion temperature, u_i the specific energy per unit of interface area and A_i the total interface area of the emulsion. Thermal resistance inside the vessel was neglected due to the strong internal convection caused by the impeller and, since aluminum is a very effective heat conductor, its temperature can be considered to be same as the emulsion. In steady equation (1) becomes:

$$\dot{W}_u = \dot{Q} \tag{2}$$

Thus, if the electric power input, $\dot{W}_{input}$, is known then the internal losses of the homogenizer are $\dot{W}_{input} - \dot{Q}$ and its efficiency η becomes :

$$\eta = \dot{W}_u / \dot{W}_{input} = \left[\dot{Q} / \dot{W}_{input}\right]_{steady\ state} \tag{3}$$

This efficiency can be assumed to depend on the rotation speed and fluid being stirred.
The specific interfacial energy of the emulsion is ruled by the interfacial tension [7]:

$$u_i = \sigma - T_i \frac{d\sigma}{dT_i} \tag{4}$$

where σ is the interfacial tension and T_i the interface temperature.
The interfacial area A_i can be related to the Sauter mean drop diameter, d_{32}, defined by:

$$d_{3,2} = \sum_{k=1}^{n} d_k^3 \Big/ \sum_{k=1}^{n} d_k^2 \tag{5}$$

through the relation:

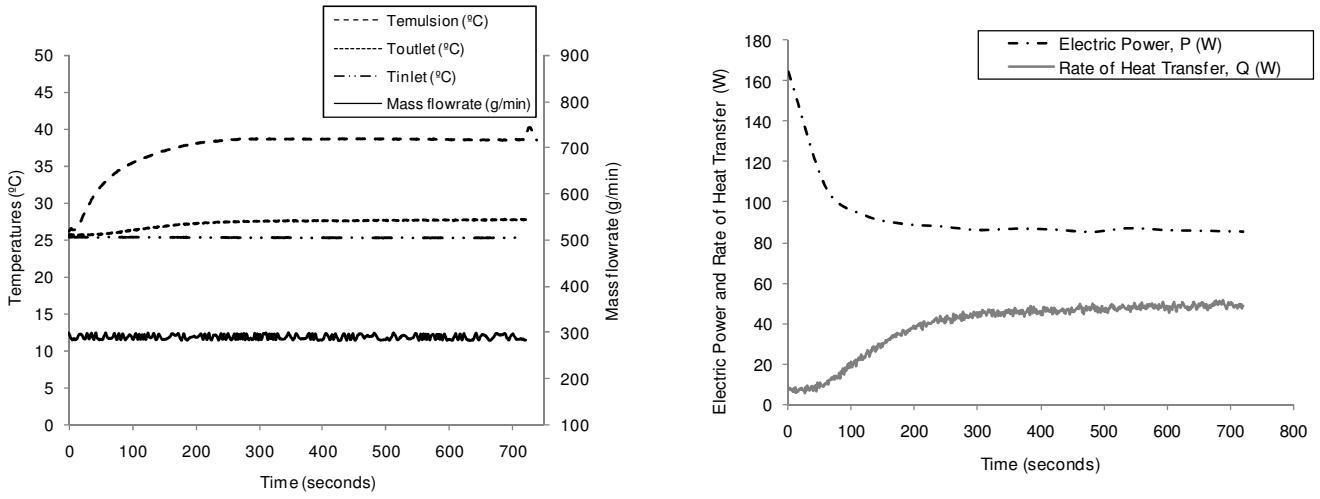
$$\frac{A_i}{\mathcal{V}} = \frac{6\alpha}{d_{3,2}} \tag{6}$$

where α is the water volume fraction in the emulsion. From equations (4) and (6) the interfacial energy per unit emulsion volume is:

$$\left(\frac{u_i A_i}{\mathcal{V}}\right)_{emulsion} = \frac{6\alpha}{d_{3,2}}\left(\sigma - T_i \frac{d\sigma}{dT_i}\right) \tag{7}$$

RESULTS AND DISCUSSION

Typical time evolutions of temperature, power input and cooling heat transfer are shown in Figure 3 for a water fraction of 0.1, 14000 rpm stirrer speed and a constant temperature 25 ºC in the water bath. Those results indicate that 12 minutes was enough to achieve steady state and are in agreement with the behavior of single phase tests, previously run in order to validate the system.



a) *b)*

Figure 3. Typical time evolutions of temperatures, power input and heat transfer.

In Fig 3a, at t = 0 sec, all the temperatures were 25 ºC, i.e. the same temperature of the water bath. Then the emulsion temperature grows continuously due to the shear produced by the impeller. This fact resulted in an increase of the outlet temperature of the water jacket. At the same time, the increase of emulsion temperature caused a decrease in its viscosity, thus the power input decreases. At t = 720 s the impeller was turned off, but a peak in emulsion temperature was noticed (Figure 3a). It can be attributed to the dissipation of kinetic energy of the emulsion due to the high speed induced by the stirrer; the kinetic energy was dissipated into heat causing an extra raise of approximately 3ºC in emulsion temperature.

It is clear in Figure 3 that the steady state was achieved at approximately t = 300 sec. In this run the final values of $\dot{W}_{input} \cong 86\,\mathrm{W}$ and $\dot{W}_u = \dot{Q} \cong 50\,\mathrm{W}$ are found. Table 3 summarizes the final values These results are in agreement with those obtained by other researchers e.g. [10].

The uncertainties in heat transfer were around 3 % and electric power input is 5 %. The average efficiency was 50 % for any experimental condition. Tests carried out with single-phase fluids (water, glycerin and crude oil), also provided the same average efficiency. It can be also noted in

Table 3 that the power input and heat transfer both increase as the rotation speed increases, for a given water fraction, as expected.

Table 3
Steady State Energy Balance Terms for the Emulsion Generation Experiments

Agitation speed (rpm)	Water volume fraction (%)	$\dot{W}_{input}$ (W)	$\dot{Q}$ (W)	$\dot{W}_{losses}$ (W)	η (%)
14000	0.1	86	48.3	37.7	56
	0.25	97.3	51	46.4	52
	0.4	95.5	51.8	43.7	54
22000	0.1	196	93	103	47
	0.25	203	102.7	100	51
	0.4	196.7	97.6	99	50

Integrating the above instantaneously measured energies between t = 0 and t = 720 s, gives the results shown in Table 4. Considering that the kinetic energy (E_k) was dissipated as heat, this term was calculated as an extra increase in internal energy (U) at the end of the run as explained above.

Table 4
Overall Energy Terms between t = 0 and t = 720 s

Agitation speed (rpm)	Water volume fraction, α	$W_u/\mathcal{V}\Big\|_0^{12}$ (J/cm³)	$Q/\mathcal{V}\Big\|_0^{12}$ (J/cm³)	$U/\mathcal{V}\Big\|_0^{12}$ (J/cm³)	$E_k/\mathcal{V}\Big\|_0^{12}$ (J/cm³)
14000	0.1	443.1	349.7	80.2	13.2
	0.25	442.7	321.1	103.2	18.3
	0.4	438.7	305.6	111.1	22.0
22000	0.1	813.2	702.7	96.6	14.0
	0.25	796.8	659.4	121.2	16.2
	0.4	828.6	658.3	147.6	22.6

It can be observed the energy cost to disperse two immiscible fluids is high, however about 80 % of such energy is dissipated into heat and only 20 % is expended to increase the total energy of the emulsion (internal energy, kinetic energy). The energy input increases with a increasing speed rotation. The increase in water content causes an increase in internal and kinetic energy and a decrease in heat transfer. The energy stored at the interface has a much lower magnitude and can not be accurately determined from integration of equation (1). Thus, this term was evaluated with the help of equation (7).

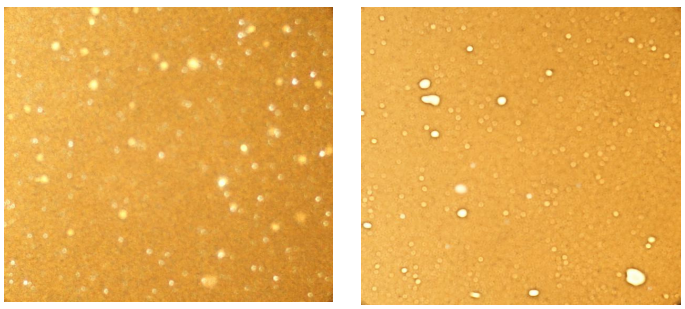


Figure 4. Micrographs of water-in-oil emulsions.

Figure 4 illustrates photographs of sampled w/o emulsions. Droplet size evaluation was accomplished from the micrographs obtained at the microscope. Through the images it could be concluded that the droplet sphericity could be considered as 1. The sizes of 500 – 900 droplets were measured and were distributed in 10 μm ranges. The histograms of Figure 5 show a log-normal distribution for all experiments. The polidispersity observed, mainly at 14000 rpm, may be related to high viscosity of continuous phase and non-uniformity in shear distribution within the emulsion which tends to cause a larger distribution of droplet sizes.

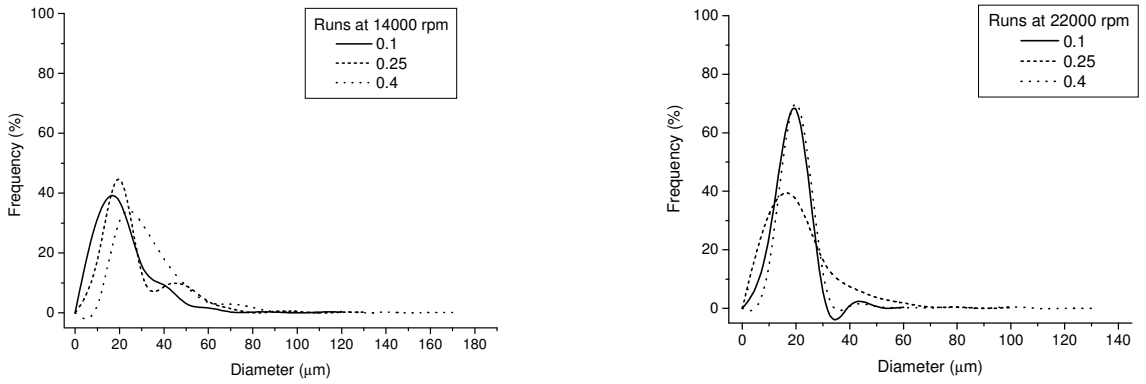

Figure 5. Histograms obtained from experimental runs.

Table 5 summarizes the values of the Sauter, mean, maximum and minimum drop diameters. Through this table the differences between the techniques become clear. The Sauter mean diameter, used in studies related to interface phenomena is significantly higher than the mean diameter. The standard deviations of different runs were around to 30 %, and can be attributed to poli-dispersed distribution of droplet sizes.
It can be observed that d_{32} decreases with increasing rotation speed at a given water fraction, as expected, and increase with increasing water fraction at a given rotation speed. The same trends are reported by other authors [12].

Table 5
Comparison between Different Definitions of Average Drop Size

Speed Agitation	Water Volume Fraction	d_{32} (μm)	Mean diameter (μm)	Mininum diamter (μm)	Maximun diameter (μm)
	0.1	45	18	3	113
14000 rpm	0.25	50	23	4	121
	0.4	60	30	8	163
	0.1	21	14	3	57
22000 rpm	0.25	37	18	3.5	92
	0.4	42	16	2	132

Figure 6 shows that interfacial tension (σ) decreases with increasing temperature, reproducing the commonly accepted result. The specific interfacial energy, u_i, was obtained from equation (4) and is also shown in Figure 6. The term $d\sigma/dT$ was determined by curve fitting of the data in Table 2 using a third degree polynomial. It is interesting to note that the specific interfacial energy is significantly higher than the interfacial tension and increases with increasing temperature. This is due to the second term of the r.h.s. of equation (4), which represents the thermal contribution to u_i .

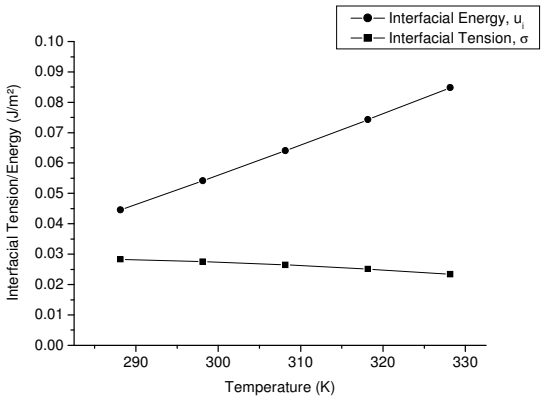

Figure 6. Interfacial tension and specific interfacial energy versus temperature.

The interfacial area per unit volume as calculated from equation (6) is shown in Table 6. This quantity clearly increases with increasing agitation speed and water volume fraction, as expected. The obtained values are much higher than reported in other studies; the difference may be attributed to the higher speed of the impeller used in the present study.

The interfacial energy per unit volume, $u_i A_i/\mathcal{V}$, is also shown in Table 6. This energy also depends on the specific interfacial energy which is related to the final temperature of each experiment. Their values range from 0.09 to 0.26 J/cm³, which represent a very small fraction of the total energy per unit of volume provided to the emulsion (Table 4.

Table 6
Total Interfacial Area and Interfacial Energy per Unit Volume of Emulsion, $u_i A_i/\mathcal{V}$

Speed Agitation	Water Content	$A_i/\mathcal{V}$ (m^{-1})	$u_i A_i/\mathcal{V}$ (J/cm³)
	0.1	13 000	0.09 ± 0.03
14000 rpm	0.25	31 000	0.22 ± 0.05
	0.4	42 000	0.26 ± 0.05
	0.1	30 000	0.22 ± 0.09
22000 rpm	0.25	42 000	0.20 ± 0.05
	0.4	58 000	0.10 ± 0.03

CONCLUSION

In this study the different terms of the energy balance during the generation of a water-in-oil emulsion in laboratory were measured. The method used for emulsion generation was that of shearing the emulsion with a high speed impeller in a hermetically closed vessel. The measured terms include: impeller work, heat transfer, internal energy, kinetic energy and interfacial energy. The later term was very small and could only be determined from drop size information (Sauter diameter) and interfacial energy data. Uncertainties in all energy terms except interfacial energy where within 8 %, whereas for interfacial energy it reached 30 %. The stirring method provided high kinetic energy dissipation in the vessel. From the energy provided to the emulsion about 80 % was converted into heat, and just 20 % caused a change in internal and kinetic energies (this transformed into internal energy by dissipation after the impeller was turned off). This energy partition is due to the highly dissipative nature of the method used for emulsion generation.

It was observed that the Sauter mean diameter decreases with increasing agitation speed and increases with increasing water fraction. A high average interfacial area (~ 30000 m^{-1}) was found due to the high speed of the impeller in comparison with conventional devices.

Despite the relatively high interfacial area per unit volume, the interfacial energy per unit of volume obtained was roughly 0.20 J/cm³ for both rotation speeds, which represents a vanishing fraction of the energy provided to the emulsion (440 J/cm³ at 14000 rpm and 800 J/cm³ at 22000 rpm). This means that the energy required to disperse two immiscible fluids is very high, but just a very small portion of it will be expended to creation of further interfacial area,

INTERACTION BETWEEN TWO NEIGHBOURING GAS BUBBLE COLUMNS - MODELLING AND EXPERIMENTAL INVESTIGATION

R. Mosdorf*, K. Jagielski
Białystok Technical University,
15-351 Bialystok, ul. Wiejska, Poland,

ABSTRACT. In the paper the results of simple experiment of investigation of interaction between two neighboring bubble columns have been presented. The video recorded by high speed camera has been used to determine the bubbles departure frequency and theirs paths and velocities. The process of mixing neighboring bubble columns has been observed. To explain this phenomenon the simulation of gas bubble movement in the liquid has been made with using the stabilized finite element method (FEM) and level set method. The interaction between two columns with different spacing between columns and different location of bubbles has been discussed. It has been shown that when vertical locations of bubbles in neighboring columns are different and the distance between columns is small then bubbles located higher attract bubbles from the neighboring column. Finally two columns attract each other and form the single bubble column.

Keywords: Bubbles, bubble columns interaction, FEM, level set.

INTRODUCTION

The knowledge of bubble and bubble columns dynamics is of key importance in industrial applications such as aeration, fermentation, saturation, homogenisation, degassing, fluidization, smelting, froth flotation, boiling, etc. Despite of numerous experimental and theoretical investigations a reliable model even for the simplest case of single bubble formation still remains a formidable task. The investigations of the hydrodynamic behavior of bubble columns involve both the large-scale phenomena and the local phenomena. The local phenomena refer to the dynamic of single bubble, the large-scale phenomena are connected with the flow regime around the bubble column.

Numerous modelling studies have been conducted on the bubble formation from a single orifice or nozzle submerged in liquids [1, 2-5], among others. The basis of many theoretical models is in the assumption that the bubble is spherical and by application of a force balance acting on the bubble due to the main effects of buoyancy, surface tension, gas momentum effects and liquid inertia effects the motion of the bubble can be predicted. Lately, in [6] a comprehensive model has been presented that takes into account instantaneous interactions between successive bubbles as well as incorporates the wake effect of the previous bubble. Furthermore, it is known that the volume of the gas chamber connected to the orifice (nozzle) is an important factor in determining the initial bubble size and frequency of bubble emission. Two limiting modes of bubble formation are distinguished: constant flow rate regime (CFRR) and constant pressure regime (CPR). The CFRR can be obtained by imposing a strong restriction between the settling chamber and the injection point, in such a way that the incoming flow of the bubbles will be controlled and therefore be constant [7, 8, 9]. The CPR occurs whenever the chamber volume is sufficiently large and the pressure in the gas chamber is maintained constant. With progression of time and the extent of bubble formation, the pressure drop across the

* Corresponding author: dr hab. inż. R. Mosdorf

E-mail address: mosdorf@ii.pb.bialystok.pl

orifice (nozzle) varies and thereby results in a non-constant flow rate. In [10] has been suggested that the bubbles are formed under CFRR provided that the orifice Reynolds number is larger than 1000, and CPR prevails for orifice Reynolds number smaller than 1000. Lately, it has been stated [9], that it is impossible to obtain a CFRR, even using a sonic hole.

According to [11] bubble motion and bubble shape are controlled by deterministic forces, such as body force and drag force caused by the convective motion, and the complex and non-linear input of the liquid motion including wake and turbulent motion surrounding the bubbles. Therefore new approaches based on fractal and deterministic chaos analyses have been applied to investigate the complex phenomena of multi-phase systems [12-14]. The concept of non-linear dynamics systems has also been applied to study chaotic features of gas bubbling from a single nozzle (orifice) [11, 15- 19].
When the distance between nozzles is relatively large then bubble motion in each column is independent of the processes occurring in the neighbour column. The bubble flow in column depends only on the hydrodynamic forces occurring inside the column. Therefore the single bubble column can be treated as the dynamical system with complex properties. Behaviours of this system can be periodic or chaotic as it has been shown in papers [6,17-19]. When the distance between nozzles become smaller then the bubble motion in each column depends on processes occurring in neighbour column. The paths of the bubbles from neighbouring columns cross each other and finally create the common bubble column. For investigation of the dynamic of bubble columns it is necessary to track paths of bubbles emitted from all nozzles.

The main aim of the paper is to test the method of estimation of bubble velocities and bubbles departure frequency basing on the high speed video with using the cheep camera Casio EX FX1. The investigation presented in the paper has a preliminary character. The investigation is the first phase of preparing the special software for automatic investigation of dynamic of bubbles in interacting columns. In the paper the preliminary results of experimental investigation of bubble velocities in the interacting bubble columns have been presented. The simple model based on the stabilized finite element method and level set method has been used to investigate the liquid velocity structure in interacting bubble columns.

PRELIMINARY EXPERIMENTAL INVESTIGATION

The main aim of experimental investigation is to test the method of estimation of bubble velocities and bubbles departure frequency basing on the high speed video. It has been tested usability of the cheep camera Casio EX FX1(1200 fps) for identification of bubble departure frequency and movement.

In the experiment the air bubbles motion in the tank (40cmx50cmx5cm) filled with distillated water has been investigated. The bubbles were generated from 5 mm diameter plastic nozzles. The behavior of bubbles in case of spacing between nozzles in the range of 6-30 mm has been investigated. Each nozzle had its own simple air supply system. In the air supply system the aquarium air pumps has been used. The observation of the single bubble trajectory has been used to estimate bubble velocity.

The typical behavior of interacting bubble columns has been presented in Figure 1. Bubbles departing from neighboring nozzles attract each other and finally form a common bubble column located between twin nozzles. The bubble motion in this column is characterized by the large oscillation of bubbles horizontal location.

In Figure 1d the reconstruction of bubble path in case of two columns interaction has been shown. This is reconstruction of the path of bubble departing from the left nozzle. This path may be divided into three parts are schematically shown in Figure 1d. In the area ‘1’ the bubble is moving into direction of neighbour column. In the area ‘2’ bubbles from two nozzles move straight up forming the common bubble column. In the area ‘3’ bubbles in single column become separate because of horizontal movement of the bubbles.

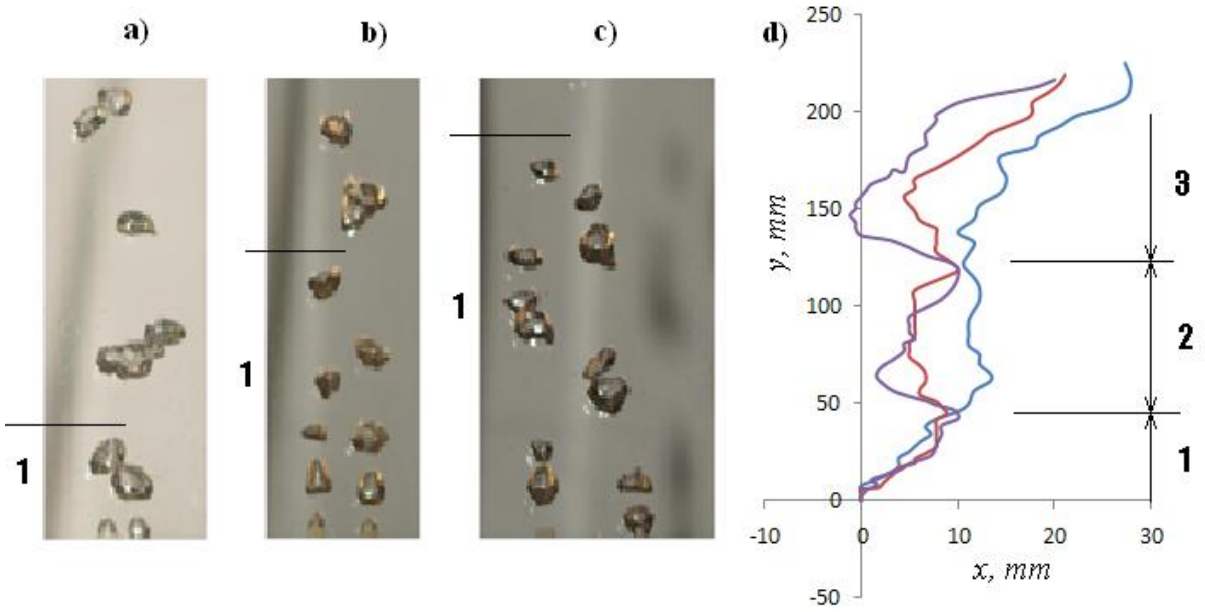

Figure.1. Interacting bubble columns for different spacing between nozzles. a) 6 mm. b) 12 mm. a) 26 mm. d) Paths of single bubbles.

For a single isolated spherical bubble, the terminal velocity can be estimated using formula [23]:

$$u_\infty = 0.707\sqrt{g d_e} \tag{1}$$

where g is the gravity acceleration, d_e is an equivalent bubble diameter (diameter of a sphere with the same volume as the bubble) can be predicted by the following equation [24]:

$$d_e = 2\left[\frac{\sigma R_o}{g(\rho_l - \rho_g)}\right]^{1/3}, \tag{2}$$

σ is the surface tension of water, R_o is the radius of the gas nozzle, ρ_l is the density of liquid and ρ_g is the density of gas.

For water and air bubble the terminal velocity calculated with using equation (1) is equal to 198 mm/s.

The bubbles vertical velocity has been calculated with using the recorded video. The example of results has been shown in Figure 2. The bubble departure frequency in case of single nozzle was about 11 bubbles/s and in case of twin nozzles - 30 bubbles/s for each nozzle. In Figure 2a it has been shown the vertical velocity of single bubble in single bubble column presented in Figure 2c, where the tracking bubble was marked with a red circle on the beginning and the end of the recorded path. In Figure 2b it has been shown the vertical velocity of separated single bubble mowing up when two bubble columns interact. The tracked bubble has been shown in Figure 2d.
In both mentioned cases vertical velocities of bubbles are greater than terminal velocity calculated using equation (1). It happens because the equation (1) calculates the velocity in stagnate liquid but the bubbles which are moving in the column create the liquid circulation around the column, finally they flow in moving liquid. The measured velocity is a sum of liquid velocity and bubble velocity in liquid.

In the common bubble column created by bubbles departing from two nozzles the standard deviation of horizontal velocity of bubbles is greater than in case when bubbles depart from the single nozzle. The mean standard deviation of vertical bubble velocity in the column from single

nozzle (Figure 2c) is equal to 70 mm/s, while in case of common bubble column (Figure 2d) it is equal to 120 mm/s.

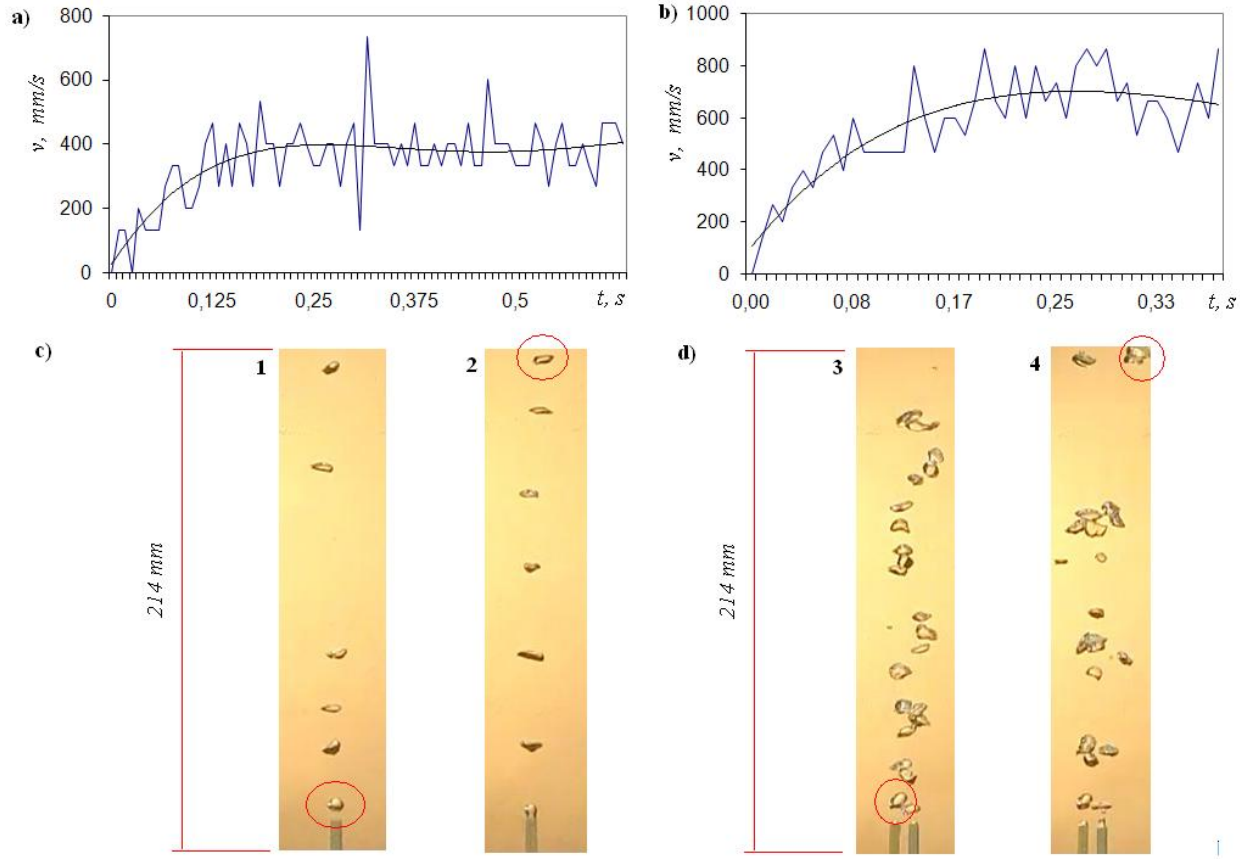

Figure.2. The vertical velocity of air bubbles. a) The vertical bubble velocity changes in time in case of single nozzle. b) The vertical bubble velocity changes in time in case of twin nozzles. c) bubble location at the beginning and the end of the bubble motion in case of single nozzle. d) bubble location at the beginning and the end of the bubble motion in case of two nozzles. Bubble departure frequency in case of single nozzle is 11 bubbles/s and in case of twin nozzles - 30 bubbles/s for each nozzle. The nozzles diameter is equal to 5 mm, the equivalent bubble diameter is equal to 6.7 mm, distance between two nozzles is equal to 14 mm.

MODELLING OF GAS BUBBLES INTERACTION

The simulation of gas bubble movement in liquid has been made with using the stabilized finite element method and level set method. The time-dependent COMSOL Multiphysics solver [20] with streamline diffusion (Petrov-Galerkin/Compensated, tuning parameter equal to 0.25) has been used for solving 2D Navier-Stokes equations [20]:

$$\rho\left(\frac{\partial \vec{u}}{\partial t}+\vec{u}\cdot\nabla\vec{u}\right)-\nabla\cdot\left[\mu\left(\nabla\vec{u}+\nabla\vec{u}^{T}\right)\right]+\nabla p=\sigma\kappa\vec{n}\delta+\rho\vec{g}$$
$$\nabla\cdot\vec{u}=0 \qquad (3)$$

In the level set method the zero level set at $\varphi = 0$ determines the position of the interface. The changes in time of level set function φ have been described by the following equation [21]:

$$\frac{\partial \varphi}{\partial t} + \vec{u} \cdot \nabla \varphi = 0 \tag{4}$$

In the simulation the fluid density has been described by the following equation [21]:

$$\rho = \rho_g + H(\varphi) \cdot (\rho_l - \rho_g) \tag{5}$$

where $H(\varphi) = \begin{cases} 0 & if \quad \varphi < 0 \\ 1 & if \quad \varphi > 0 \end{cases}$

Under the evolution of equation (4), the values of the level set function that are close to zero may move with velocities different than those of the zero values of level set function. Therefore, the φ distance field gets distorted ($|\nabla \varphi|$ becomes different than 1). In this case the gas volume changes during the simulation. The re-initialization of the level set function in regular intervals in order to rebuild the signed distance function is necessary. The direct application of re-initialization procedure in the Comsol solver is difficult because of their small ability to modification of solving procedure. Therefore the Comsol proposes a slight modification of equation (6) by adding the diffusion at the interface to maintain the bubble volume during the simulation. Finally, the following equation:

$$\frac{\partial \varphi}{\partial t} + \vec{u} \cdot \nabla \varphi = \delta(\varphi) \cdot \nabla \cdot (D \nabla \varphi) \tag{6}$$

has been solved instead of equation (6) [20].

The simulation has been made for air and water: ρ_l = 1000 kg/m^3, ρ_g = 1 kg/m^3, σ = 0.07 N/m, g = 10 m/s^2, μ = 0.075 Pa·s. The two dimensional air bubbles flow in tank (60 mm*60 mm) filled with water has been considered. The area of container has been divided into square elements (80*80). The velocity and pressure has been set to zero at t = 0. Boundary settings: no-slip conditions, u = 0, have been used on boundary of liquid container.

In Figure 3 it has been shown the results of simulation of bubble flow in two neighboring bubble columns, each one containing two bubbles. It has been considered two initial spacing between columns. The grey area indicates where the vertical velocity of liquid is greater than zero. When the spacing between columns is enough large (Figure 3a) then the liquid between columns flows down. In case of small spacing between columns (Figure 3b) the structure of liquid flow between bubbles becomes complex and liquid between columns flows up.

In Figure 4 it has been shown the time evolution of two initial location of bubbles in neighboring columns. In Figure 4a and b the initial horizontal locations of bubbles in columns are different. Finally, after the time 0.1 s two bubbles in the right column join and all bubbles start to form common bubble column. This process has been observed in the experiment. In Figure 4c and d the initial locations of bubbles in columns are the same. Finally, after 0.1 s bubbles in both columns join and new bubbles start to repeal. The area of liquid between bubbles where liquid flows down (Figure 4d) is responsible for bubbles repealing. This area disappears when initial locations of bubbles are different in both columns (Figure 4b).

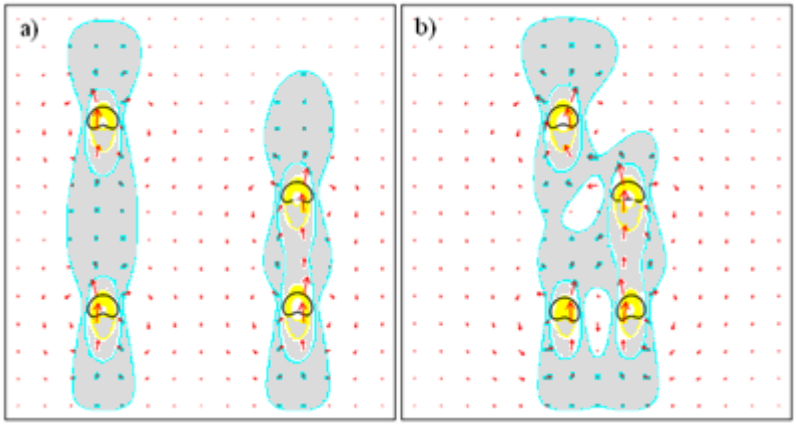

Figure.3. Liquid velocities in two interacting bubble columns. a) Distance between columns is equal to 25 mm. b) Distance between columns is equal to 15 mm.

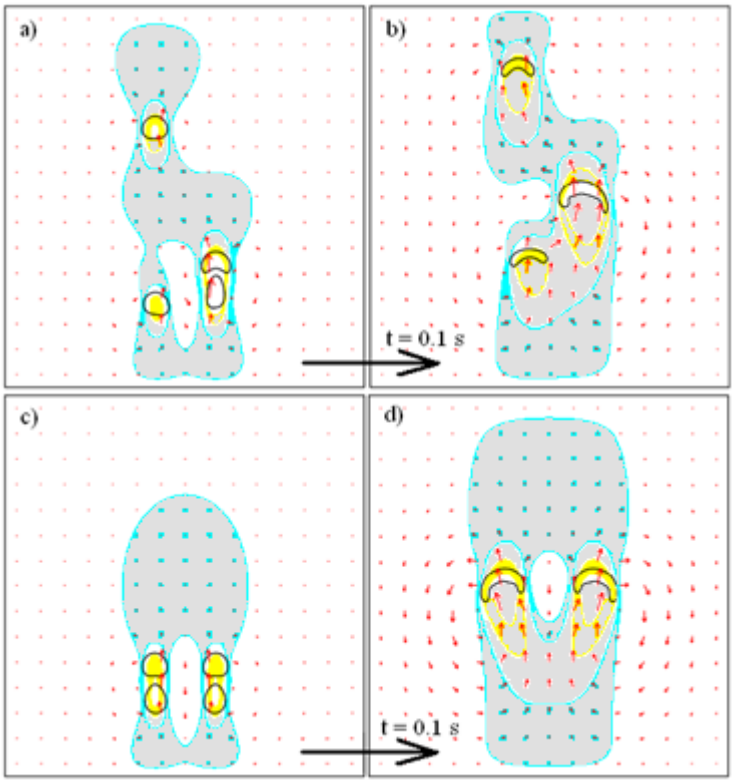

Figure.4. Bubbles displacement in 0.1 s. a), b) Creation of single bubble columns. c), d) Increasing distance between bubbles.

CONCLUSIONS

In the paper the results of simple experiment of interaction between two neighboring bubble columns has been presented. The video recorded by high speed camera has been used to determine the bubbles departure frequency and bubble paths and velocities. It has been found that bubble paths may be divided into three parts. In the first part the bubbles are moving into direction of neighbour column, in the second one the bubbles are forming the common bubble column. In the third one the bubbles movement in common column becomes instable. It has been found that the vertical velocity of bubbles was greater than terminal velocity of bubble in the stagnate liquid.

For explanation of the mechanism of mixing the neighboring bubble columns the simulation of gas bubble movement in the liquid has been made with using the stabilized finite element method (FEM) and level set method. It has been shown that when vertical locations of bubbles in neighboring columns are different then higher located bubbles attract bubbles from neighboring column. Finally, the columns attract each other and form the common bubble column.

The investigation presented in the paper have a preliminary character.

ABSTRACT. Paper deals with analysis of application of two-phase ejector as a second stage compressor in refrigeration compression systems. The thermodynamic reason for the efficiency improvement due to application of the ejector is effect of difference in compression work for liquid and vapour phases. The own approach of the calculation of the compression-ejector refrigeration cycle has been proposed in the paper. This approach is based on the set of two performance characteristics: one for the ejector and the second one for the rest of the refrigeration installation. On the basis of the above approach the limiting conditions of operation of the systems have been established for selected refrigerants. It has been showed that possible increase of coefficient of performance of the system strongly depends on the entrainment ratio of the two-phase ejector.

Keywords: *refrigeration cycle, ejector, two- phase flow, compression*

COMPRESSION – EJECTION REFRIGERATION SYSTEM

The paper deals with aspects of application of two-phase ejector as a second stage compressor in refrigeration compression systems. The schematic of the investigated system is presented in Figure. 1. Vapour compressed in the mechanical compressor is sucked by the ejector. The motive fluid in the ejector is liquid delivered by a mechanical pump. The presented configuration is totally novel approach for improving of the efficiency of the refrigeration systems by means of two-phase liquid-vapour ejector. This configuration was proposed and patented by Bergander [1,6].

The thermodynamic reason for the efficiency improvement is effect of difference in compression work for liquid and vapour phases. Therefore increasing the efficiency of the standard single-stage vapour compression cycle is caused through a reduction of mechanical compression at the expense of harnessing kinetic energy of vapour in the ejector device.

The compression-ejection cycles in *p-h* and *T-s* diagrams are presented in Figure. 2. The suction point 1 is located at the saturation line. However, there is no obstacles to take into consideration also superheating of the sucked vapour in the analysis. The isentropic compression process in the mechanical compressor was assumed in these charts. However, the internal efficiency of the mechanical compressor has been included in the analysis presented in this paper. The only reason the isentropic process was chosen is the problem with the appropriate representation of the discharge parameters from real mechanical compressors in refrigeration systems. Moreover assumption of the isentropic compression process in the mechanical compressor is the common approach made in the calculations of the compression refrigeration systems.

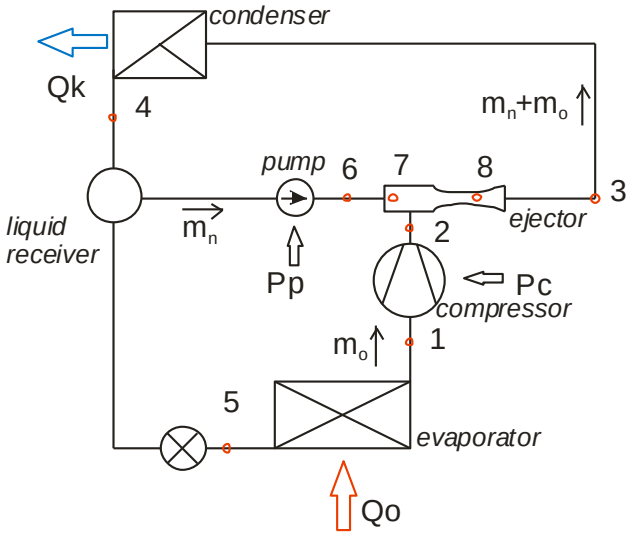

Figure. 1. Schematic of refrigeration compression system with two-phase ejector as a second stage compressor.

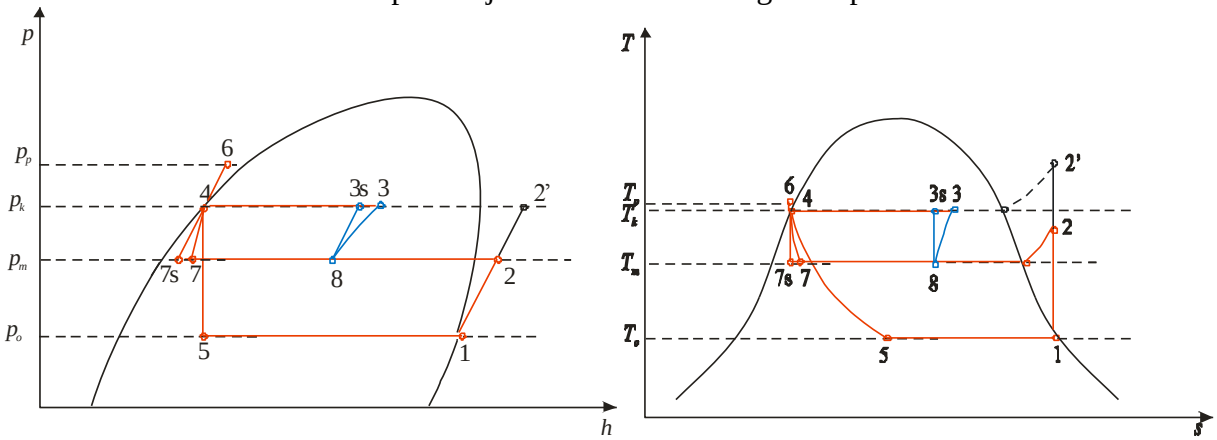

Figure. 2. Compression-ejection cycle of the system presented in Figure. 1.

Important feature of the system is two additional pressures, i.e. inter-stage pressure p_m and corresponding inter-stage saturation temperature T_m, as well as pump motive pressure p_p and liquid phase temperature T_p. Therefore the discharge of the mechanical compressor in the discussed system is represented by point 2 while in classic one-stage system the discharge will be located at the point 2'.

The next assumption made in Figure. 2 deals with liquid parameters at the outlet of the condenser. No subcooling was taken into account in these charts. Therefore liquid state is represented by point 4 located at the liquid saturation line. Isentropic process of liquid compression was assumed in Figure. 2. If the expansion process of the liquid phase occurs isentropically then the outlet of the ejector motive nozzle is represented by the point 7s. Taken into account efficiency of the motive nozzle – real outlet is located at the point 7. In most practical cases wet vapour may be expected at the outlet of the motive nozzle as the flashing process will occur. The quality of the vapour emanating from the motive nozzle depends on the nozzle efficiency as well as possible liquid subcooling for the given operation pressures in the system.

A good representation of the operation of the ejector at the thermodynamic charts is by no means a simple task as a combination of compression and mixing processes occur at the mixing chamber simultaneously. Therefore processes occurring inside the mixing chamber of the ejector may be presented by assumed representation process lines. In Figure. 2 common approach was applied: the mixing process and compression process due to momentum exchange were separated. Moreover,

the mixing process is assumed as the isobaric process of the discharged vapour from mechanical compressor 2 and fluid expanded in the motive nozzle 7. Therefore the mixing process 7-8-2 was assumed in Figure. 2. Compression process due to momentum and energy transfer between motive fluid and secondary fluid (vapour discharged form mechanical compressor) is represented by compression line 8-3s for the ideal case of isentropic compression and 8-3 for real compression in the mixing chamber and the diffuser. At this stage of research the possible discussion on share of the compression process between mixing chamber (due to momentum and energy transfer between motive and secondary streams) and the diffuser (due to increasing of cross-section area) is not possible, and moreover there is no clear need for it. Location of point 8 as well as point 3 depends on the entrainment ratio of the ejector which is not visible in the thermodynamic charts.

Condensation process is represented by line 3-4. It means that wet vapour enters the condenser. Liquid phase flows to the receiver and then is delivered to pump to motive the ejector and main part of the liquid is delivered to the expansion valve feeding the evaporator. The operation of the evaporator (process line 5-1) should not be affected by reorganisation of the system due to two-phase ejector. The saturated vapour at the evaporator outlet was assumed. However, in the case of feeding of the evaporator by means of the thermostatic expansion valve superheated vapour enters the mechanical compressor. This may be included in the analysis without any obstacles.

COMPRESSION-EJECTION CYCLE ANALYSIS

The general purpose of this paper is to provide with rational methodology based on which it is possible to assess possible improvement of the *COP* due to application of the second stage compression in two-phase ejector in compression refrigeration system. Moreover, there is a clear need to apply such methodology in order to establish the range of the operation parameters of the refrigeration system in order to establish a preliminary geometry of the two-phase ejector and the pump performance.

The proposed approach is based on the set of two performance characteristics: one for the ejector and the second one for the rest of the refrigeration system, as it was depicted in Figure. 3. The operating parameters of the whole system can be determined then by the intersection of these two characteristic lines. This is the very similar method as in the case of the well known calculation procedure of the pressure rise and liquid flow rate of the pump system. The similar approach has been applied by the authors for the case of two-phase ejector as a booster compressor in refrigeration systems [2,3]. However, in the case of the discussed system the configuration is completely different and this methodology has to be applied taken into consideration the specific system features.

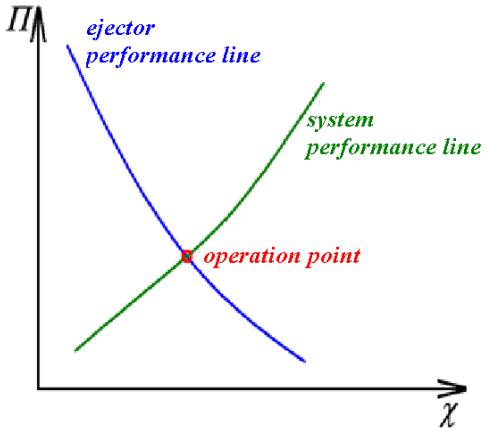

Figure. 3. Idea of the performance line approach: Π is the dimensionless compression ratio, see eq. (21); χ is the volumetric entrainment ratio.

It necessary to define the main operation parameters and classify them as fixed for the discussed application and parameters dependent on the ejector operation. The following quantities are assumed as fixed for given application of the refrigeration system:

- evaporation temperature t_o and corresponding evaporation pressure p_o (because of saturated state in the evaporator);
- condensation temperature t_k and corresponding condensation pressure p_k (because of saturated state in the condenser);
- refrigeration capacity $\dot{Q}_o$;
- vapour superheating at the outlet of the evaporator ΔT_o and condensate subcooling at the outlet of the condenser ΔT_k.

The internal efficiency of the compressor η_{ci}; mechanical efficiency of the compressor η_{cm}; and liquid mechanical pump efficiency η_p have to be also treated as known quantities. There are assumed as constant in this paper. The following cycle points can be established unambiguously on the basis of the above parameters (see Figure. 2): 1, 4, 5, and 2'. If so, then the mass flow rate through the evaporator is also known as (see Figure. 1):

$$\dot{m}_o = \frac{\dot{Q}_o}{h_1 - h_5}. \tag{1}$$

The following quantities depend on the operation of the ejector and pump, i.e. depend on the performance which is not known:

- inter-stage pressure p_m and corresponding inter-stage temperature t_m (because of saturated state in the mixing chamber and the diffuser of the ejector at the thermodynamic equilibrium conditions);
- pump discharge pressure p_p (discharge temperature t_p of liquid depend on the efficiency of the pump and may be calculated on the basis of the discharge pressure);
- motive liquid mass flow rate $\dot{m}_n$ flowing through the pump.

The rest of the characteristic cycle points may be predicted on the basis of the above parameters: 2, 6, 7s, 7, 8, 3s and 3. Therefore:

$$h_2 = h_2(p_m);\ h_6 = h_6(p_p);\ h_{7s} = h_2(p_m, p_p);\ h_7 = h_2(p_m, p_p); h_8 = h_8(p_m, p_p, \dot{m}_n);\ h_3 = h_3(p_m, p_p, \dot{m}_n).$$

These points may be calculated only the performance of the ejector is known. The specific theoretical power consumption by the mechanical compressor:

$$P_{tc} = \dot{m}_o(h_2 - h_1), \tag{2}$$

as well as theoretical power consumption by the mechanical pump:

$$P_{tp} = \frac{\dot{m}_n}{\rho_4}(p_p - p_k). \tag{3}$$

The actual power consumptions may be calculated as follows:

$$P_c = \frac{1}{\eta_{ci}\eta_{cm}} P_{tc}, \tag{4}$$

and

$$P_p = \frac{P_{tp}}{\eta_p} = \frac{1}{\eta_p}\frac{\dot{m}_n}{\rho_4}(p_p - p_k). \tag{5}$$

The coefficient of performance of the whole system is defined as follows:

$$COP = \frac{\dot{Q}_o}{P_p + P_c}. \tag{6}$$

Note that all above quantities cannot be calculated without specific knowledge about the operation of the ejector.

ANALYSIS OF EFFICIENCY INCREASE DUE TO EJECTOR APPLICATION

The general reason for application of the ejector in compression system in the discussed configuration (see Figure. 1) is possible increase of the *COP* defined by eq. (6). It may be assumed that in the case of classic compression system the following system efficiency can be defined:

$$COP_c = \frac{\dot{Q}_o}{P_{cc}}, \tag{7}$$

where the power consumption by the compressor in classic compression system is equal to:

$$P_{cc} = \frac{1}{\eta_{ci}\eta_{cm}} \dot{m}_o \left(h_{2'} - h_1\right), \tag{8}$$

The following condition for increase of the system efficiency can be established:

$$P_{cc} - P_c > P_p, \tag{9}$$

so the following relationship can be found:

$$\frac{1}{\eta_{ci}\eta_{cm}} \dot{m}_o \left(h_{2'} - h_2\right) > \frac{1}{\eta_p} \frac{\dot{m}_n}{\rho_4} \left(p_p - p_k\right). \tag{10}$$

Now it is possible to introduce the entrainment ratio:

$$U = \frac{\dot{m}_o}{\dot{m}_n}, \tag{11}$$

the efficiency modulus:

$$E = \frac{\eta_{ci}\eta_{cm}}{\eta_p}, \tag{12}$$

as well as thermodynamic dimensionless work potential:

$$W = \frac{p_p - p_k}{\rho_4 \left(h_{2'} - h_2\right)} = W\left(U, p_m, p_p\right). \tag{13}$$

Therefore the condition for the system efficiency increase is as follows:

$$\frac{1}{E} \frac{U}{W\left(U, p_m, p_p\right)} > 1. \tag{14}$$

Note that from direct relationship describing specific enthalpies *W* does not depend directly on *U*. However, because compression produced by the ejector depends on *U*, therefore the dimensionless work potential has to depend on *U*. If the theoretical case is considered for isentropic processes, then $E = 1$, and the following condition has to be fulfilled in order to increase the efficiency of the cycle:

$$U_s > W\left(U_s, p_m, p_p\right), \tag{15}$$

where U_s is the mass entrainment ratio for isentropic ejector and compressor, and ideal pump.
Note that the following compression may be defined:

$$\pi_p = \frac{p_p}{p_m} \quad ; \quad \pi_k = \frac{p_k}{p_m} \quad ; \quad \Pi = \frac{p_k - p_m}{p_p - p_m} = \frac{\pi_k - 1}{\pi_p - 1} < 1, \tag{16}$$

Therefore:

$$W = \frac{p_p - p_k}{\rho_4 \left(h_{2'} - h_2\right)} = \frac{p_k}{\rho_4} \left(\pi_p - 1\right) \frac{1}{h_{2'} \left(1 - \frac{h_2}{h_{2'}}\right)} = W\left(U, \pi_p, \pi_k\right). \tag{17}$$

It is clear now that *W* may be interpreted as the ratio of the specific work of isochoric liquid compression between pressures p_p and p_k to the specific work of isentropic vapour compression between points 2 and 2'. It is not possible to draw any conclusion from eq. (17) without any specific information on the ejector performance or the system performance.

REFRIGERATION SYSTEM AND EJECTOR PERFORMANCE

Graphical representation of this approach is presented in Figure. 3. The performance line of the system may be written as the following relation:

$$U = f_s(\Pi). \tag{18}$$

Physically equation (18) describes system demands for the ejector performance based on energy balance for the ejector:

$$\dot{m}_n h_6 + \dot{m}_o h_2 = (\dot{m}_n + \dot{m}_o) h_3, \tag{19}$$

Therefore from eq. (19) mass entrainment may be calculated:

$$U = \frac{h_3(U) - h_6(p_p)}{h_2(p_m) - h_3(U)} = f_s(\Pi, U). \tag{20}$$

Assuming initially the entrainment ratio U, then enthalpy at outlet from ejector can be found from eq. (20). Energy balance equation between inlet and outlet of the motive nozzle can be written as:

$$h_6 = h_7 + \frac{1}{2} w_7^2. \tag{21}$$

Energy equation for mixing chamber may be written as follows:

$$h_7 + \frac{1}{2} w_7^2 + U h_2 = (1+U)\left(h_8 + \frac{1}{2} w_8^2 \right) = h_6 + U h_2. \tag{21}$$

The mixture velocity in the mixing chamber before compression is calculated on the basis of the momentum equation as well as assumption of the isobaric mixing:

$$w_8 = \frac{w_7}{1+U}. \tag{22}$$

Combining eqs. (21) and (22):

$$h_6 + U h_2 = (1+U)\left[h_8 + \frac{1}{2} \frac{w_7^2}{(1+U)^2} \right]. \tag{23}$$

From eq. (23) it is possible to calculate the specific enthalpy at the point 8, so:

$$h_8 = \frac{h_6 + U h_2}{1+U} - \frac{1}{2} \frac{w_7^2}{(1+U)^2}. \tag{24}$$

If the compression process will be isentropic, then the specific enthalpy at the point 3 is equal to:

$$x_8 = \frac{h_8 - h'_m}{h''_m - h'_m}, \tag{25}$$

where h'_m and h''_m are the specific enthalpies of saturated liquid and saturated vapour, respectively, at the inter-stage pressure p_m. Then:

$$x_3 = \frac{s'_m + x_8 (s''_m - s'_m) - s'_k}{s''_k - s'_k}, \tag{26}$$

where s'_m and s''_m are the specific entropies of saturated liquid and saturated vapour, respectively, at the inter-stage pressure p_m, s'_k and s''_k are the specific entropies of saturated liquid and saturated vapour, respectively, at the condensation pressure p_k. Then:

$$h_3 = h'_k + x_3 (h''_k - h'_k), \tag{27}$$

where h'_k and h''_k are the specific enthalpies of saturated liquid and saturated vapour, respectively, at the condensation pressure p_k. Combining eq. (20) and (27) make possible finding relation defined by eq. (18). Note that this is indirect relationship and therefore numerical calculations are necessary to find relation between compression ratio and entrainment ratio demanded by the system.

The performance line of the ejector may be written as the following relation:

$$U = f_e(\Pi). \tag{28}$$

Physically equation (28) describes ejector possibilities based on given ejector geometry and operation parameters. Butrymowicz [2,3,4] developed the theoretical model of the two-phase ejector. However, this model cannot be directly applied to the discussed case because it is dedicated for the isothermal compression case. It should be noted that there are some simple equations describing roughly two-phase ejectors performance, e.g. Sokolov and Zinger [5] proposed the following equation:

$$\frac{1}{\Pi} = 2\frac{\varphi_n}{\varphi_s} b\left[\varphi_n\varphi_m\varphi_s - \left(1 - \frac{\varphi_m}{2\varphi_n}\right) b(1+\chi)^2\right]. \tag{29}$$

Here: φ_s - velocity coefficient for the suction nozzle; φ_m - velocity coefficient for the mixing chamber. Basing on eq. (29) it is also possible to find out relationship (28). However, it should be noticed that eq. (29) may be treated as a very rough estimation of the water-air ejector.

CALCULATION RESULTS FOR ISENTROPIC CYCLE

The most important results are given by eq. (20) for the case of isentropic processes. The relationship between dimensionless work W and pumping compression ratio are given in Figure. 4 and Figure. 5 for the two cases of refrigerants: R-507 (and R-404A), and R-22, respectively.

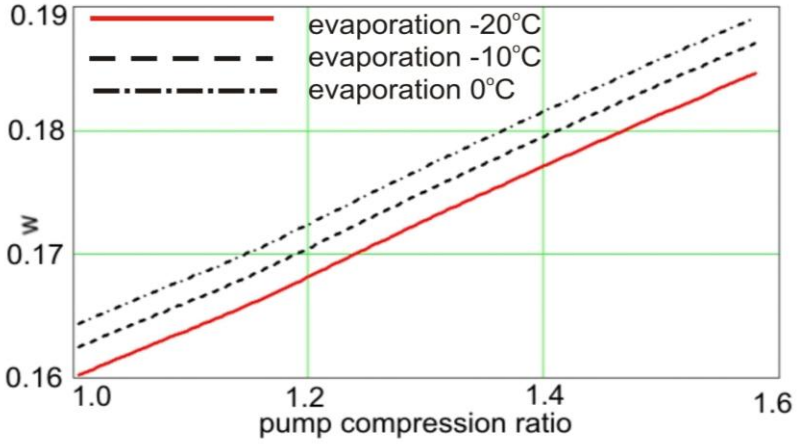

Figure. 4. Calculation results of the dimensionless work potential W versus pump compression ratio π_p for refrigerant R-507 (and R-404A); condensation temperature t_k = +40 °C; E = 1.

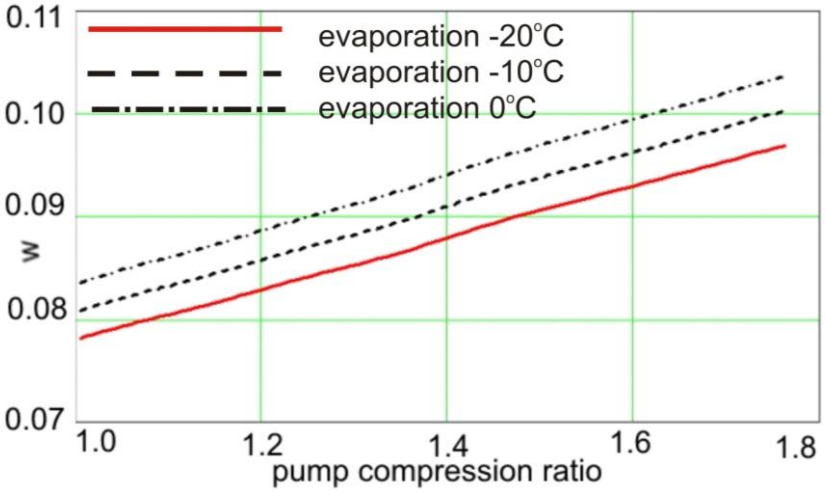

Figure. 5. Calculation results of the dimensionless work potential W versus pump compression ratio π_p for refrigerant R-22; condensation temperature t_k = +40 °C; E = 1.

It is evident from these results that the condition given by eq. (20) should be always fulfilled for both refrigerants only if the mass entrainment ratio will be higher than numerical values of W given in these figures. For refrigerant R-22 this condition should be fulfilled more easier than for refrigerant R-507 (and R-404A as well). The volumetric entrainment ratio required by eq. (15) are $\chi < 5$ in most cases. That means it should be possible to prepare the appropriate geometry of the ejector to ensure the required range of the entrainment ratio.

CONCLUSIONS

The own approach of the analysis of the operation of the ejection-compression system has been proposed in this paper. Based on this analysis the limiting entrainment ration of the two-phase ejector has been predicted for given operation conditions. However, the experimental research of the operation of high-pressure two-phase ejector is required in order to operate with reliable ejector performance in the analysis.

IMPROVING PERFORMANCE OF SPLIT-AIR-CONDITIONER WITH AN EVAPORATIVELY COOLED CONDENSER UNDER VARIOUS AMBIENT TEMPERATURE

E. Hajidavalloo*, H. Eghtedari
Mechanical Engineering Department, Shahid Chamran University, Ahvaz, Iran

ABSTRACT. Increasing coefficient of performance of split type home-air-conditioners is a challenging problem especially in hot weather conditions. Application of evaporatively cooled air condenser instead of commonly used air condenser is a solution to this challenge. In this paper an evaporative cooler was designed and coupled to the existing air condenser of a split air conditioner to evaluate its effect on the cycle performance under various ambient air temperatures up to 49°C. Experimental results show that application of evaporatively cooled air condenser has significant effect on performance improvement of the cycle and improvement increases as ambient air temperature increases. It is found that by using evaporatively cooled air condenser in hot weather conditions, power consumption can be reduced up to 21% and performance of the cycle can be improved up to 52%.

Keyword: *evaporative cooler, split air conditioner, energy saving, condenser*

INTRODUCTION

Power consumption is a major concern in vapor compression cycle especially in the home air conditioners with air cooled condensers working in hot weather conditions. Temperature of air cooled condenser is directly depended on the ambient air temperature, therefore, in the area with very hot weather in summer, the condenser temperature and pressure increase considerably which consequently increases the power consumption of the air conditioner due to increase in pressure ratio. Increasing condenser temperature also decreases cooling capacity of the cycle due to reduction of liquid content in the evaporator. These two effects decrease performance of air conditioner considerably [1]. In order to increase the performance of air conditioner it is required to decrease the condensing temperature. To reach this goal, one of the easiest ways is the application of direct evaporative cooler in front of the condenser to cool down air temperature before passing over the condenser. Using evaporative cooler in front of the air condenser can be considered as energy efficient, environmentally friendly and cost-effective method to enhance the performance of air conditioners. Since huge numbers of air conditioners are used in the residential sector, therefore, any small improvement in the performance of the cycle will have huge effect on the power consumption of the whole network.
Water consumption in this system is very small and there is not any risk of scale or rust on the condenser tubes because there is not any direct contact between water and tubes.
There is little work to address the different aspects of using direct evaporative cooler in front of the air condenser. Goswani et al. [2] employed an evaporative cooler on the existing 2.5 ton air conditioning system by using media pad and reported 20% power saving for the retrofitted system

when ambient air temperature was 34°C. Zhang et al. [3] investigated on the evaporative cooler filled with corrugated holed aluminum foil and presented correlations to predict the performance, pressure drop and temperature outlet of the cooler. They used correlations to predict the improvement of an air-cooled chiller by comparing the exit temperature of evaporative cooler with performance curve of the chiller and reported that COP of the chiller could be improved bout 39%. Yu and Chan [4] simulated an air–cooled chiller equipped with a direct evaporative cooler and showed up to 14.4% reduction in power consumption and up to 4.6% increase in the refrigeration effect. Hajidavalloo [5] investigated the effect of using evaporative cooler in the window air conditioner by injecting water on the media pad installed in front of the condenser entrance and reported 16% reduction in power consumption and 55% improvement in total performance.
Despite large potential of evaporative cooling system to reduce power consumption of split air-conditioners, there is few investigation in this area and it seems much work are required to address different aspect of this system. In this work experimental investigation was used to evaluate the effect of using an evaporative condenser on the behavior of a split air conditioner under variable ambient air conditions.

SYSTEM DESIGN AND EXPERIMENTAL SET-UP

An existing split air-conditioner (1.5 ton) made by Mitsubishi Electric was used in the experiments. Consistent with the shape of condenser, a frame was built and filled by cellulous media pad (packing) with 5 cm thickness and installed in front of the air condenser as shown in Figure 1. A water circulation system was built to inject water on the top of the media pad by using a pump. Hot ambient air passed over the evaporative media pad and get cooled and then passed over the condenser and finally exits from back side of the condenser. Digital AC clamp power meter [Kyoritsu 2017, with 1.5% accuracy] was used to measure the electrical current of the compressor. The pressure in inlets of condenser and evaporator were measured by special type Bourdon gauges suitable for refrigeration system with accuracy of ±0.05 bar. Based on the experimental evidence, pressure drop in condenser and evaporator was considered 7% and 5% respectively. Calculations show that the pressure drop has no significant effect on the results.

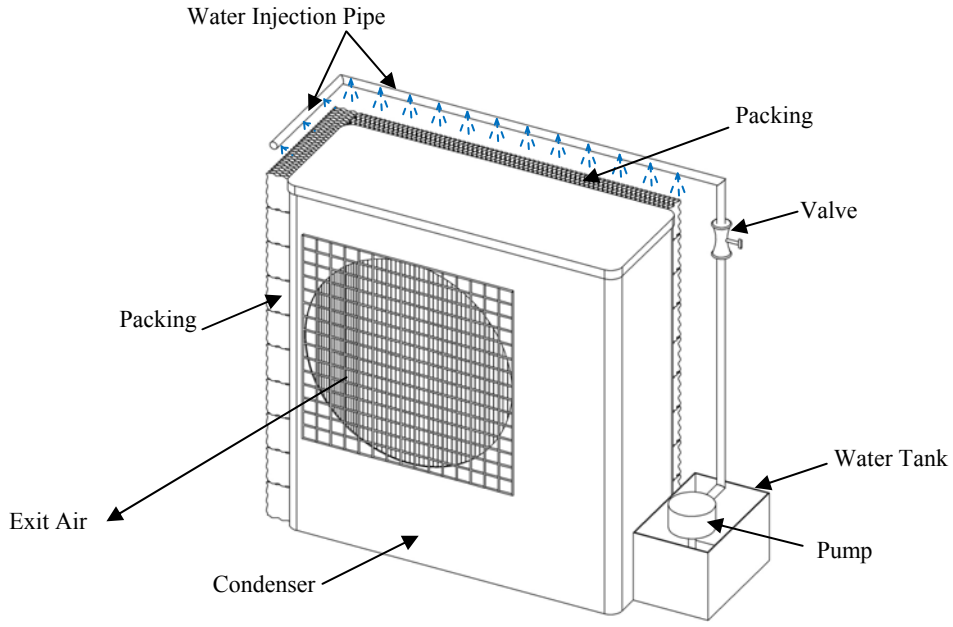

Figure 1. Schematic view of the retrofitted condenser

Temperatures of refrigerant and circulation air at different points were recorded with K-Type thermocouples and the signals were connected to the computer by using data acquisition system type MIO-64E-3 and analyzed by LabView program from National Instrument. Before temperature measurement, the surface of tube was polished for removing any dust or rust and then the thermocouple probe was laid down on the surface. In order to reduce the thermal contact resistance between thermocouple probe and tube surface, thermal grease was used in the point of contact. Insulating tape was wrapped around the tube to push the probe against the tube surface and also prevent any convection effect of ambient air on the temperature readings. The water consumption rate due to evaporation effect was measured by using water level change in the tank during the test period.

AC: Air Condenser, EC: Evaporative Condenser

EXPERIMENTAL RESULTS

In order to estimate the effect of evaporative cooling on the system and compare the results of two different types of air conditioners, experimental tests were performed in two consequent stages. In the first stage, air cooled condenser was used and in the second stage evaporative cooled condenser was used. Data were recorded after steady state condition was established and the properties of refrigerant and air remained constant (after 20 min.). Many experimental tests were performed at different ambient temperature. The results of tests at three different temperatures (35, 44, 49°C) are shown in Table 1. As shown in this table electric current, condenser pressure, compressor exit temperature increase considerably as ambient temperature increases.

Figure 2 shows the experimental results on the P-h diagram when ambient temperature was 35.0°C. The results show condenser and evaporator pressure of the retrofitted system reduced about 15% and 3% respectively and the pressure ratio reduces about 13%. Also in the retrofitted system the temperature of the condenser dropped down about 7°C while the evaporator temperature reduced about 1°C. Electric current consumption of system reduces about 12%.

Figure 3 shows the experimental results on the P-h diagram when ambient temperature was 49.0°C. As shown, condenser pressure reduced from 21.7 to 17.3 bar which shows 20% reduction and evaporator pressure reduced from 7.1 to 6.8 bar which shows only 4% reduction. The pressure ratio across the cycle reduces from 3.05 to 2.54 which shows 17% reduction. Also in the retrofitted

system the temperature of the condenser dropped down about 10°C while the evaporator temperature reduced about 1.5°C. Electric current consumption of system reduces about 21%.

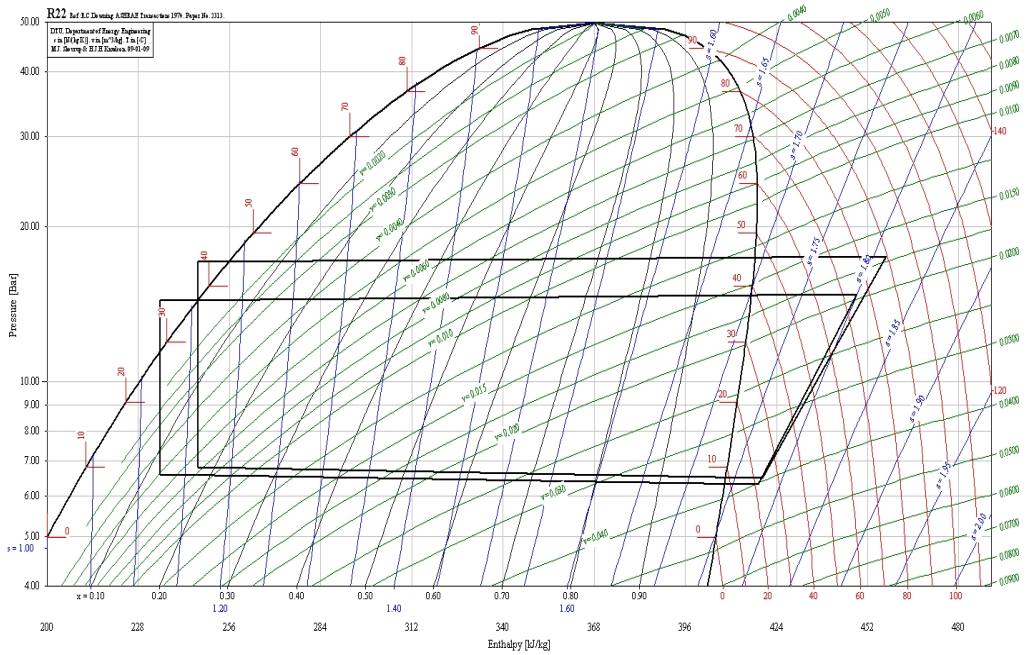

Figure 2. The P-h diagram of conventional and evaporative cooling cycle at T_{amb}=35.0°C

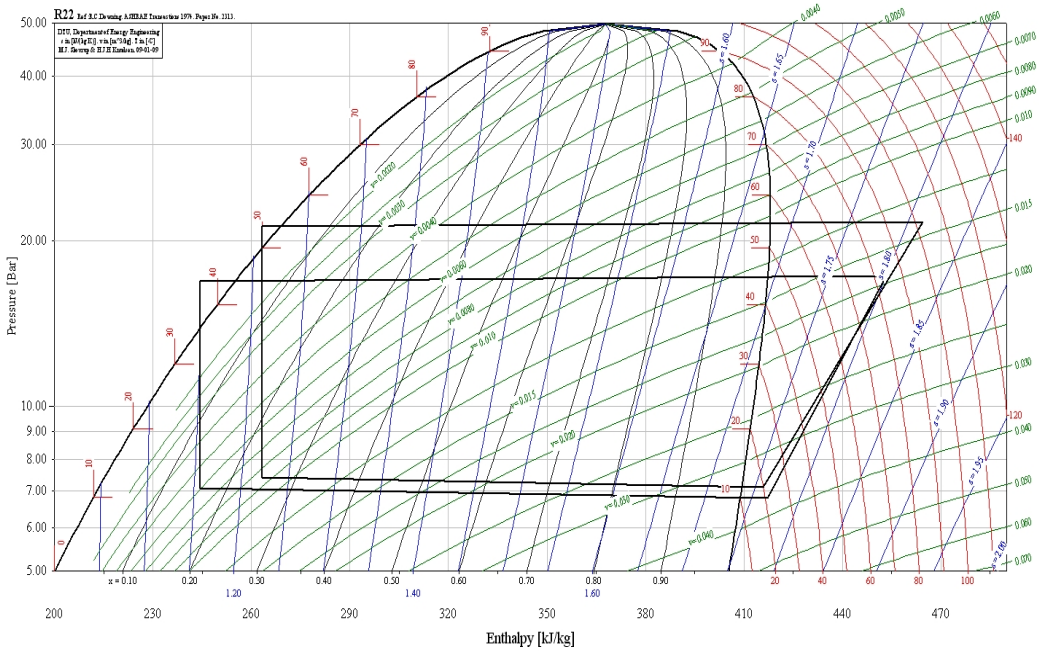

Figure 3. The P-h diagram of conventional and evaporative cooling cycle at T_{amb}=49.0°C

PERFORMANCE RESULTS AND DISCUSSION

Based on the experimental results, thermodynamic properties of refrigerant at different points of the cycle were obtained (Figure 2 and 3) in order to calculate mass flow rate, cooling capacity and COP. Equations (1-4) are used to calculate the desired parameter. Actual power consumption can be obtained by using Eq. (1) since the voltage, current and cosφ are known. Mass flow rate can be obtained by Eq. (2). Cooling capacity and COP can be obtained by using equation. (3) and equation.

(4) respectively. In all equations, subscripts (1), (2), (3) and (4) stand for exit conditions from compressor, condenser, capillary tube and evaporator respectively.

$$Wc = VI\cos\phi \tag{1}$$

$$m = \frac{W_c}{h_2 - h_1} \tag{2}$$

$$Q_c = \dot{m}(h_1 - h_3) \tag{3}$$

$$COP = \frac{h_1 - h_3}{h_2 - h_1} \tag{4}$$

Table 2 and 3 shows the results of calculation for tests at ambient temperatures at 35.0 and 49.0°C respectively. Comparing the results of two tables shows that as ambient temperature increases effect of using evaporative air cooling increases. Power reduction improvement increase from 12% to 21%, refrigeration effect improvement increase from 6.1% to 13.3% and COP improvement increases from 33.0% to 52.2%. The results are in consistent with findings of other researches [3-5].

Table 2
Performance results of air conditioner after retrofitting (T_{amb}=35.0°C)

Parameter	Unit	Conventional	Evaporative	Variation
W_c	kW	1.484	1.295	-12.6%
m	gr/sec	0.03905	0.04286	9.7%

β	-	3.14	4.78	52.2%

Effect of ambient temperature on the cycle performance

Many tests at different ambient conditions ranging between 35.0 to 49.0°C were performed in order to have better understanding of the cycle behavior. Figure 4 compares the variation of refrigeration effect for two condensers in terms of ambient air temperature. It can be seen that the performance of the evaporative cooled condenser is much better than the air cooled condenser and the improvement increases as ambient temperature increases. Figure 5 compares the variation of compressor work for two condensers in terms of ambient air temperature. As seen, with increasing air temperature compressor work is increased and there is considerable difference between two condensers performance. Figure 6 shows variation of COP versus ambient air temperature for two type condensers. As the experimental results show the difference between two curves is very large and it increases as ambient air temperature increases.

Decreasing the COP of evaporative cooled air condenser with ambient air temperature is the result of increasing the air temperature after the pad. Figure 7 shows the temperature of air after the pad in

terms of ambient air temperature. The air temperature after the pad depends on many parameters like ambient wet bulb temperature, rate of water injection, air velocity and thickness and shape of the pad [3]. It is possible to decrease air temperature after the pad to approach ambient wet bulb temperature in order to get the best performance. This needs many other tests and changes in the experimental set up like increasing the pad thickness and water injection rate which was not in the scope of this paper.

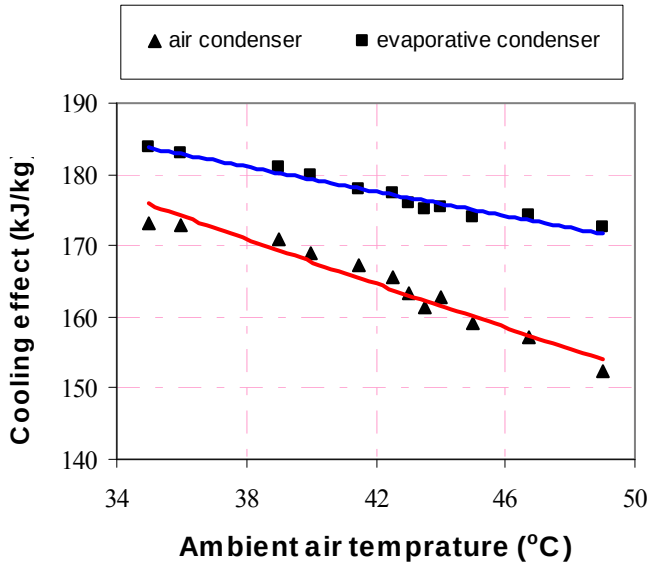

Figure 4. Cooling effect variation at different ambient air temperature

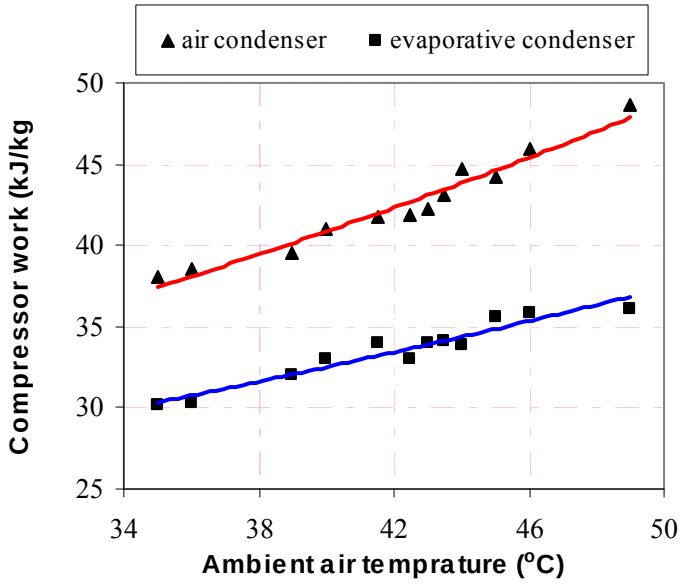

Figure 5. Compressor work variation at different ambient air temperature

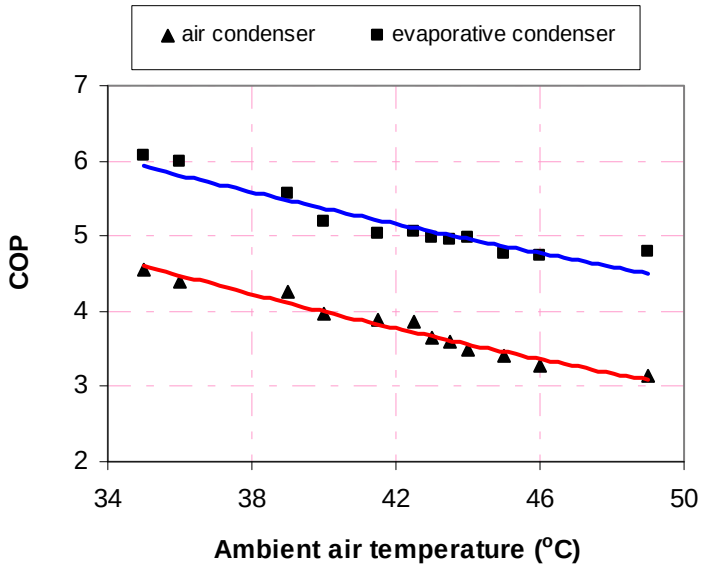

Figure 6. COP variation at different ambient air temperature

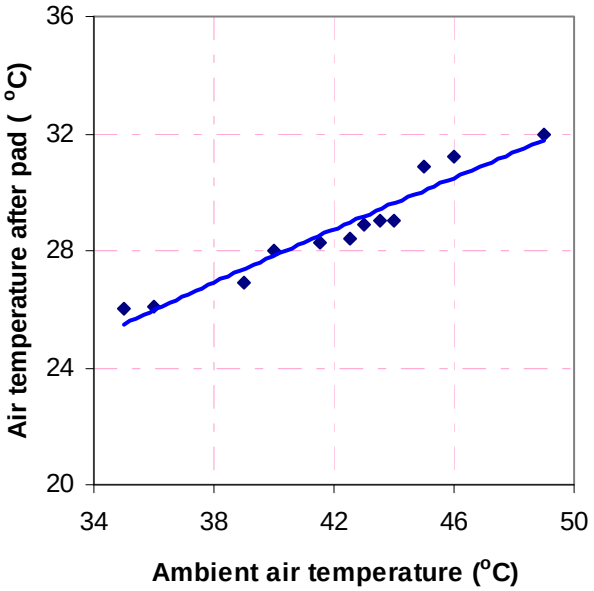

Figure 7. Air temperature after pad

Error analysis

Error analysis for estimating the maximum uncertainty in experimental results was done [6]. It was found the maximum uncertainty in the results is belonging to COP by 3.4%.

CONCLUSIONS

Effective use of energy sources needs more efficient use of air conditioners. Evaporative cooler coupled to the air condenser is an efficient, reliable and cost-effective method to increase the performance of split type air conditioner. Experimental results show that increasing ambient air temperature decreases the coefficient of performance of air cooled condenser considerably but it has less effect on the performance of evaporatively cooled condenser. Power consumption can be decreased up to 21% and performance can be improved up to 52% by application of evaporative condenser. It is found that evaporatively cooled air conditioner works more efficiently as air

temperature increases, therefore, its application in very hot weather condition is highly recommended.

NOMENCLATURE

FLOW STABILITY IN TUBE – THERMODYNAMIC ANALYSIS

P. Novotný[1, 2, *], F. Maršík[2]
[1]Faculty of Mechanical Engineering CTU in Prague, Prague, Czech Republic
[2]Institute of Thermomechanics AS CR, v.v.i., Prague, Czech Republic

ABSTRACT. Flow stability in tube is analysed by using the new thermodynamic condition of stability. This condition is derived from the thermodynamics, especially from the extremal condition for the total energy. In this paper is indicated the theoretical solution of the flow between two rotating cylinders. The Poiseuille and the Couette flow into the annulus are taken as the examples. This analysis supports the experimental findings, i.e., the strong influence of vortex core rotation on the enhancement of flow stability.

Keywords: *vortex, flow stability, hydrodynamics stability, balance of entropy*

INTRODUCTION

Flow field instabilities play important part for the distribution of the substances and are important in flows in the atmosphere, in the ocean, in blood vessels, around streamlined bodies, in jets, mixing layers; in fact, in almost any flows. The flow stability can be defined based on the kinetic energy of disturbances or based on critical Reynolds number, see [4]. Inviscid stability theorems like Rayleigh's inflexion point theorem, Fjörtoft's theorem are used at present, see [4, 3]. On the other hand the flow stability problem can be solved based on the new thermodynamic stability conditions, which is now under development at the Institute of Thermomechanics AS CR. This thermodynamics stability condition is derived from the new formulation of thermodynamics and represents the measure of the attenuation of the fluctuations of the total energy. This theoretical research is accompanied by the experimental research, which will be published later.

CONDITION OF STABILITY

General form for the balance of entropy is, see [2]

$$\frac{DS}{Dt} - J(S) = P(S) \geq 0 \tag{1}$$

Where S is the entropy, $J(S)$ denotes the total flux of the entropy through the system and $P(S)$ denotes the production of the entropy of the system. The entropy production $P(S)$ gives the important information about the fluid flow stability of thermoviscose fluid. To obtain the convenient form of needed stability condition we have to use for analysing of the fundamental thermodynamic inequality the total enthalpy

* Corresponding author: Pavel Novotný

E-mail address: Pavel.Novotny@fs.cvut.cz

$$h_c(s,p) = \frac{|v^2|}{2} + u + \frac{p}{\rho} + \phi \tag{2}$$

The final form of the thermodynamic condition of stability for the thermoviscose fluid has following form

$$\pi = -\frac{q^j}{T} \cdot \frac{\partial T}{\partial x^j} + v_i \cdot \frac{\partial t_{dis}^{ij}}{\partial x^j} + t_{dis}^{ij} \cdot \frac{\partial v_i}{\partial x^j} \geq 0 \tag{3}$$

Inequality (3) is so called the modified fundamental thermodynamic inequality and for our purposes is taken as ***the thermodynamic criterion of stability of thermoviscose flow***.

The cylindrical coordinates are convenient for the tube flow ($x^1=r$, $x^2=\varphi$, $x^3=z$). Relation between the Cartesian coordinates ($x^1=x$, $x^2=y$, $x^3=z$) and the cylindrical coordinates ($\xi^1=r$, $\xi^2=\varphi$, $\xi^3=z$) are given as follows $x = r\cdot\cos\varphi$, $y = r\cdot\sin\varphi$, $z = z$. For the isentropic flow with constant density ρ, viscosity μ , constant temperature T a rotational flow in the axial direction i. e. $\vec{v} = (v^r, v^\varphi, v^z) = (0, v^\varphi(r), v^z(r))$ is supposed. The general thermodynamic condition of stability (3) for the isothermal fluid has after transformation the following form

$$\pi = \mu \cdot v^\varphi \cdot \frac{\partial^2 v^\varphi}{\partial r^2} + \mu \cdot \left(\frac{\partial v^\varphi}{\partial r} - \frac{v^\varphi}{r}\right) \cdot \left(-\frac{v^\varphi}{r}\right) + \mu \cdot \left(\frac{\partial v^\varphi}{\partial r} - \frac{v^\varphi}{r}\right) \cdot \left(\frac{\partial v^\varphi}{\partial r}\right) +$$
$$+ \mu \cdot \left(\frac{\partial v^z}{\partial r}\right)^2 + \mu \cdot v^z \cdot \left(\frac{\partial^2 v^z}{\partial r^2} + \frac{1}{r} \cdot \frac{\partial v^z}{\partial r}\right) \geq 0 \tag{4}$$

APPLICATION TO THE COUETTE – POISEUILLE FLOW

The total flow is assumed as superposition of the two flows – Poiseuille flow in the axial direction and Couette flow in the tangential direction, Figure 1.

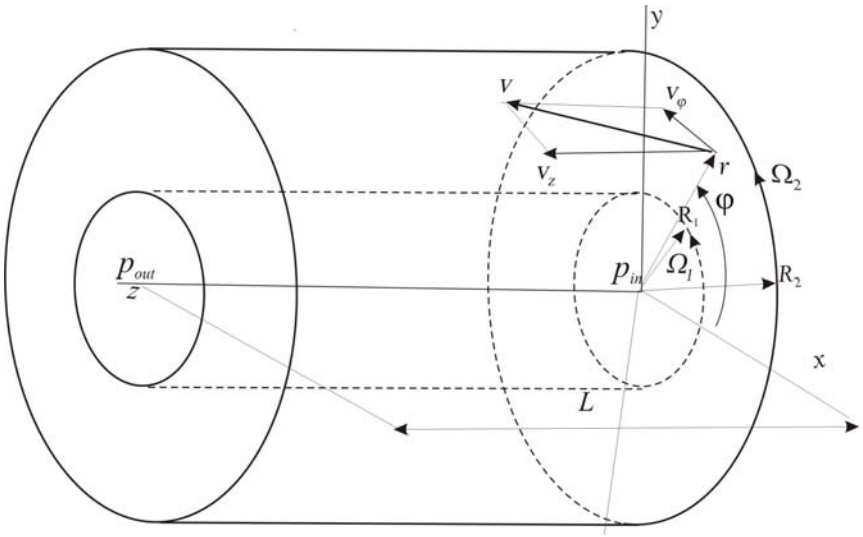

Figure 1. Scheme of the vortex tube.

The velocity profile in the annulus for the Poiseuille flow is given as the analytical solution of the Navier-Stokes equations in the form

$$v^z(r) = A_p \cdot R_2^2 \cdot \left\{ 1 - \left(\frac{r}{R_2}\right)^2 + \left[1 - \left(\frac{R_1}{R_2}\right)^2 \right] \cdot \frac{\ln\left(\frac{r}{R_2}\right)}{\ln\left(\frac{R_2}{R_1}\right)} \right\} \tag{5}$$

Where the flow parameter $A_p = \frac{p_{in} - p_{out}}{4 \cdot \mu \cdot L} = const.$ represents the driving pressure gradient. Analogously to tube flow, the exact solution of the Navier-Stokes equations between two rotating cylinders (so called the Couette flow) is given as, [1]

$$v^{\varphi}(r) = r \cdot \omega(r) \tag{6}$$

Where

$$\omega(r) = A + \frac{B}{r^2} \tag{7}$$

The parameters A and B have the form

$$A = -\Omega_1 \cdot \eta^2 \cdot \frac{1 - \frac{\overline{\mu}}{\eta^2}}{1 - \eta^2}, B = \Omega_1 \cdot \frac{R_1^2 \cdot (1 - \overline{\mu})}{1 - \eta^2}, \overline{\mu} = \frac{\Omega_2}{\Omega_1}, \eta = \frac{R_1}{R_2} \tag{8}$$

To obtain the non-dimensional form of the thermodynamic condition of stability (4) in the radial coordinate $\tilde{r} = r/R_2$, we put in the formulas (5), (6), (7) and (8) into inequality (4). After some algebra the thermodynamic stability condition has the final form, where are the contributions both of the Poiseuille flow and Couette flow to the global stability, separated

$$\frac{\pi}{\Omega_1^2 \cdot \mu} = \frac{2 \cdot \eta^2 \cdot (1 - \overline{\mu})}{\tilde{r}^2 \cdot (1 - \eta^2)} \cdot \left[\frac{3 \cdot \eta^2 \cdot (1 - \overline{\mu})}{\tilde{r}^2 \cdot (1 - \eta^2)} - \eta^2 \cdot \frac{1 - \frac{\overline{\mu}}{\eta^2}}{1 - \eta^2} \right] +$$

$$+ CP \cdot \left[8 \cdot \tilde{r}^2 - 4 - 4 \cdot \frac{1 - \eta^2}{\ln\left(\frac{1}{\eta}\right)} \cdot \ln(\tilde{r}) - \frac{4 \cdot (1 - \eta^2)}{\ln\left(\frac{1}{\eta}\right)} + \frac{(1 - \eta^2)^2}{\tilde{r}^2 \cdot \ln\left(\frac{1}{\eta}\right)^2} \right] \geq 0 \tag{9}$$

The parameter CP (the coupling number) indicates an interaction of both velocities fields from point of view their stability and is defined as follows

$$CP = \frac{A_p^2 \cdot R_2^2}{\Omega_1^2} \sim \frac{v_{z\max}^2}{(R_2 \cdot \Omega_1)^2} \tag{10}$$

where $v_{z\max}^2$ is maximal axial velocity. For the low value of *CP* the influence of the disturbances of the Poiseuille flow on the total flow is insufficient.

APPLICATION TO THE VORTEX TUBE

We consider the vortex tube, see Figure 1, where is R_1 = 4.4 mm, R_2 = 8.8 mm, Ω_1 = 30 rad/s, A_p = 4500 Pa/Pa·s·m. We apply the new thermodynamic stability condition (9) to the three following flow regimes; for $\overline{\mu} = 1$, $\overline{\mu} = 0.5$ and $\overline{\mu} = 0$. The viscosity is taken as the constant ($\mu = 1 \cdot 10^{-3}$ Pa·s).

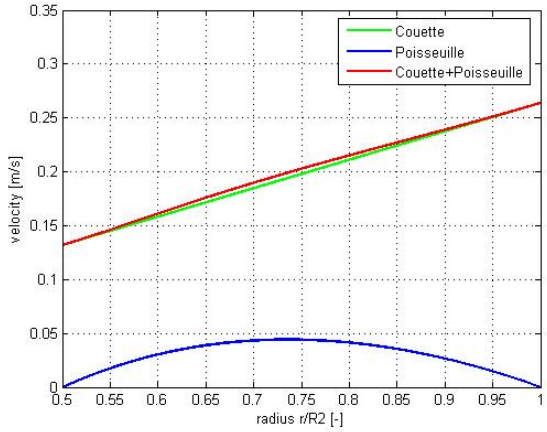

Figure 2. Velocity field of the Couette (green line), of the Poiseulle (blue line) and the total flow (red line) for $\overline{\mu} = 1$.

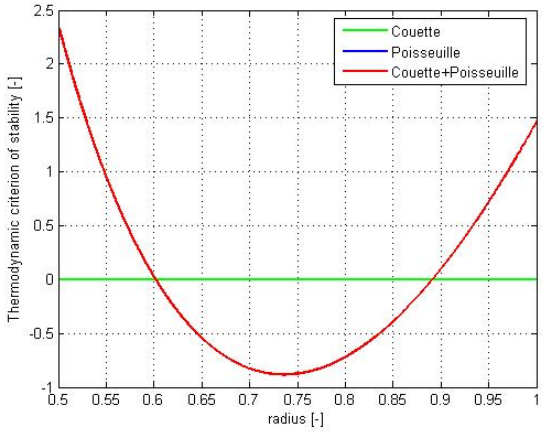

Figure 3. The stability condition for the Couette (green line), of the Poiseulle (blue line, it coincides for this case with red line) and the total flow (red line) for $\overline{\mu} = 1$.

Angular velocities of the inner cylinder and the outer cylinder are for $\overline{\mu} = 1$ equal, i.e. $\Omega_1 = \Omega_2$ and $v_{\varphi\max} = R_2 \cdot \Omega_2$. The Couette flow has the linear character; the Poiseuille flow has the parabolic character in this case. The total flow, which is composed from the Couette and the Poiseuille flow, is plotted in the Figure 2 (red line). The Couette flow is for this case at the margin of the stability, see Figure 3. So that the Couette flow has not the influence on the stability of the total flow. It is the reason why is the total flow core unstable alike the Poiseuille flow core, the stability curves of both flows coincide.

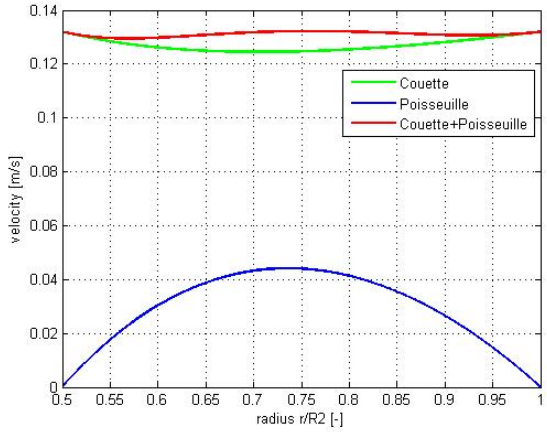

Figure 4. Velocity field of the Couette (green line), of the Poiseulle (blue line) and the total flow (red line) for $\overline{\mu} = 0.5$.

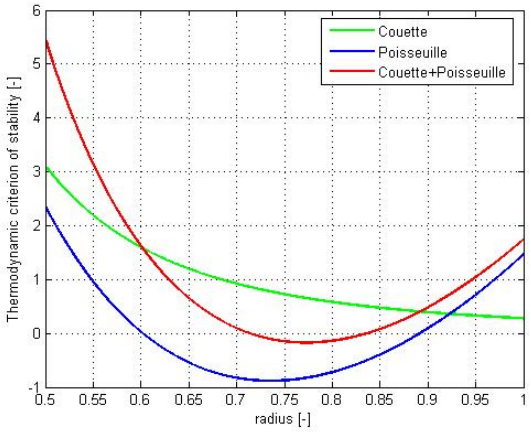

Figure 5. The stability condition for the Couette (green line), of the Poiseulle (blue line) and the total flow (red line) for $\overline{\mu} = 0.5$.

The similar case ($\overline{\mu} = 0.5$) is shown in the Figure 4. The value of the stability criterion (9) is for the Couette flow positive, see Figure 5; so that the Couette flow has the stabilizing influence on the stability of the total flow, nevertheless the total flow core is still unstable, see Figure 5.

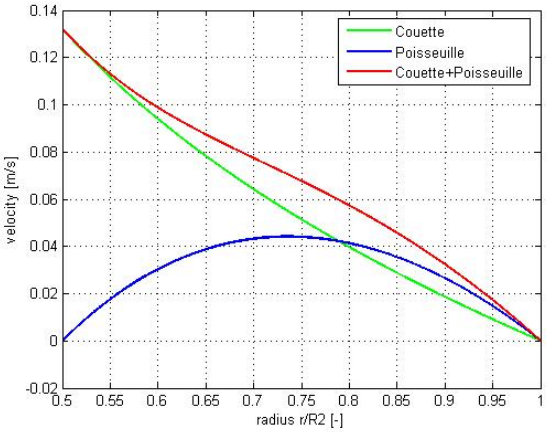

Figure 6. Velocity field of the Couette (green line), of the Poiseulle (blue line) and the total flow (red line) for $\overline{\mu} = 0$.

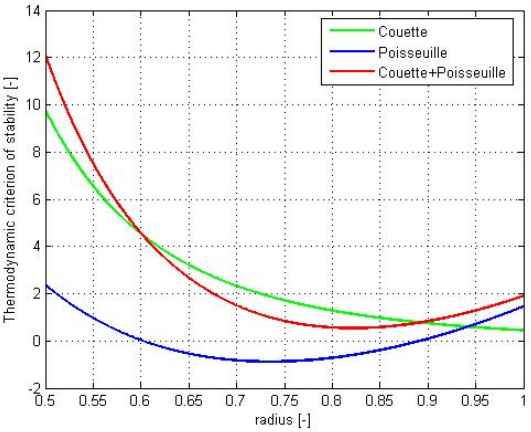

Figure 7. The stability condition for the Couette (green line), of the Poiseulle (blue line) and the total flow (red line) for $\overline{\mu} = 0$.

The strong stabilizing influence of the Couette flow on the Poiseuille flow and consequently on the total flow, is reached for $\overline{\mu} = 0$, see Figure 6. The stability criterion of the Couette flow in this case prevailing, see Figure 7. The total flow is for $\overline{\mu} = 0$ completely stable. This case is physically very close to the potential vortex flow.

CONCLUSION

The Couette flow for $\overline{\mu} = 1$ (solid body rotation) is at the margin of the stability and the Poiseuille flow core is unstable, see Figure 1 and Figure 2. The unstable core of the Poisseuille flow

predominates over the Couette flow so that the core of the total flow, which is composed from the Couette and the Poiseuille flow, is unstable too. However, for $\overline{\mu} = 0.5$, the Couette flow is stable and the core of the Poiseuille flow is unstable, see Figure 3 and Figure 4. The total flow core is more stable then the Poseuille flow core itself, nevertheless the total flow core is still unstable. For $\overline{\mu} = 0$ the stabilizing effect of the Couette flow is strong enough, Figure 6 and Figure 7, so the total flow, which is composed from the Couette and the Poiseuille flow, is completely stable. The possibility to stabilize Poisseuille flow by the given Couette flow follows directly from the thermodynamic stability condition (9) only. Such condition cannot be obtained from the Rayleigh's criterion itself.

We can conclude, that the stable annular flow can be reached in such vortex tube configuration, where the Couette flow is dominant.

Thermodynamic criterion of stability is in comparison with the Rayleigh theory more general and includes as well the influence of the viscosity. This theory is in general applicable not only for steady flows, but even for unsteady flows.

EFFICIENCY DEPENDENCE ON FUEL IN THE BRAYTON CYCLE

I. López*, R. Nieto, C. González, A. Jiménez
ETSI Industriales
Universidad Politécnica de Madrid, Madrid, Spain

ABSTRACT. This study belongs to a broader line of research on exergy analysis of industrial systems. The paper presents a comparison between the efficiencies of a standard Brayton cycle when run on different fuels. The fuels are the first compounds of the alkane series. The main goal of this study is to characterize the exergetic performance of the series in order to identify a trend, so as to understand the influence of C2+ components in alternative fuels to methane: syngas and unprocessed natural gas. The study has centred on cycle thermodynamics, leaving aside turbine design issues and other concerns of new fuels. Simulations have been carried out with the proprietary software PATITUG. Gases have been modelled as Lewis-Randall mixtures with truncated virial equations. Methane proves to be the most exergetic-efficient. A decreasing trend in efficiency has been observed as the series progresses, justified by a linear rise in the specific power at the turbine against an exponential growth of the chemical exergy.

Keywords: *Gas turbine fuels, Exergy analysis, Combined cycle, Power Generation.*

INTRODUCTION

The current complex economic, strategic and energetic scenarios lead to a strong drive for alternative fuels or fuel interchangeability in many sectors, and especially in the power generation sector [1, 2]. Unprocessed methane has been traditionally the preferred fuel. However, it is not always available at new plant sites and its prices are rising [3]. Besides, other fuels and technologies such as coal or biomass in integrated gasification combined cycle, IGCC, present a significant environmental potential when combined with carbon dioxide capture facilities [4, 5, 6].

This situation results in two main alternative fuels to processed methane for power generation: unprocessed natural gas and syngas [7], obtained from coal or biomass [8]. However, the properties of these fuels may differ significantly from processed methane in many aspects, from reachable flame temperatures to maintainability issues.

Although there exist a number of application studies related to alternative fuels and their associated processes, there exists a need for systematic studies of their thermodynamic implications [11, 12, 13, 14]. In this line, this paper attempts to portrait the different performance trends of the first elements of the alkane series as fuels for power generation. Alkanes are relevant to the current alternative fuels. Unprocessed natural gas may contain up to 20% of non-methane compounds, of which the most part are alkanes, usually up to pentane and exceptionally heavier. Similarly occurs with syngas [14, 15].

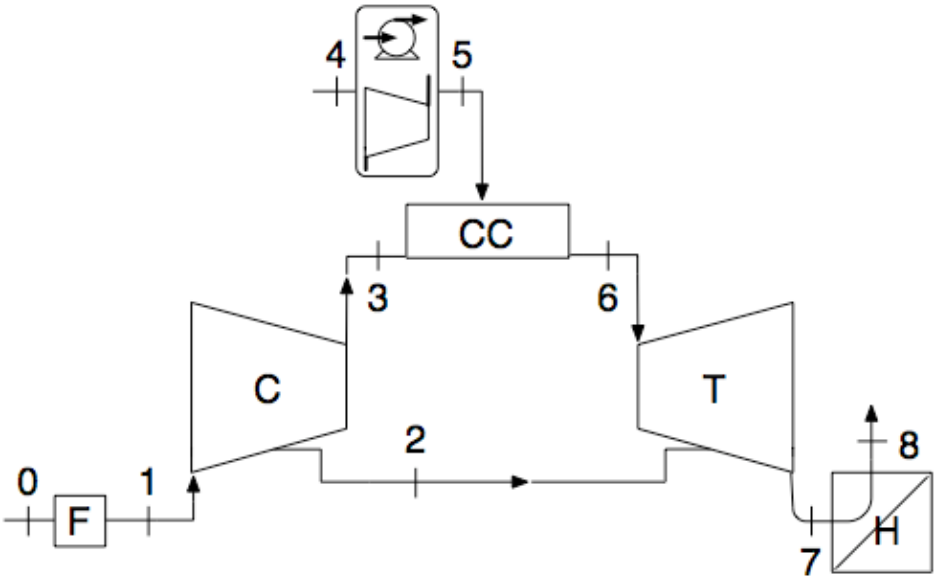

Figure 1. Diagram of the standard Brayton cycle considered

The study presented here consists in a series of simulations of a standard Brayton cycle for power generation, in which the different pure alkanes are considered as fuels. Different turbine inlet temperatures and compression ratios are considered for each. Practical considerations such as corrosion or turbine maintenance are not treated. A series of curves is obtained showing the trend of exergetic efficiency with the number of carbons of the compound.

Simulations have been carried out with the PATITUG software developed at ETSII. It is oriented to themodynamic design and analysis of elements and cycles. It allows configuring the different thermodynamic parameters of all elements in the considered plant, not being restricted to commercial devices. It also provides accurate thermodynamic treatment of pure substances, mixtures and chemical reactions through different models that can be selected. Although PATITUG is normally used for academic purposes, other studies related with this paper have been carried out in the past [16].

DESCRIPTION OF THE STUDY

The considered Brayton cycle is represented in figure 1. Air enters the cycle at point 0, and is filtered before entering the compressor at 1. A partial extraction for turbine refrigeration is made at 2. The output of the compressor enters the combustion chamber at 3, where it reacts with the fuel being compressed or pumped from 4 and entering the chamber at 5. After a complete combustion, the gases enter the turbine at 6, and are expanded. The gases leave the turbine at 7, entering a heat exchanger, where exergy is assumed to be transferred to a steam cycle. Finally, the gases leave the plant at 8.

This setting has been adjusted to standard values in order to make it representative of a general configuration. For each fuel, an exergy analysis is performed for a range of working temperatures and pressures.

Exergetic Efficiency

The exergetic efficiency of the cycle is calculated as the ratio between the net exergy obtained and the chemical exergy of the fuel, e_4, as indicated in equation (1).

Thus, the net exergy obtained is the power balance of the cycle, allowing a factor η for mechanical losses in turbine, compressor and fuel injection, plus the exergy obtained at the heat exchanger, assumed 0.7 of the total:

$$\xi = \frac{\eta(\dot{W}_T + \dot{W}_C + \dot{W}_{4-5}) + 0.7(\dot{E}_7 - \dot{E}_8)}{\dot{m}_4 e_4} \quad (1)$$

In order to isolate the effect of the fuel and to ensure comparability of results, the turbine has been assumed to be designed specifically for the particular fuel of the studied case. In this way, the possible influence on efficiency of running a turbine on a different fuel to that it was designed for is eliminated.

Operating Conditions

For the sake of simplicity and representativeness of the study, only turbine inlet temperature, T6, and compressor ratio, P3/P1, are varied. T6 is studied in the range 1000-1450 ºC, and P3/P1 in 10-40.

However, the operating conditions of the cycle are determined by a large series of factors which shall be assumed in standard values, as will be described following.

Pressure losses at the inlet filter, F, are taken 196.3 Pa. Isentropic efficiencies of compressor, C, and turbine, T, 0.845. Fuel compressor or pump (in the case of liquid fuels) have isentropic efficiencies of 0.84. Pressure losses at the combustion chamber, CC, are modelled as P6=0.9601P3. Heat losses in CC are taken 0.34% of m_4e_4. The mass flow at 2 has been assumed 6.2% of intake flow. Pressure at 7 has been assumed 2499 Pa over ambient pressure, P0. Temperature at 8, 120 ºC. Finally, air is assumed to enter at ISO conditions, 15 ºC, 1.01325 bar and 60% RH, and fuel is assumed to enter at 4 at 15 ºC and 10.34 bar.

Considered Fuels

Considered fuels: methane, ethane, propane, n-butane, isobutane, n-pentane, hexane and heptane.

Chemical Reaction

The combustion reaction considered is a simplification of the real case. Dry air has been modelled as a mixture of O2, N2, Ar and CO2. Minor components of air such as metals has been neglected [5]. The quantity of water in air has been adjusted to the considered RH. No formation of NOx has been considered. Finally, combustion has been assumed to take place in excess of air with respect to the stoichiometric ratio, in the proportion necessary to obtain the considered turbine inlet temperatures (calculated by PATITUG for each case). Thus, the basic reaction is:

$$C_kH_{2k+2} + \frac{3k+1}{2}O_2 \longrightarrow kCO_2 + (k+1)H_2O$$

Thermodynamic Properties of Substances

As it has been mentioned by some authors [11], thermodynamic properties of combustion gases may vary significantly from the perfect gas. Thus, an adequate thermodynamic model may be critical for obtaining meaningful results.

In this study, air flow and combustion gases have been treated as a Lewis-Randall ideal mixture. Pure components have been modelled with virial equations of state truncated after the second term.

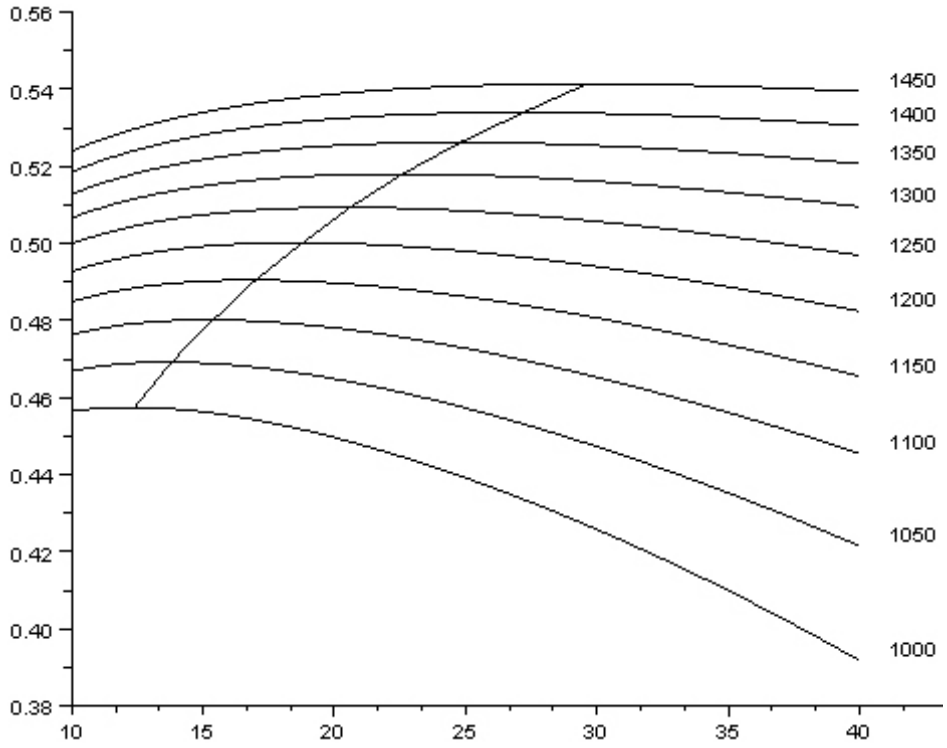

Figure 2. Exergetic efficiency curves for methane

Fuel, in the 4-5 process, is modelled by the Lee-Kesler equation of state. This is necessary to treat adequately the liquid state in which most alkanes enter at point 4.

In both liquids and gases, specific heat has been modelled as a function of temperature. Properties have been obtained from [17]. The chemical exergies of alkanes have been obtained from [18] and adapted to the conditions of the cycle.

RESULTS

Reference Case

Combustion of methane has been taken as the reference case. The excess of air over stoichiometric ratio has been adjusted for the different values of turbine intake temperatures, T6.

Results are shown in figure 2. Exergetic efficiency of the combined cycle is represented against the ratio P3/P1. Each line corresponds to the indicated temperature (in ºC).

Alkanes up to pentane are the most common C2+ components in unprocessed natural gas. The following figures represent the difference between the exergetic efficiencies of ethane and heptane with methane. Intermediate compounds are not shown but follow the trend.

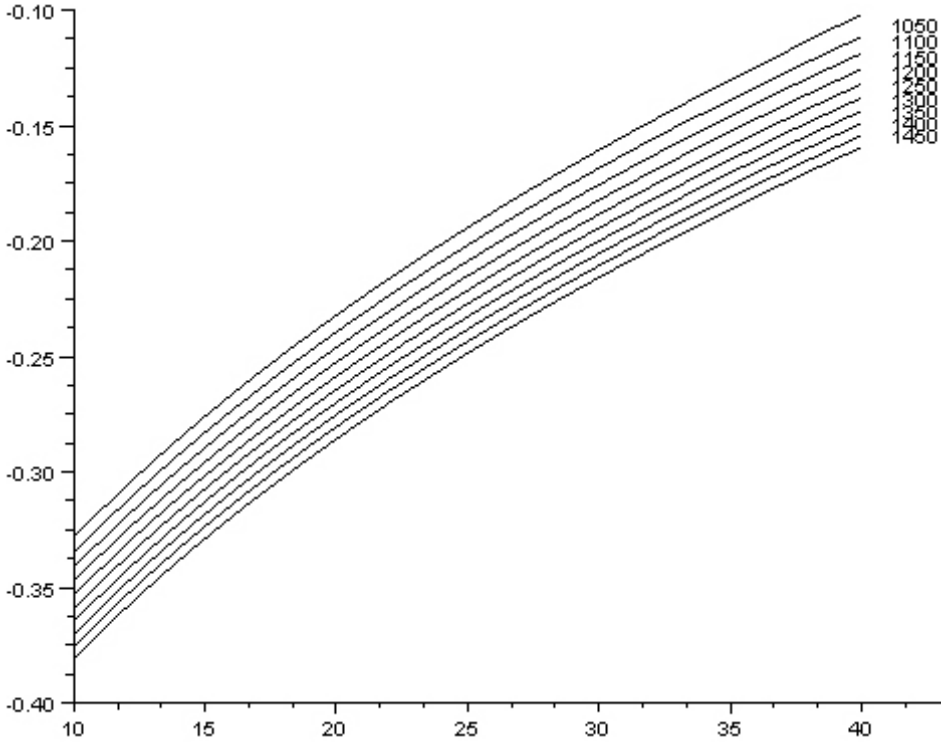

Figure 3. Difference of exergetic efficiencies between ethane and methane

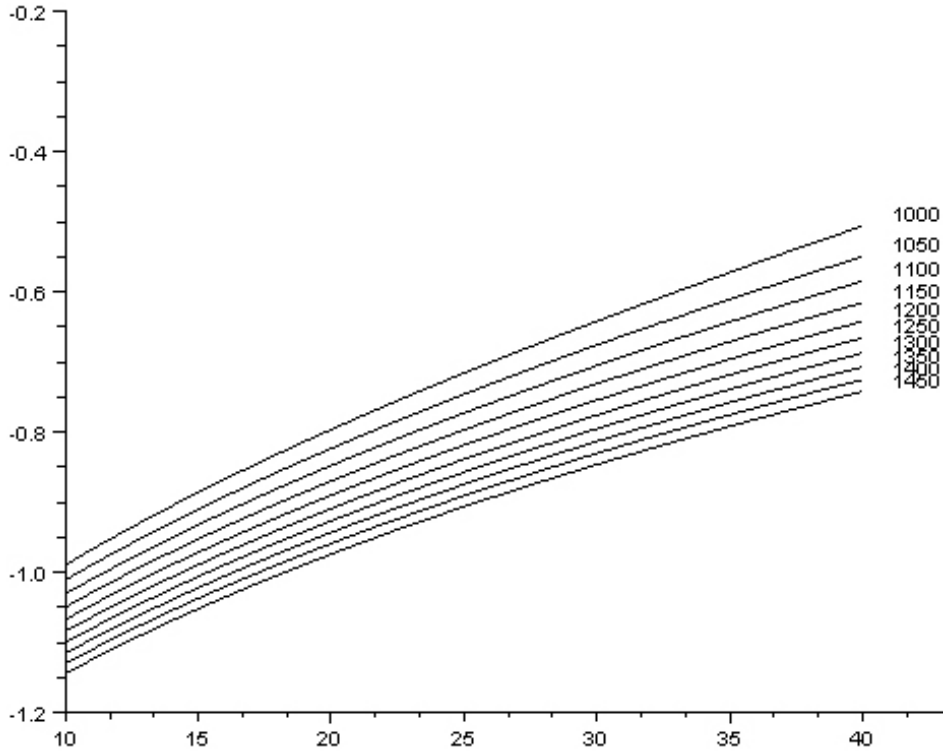

Figure 4. Differences of exergetic efficiencies between heptane and methane

DISCUSSION AND CONCLUSIONS

At a given turbine inlet temperature, a clear decreasing trend in the exergetic efficiency of the combined cycle can be observed along the considered series of alkanes, shown in figures 3 and 4. It can also be observed, although the curves for intermediate compounds have not been shown, that the difference of exergy efficiencies is narrower between consecutive compounds of higher order than between the first of the series. This effect seems correlated with the decrease of the molar fraction of water in combustion gases, which decreases significantly between the first elements of the series but tends asymptotically to 0.5.

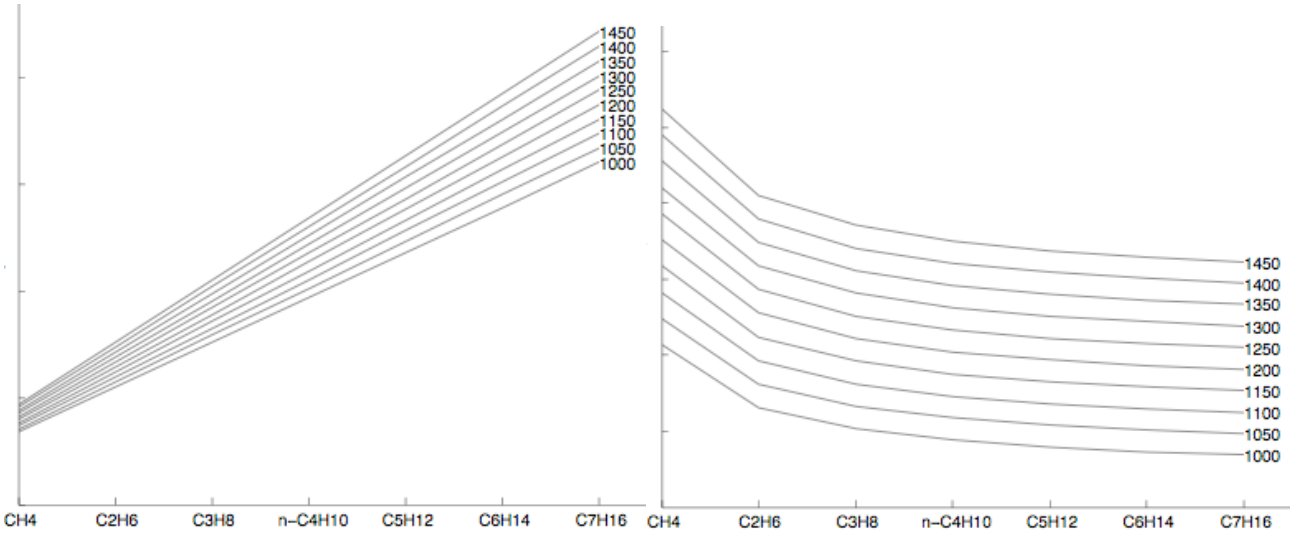

Figure 5. Left: Evolution of the specific power at the turbine for a given P_7/P_6 ratio
Right: Evolution of the turbine power contribution to exergetic efficiency

We may realize that, with respect to the turbine, the only difference between cases is the composition of the gases, and therefore their specific heat. A clear, rising trend with the number of carbons of the compound can be observed in the specific power produced at the turbine, as shown in figure 5 (left).

Given that heavier compounds exist as liquid at the input conditions considered in this study, meaning less compression power needed between 4 and 5, this could lead to expecting higher exergetic efficiencies for these substances. However, it can be seen in the previous section that the real trend is the opposite.

This can be explained by analyzing the evolution of the main contribution to exergetic efficiency, the turbine power term in equation (1). While the rising trend of specific power is clearly linear, in figure 5 (right) it can be seen that for a given turbine outlet/inlet pressure ratio, the decrease of the turbine term is exponential.

In summary, we may conclude that although there exists a decreasing trend with the number of hydorcarbons in exergetic efficiency, the differences are relatively small. Given that the content of C2+ compounds in turbine fuels will in general not exceed 20%, it is expectable that the effect in the overall efficiency will be negligible. However, this study has assumed several simplifications such as no

formation of NOx and total combustion, and bypassed turbine design questions. The influence in exergy of some of these aspects will be assessed in future stages.

Turbulence

TURBULENT FLOW IN A RIBBED CHANNEL ANALYSED BY THE PROPER ORTHOGONAL DECOMPOSITION

L. Wang[1*], M. Salewski[2], B. Sundén[1]
[1] Lund University, Lund, Sweden
[2]Risø National Laboratory for Sustainable Energy, Technical University of Denmark, Roskilde, Denmark

ABSTRACT. Particle image velocimetry (PIV) measurements and proper orthogonal decomposition (POD) are used to explore the turbulent structures in a ribbed channel. In this study, only one channel wall is equipped with square ribs which are oriented transversely to the main stream direction. The ribs obstruct the channel by 20% of its height and are arranged 10 rib heights apart. The results include mean streamlines, Reynolds shear stresses, two-point correlation coefficients, POD eigenvalues and eigenfunctions. By means of the POD analysis, the underlying flow features are identified, which are the strong upward ejections from the leading edge of the rib. Essentially, these motions give rise to the sharp peaks in the fluctuating turbulent kinetic energy and make great contributions to the Reynolds shear stress.

Keywords: *Particle image velocimetry, proper orthogonal decomposition,*

INTRODUCTION

The proper orthogonal decomposition (POD), which is based on the Karhunen-Loéve (K-L) expansion [1], was proposed by Lumley [2] as an unbiased technique for studying the coherent structures in turbulent flows. Unlike many other techniques, for instance conditional sampling, POD does not need any assumptions about the flow. The method decomposes the fluctuating velocity field into a sum of mutually orthonormal eigenfunctions weighted by random coefficients. The best correlated structures, in an average sense, of the turbulent velocity field are extracted [3]. An important feature of this decomposition is that the contribution of the extracted structures to second-order turbulence statistics can be determined [4].

Turbulent flows in a channel roughened with periodic transverse ribs are frequently encountered in various engineering applications, for example gas turbine cooling. Numerous experimental studies have been carried out to investigate the heat transfer characteristics in a ribbed channel. In the present study, the proper orthogonal decomposition technique is employed to study the flow structures in a ribbed channel. Two-dimensional particle image velocimetry is used to generate the instantaneous velocity data in a streamwise vertical plane. In this study, only one channel wall is fitted with periodic transverse square ribs. The ribs obstruct the channel by 20% of its height and are arranged 10 rib heights apart. The organization of this paper is as follows. Section 2 describes the experimental setup and measurement technique. Section 3 briefly formulates the theory of POD. The results and discussions are presented in section 4. The conclusion is given in section 5.

EXPERIMENTAL PROCEDURE

The experimental setup consists of a 750 mm long smooth channel followed by a rib-roughened section of equal length. The cross section of the channel is 50 mm × 50 mm. In the ribbed section, only one wall is quipped with periodic transverse ribs. The ribs obstruct the channel by 20% of its height and are arranged 10 rib heights apart. Two-dimensional velocity measurements are made in the vertical symmetry plane, as shown in Figure 1. The Reynolds number, based on the bulk-mean velocity U_0 and the height of the channel, is fixed at 22,000 throughout this paper.

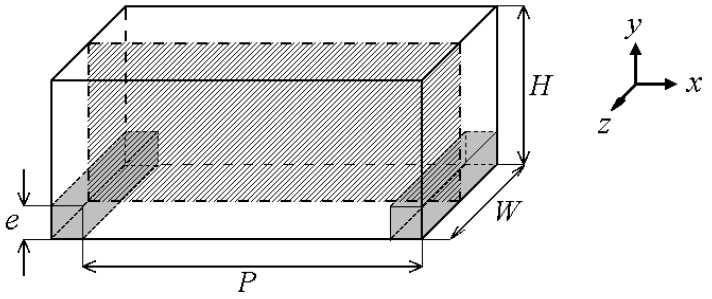

Figure 1. Rib configuration and measurement plane

A commercially available PIV system developed by Dantec Dynamics is used in the present investigation. A Quantel Q-switched Nd:YAG laser provides the pulsed illumination with a wavelength of 532 nm. The duration of each pulse is 10 ns and the maximum output energy is 120 mJ. The size of interrogation window is 32 × 32 pixels with 50% overlapping. The spatial domain contains 79 × 34 vectors, and the spacing between vectors is 0.67 mm. An ensemble of 1000 instantaneous velocity samples is generated with acquisition rate 4 Hz. Throughout this paper, reference quantities for length and velocity are rib height e and U_0, respectively. For the sake of convenience, all the times are normalized by 0.25s, which is the reciprocal of the acquisition rate in PIV.

OVERVIEW OF POD

The POD is a non-prejudiced technique for studying the structures in turbulent flows. The resulting structures are optimal in the sense that they represent the most common events occurring in the fluctuating fields. Consider, for example, an ensemble of fluctuating velocity fields $u'_i(x_j,t)$ which is time-dependent, non-homogeneous, and square-integrable (with finite kinetic energy) on a finite domain Ω (i, j = 1, 2, 3). We seek functions such that the mean-square energy projection onto them is maximized. By applying the calculus of variations, this leads to the following integral eigenfunction problem:

$$\int_{\Omega} R_{ij}(x_l,x'_k)\phi_j(x'_k)dx'_k = \lambda\phi_i(x_l) \tag{1}$$

where the kernel $R_{ij} = < u'_i(x_l,t)u'_j(x'_k,t) >$ is the two-point velocity correlation tensor. Each eigenfunction $\phi_i^{(n)}(x_l)$ is associated with a real positive eigenvalue $\lambda^{(n)}$, and the eigenfunctions form a complete set. That is, the random velocity field $u'_i(x_j,t)$ can be expressed as the linear superposition of the eigenfunctions

$$u'_i(x_j,t) = \sum_{n=1}^{M} a_n(t)\phi_i^{(n)}(x_j) \tag{2}$$

in which $a_n(t)$ are time-dependent coefficients. By projecting the $u'_i(x_j,t)$ on each of the eigenfunctions, we have

$$a_n(t) = \int_\Omega u'_i(x_j,t)\phi_i^{(n)}(x_j)dx_j \tag{3}$$

In addition, it is shown that temporal coefficients are uncorrelated and that the eigenfunctions are mutually orthonormal to each other. That is,

$$< a_n(t)a_m(t) >= \lambda^{(n)}\delta_{mn} \tag{4}$$

$$\int_\Omega \phi_i^{(n)}(x_j)\phi_i^{(m)}(x_j)dx_j = \delta_{nm} \tag{5}$$

It is useful to define the fluctuating kinetic energy E(t)

$$E(t) = \int_\Omega u'_i(x_j,t)\cdot u'_i(x_j,t)dx_j = \sum_{n=1}^{M} a_n(t)\cdot a_n(t) \tag{6}$$

To compute the eigenfunctions effectively, the snapshots technique is employed which was introduced by Sirovich [5] . The eigenvalues are arranged in descending order with $\lambda^{(1)}$ as the largest eigenvalue. As a result, $\phi^{(1)}(x,y)$ represents the 'dominant' turbulent structure.

RESULTS

Prior to presenting the various turbulence statistics and POD results, it is helpful to display some global flow features. Figure 2 shows the mean streamlines around the rib. The most striking feature is the formation of a large recirculation bubble downstream of the rib which is bounded between the free separated shear layer and the wall. A secondary vortex is also perceived in the leeward corner as the backward flow approaches the vertical surface. In addition, another vortex is observed in the windward corner in which the flow is subjected to a strong adverse pressure gradient.

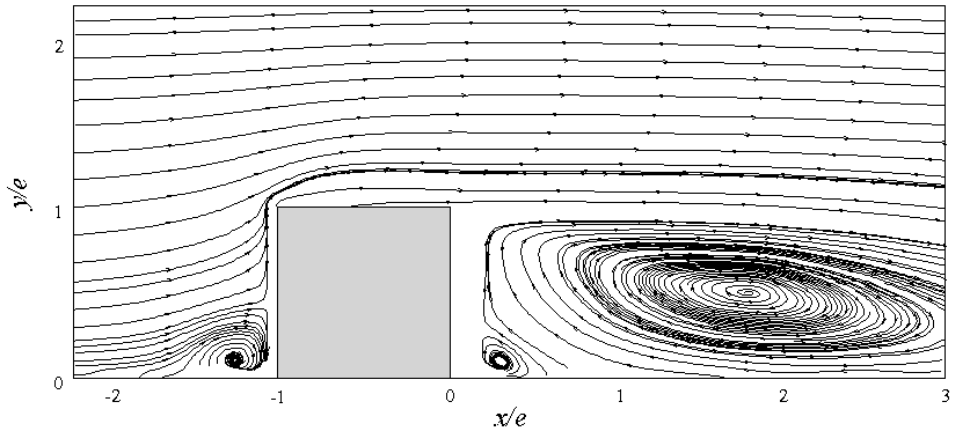

Figure 2. Mean streamlines around the sixth rib

The contours of Reynolds shear stresses are given in Figure 3. In this figure, only the quantities greater than $0.5<-u'v'>_{max}$ are demonstrated in order to highlight the region with large Reynolds shear stresses. It is clear that the maximum Reynolds shear stresses reside in the region upstream of the leading edge of the rib. In the separated shear layer, the general trend is that the Reynolds shear stresses rise up gradually with increasing distance from the rib.

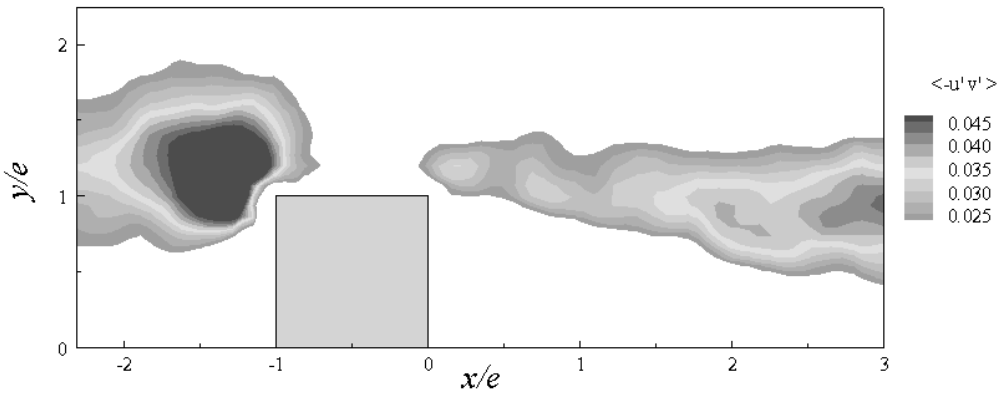

Figure 3. Contour of Reynolds shear stress, the quantities are normalized by U_0^2

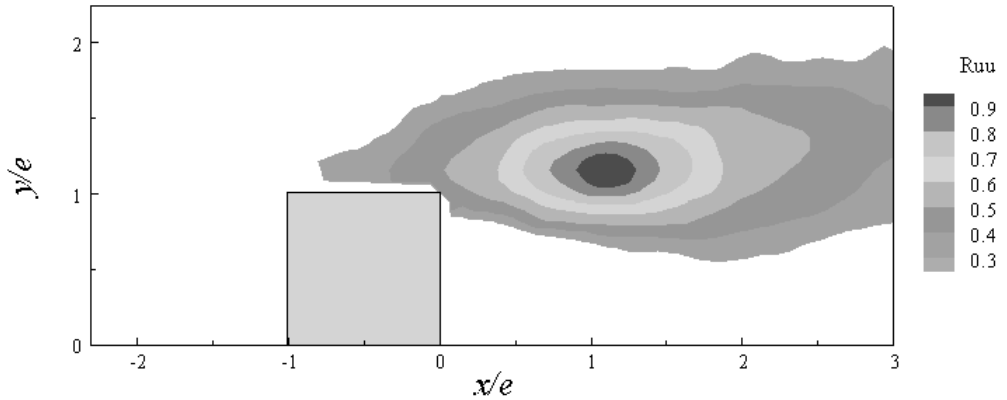
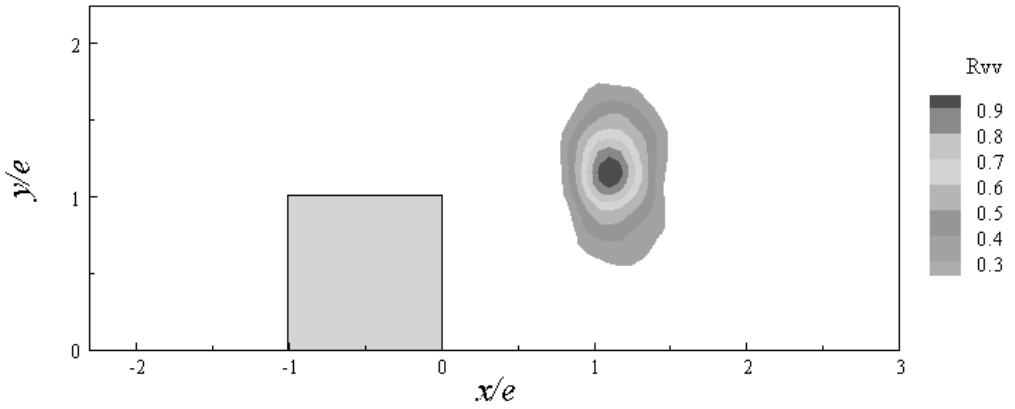
Since the extraction of POD modes is based on the autocorrelation tensor R_{ij}, it is of interest to examine the two-point correlation coefficients of original data to give an indication of the spatial structure of the flow. The correlation coefficient is defined as

$$R_{u_i u_j} = \frac{< u'_i(x_l) u'_j(x_k) >}{\sqrt{< u'^2_i(x_l) >< u'^2_j(x_k) >}} \tag{7}$$

where $u'_i(x_l)$ and $u'_j(x_k)$ are two instantaneous velocity fluctuations. In this paper, we only consider the correlation coefficient of the u' and v', denoted R_{uu} and R_{vv}, respectively. Figures 4a and 4b show the contours of R_{uu} and R_{vv} in the x-y plane, respectively. The reference location is point A (x/e = 1.1, y/e =1.1) which resides in the separated shear layer. In order to highlight the strongly-correlated events, the quantities below the value 0.3 are discarded. In Figure 4a, the elongated contours of R_{uu} are nearly aligned in the x-direction. For highly correlated regions (R_{uu} > 0.6), the contours are almost symmetrical. Further away from the reference point, the contours are obviously asymmetrical. The downstream extent of R_{uu} is much larger than the upstream extent which is shortened by the presence of rib. In Figure 4b, the contours of R_{vv} are approximately aligned in the y-direction. For the contour R_{vv} = 0.3, the normal extent of correlation is about twice as large as the streamwise extent. Comparing Figure 4a to Figure 4b, it is found that the spatial extent of R_{uu} is considerably greater than that of R_{vv}. This may be attributed to the generation of roller vortices (a series of vortices) in the separated shear layer which gives rise to a fairly long length scale for R_{uu}.



(a)



(b)

Figure 4. Contours of two-point correlation coefficients. (a) R_{uu} , (b) R_{vv}

POD decomposes the flow field into modes having various scales, and it allows us to evaluate the distribution of energy as a function of scale. Figure 5 shows the energy content, i.e. the summation of eigenvalues, versus the number of POD modes. It is shown that the first 100 modes contain 90% of the turbulent kinetic energy (TKE) in the flow domain. This cannot be considered as an effective convergence when comparing to decomposition of other flows. The slower convergence, generally speaking, is attributed to a large variety of scales present throughout the flow. As energy cascades across a fairly large range of scales, a wide range of energy distribution over POD modes is expected. Specifically, two causes lead to the increase in the range of scales. One is the additional length scales imposed onto the turbulence owing to the presence of rib, for example the rib height or the reattachment length; the other is the relatively high Reynolds number used in the present study. In turbulent flows, the higher Reynolds number always characterizes the broader range of scales.

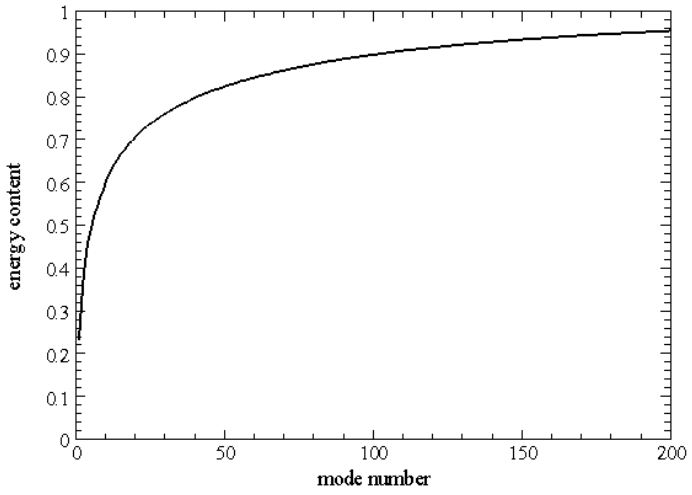


Figure 5 Energy content, sum of the eigenvalues versus the number of modes

In what follows, attention is paid to the fluctuating kinetic energy of the flow E(t), which can be calculated directly from the time-dependent coefficients a_n(t) in Eq. (6). Figure 6 plots the temporal evolution of E(t) based on 100 modes. Most noticeable are two sharp peaks at $t^+ = 33$ and $t^+ = 195$, in addition to a number of smaller peaks. The sharp rise of turbulent kinetic energy, essentially, is

attributed to the characteristic events occurring in flow fields. To gain further insights into the turbulent structures, a reconstructed instantaneous velocity field corresponding to the sharp peak is examined. Figures 7a and 7b demonstrate the reconstructed instantaneous velocity fields at $t^+ = 33$ and $t^+ = 195$, respectively. It should be noted that the velocities are obtained by adding the mean flow field $< U(x,y) >$ to the reconstructed fluctuating velocity field, i.e. $u(x,y,t) = < U(x,y) > + \sum_{n=1}^{100} a_n(t)\phi^{(n)}(x,y)$. In Figures 7a and 7b, the pronounced flow feature is the strong upward ejection from the leading edge of the rib. The magnitude of normal velocity is so large that it is comparable to the mean streamwise velocity <*U*> in the centre of the channel. When the rapid upward motion encounters the incident main stream, a sharp inclined shear layer is observed. The fluids, once ejected from the leading edge, move towards the central region along a curved path. In addition to $t^+ = 33$ and 195, we also analyze the instantaneous flow fields at $t^+ = 19$, 177, 599, 674, 698, 771, 836, and 964, which correspond to the smaller peaks in *E*(t) (where *E*(t) > 3). Except for the instant $t^+ = 599$, the upward ejection from the leading edge of the rib is a common flow feature.

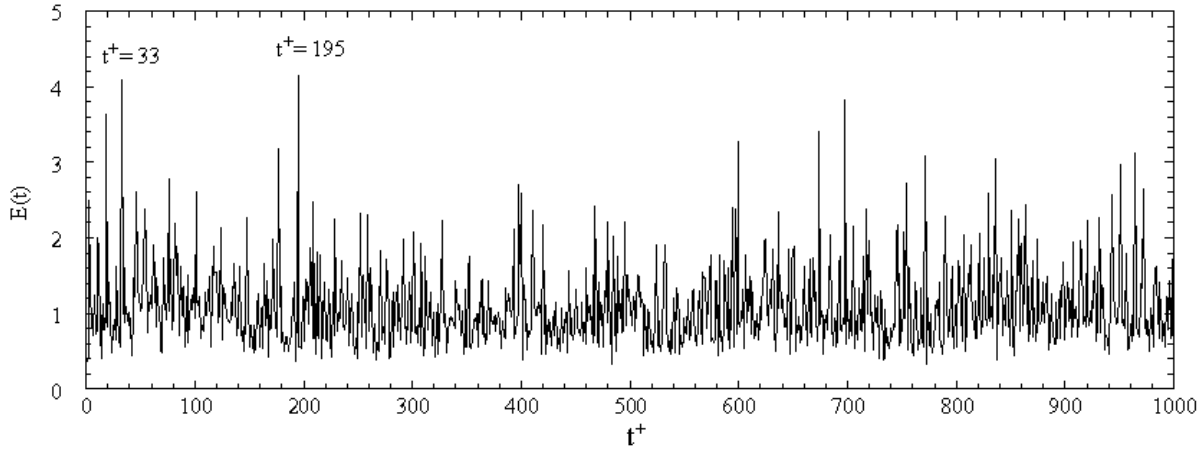

Figure 6. Temporal evolution of the fluctuating turbulent kinetic energy *E*(t)

Apart from the strong upward ejections, Figures 7a and 7b illustrate the vortical structures as well. In Figure 7a, a big recirculation bubble is visible downstream of the rib; in Figure 7b, three vortices are recognized in the separated shear layer. In order to view the vortical structures in great detail, Figure 8 presents the scaled-up velocity field corresponding to Figure 7b. In this figure, three distinct vortices are observed at *x/e* = 0.6, 1.6, and 2.6, respectively. These provide strong evidence that the roller vortices are generated by the Kelvin-Helmholtz instability. The vortex at *x/e* = 0.6, to the first order, is circular. However, the obvious asymmetry around its core suggests that its principal axis is inclined to the *x*-*y* plane. The vortex at *x/e* = 1.6 shows an apparent spiral pattern. The vortex at *x/e* = 2.6 begins to lose its coherence which may be attributed to the secondary instabilities applied on the primary Kelvin-Helmholtz rollers. In contrast to the roller vortices in the separated shear layer, the vortex in the wall region (*x/e* = 2.2, *y/e* = 0.2) seems to characterize the boundary layer development as the backward flow approaches the upstream rib.

CONCLUSIONS

By applying POD, the underlying flow features are extracted, and the second-order turbulence statistics are reconstructed. In this study, the most noticeable flow features are the strong, highly-intermittent upward ejections from the leading edge of the rib. Essentially, these underlying motions result in the sharp peaks in the fluctuating turbulent kinetic energy and make great contributions to the Reynolds shear stress. It is supposed that the upward ejections are triggered by the large-scale motions which are swept downward from the outer region as the separated shear layer curves and reattaches on the wall.

EFFECTS OF WALL PERMEABILITY ON TURBULENCE

K. Suga*, Y. Matsumura, Y. Ashitaka, S. Tominaga, M. Kaneda
Osaka Prefecture University, Sakai, Japan

ABSTRACT. PIV measurements are carried out for turbulent flows in a channel with a porous bottom wall. It is found that the laminar to turbulent transition occurs even at the bulk Reynolds number of Re_b=1300 and the flows become more turbulent in the case of high permeability. To confirm the effects of the wall roughness and the wall permeability, detailed discussions are made assuming the effective wall roughness for the porous media. The results clearly indicate that the turbulence is induced by not only the wall roughness but the wall permeability. The measurements have also revealed that as Re_b and /or the wall permeability increase, the wall normal fluctuating velocity is amplified drastically near the porous wall due to the effects of the wall permeability. This leads to the increase of the turbulent shear stress resulting in the higher friction factor of turbulent porous boundary layer flows.

INTRODUCTION

Highly permeable materials are used in various engineering devices such as catalytic converters, fuel cells, etc. due to the advantages of heat and mass transfer and chemical reaction by their large contact area. It is readily understandable that to provide the gas/fuel inside the porous media for chemical reaction, mass transfer enhancement over the porous wall is crucially important. Flows and mass transfer around porous media are thus of interest in industrial designing processes. However, not so much knowledge is available about the flow physics near highly permeable walls particularly in turbulent flow regimes though many research studies were historically performed.

Beavers and Joseph [1] firstly reported that the friction over porous walls of laminar flow regimes reduced due to the porosity. However, in turbulent flow regimes, the friction factors over porous walls were found to be higher than those over impermeable rough walls (e.g. Zagni and Smith [2], Zippe and Graf [3]). Kong and Schetz [4] assumed that the increase of the skin friction was due to the combined effects of roughness and porosity. Recently, the numerical study by Breugem et al. [5] revealed the turbulence structure over permeable walls and that the turbulent transfer was weakly blocked at the porous wall leading to weak streaky structures. In their simulation, they applied a volume averaging for the porous layer with the assumption that the permeability was a function of the porosity and hence it was unclear whether such phenomena were due to the porosity or due to the permeability of the wall.

Therefore, those studies in the literature did not try to discuss separately on the effects of the wall permeability from those of the porosity. Although the modern experimental techniques are far advanced, studies on highly permeable turbulent boundary layer have not been done yet and the detailed flow physics to explain such specific phenomena is still undeveloped. Therefore, in the

present study, to discuss and understand the turbulence mechanism over porous permeable materials, two velocity components of the turbulent fields over porous walls are measured by the modern PIV.

EXPERIMENTAL METHODS AND PROCEDURES

Figure 1(a) illustrates the present experimental setup. Tap water is pumped up from the tank, and the water flow is rectified by the honeycomb-bundled nozzle. Then the flow is introduced into the channel whose length is 3.0 m to achieve the full flow development. The channel consists of a solid smooth acrylic top wall while the bottom wall is made of a porous medium (foamed ceramics whose photo is included in the figure). The thickness of the porous wall is 0.03 m which is the same as the channel height H for the clear fluid region whose width is 0.3 m. Thus the aspect ratio of the cross section is 10. The channel continues to the 1m-length test section where the flow fields are measured by PIV (Dantec, Nd:YAG laser system). This device consists of a double-pulse Nd-YAG laser with the frequency of 532nm, a CCD camera of 30 fps, a camera lens and a computer for the data acquisition. The laser light is expanded to a sheet light with approximately 1mm-thickness and irradiates the symmetry plane of the channel where the instantaneous images are recorded by the CCD camera. The recorded area is $30\times30\text{mm}^2$ with 2048×2048 pixels.

For the PIV measurement, acrylic colloid particles, whose diameters and specific gravity are respectively 0.1-1 μm and 1.19, are used as the tracer particles. The number of the particle is adjusted over 5 in one control volume whose size is set to 64×16 pixels. The lens magnification is adjusted so that one particle is captured by 3.1 pixels and more. The image sampling rate is varied depending on the maximum particle moving distance in Δt. In the present experiments, the maximum moving distance is limited to 25 % length of the control volume.

After the recordings, recorded data are calculated by fast Fourier transform [6] with 50 % overlapping for the data precision in the normal velocity component. Therefore, the number of the control volume in the recorded area is 63×255. The velocity vectors are calculated from non-overlapped sequential 159 image pairs due to the limitation of the device specifications. For the sufficient precision, this procedure is repeated at least 20 times and integrated (3180 image pairs in total), and then the final vector data are obtained by averaging in the streamwise direction. Thus, totally 200340 velocity signals are used for the statistics at the single point in the wall normal direction.

The experimental parameters are the type of the porous media and the bulk Reynolds number Re_b. The representative characteristics of porous media are the porosity φ, the permeability K and the mean pore diameter D_p. The porosity is the ratio of the void volume to the total volume. The void volume is obtained by measuring the residual volume soaked into water. The permeability is obtained from the Darcy-Forchheimer equation [7] with the measured pressure difference, the Darcy velocity and fluid viscosity using the rig shown in Figure 1(b). The mean pore diameter D_p is measured from photographic images. The resultant three characteristics of the presently used porous media are listed in Table 1. In this study, three types of the foamed ceramics are employed as the bottom wall. Those media have quite same porosity, however, the permeability varies. Indeed, as in Table 1, the permeability of case #06 is 4.5 times as large as that of case #20.

Another experimental parameter Re_b is defined as $\text{Re}_b = U_b H/\nu$ where U_b is the bulk mean velocity and ν is the kinematic viscosity of the fluid. By averaging the integrated velocity profile across the channel, U_b is calculated. (Even if the flow rates inside the porous walls are included to calculate U_b , only a few percent increase of U_b can be estimated. In fact, the flow rate inside the porous wall estimated by using the Brinkman equation is 2% of the clear channel region's at Re_b=1300 of the highest permeability case #06.) In the present experiments, Re_b is set approximately between 1000 and 10000 covering both the laminar and turbulent flow regimes.

case #20	0.82	0.2	1.7

RESULTS AND DISCUSSIONS

Mean velocity profiles

Figure 2 shows the mean velocity distribution presently measured. Velocity distribution across the channel is normalized by the bulk velocity U_b. The surface of the foamed porous ceramics (y/H = 0) is determined as the outermost perimeter. The other side (y/H = 1.0) represents the solid acrylic wall. Near the top wall (y/H ~ 1.0), the velocity converges to 0 due to the non-slip boundary. On the contrary, the velocity near the porous wall (y/H ~ 0.0) increases as $\mathrm{Re_b}$ increases. This indicates the flow has an effective "slip velocity" at the surface of porous media due to the streamwise space averaging. (This slip velocity is further discussed later.) As the velocity slip becomes remarkable, the velocity profile changes into that of turbulent flow. The onset of the turbulence is shifted to the smaller $\mathrm{Re_b}$ than the ordinary critical Reynolds number. This effect is more apparent for case #06 than in case #20. Indeed, it is clearly indicated in Figure 2 that in case #06 the flow is turbulent from $\mathrm{Re_b}$ = 1300 while in case #20 the flow is still laminar even at $\mathrm{Re_b}$ = 2100. This can then confirm that porous media enhance the onset of the turbulence. It can be guessed that this enhancement is due to the wall permeability since all the tested porous media have nearly the same porosity.

To characterize the turbulent flow induced by the porous media, log velocity profiles are obtained for the mean velocity near the porous wall, which is shown in Figure 3. (Due to the page limit, the profiles of case #13 are omitted hereafter.) Superscripts p represents 'porous' and the U^{p+} and y^{p+} are normalized using the friction velocity u_τ^{p} obtained by extrapolating the measured Reynolds shear stress distribution (shown later). As $\mathrm{Re_b}$ increases, U^{p+} decreases and the turbulent regime sifts away from the wall, which is remarkable for the high permeable wall (case #06). This means the increase in the friction velocity. The turbulent region can be fitted by the least-square law to the equation:

$$U^{p+} = \frac{1}{\kappa}\ln y^{p+} + B \tag{1}$$

The corresponding fitted line is added in the figures and coefficients κ and B are listed in Table 2. Obviously, the Kármán constant κ varies ($0.3 < \kappa \leq 0.4$) according to $\mathrm{Re_b}$ and the porous media. This

Table 2 Coefficients for the fitted line in Figure 4 by equation (1)

porous media	Re_b	κ	B
case #06	1300	0.40	4.0
	2200	0.40	-0.6
	2800	0.40	-2.0
	5400	0.35	-6.0
	9500	0.34	-8.5
case #20	2400	0.40	3.3
	5500	0.36	-1.9
	10200	0.31	-6.9

suggests that as Re_b increases the turbulence structure near a porous wall differs from those along rough walls since the Kármán constant does not change so much in rough wall turbulence [8].

Transition in the slip velocity

In Figure 2, the velocity near the porous wall has a jump depending on Re_b. The dependence of the slip velocity U_w on the Re_b is further discussed. Figure 4(a) shows the transitional behaviour of the slip velocity estimated by the extrapolation of the velocity distribution to the wall surface. In all the cases, there can be found narrow transitional regions where U_w/U_b increases steeply. In fact, in case #20, the transition begins at $Re_b > 2000$, while it does at $Re_b > 1000$ in case #06. In case #13 the tendency shown is in between those of cases #06 and #20. Consequently, apparent effects of the porous characteristics can be found on the turbulence transition. After the transition to the turbulence, the slip velocity becomes almost constant and the value of U_w/U_b tends to be larger in higher permeability cases. These characteristic profiles of the slip velocities have a quite unified profile against the permeability Reynolds number Re_K ($=u_\tau^p K^{1/2}/\nu$) as shown in Figure 4(b). This means Re_K can be a good measure for permeable turbulent boundary layers.

Roughness effects

Through the above discussions, it is confirmed that turbulence is induced by the porous surface. However, it is still unclear that the role of the wall permeability for the turbulence enhancement since wall roughness also induces turbulence. To clarify the factor to induce the turbulence by the wall permeability, the effects of surface roughness are discussed.

Although the turbulence is induced by both the wall roughness and permeability, the discussions here assume that all the turbulence effects come from the wall roughness only. The velocity profiles in Figure 3 are re-plotted in Figure 5 with the consideration of the effective roughness height Δy. Since the porous wall does not have a definite bottom, the present study estimates Δy by applying the extended Brinkman equation [5] to the flow profile inside the porous media as schematically shown in Figure 5. Then the velocity profile can be fitted by using Cebeci-Bradshaw's correlation [9]. This correlation is based on the assumption that all the turbulent enhancements come from the wall roughness and its profile is as follows;

$$U^{p+} = \frac{1}{\kappa}\ln\left(y+\Delta y\right)^{p+} + 5.2 - \left(5.2 - 8.5 + \frac{1}{\kappa}\ln h^{p+}\right)\sin\left(0.4258[\ln h^{p+} - 0.811]\right), \quad \text{if} \quad 2.25 < h^{p+} < 90$$

$$U^{p+} = \frac{1}{\kappa}\ln\frac{\left(y+\Delta y\right)^{p+}}{h^{p+}} + 8.5, \quad \text{if} \quad h^{p+} \geq 90 \qquad (2)$$

where h^{p+} is the dimensionless equivalent sand grain roughness height. The fitted line is added in Figure 5 and the obtained κ, h^{p+} and corresponding dimensional equivalent sand grain roughness height h are summarized in Table 3. The gradient of the slopes is not constant in $\mathrm{Re_b}$ and thus the corresponding κ varies. The height h increases as $\mathrm{Re_b}$ and the value of h in case #06 is larger than that in case #20. This corresponds to that the roughness effects are remarkable in case #06 and depend on $\mathrm{Re_b}$.

However, this fact does not agree with the original concept of the correlation since the dimensional equivalent sand grain roughness height does not normally change by $\mathrm{Re_b}$ in the rough wall turbulence. Therefore, the tendency in the present experimental data implies that the other effects also contribute to the turbulence. The permeability is thus the factor to be considered and its contribution to the turbulence is discussed in the next section in terms of the turbulent intensities.

Figure 6 shows the profiles of κ, h^{p+} and Δy^{p+} listed in Table 3 against the permeability Reynolds number Re_K. It clearly shows that those profiles can be unified with single correlation lines:

$$\kappa = 0.23\,\mathrm{Re}_K^{-0.23}, \quad h^{p+} = 25.6\,\mathrm{Re}_K^{1.6}, \quad \Delta y^{p+} = 36.8\,\mathrm{Re}_K^{1.2} \qquad (3)$$

With those correlations, the experimental correlation of the mean velocity over permeable walls can be derived.

Turbulent intensities and Reynolds stress

The turbulent intensities are calculated to clarify the effect of the wall permeability. The distribution profiles of the turbulent root mean square velocity components u'^{t+}, v'^{t+} are plotted in Figure 7. (The values with the superscripts "$t+$" mean the normalized value using the top wall friction velocity u_τ^t obtained by extrapolating the measured Reynolds shear stress.) In case #06, u'^{t+} near the porous wall ($y/H \sim 0$) is not affected by Re_b, except $1300 < Re_b < 2200$ where transition to turbulence occurs. On the contrary, v'^{t+} keeps increasing as the increase of Re_b even after the transition to turbulence. This apparently represents that the normal velocity fluctuation is enhanced by Re_b, which suggests the promotion of the penetrating flow into the porous media at high Re_b. In case #20 the flows have the same tendency. Therefore, the mechanism of the turbulent enhancement by the

porous media can be explained by the increase in the wall normal velocity fluctuation related to the bulk flow velocity.

Comparing at almost the same Re_b, the value of v'^{+} in case #06 is larger than that in case #20. As shown in Table 1, case #06 has larger permeability than in case #20 despite the same porosity. These facts imply that the penetration flow is affected by the permeability in addition to Re_b. In other words, the blocking effects by the porous wall are reduced by the wall permeability, which become remarkable at higher Re_b.

The Reynolds shear stress $-\overline{u'v'}$ is plotted in Figure 8. Due to the large contribution of v'^{+} shown in Figure 7, $-\overline{u'v'}$ near the porous wall monotonically increases as the permeability and Re_b. In addition, the value of $-\overline{u'v'}$ in case #06 is larger than that in case #20 compared at the corresponding Re_b. This represents that the turbulent shear stress depends on the permeability and Re_b. That is, the higher wall permeability can obtain higher turbulence effects at lower Re_b.

CONCLUSIONS

The turbulent flows over permeable walls are studied by using PIV measurements at different wall permeability and Reynolds numbers. The velocity slip occurred on the porous wall and simultaneously the turbulence is induced at the low Reynolds number. The velocity slip transits in a narrow range of the bulk Reynolds number. The velocity distribution near the porous wall becomes different to that for a solid wall. The estimated effective sand grain roughness height is found to be affected by the Reynolds number, which suggests that the turbulent flow is induced not only by the porous roughness but by the wall permeability. From those data, an experimental correlation of the logarithmic layer of the mean velocity is deduced. The wall normal velocity fluctuation component reveals that the flow penetration into the wall is a key factor to induce the turbulence on the permeable wall and its contribution is affected by the permeability. The increase in the wall normal velocity fluctuation also enhances the turbulent shear stress. Consequently, on the permeable walls, both the wall roughness and the wall permeability are important to induce turbulence. The higher permeable wall flow at lower Reynolds numbers can posses the same turbulence effects as those in the lower permeable wall flow at higher velocity, which can be applied to the engineering devices.

ASSESSMENT OF ANISOTROPY IN THE NEAR FIELD OF A RECTANGULAR TURBULENT JET

A. Cavo[1], G. Lemonis[2], T. Panidis[1, *]
[1] Laboratory of Applied Thermodynamics, University of Patras, Patras, Greece
[2] Hellenic Aerospace Industry S.A., Schimatari, Greece

ABSTRACT. The anisotropy in the near field of a rectangular turbulent jet with aspect ratio 6 is experimentally assessed. The presented data were obtained using an in-house constructed 12-sensor hot wire probe consisting of three closely separated orthogonal 4-hot wire velocity arrays. Measurements have been conducted in a jet with Reynolds number Re_D = 21000 at distances from the nozzle exit, x/D =1, 3, 6 and 11, where D is the width of the nozzle. The results of the present study indicate that the direct production of turbulent energy by the mean shear leads to a strong anisotropy in the fluctuating fields for $0<x/D<11$. Moreover, it is clear that the large scales have not relaxed to isotropy in spite of the absence of the mean shear at the centreline of the jet.

Keywords: *Rectangular jet, turbulent jet, mixing layers, plane jet, free jet*

INTRODUCTION

A rectangular turbulent jet has many practical applications in aerospace, in mechanical and chemical engineering. There were many experimental investigations in jets issuing from rectangular nozzles which have enhanced our understanding of the underlying physics of these flows mainly from information on the velocity field (Krothapalli et al. 1981, Sfeir 1979, Sforza & Stasi 1979, Grinstein 2001, etc). It has been well documented from many researchers that aspect ratio of the nozzle and initial conditions at the jet exit play an essential role in the distribution of the rectangular jets' properties, especially in the near field (Quinn 1992, Lazanova & Stankov 1998, Deo et al. 2007, etc). The intention of this work is to assess the anisotropy in the near field of a rectangular turbulent jet an issue not extensively covered in current literature, due to inherent difficulties in measuring the relevant characteristic properties. A unique attribute of the present study is that the spatial derivatives in all three directions of the three components of the fluctuating velocity field have been directly measured using a 12-sensor hot wire anemometry probe. The performance of the 12-sensor probe in the near field of a rectangular turbulent jet has been assessed by Cavo et al. (2007) in comparison with corresponding measurements with an X-wire probe and other experimental and numerical studies.

EXPERIMENTAL ARRANGEMENT

The jet exits from a rectangular nozzle with length L=300 mm and width D=50 mm (Figure 1). The aspect ratio is AR=L/D=6. The experiment was conducted at a Reynolds number $Re = U_0 D/\nu = 21000$, where U_0 is the exit velocity from the nozzle and ν is the air's kinematic viscosity at environmental temperature (23°C). The streamwise turbulence intensity distribution at

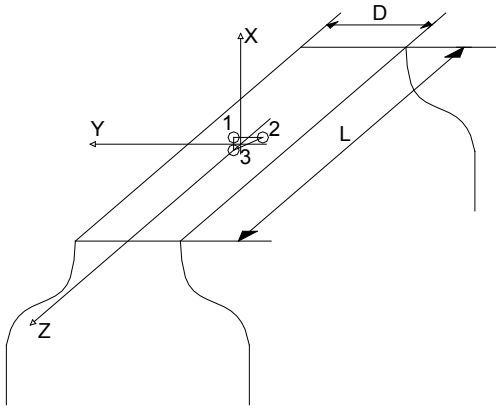

Figure 1 Jet nozzle and coordinate system

the nozzle exit was uniform and had a constant value of about 1%, except in the boundary layers adjacent to the nozzle lips, where the maximum value was about 2%. The initial boundary layers developed on the nozzle lips are characterised as laminar (Cavo et al. 2007).

The 12-sensor probe manufacturing, probe calibration and data reduction techniques rely upon previous work of Lemonis (1995), and have been further improved and refined at the Laboratory of Applied Thermodynamics of the University of Patras. The probe composing of three 4-wire arrays (Figure 2) measures simultaneously the three-dimensional velocity vector components at the centroids of the three arrays on a cross plane of the flow field. Spatial velocity derivatives are estimated using a forward difference scheme of first order accuracy. Streamwise velocity derivatives are estimated using Taylor's frozen turbulence hypothesis. Details regarding the design and operation of the 12-sensor probe as well as the experimental facility, used in the present experiment can be found in Cavo et al. (2007).

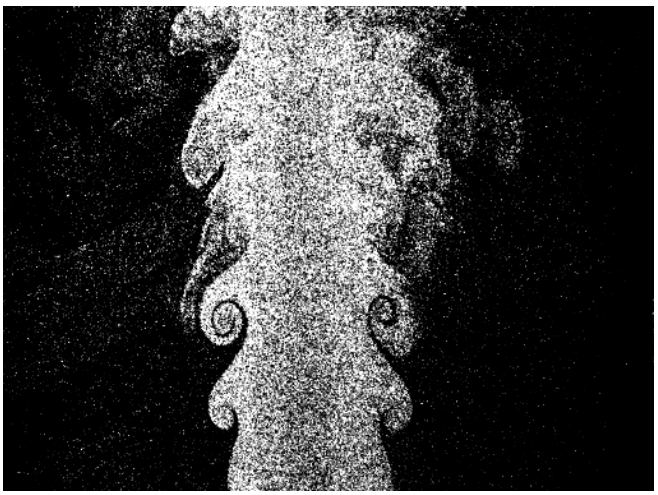

Figure 3. Flow visualization of a rectangular jet in the near field region

EXPERIMENTAL RESULTS

The behaviour of the planar jet due to the merging of the mixing layers is consistent with the eventual breakdown of the structures generated from the rollup and pairing of spanwise vortices ($0 \le x/D \le 4 \div 5$) to strongly three-dimensional turbulence. Figure 3 shows a characteristic flow visualization image of the rectangular jet in the near field region. Rockwell & Niccolls (1972) results, as well as the present visualization, indicate that near the nozzle exit the large-scale structures in the flow field are predominately symmetric for flat exit profiles. When the shear layers interact downstream, these structures reorganize into an asymmetric configuration in the fully developed region of the jet.

Measurements of the present study have been conducted in the jet at distances from the nozzle exit, x/D =1, 3, 6 and 11. Experimental results based on measurements with the 12 wire and the X wire probe are compared with several experimental and computational (DNS) data of other investigations on plane jets (Browne et al. 1983, 1984, Everitt and Robins 1978, Gutmark and Wygnanski 1976, Ramaprian and Chandrasekhara 1985, Stanley et al. 2002), rectangular jet (Quinn 1992) and two stream mixing layer (Bell and Mehta 1990, Spencer and Jones 1971, Wygnanski and Fiedler 1970) of various Reynolds numbers.

Mean velocity-vorticity field

The mean streamwise velocity, U, profiles normalized by the centreline velocity, U_c, at different stations are shown in Figure 4, in comparison with corresponding measurements of the X-wire probe (Cavo et al. 2007) and experimental results of other investigators. The velocity at the exit plane of the nozzle presented an almost top hat profile as evidenced by x/D=1 measurements. Further downstream the profiles assume a bell shaped distribution and are in agreement with corresponding profiles of Quinn (1992) and Browne et al. (1984). The presented results at x/D=6 and 11 indicate that planar jet similarity as far as the mean velocity distributions are concerned may be claimed at least for a limited range, within the two dimensional region of rectangular jets.

In rectangular jets downstream derivatives of mean velocity components are expected to be small compared to cross-stream derivatives, $\partial/\partial x << \partial/\partial y$. Under these conditions, the dominant mean vorticity component $\Omega_z = \partial V/\partial x - \partial U/\partial y$ can be estimated approximately as $-\partial U/\partial y$ and a reasonable estimate of Ω_z may be obtained by differentiating the distribution U(y).

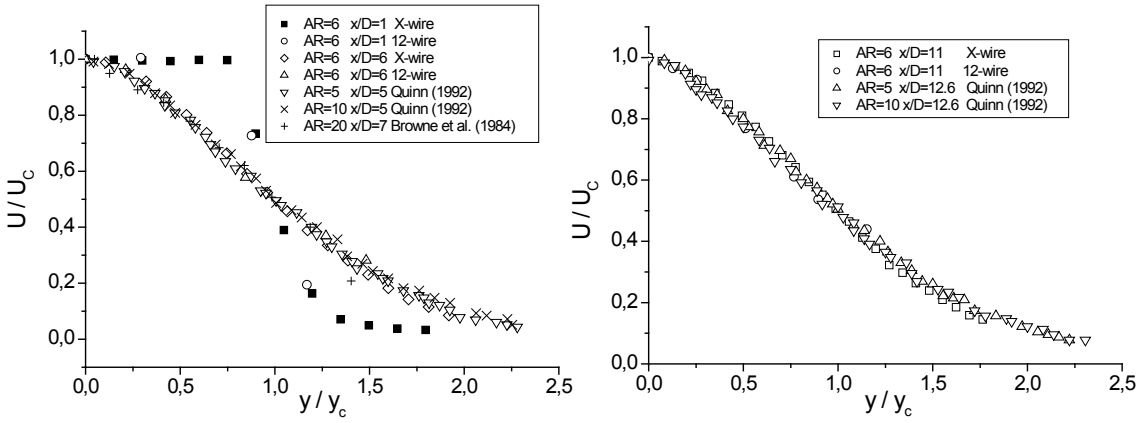

Figure 4. Mean streamwise velocity profiles (x/D=1, 3, 6, 11)

Figure 5 depicts lateral profiles of mean spanwise vorticity, Ω_z, at different locations downstream (Cavo et al. 2007). Two kinds of estimates are presented. Based on the above analysis Ω_z is first estimated calculating the $\partial U/\partial y$ derivative, differentiating U(y) curve measured with the X wire. The second Ω_z estimate is obtained by averaging the time series of local instantaneous spanwise vorticity results of the 12-wire probe. Close to the nozzle exit high values of vorticity are observed in the shear layers developing between the jet and the ambient fluid, whereas doesnsteam measurements indicate the diffusion of vorticity from the shear layers towards the centre and the edges of the jet.

Turbulent velocity-vorticity field

Figure 6 shows measurements of the root mean square (rms) values of the three fluctuating velocity and vorticity components at x/D=1, 3, 6, 11. The profiles have been normalized with U_0 and U_0/D respectively. These results demonstrate the growth of velocity-vorticity fluctuations in the potential core region (x/D=1, 3) within the shear layer due to rollup and pairing of spanwise vortices. The lateral distributions of the velocity-vorticity components are significantly changed downstream by the interaction of the shear layers. This change is associated with the growth of fluctuations around

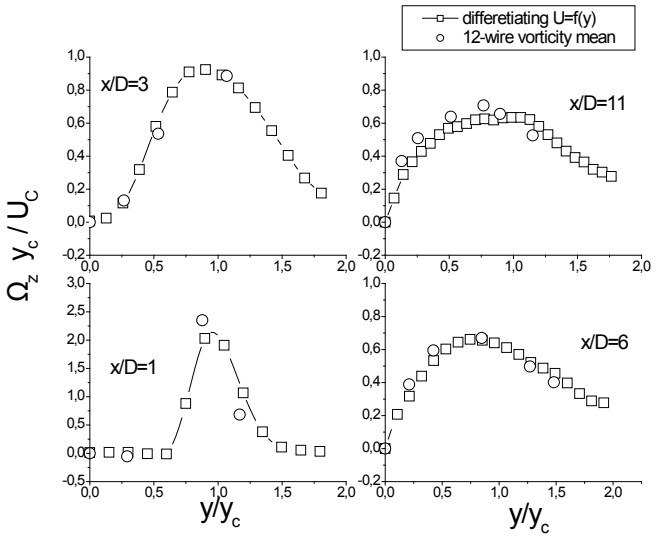

Figure 5. Mean spanwise vorticity distributions (x/D=1, 3, 6, 11)

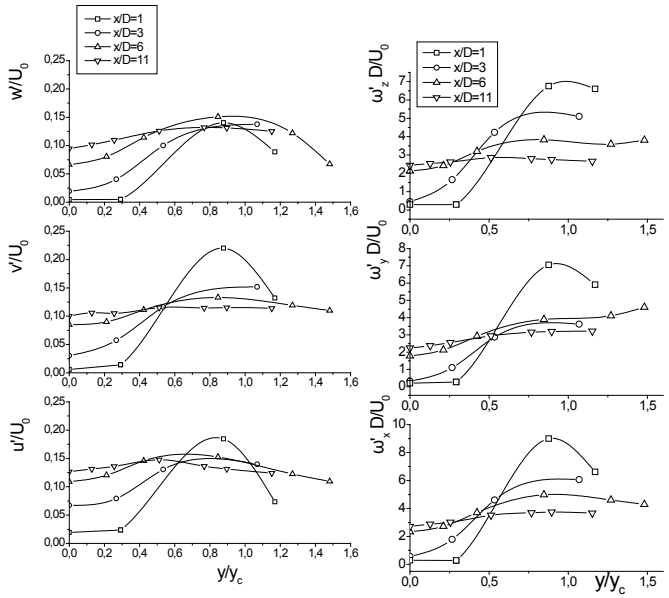

Figure 6. Measured rms value of the three fluctuating velocity-vorticity components

the axis area and with decrease of rms values within the shear layers (x/D=6, 11). This behaviour is characterized by the turbulence diffusion from shear layers towards the centre and edges of the jet. It seems that areas with low or high levels of velocity turbulence are associated with corresponding levels of vorticity turbulence respectively.

Assessment of anisotropy

The normal Reynolds stresses anisotropy levels at $y/y_c \approx 1$ in the near field region of the rectangular jet are shown in Table 1 compared to available experimental and numerical (DNS) data. The direct production of energy by the mean shear at x/D=1 seems to lead to a strong anisotropy in the fluctuating field in this region of the jet, amplifying the $\overline{vv}/q^2$ component. As expected this anisotropy is reduced downstream and jet development seems to be characterized by a redistribution of energy between the three directions probably due to pairing, which is the main mechanism of the evolution of the shear layer (Grinstein 2001). This process results in the augmentation of the other two normal stresses at the expense of the $\overline{vv}$ component, which eventually becomes less than the isotropic value. Differences with Stanley et al. (2002) results should probably be attributed to the different initial and boundary conditions whereas all other results on plane jets depicted in table 1 have been obtained in the full development region.

On the jet centreline at x/D=11 (Table 2) the streamwise component is higher than the isotropic level while the lateral and spanwise components are below this level. It is clear that the large scales have not relaxed to isotropy in spite of the absence of mean shear at the centreline. As shown in Table 2, the present results are in a good agreement with the experimental results of Gutmark & Wygnanski (1976) and Browne et al. (1983) for fully developed jets.

Table 3 lists the normal velocity derivative variances on the centreline as well as in the high-shear regions. While DNS results are very close to the isotropic value, the deviations of the present results from it are significant. The different values between the two cases should be attributed to the different stage of the flow development, since the results of Stanley et al. (2002) indicate that at x/D=11 the jet has reached full development. As stated in their work the large scales of the flow relax slowly to isotropy in the absence of mean shear at the centreline whereas the small scales

adjust quite rapidly. The results of the present work indicate that the jet has not reached the full development region in accordance with experimental results of previous studies indicating that full development of planar jets is attained at distances x/D>30-40.

The development of rectangular jet in the near field after the interaction of the shear layers which occurs beyond the tip of the jet potential core, similar to that of a plane jet, is controlled by large-scale coherent vortical structures which are characterized by their persistence. On the other hand, vortices in the full development region have lost most of their energy. Consequently it is expected that the near field region will be characterized by anisotropy whereas the flow may relax towards isotropic attributes in the fully developed region. Table 4 shows the variance of the cross-derivative terms at x/D=11, where the same differences between the two investigations are observed. This behaviour is attributed also to the different initial and boundary conditions of the two studies. As is well known jet development in the near field is expected to be influenced mainly by aspect ratio and factors such as jet exit formation, Reynolds number and room turbulence (Cavo et al. 2007).

CONCLUSIONS

The anisotropy in the near field of the turbulent rectangular jet of aspect ratio 6, at Re=21000 has been illustrated and discussed in detail. The results obtained with a 12 sensor hot wire probe indicate that the formation and development of large-scale vortices in the shear layers of the rectangular jet lead to the anisotropy of the flow. A strong advantage of the current results in comparison with other studies is that the spatial derivatives of the three components of the fluctuating velocity field in all three directions have been directly measured.

PRESSURE FLUCTUATIONS PRODUCED BY A JET IMPINGING ON A WALL AT NORMAL AND OBLIQUE INCIDENCE

ABSTRACT. The spatio-temporal characteristics of the wall pressure produced by an axisymmetric jet impinging on a round plate are examined. The particular emphasis of this examination is to study the influence of the jet impingement angle on the unsteady wall-pressure field. This is accomplished by measuring the surface-pressure fluctuations using an array of 30 microphones that are arranged in radial as well as azimuthal configurations. Data are reported for a jet Reynolds number of 16500, a plate-to-jet-exit separation distance of 4 and normal as well as oblique impingement angles. The results show that oblique impingement leads to substantial asymmetry in the wall-pressure field involving both magnification as well as attenuation of the pressure fluctuations. The former is found in the half plane where the jet experiences more obtuse turning relative to normal impingement and the latter in the half plane where the jet makes a sharper turn.

Keywords: *jets, free-shear flows, turbulence, pressure fluctuations*

INTRODUCTION

Impinging jets are significant to many practical engineering applications, including heating, cooling and drying. Many studies of impinging jets have focused on the examination of the heat transfer from the impingement plate (e.g. Yan *et al.* [1], Viskanta [2], Lytle and Webb [3] and Webb and Ma [4]) and the flow field (Didden and Ho [5], Popiel and Trass [6] and Landreth and Adrian [7]). In contrast, there is little information regarding the space-time characteristics of the pressure fluctuations (p') acting on the impingement plate. The exceptions are two recent studies by Hall and Ewing: one [8] where two-point wall-pressure measurements are employed and the other [9] based on the use of extensive wall-pressure-sensor-array measurements. Such information has direct relevance to unsteady loading on the impingement plate as well as flow-induced noise and vibration. Moreover, the intensity of p' is indicative of the strength of the associated turbulent flow structures, which are responsible for significant enhancement in heat transfer in impinging jets.

In the vicinity of the impingement plate, the flow field of a round impinging jet may be divided into two regions: a stagnation region ($r/D < 1$; r is the radial coordinate measured from the centre of the jet and D is the jet diameter), where the turning of the jet to become parallel to the plate takes place, and a wall-jet region ($r/D > 1$). Using data from azimuthal wall-pressure arrays, Hall and Ewing [9] found the dominant p' modes to be helical in the stagnation region. The strength of these modes, which the authors linked to the flow structures existing in the jet prior to its impingement on the plate, increased with increasing distance between the jet exit and impingement plate. In the wall-jet region, Hall and Ewing [9] found axisymmetric and helical structures to be significant. Both modes had the same frequency, which was different from the much lower frequency of the helical modes found in the

stagnation zone, and they decayed in strength with increasing separation between the jet exit and the plate. This led the authors to conclude that the helical modes identified for $r/D > 1$ were not the same as those originating in the jet and found in the stagnation zone. Instead, Hall and Ewing [9] hypothesized that an asymmetric interaction of the jet's flow structure with the impingement plate caused the formation of the helical modes observed in the wall jet.

Although the investigations of Hall and Ewing [8] and [9] provide considerable insight into the spatio-temporal characteristics of the wall pressure, similar information is lacking for oblique jet impingement. The present study employs an approach similar to that of Hall and Ewing to fill this gap for a round jet impinging on a circular disc.

EXPEIMENTAL SETUP

The experimental setup is illustrated in Figure 1: an axisymmetric air jet with a top-hat exit velocity profile and a diameter D = 25.4 mm impinges on a flat, circular disc. The diameter of the disc is 12D, which is more than an order of magnitude larger than the jet diameter in order to minimize disc-edge effects on the measurements. The impingement disc is located at a distance H away from the jet exit and could be inclined to cause deviation from normal impingement by an angle γ (see Figure 1).

Unsteady-surface-pressure (p') data are acquired using 30 microphones embedded in the impingement plate. Each microphone is a Panasonic WM-61A electret microphone with a package diameter of 6 mm and a sensing-hole diameter of 2 mm (approximately 0.08D). The frequency response of all microphones is obtained from calibration against a Brüel and Kjær ¼" microphone (model 4938-A-011) in a plane wave tube. The calibration procedure is similar to that employed by Daoud and Naguib [10]. The sensors are configured into one radial array at an azimuthal angle θ = 90°, and two azimuthal arrays at r/D = 1 and 2.33, as depicted in Figure 2 (also note the coordinate-system's definition in the figure). The radial array contains eight microphones that are spaced 0.33D apart starting from r/D = 0. On the other hand, the azimuthal array at r/D = 1 contains eight uniformly distributed microphones, while the one at r/D = 2.33 has sixteen microphones with an angular spacing of 22.5°. Microphone signals are sampled simultaneously at the rate of 5000 samples/s for a jet exit velocity U_j = 10 m/s, H/D = 4, and γ = 0 and 30°. The corresponding jet Reynolds number based on diameter is $Re_D \approx 16500$.

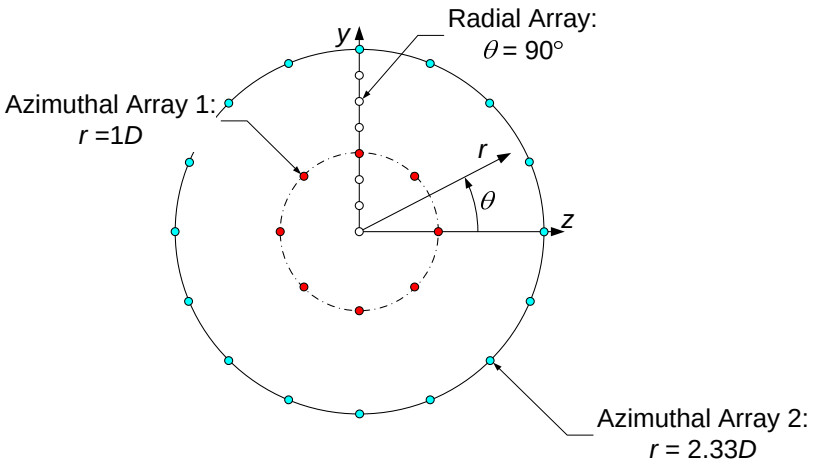

Figure 2. Microphone-array configuration

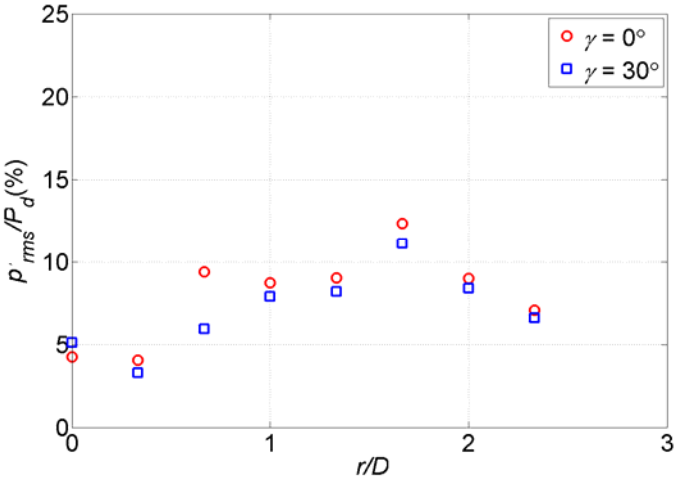

Figure 3. Radial distribution of the *rms* pressure fluctuations along the ray $\theta = 90^o$ for normal ($\gamma = 0^o$) and oblique ($\gamma = 30^o$) impingement. P_d is the dynamic head based on jet velocity: $P_d = \frac{1}{2}\rho U_j^2$

RESULTS AND DISCUSSION

Figure 3 depicts the radial distribution of the root-mean-square (*rms*) pressure fluctuation normalized by the dynamic head ($P_d = \frac{1}{2}\rho U_j^2$) for normal (red circles) and oblique (blue squares) impingement. The distribution is obtained along the line corresponding to $\theta = 90^o$, which coincides with the axis around which the impingement plate is rotated. Overall, no significant differences are seen in the pressure fluctuation distribution between the two cases. One exception is at $r/D = 0.67$, where p'_{rms} is larger for normal impingement. This location is inside the stagnation zone ($r/D < 1$) in the vicinity where the shear layer interacts with the plate. The deviation is possibly indicative of a stronger interaction of the shear layer with the plate at normal incidence.

The normal-impingement p'_{rms} results are consistent with those obtained recently by Hall and Ewing [9]. In particular, the latter authors find two peaks in the *rms* distribution: one in the stagnation zone, where the shear-layer interacts with the plate, and the other in the wall-jet region at $r/D = 1.5$. Hall and Ewing associated the latter peak with the formation of secondary vortices caused by the interaction of the convecting vortex structures, which originate in the jet shear layer, with the impingement plate. The present results show a subtle peak at $r/D = 0.67$ in the stagnation zone, and a prominent one at $r/D = 1.67$ beneath the wall jet. The stagnation-zone peak is substantially less observable than that identified by Hall and Ewing. The more energetic peak in the latter study is believed to result from the turbulent character of the jet flow, which forms at the exit of a fully-

developed turbulent pipe flow. In contrast, in the present study, the jet discharges from a plenum at the exit of a contoured nozzle.

The power spectral density ($\phi_{p'p'}$) plots corresponding to the *rms* data of Figure 3 are displayed in Figures 4 and 5 for normal and oblique impingement respectively. With the exception of the spectrum at r/D = 0.67, which contains more fluctuation energy in the former case, no major deviation in the behaviour of the spectra is seen between the two cases. Focusing on Figure 4, a local spectrum peak is found at a normalized frequency $fD/U_j \approx 0.4$ near the stagnation point (r/D = 0 and 0.33). At larger r/D values, but still within the stagnation zone, the spectrum becomes broader, the fluctuation energy increases (as seen from the rise in the spectrum) and the spectral peak shifts to $fD/U_j \approx 0.3$ at $r/D = 0.67$. The increased broadness of the spectrum presumably results from broadband turbulence in the shear layer influencing the pressure fluctuation at locations where the shear layer interacts with the wall. As will be seen from the analysis of the cross spectra, the superposition of these broadband fluctuations onto those produced by the coherent motion causes the shift in the spectrum-peak frequency found at r/D = 0.67. In other words, the change in spectrum-peak frequency is not a manifestation of the change in the frequency of the pressure-signature of the convecting coherent structures in the flow.

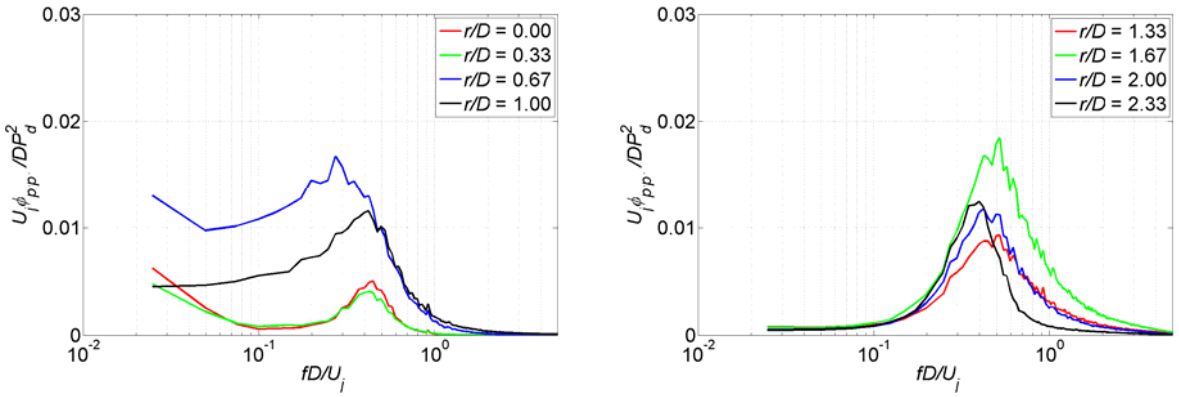

Figure 4. Power spectral density at different radial locations along the ray $\theta = 90^o$ for normal impingement: stagnation zone (left); wall-jet zone (right)

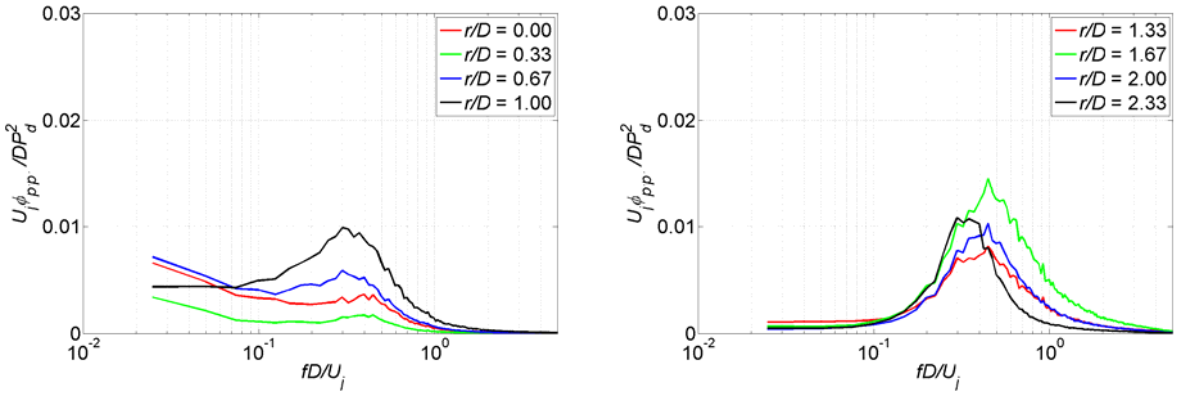

Figure 5. Power spectral density at different radial locations along the ray $\theta = 90^o$ for oblique impingement: stagnation zone (left); wall-jet zone (right)

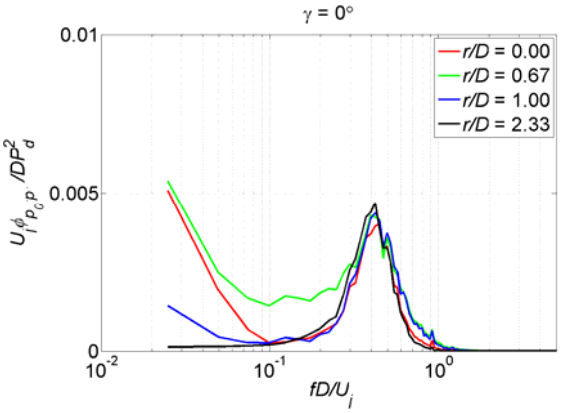

Figure 6. Radial distribution of the cross spectral density of the wall pressure for normal impingement. Lines with different colours indicate different radial locations

In the wall-jet region ($r/D \geq 1.33$: right plot in Figure 4), the spectrum peak shifts to $fD/U_j \approx 0.5$ and is unaffected by the increase in r/D up to a value of 2.0. Farther downstream at $r/D = 2.33$, the peak shifts back to the value found near $r/D = 0$; i.e. $fD/U_j \approx 0.4$.

The back/forth shift of the dominant spectrum peak with increasing r/D leads to ambiguity in identifying the frequency of the convective coherent flow structures. These structures are presumably vortices that originate in the jet shear layer, impinge on the wall and spread outwards along the radial direction. To clarify this issue, the cross spectral density between the pressure signal measured at $r/D = 0$ (p'_0) and that measured at different radial locations along $\theta = 90^o$ ray is computed and displayed in Figure 6. Unlike the power spectral density, which depicts fluctuations produced by all flow structures, peaks in the cross spectral density correspond to frequencies at which the pressure fluctuations at $r/D = 0$ are highly correlated with those found at other radial locations. Figure 6 shows that in fact the cross-spectrum peak remains at $fD/U_j \approx 0.4$ over the *entire* radial range of observation. As discussed earlier, the shift in the spectrum peak in Figure 4 (left) to $fD/U_j \approx 0.3$ at $r/D = 0.67$ is likely an artefact of the pressure signature of broadband turbulence from the shear layer. On the other hand, the shift to higher frequency of $fD/U_j \approx 0.5$ in the range $1.33 \leq r/D \leq 2.00$ (Figure 4; right) is in the zone where researchers have found secondary vortices to form through interaction of the convecting primary vortices with the wall. The cross-spectrum analysis provides unambiguous evidence that the pressure signature of the convective coherent flow structures (i.e. those producing a coherent pressure signature at all microphones in the radial array) occurs at $fD/U_j \approx 0.4$. Although Figure 6 only provides information on the coherence of these structures, independent evidence of their convective nature is found later when considering the cross-correlation results.

It is somewhat surprising that the above results don't show striking difference in the level and frequency content of the wall-pressure fluctuation between the normal and oblique impingement. However, so far the discussion has focused on the pressure fluctuations along the axis around which the impingement plate is rotated, which in fact remains in the same spatial location relative to the jet in both cases. Thus, to better understand the effect of the jet's impingement angle, attention is redirected to the azimuthal structure of the wall-pressure field. Figure 7 displays polar contour plots of the power spectra at different azimuthal angles for $r/D = 2.33$ and $\gamma = 0$ & 30°. The colour bar shown on the right side of the figure gives the spectrum magnitude normalized by the largest peak, and fD/U_j values are given by the radial coordinate (shown in red). Note that for $\gamma = 30°$, the jet turning angle becomes more acute relative to $\gamma = 0°$ for $270^o < \theta < 90^o$ and more obtuse for $90^o < \theta < 270^o$. The results in Figure 7 show that the oblique impingement causes the pressure fluctuations to become asymmetric and more dominant on the side where the jet turning angle is more obtuse (i.e. $90^o < \theta < 270^o$). This asymmetry is associated with substantial decrease in p' level relative to

normal impingement in the range $270^o < \theta < 90^o$. To see this, the power spectral density of the pressure fluctuations at $\theta = 0^o$ and $r/D = 2.33$ is displayed for the normal and oblique impingement cases in the left plot in Figure 8. The figure clearly demonstrates the substantial reduction in the level of pressure fluctuations for the case of more acute turning of the jet. On the side where the jet experiences more obtuse turning, the opposite scenario takes place and the pressure fluctuations are much higher than in the case of normal impingement, as seen from the comparison of the spectra in the right plot in Figure 8.

Another significant effect of oblique impingement is found when examining the azimuthal distribution of the convection velocity (u_c). Here, u_c along a given θ direction is computed from the cross-correlation between the pressure signal measured by one microphone in the smaller aziumthal array ($r/D = 1$) and its counter part at the same azimuthal angle in the bigger azimuthal array ($r/D = 2.33$). An example of the correlation results for $\theta = 180^o$ is depicted in Figure 9 in which the correlation coefficient ($R_{p'p'}$); i.e. the correlation magnitude normalized by the product of p'_{rms} at $r/D = 1$ and 2.33, is plotted versus the time delay between the signals measured at the two different locations. As seen in the figure, the largest correlation is found at a time delay of $\tau_p U_j/D \approx 2$. That such a time delay is required between the observance of a pressure signature at $r/D = 1$ and the occurrence of a similar signature at $r/D = 2.33$ is reflective of the existence of convective pressure-producing flow structures. The radial convection velocity can be computed by dividing the radial offset between these two locations by the time delay of the correlation peak, or: $u_c/U_j = 1.33/2 \approx 0.67$ at $\theta = 180^o$.

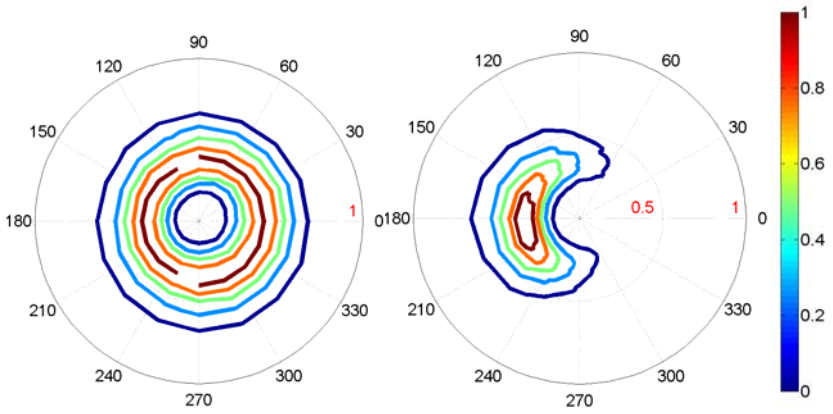

Figure 7. Contour plot of the azimuthal distribution of p' spectra at $r/D = 2.33$: $\gamma = 0$ (left) and 30° (right). The colour bar gives the spectrum magnitude normalized by the largest peak, and the normalized frequency fD/U_j values are given by the radial coordinate (shown in red)

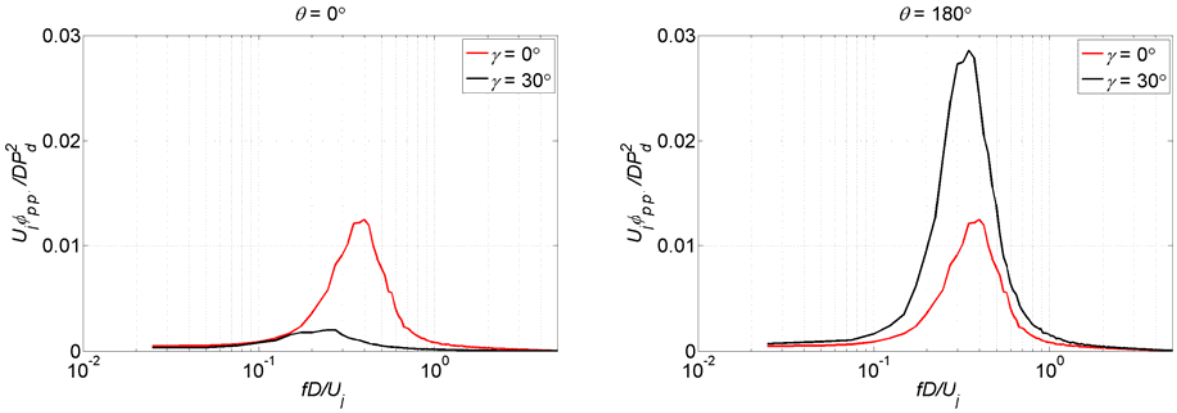

Figure 8. Comparison between the wall-pressure power spectral density for normal and oblique impingement at $r/D = 2.33$: $\theta = 0^o$ (left) and $\theta = 180^o$ (right)

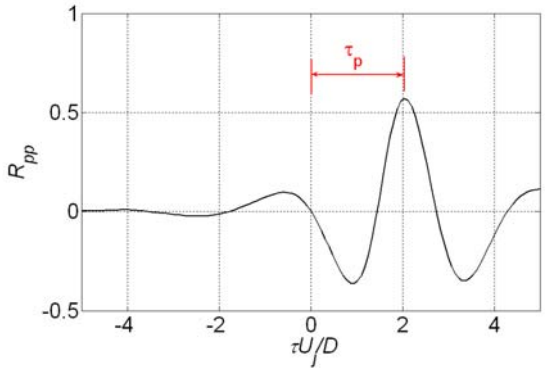

Figure 9. Cross-correlation between p' at $r/D = 1$ and p' at $r/D = 2.33$ along the azimuthal ray $\theta = 180°$ for $\gamma = 30°$

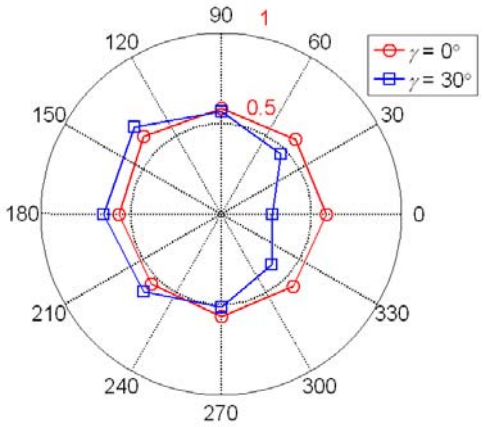

Figure 10. Azimuthal distribution of u_c/U_j for normal ($\gamma = 0^o$) and oblique ($\gamma = 30^o$) impingement (values given by red text)

The full azimuthal distribution of u_c may be seen in Figure 10. The figure contains a polar plot, the radial coordinate of which gives the value of u_c/U_j at different azimuthal angles for normal (red circles) and oblique (blue squares) impingement. Examination of the results clearly demonstrates that whereas the convection velocity is axisymmetric for normal impingement, the inclination of the jet by 30^o relative to the impingement plate causes the establishment of asymmetry in the azimuthal distribution of u_c/U_j. The asymmetry is such that the convection velocity is larger than in the case of normal impingement on the side where the jet experiences more obtuse (i.e. more gradual) turning ($90^o < \theta < 270^o$), and vice versa.

CONCLUSIONS

It is found here that oblique impingement of an axisymmetric jet on a flat wall causes an asymmetry in the wall-pressure distribution relative to a jet at normal incidence. The asymmetry is such that the wall-pressure fluctuations increase in the half plane where the jet experiences more obtuse turning relative to normal incidence, and vice versa. These larger pressure fluctuations, which are reflective of the enhancement in the strength of the flow structures, are associated with a larger convection velocity than in the normal jet. An interesting implication of the present results is the possibility of the existence of an optimum obtuse turning angle where the enhancement in the strength of the flow structures is maximized.

ABSTRACT. The dynamic local quenching and recovery phenomena of impinging lean premixed CH_4 air flame (LPF) and lean CH_4 diluted or N_2 diffusion flame (LDF) have been investigated experimentally for fundamental studies of the heterogeneous lean combustion. The reacting flows are visualized by a high speed time series of particle image velocimetry (PIV).

The local quenching phenomena can be observed frequently when approaching the extinction limit. The large scale local quenching may trigger to develop the global extinction. However, in many cases, the flame can recover from the local quenching phenomena.

Two distinct local quenching recovery mechanisms exist. One is a passive local quenching recovery mode and other is an active local quenching recovery mode. In the passive local quenching recovery mode, the local quenching occurs slightly outside of the stagnating point. The local quenching area drifts outward from the stagnating point. Finally, the flames can be automatically recovered from the local quenching phenomena in accordance with the opposite flow properties. In the active local quenching recovery mode, local quenching occurs including the stagnating point. In this case, the flame recovers by the self-propagating wrinkled flamelet. From these results, an active local quenching recovery mechanism is useful to extend the extinction limits. The mechanism works well in the turbulence added in the premixed gas and also the mixture has to be in the self-propagating condition. In addition, the local quenching area might recover by the reacting flow transported by the eddy.

Keywords: *lean combustion, premixed flame, diffusion flame, turbulent flow, quenching*

INTRODUCTION

Extinction is one of the important subjects in combustion studies. In order to understand extinction phenomena, we need to know extinction is induced by many factors. Heat loss and flame stretch are two major factors. Lewis number effects are also important as an additional factor to discuss a stretched laminar flame which is under controlled by molecular level heat and mass diffusion. Up to now, many studies were carried out and the extinction mechanism and phenomena are summarized in combustion textbooks [1]. The extinction mechanism can be clearly understood in the laminar flame. When we measured extinction limits of turbulent flames, extinction limits do not fall on the same line as with laminar flames. The extinction limits of turbulent flames are plotted on the belt [2].

In the region of wrinkled laminar flamelets, stretched laminar flame concepts can be applied in the local flame structure. It is worthwhile to forces that the extinction in turbulent flame induced by compound factors such as the heat loss, the stretch, the Lewis number and so on. The extinction occurs suddenly while one of the stronger factors may become the trigger. The powers of each

extinction induced factors are fluctuating due to turbulence energy. The extinction limits of the turbulent flame, therefore, may not show the line. It has been made clear by a high speed move that instantaneously the flamelet of turbulent flame is locally quenched and the local quenching becomes trigger to develop whole flame extinction. However, the flame may sometimes recover from the local quenching [3, 4]. We would like to recommend distinguishing the technical terms, "extinction" and "quenching". The "extinction" here refers to whole flame is extinguished such as there is no flame in the burner. The "quenching" here refers to partially flame front is extinguished such as one or more part of the flame front disappear but the flame is still reacting in the burner.

Our questions to start this study are: how to induce the whole extinction by the local quenching, how to recover the flame from the local quenching and also to define the extinction limits in a turbulent flame that exist within the wrinkled laminar flamelet regime. Our selected flow filed is an opposite flow that impinges with lean premixed flame and lean non-premixed or diffusion flame. The one of the great success to reduce the fuel consumption rate is a heterogenous combustion in internal combustion engines [5, 6]. In fact, commercially, the modern Diesel engines and gasoline direct injection engines are operated within the stratified combustion regime. This is not only the trend in the internal combustion engines but also the practical combustors in premixed combustions are shifting from homogeneous combustion to heterogeneous combustion. Recently, some studies have been made numerically in the turbulent premixed flames within the heterogeneous mixture condition [6, 7]. However, up to now, the combined combustion phenomena, such as the lean premixed flame and lean diffusion flame have not been performed in experimentally. Therefore, we are focusing the premixed and diffusion combined lean combustion in turbulent flow namely a combined lean turbulent combustion.

Our proposed flow filed turbulent premixed and diffusion combined flames are one of the suitable geometry for the fundamental modeling of the heterogeneous combustion on the turbulent flow such as the stratified charged internal combustion engines since the reactants compositions and turbulence conditions of each burner can be controlling individually [8]. In the present study, we discussed the global extinction induced local quenching and recovery phenomena in an opposite turbulent flow burner by using the time series particle image velocimetry (PIV).

Nomenclature

U	mean velocity, m/s
d	diameter of burner nozzles, mm
L	distance between two nozzle exit, mm
r	radial coordinate, mm
y	axial coordinate, mm
Re_0	Reynolds number
υ_0	viscosity of air room temperature, m^2/s
l_0	integral length scale, m/s
u_0'	turbulent intensity, m/s
φ	equivalence ratio
χ	mole fraction of fuel
F_{st}	stoichiometric mixture fraction
W	mean molecular weight
υ	stoichiometric coefficient
y_f	flame location, mm
y_s	stagnation plane location, mm
T_o	temperature, K

Subscripts

co co-flow

EXPERIMENTAL SETUP

Figure 1 shows the schematic model of combined lean turbulent combustion. In the case of combined turbulent lean combustion, a lean premixed flame is impinged with a diluted fuel then two flames are formed in the stagnating regions. The lean fuel diluted with inert gas will be reacting with the high temperature and low oxygen concentration oxidizer from the lean or ultra lean premixed flame. In the burnt gas of the lean premixed flame, the oxidizer has the potential to re-react with the diluted fuel even though the concentration is much less than an ordinary diffusion flame. Especially, the condition of the stoichometric mixture fraction (F_{st}) defined as equation 1 is a very important index to characterize the diffusion flame structures formed in the opposite flow where χ is the mole fraction of reaction gas in a reactant flow, W is a mean molecular weight, υ is a stoichiometric coefficient, and subscripts O and F refer to the oxidizer and the fuel, respectively.

$$\mathrm{F_{st}} = (1 + \chi_F \cdot \mathrm{W}_O \cdot \upsilon_O / \chi_O \cdot \mathrm{W}_F \cdot \upsilon_F)^{-1} \quad (1)$$

In the diffusion flame formed in an opposite flow, the flame location can be divided by 3 modes depending on the F_{st} [9, 10]. In the case of F_{st}<0.5, the flame is formed in the oxidizer flow side. For the F_{st}=0.5, the flame is formed on the impinging surface. For the F_{st}>0.5, the flame is formed in the fuel flow side. If the combined flames are formed under the condition of F_{st}<0.5, it is expected that the mole fraction of the oxygen can be reduced just like in oxidizer preheating combustion [9].

Figure 2 shows the opposite burner system. The burner system consist two symmetrical nozzle type burners placed in line vertically. The exit diameters of both nozzles (d) are 40mm and the distance (L) between the two nozzle exits is set to 80mm. The mean velocity of each nozzle is set at up to 2.0m/s. The turbulence generator, namely P_4, is used as turbulence generators and it can be installed between the converging nozzle and the straight tube. Then the generated turbulent intensity is 0.37m/s and the turbulence Reynolds number ($Re_0=u'_0 l_0/\upsilon_0$) is 52, where l_0 is the integral length scale, and υ_0 is the kinematic viscosity of air at room temperature. The flow condition in the present

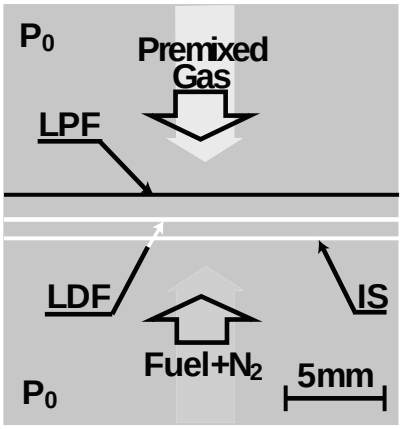
study is in the wrinkled laminar flame regime. P_0 means that no perforated plate is used and laminar stagnating flow is formed. The experiments are conducted for 2 flow combinations; one side is a laminar flow while the other side is a turbulent flow (P_0/P_4 or P_4/P_0). The CH_4 and air premixed gas flow is supplied from the upper side burner and the CH_4 diluted with N_2 non-premixed gas flow is issued from the lower side burner. Ring shape co-flows are supplied from both burners to reduce the shear turbulence generated and to extinguish secondary combustion of the unburned fuel. The co-flow velocities (U_{co}) are set equal to the main flow velocity. The coordinate y is defined as the upstream direction from the lower nozzle exit.

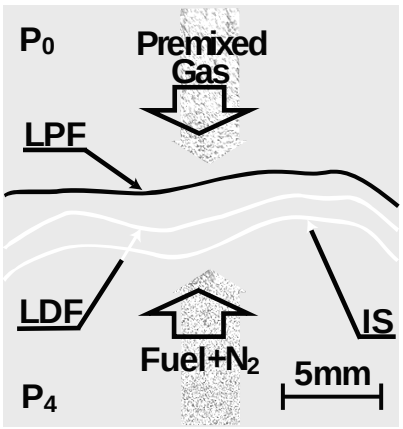
Figure 3(a) and (b) show the typical flame image for the turbulent premixed and diffusion combined flames formed in the opposite flow.

FLAMELET STRUCTURE OF PREMIXED AND DIFFUSION COMBINED FLAMES

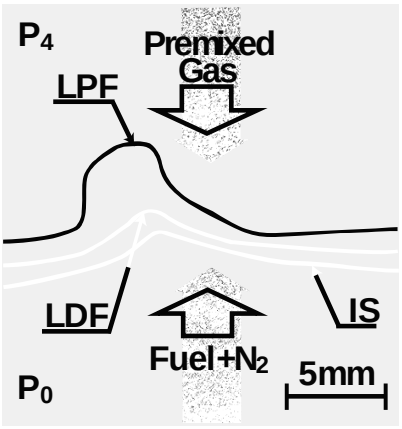
Figure 4 shows the flamelet structure for premixed and diffusion combined flames in the opposite flow for three different flow conditions. Fine alumina particles about 1μm in diameter were added in the premixed gas side while silicone oil droplets were added in the fuel + N_2 side. When both flows are laminar (Fig. 4 (a)), the lean premixed flame (LPF), lean diffusion flame (LDF) and the impinging surface (IS) are formed in parallel. In this case, F_{st}=0.36, that is F_{st}<0.5, and the LDF is formed in the burnt gas side which is a high temperature and low oxygen concentration oxidizer



(a) P_0/P_0: laminar to laminar



(b) P_0/P_4: laminar to turbulent



(c) P_4/P_0: turbulent to laminar

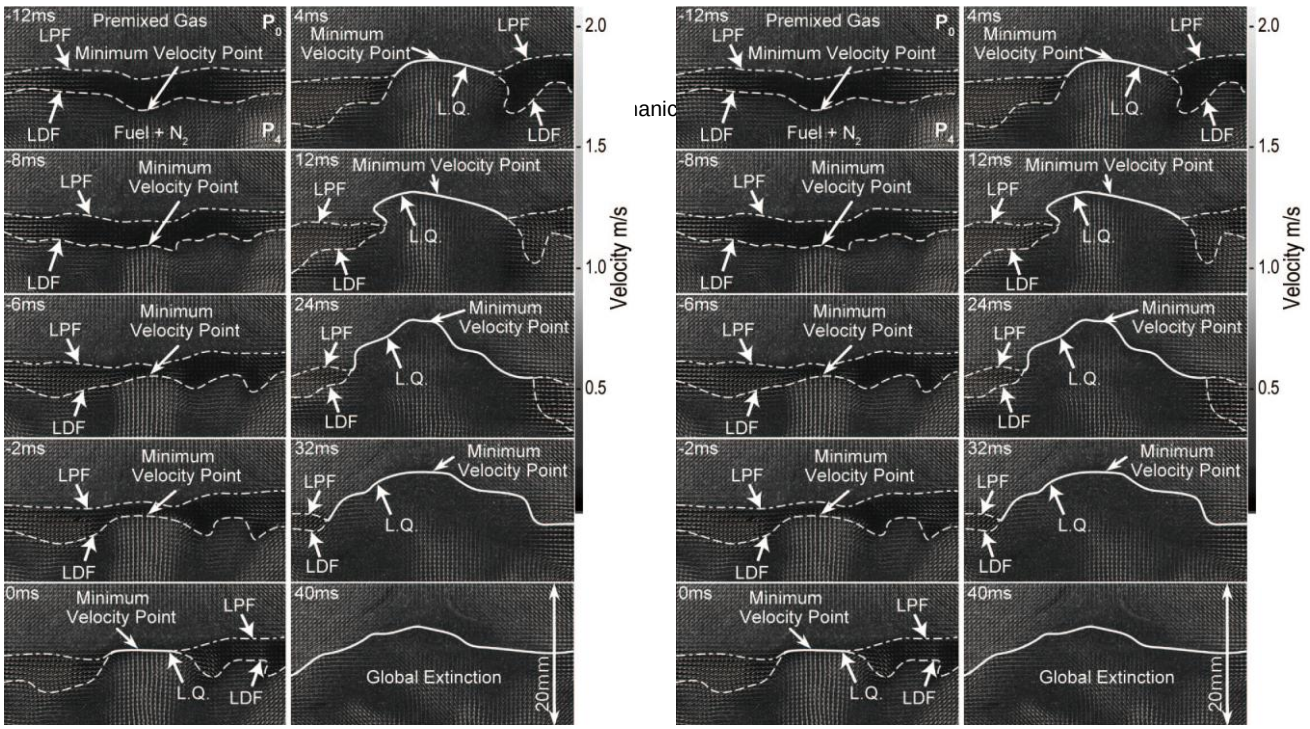
region. When the turbulence added only on the premixed gas side as shown in Fig. 4 (b) the flame front of the LPF side has a more complex structure than that of the LDF. And a LDF is also formed in the burnt gas side because of the F_{st}<0.5. The wrinkled flame front of the LDF becomes more complicated than a LPF when the turbulence is added to the diffusion flame. In this case, a LDF is also formed in the burnt gas. In the present study, the fuel of CH_4 diluted with nitrogen may react with the oxygen in the burnt gas of the lean premixed flame.

GLOBAL EXTINCTION PHENOMENA

Figure 5 shows a high speed time series of capture PIV images taken by a high speed camera Photoron Fastcam-1024PCI 100K having 1024×1024 resolution at 1000 frame/sec. The measurement field is 40mm×40mm. Fine alumina particles about 1μm are used as scattering particles added via both nozzles. A Q-Switched YAG laser having a 200mW output power and 3 kHz pulse (Photonics Industries DC 10-527) is used as a light source. The flow condition of the upper burner is laminar premixed gas flow, while that of lower burner is turbulent CH_4+N_2 flow. These frames indicate the minimum velocity point, which is identified by PIV data seems to be stagnating points. (As mentioned by Kostiuk et al [11,12], in the turbulent opposite flow the stagnating stream line moves three dimensionally near the center axis of the flow. Therefore, it is difficult to correctly identify the stagnating point from the 2D flow data so we use the minimum velocity point; the stagnating point will probably be located near there.) The first frame (see -12ms), lean premixed flame (LPF) and the lean diffusion flame (see LDF) surfaces are formed individually. In the second frame (see -8ms), the convex part of the LDF surface moves to upward. The local velocity of that region exceeds 1.5m/s and finally the LDF surface attaches to the LPF surface (see 0ms). In this part, both flames are locally quenched. The local quenching area (L.Q.) is developing to outer direction as shown in frames 0ms to 32ms. Finally (see 40ms), the local quenching area developed to the global extinction (G.E.). The local quenching developed to the global extinction phenomena at about 30~40ms. It is worthwhile to note that the minimum velocity point does not move.



(a) Passive Local Quenching recovery (b) Active Local Quenching recovery

Figures 7. Local quenching recovery mechanism for turbulence added lean premixed gas side. (P_4, P_0, ϕ_0=0.6, χ_L=7.8%, T_{st}=0.33, shutter speed: 1/100 seconds)

Figures 8. Local Quenching possibility. The regions (A), (E), and (F) are corresponding as an active, an eddy and a passive local quenching recovery modes, respectively. Definition of the extinction limit is that the flames are formed 2 seconds is the opposite flow without a pilot flame burner which is used as an igniter.

LOCAL QUENCHING RECOVERY MECHANISM

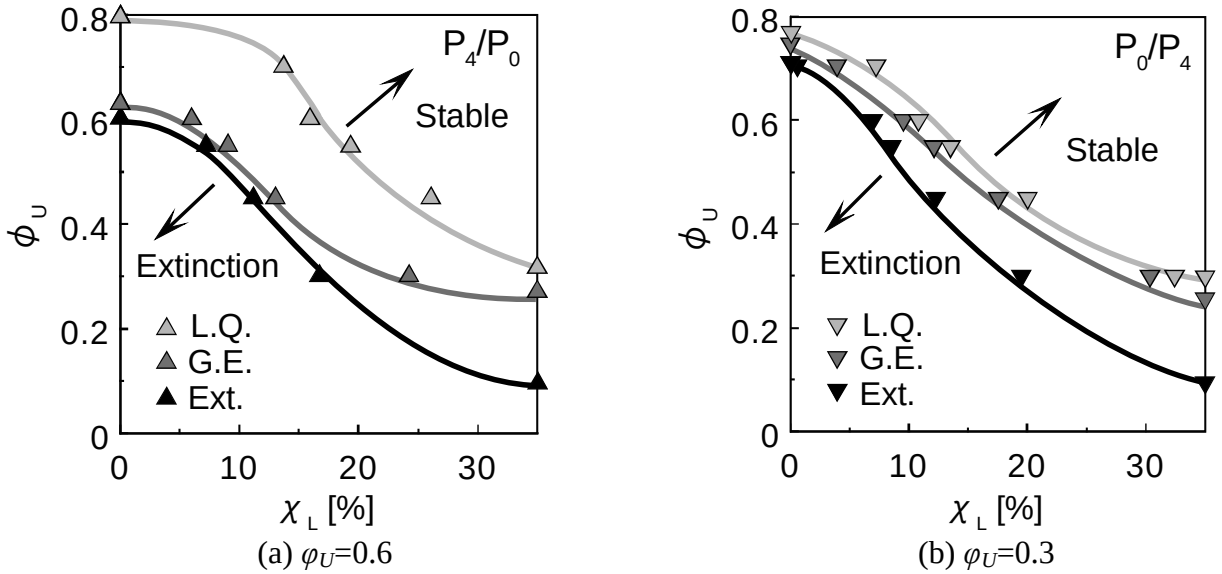
Near the extinction limit, the local quenching phenomena can be observed frequently. As shown in Fig.5, if the large area of the local quenching occurs at the stagnating point, the local quenching area develops to the global extinction. However, the local quenching does not always lead to global extinction. In many cases, the flame can recover from the local quenching phenomena. Figure 6 shows the local quenching recovery mechanism in the same flow conditions as Fig. 5. The difference between this case and Fig. 5 is that the local quenching occurs slightly outside of the minimum velocity point (see frame 0ms). In frames 4ms to 12ms, the local quenching area develops slightly. However, the local quenching area leaves the minimum velocity point (see frames 16ms to 26ms). In this case, the local quenching area cannot be spread to the whole region. The local quenching flows to outside, then the flame can automatically recover from the local quenching (see frame 30ms).

TWO DIFFERENT LOCAL QUENCHING RECOVERY MECHANISMS

Figure 7 (a) and (b) show two distinct local quenching recovery mechanisms. In these cases, the turbulence generator is set on the upper burner, while the lower approaching flow is laminar. That is, the lean premixed flames are turbulent and the lower flow diffusion flame surface will be wrinkling to receive the turbulence energy from turbulent premixed flames.

There are two distinct local quenching recovery mechanisms. In the case of passive local quenching mode shown in Fig. 7 (a), the local quenching occurs slightly outside of the minimum velocity point (see frame 0ms). The local quenching area is drifting outward from the minimum velocity point as well as Fig. 6 and then it is displaced by the stable flames. Finally, the flames can be automatically recovered from the local quenching phenomena in accordance with the opposite flow properties. We called this mechanism a passive local quenching recovery mode.

As the other local quenching recovery mechanism, Fig. 7 (b) shows an active local quenching recovery mode. In this case, the local quenching occurs at the center including the minimum velocity point (see frames 0ms~4ms). The local quenching area can spread to the whole region. The flames are active in 3-dimensional space though the flames seem globally extinguished in 2-dimensions. In fact,



Figures 9. Extinction and Quenching boundary. L. Q., G. E. and Ext. are corresponding with the local quenching start line, the global extinction start line and the extinction limits, respectively.

the LPF propagates from the right side (see 20ms). In the 24ms frame, a LPF island also appears. These flame fronts are spreading until reaching the quenching surface. In the 28ms frame, the recovered LPF surface appears and spreads to the whole area. Finally, the flames can be recovered from the local quenching phenomena. We called this recovery mechanism induced by the flame propagation an active local quenching recovery mode.

As the common feature of local quenching phenomena of Fig. 5 and Fig. 7 (b), it is worthwhile to pay attention that the local quenching occurs in the regions of the minimum velocity point. Without the self-propagation, the flame may not recover from large scale local quenching if the quenching occurs within the minimum velocity point. Therefore, with the turbulence added in the premixed flame side shown in Fig. 7 (b), the wrinkled flamelet propagation plays a very important role for the recovery mechanism.

POSSIBILITY OF LOCAL QUENCHING TO GLOBAL EXTINCTION

As discussed previously, the local quenching is a trigger to induce global extinction. Tthe possibility of local quenching to global extinction mechanisms is affected by two factors. One is that the premixed flame side can propagate self-sustainably or not. Another factor is including the turbulence in the premixed flame side or in the diffusion flame side. Figure 8 (a) and (b) show the local quenching possibility of P_0/P_4 and P_4/P_0 for φ_U=0.6 and φ_U=0.3, respectively, where the number of local quenching or global extinction is normalized by the total image number of tomographic data (N/N_0) and shown on the ordinate, while the lower burner CH_4 mole fraction (χ_L) is shown on the abscissa. The three regions, (A), (E), and (P), in these figures correspond with the quenching mode difference. In the region (A), only an active local quenching recovery mode is observed. In the region (P), a passive local quenching recovery mode is mainly observed. In the region (E), an eddy transport local quenching recovery mode is additionally observed with a passive local quenching recovery mode.

In the case of the premixed flame side having self-propagation as shown in Fig. 8 (a), the region (A) is wider than region (P). In addition, for P_0/P_4 which has turbulence only in the fuel flow side, the extinction limit corresponds to the border of the regions (A) and (P). On the other hand, for P_4/P_0, the flame can be formed even passing the extinction limit of P_0/P_4 flame and the extinction limit may extend to the end of region (A). The difference of the extinction limits between P_0/P_4 and P_4/P_0 are 7.6% based on the χ_L. That is, the extinction limit of the P_4/P_0 can be extended 7.6% by an active local quenching recovery mechanism in this experimental condition.

In the case of the premixed flame not self-propagating as shown in Fig. 8 (b), we have two regions (E) and (P), where region (E) is narrower than region (P). To work the active local quenching recovery mode in the premixed flame not having self-propagation, the flame should be supporting from diffusion flame side. However, in this condition the premixed flame side is φ_U=0.3. So it is difficult to conclude that the quenched flame can recover by the active local quenching recovery mechanism. In fact, we have observed a similar recovery mechanism to an active local quenching recovery mode. It seems the local quenching area might recover by the reacting flow which is transported by the eddy. Therefore, in this stage we would call this recovery phenomenon an eddy transport local quenching recovery mode. The extinction limit of P_0/P_4 in Fig. 8 (b) also corresponds the boundary of (E) and (P).

EXTINCTION AND QUENCHING BOUNDARY

Figure 9 (a) and (b) show the extinction and quenching limits for P_4/P_0 and P_0/P_4, respectively, where the upper burner equivalence ratio (φ_U) on the ordinate and the lower burner CH_4 mole fraction diluted with N_2 (χ_L) on the abscissa. The extinction condition at χ_L=0 means lean premixed gas impinging on 100% N_2 gas flow and corresponds to a single premixed flame extinction limit. Here, we have three boundaries which are the local quenching start line (L. Q.), the global extinction start line (G. E.) and the extinction limits (Ext.). As mentioned previously, when the fuel concentration is decreasing, the flame front is locally quenched. However, the flame front easily can recover in the first stage. In the second stage the flame may suddenly extinguish, however, if we try to reignite the flame may reform. At the extinction limits, the flame very easily extinguishes and the flame cannot be sustained for 2 seconds even if we try to reignite.

In the case of P_4/P_0 shown in Fig. 9 (a), the boundary between the G. E. and L. Q. is wider than that of P_0/P_4 shown in Fig. 9 (b). The clearance of the G. E. and Ext. in the P_4/P_0 are getting wider and increases with χ_L. On the other hand, in the case of the P_0/P_4 the clearance of the G. E. and L. Q. is nearly constant regardless of χ_L. From these results, an active local quenching recovery mechanism is useful to extend the extinction limits. The mechanism works well with turbulence added to the premixed gas and when the mixture has the self-propagating condition.

CONCLUSIONS

The local quenching and recovery phenomena of impinging lean premixed CH_4 air flame (LPF) and lean CH_4 diluted with N_2 diffusion flame (LDF) with different turbulence conditions have been investigated experimentally for fundamental understanding of heterogeneous lean combustion. The reacting flows are visualized by a high speed time series of particle image velocimetry (PIV).

The local quenching phenomena can be observed frequently when approaching the extinction limit. If the large area of the local quenching occurs in the minimum velocity point, which corresponds to the stagnating point, the local quenching area leads to global extinction. However, local quenching does not always trigger global extinction. In many cases, the flame can recover from the local quenching phenomena.

Two distinct local quenching recovery mechanisms exist. One is a passive local quenching recovery mode and the other is an active local quenching recovery mode. In the passive local quenching recovery mode, the local quenching occurs slightly outside of the minimum velocity point. The local quenching area drifts outward from the minimum velocity point. Finally, the flames can be automatically recovered from the local quenching phenomena in accordance with the opposite flow properties. In the active local quenching recovery mode, local quenching occurs including the minimum velocity point. In this case, the flame recovers by the self-propagating wrinkled flamelet. Only when the turbulence is added to the premixed flame side, an active local quenching recovery mode is observed. From these results, an active local quenching recovery mechanism is useful to extend the extinction limits. The mechanism work well if the turbulence is added to the premixed

gas and the mixture has the self-propagating condition. In addition, the local quenching area might recover by the reacting flow transported by the eddy.

LIQUID MIXING IN A BUBBLE COLUMN

ABSTRACT. The performance of a bubble column strongly depends on the liquid mixing induced by bubbles in the column. It is, therefore, important to evaluate the degree of liquid mixing for column design. However, few quantitative investigations have been carried out on two-phase turbulence and liquid mixing. In this study, a one-dimensional liquid mixing coefficient has been measured using a tracer detection method and compared with numerical simulations using a multi-fluid model. A parameter ϕ, which determines the contribution of shear-induced turbulence, was adopted in a two-phase turbulence model based on a linear superposition of bubble-induced turbulence and shear-induced turbulence. Good predictions were obtained for a wide range of gas superficial velocity and liquid superficial velocity by adding 10% contribution of shear-induced turbulence to bubble-induced turbulence, i.e. by setting $\phi = 0.1$.

Keywords: *bubble column, liquid mixing, conductance method, turbulence flow, simulation*

INTRODUCTION

The performance of a bubble column strongly depends on the liquid mixing induced by bubbles. For example, if intermediate products in successive reactions are desired, the column performance may be deteriorated by strong mixing [1]. Figure 1 shows a comparison of yields in successive reaction (A→R→S) between perfectly mixed flow and piston flow (i.e, flow without back mixing). The selectivity of R in the piston flow is larger than that in the perfectly mixed flow at any conversion of A. It is, therefore, important to evaluate the degree of liquid mixing when designing bubble columns. Though several efforts [2, 3] have been made to quantitatively measure liquid mixing in a bubble column, it is very difficult to deduce a liquid mixing model applicable to various bubble columns only from limited experimental data.

If we can develop a reliable numerical method for predicting turbulent bubbly flow in a bubble column, we will be able to overcome this situation and use the method as a tool for designing bubble columns. Hence the authors [4-8] have been developing a three-dimensional CMFD (Computational Multi-Fluid Dynamics) method based on a hybrid combination of an interface tracking method and a multi-fluid model, which we refer to as NP2-3D because it can deal with N bubble groups Plus 2 continuous phases simultaneously.

In this study, a one-dimensional liquid mixing coefficient in a bubble column has been measured using a tracer detection method and compared with NP2 predictions. Since bubbly flow in bubble columns is turbulent and liquid mixing is strongly affected by the flow, we have focused our attention on two-phase turbulence models implemented in NP2-3D.

EXPERIMENTAL SETUP

Figure 2 shows a schematic of the experimental apparatus. The column diameter is 0.3 m, and the height is 1 m. The column wall is made of transparent polyvinyl chloride. Tap water was fed from the bottom of the column, and air was sparged from the two ring-type spargers installed in the column. The spargers are 0.25 m in diameter, and have equally spaced eight holes. They are aligned at heights of 0.25 m and 0.75 m from the bottom of the column. There is one outlet at the top of the column. Table 1 shows the experimental conditions. Experiments were carried out under eight sets of conditions. All conditions were within the homogeneous flow regime as shown in Fig. 3. The system temperature and pressure were about 20.8 deg C and 0.1 MPa, respectively.

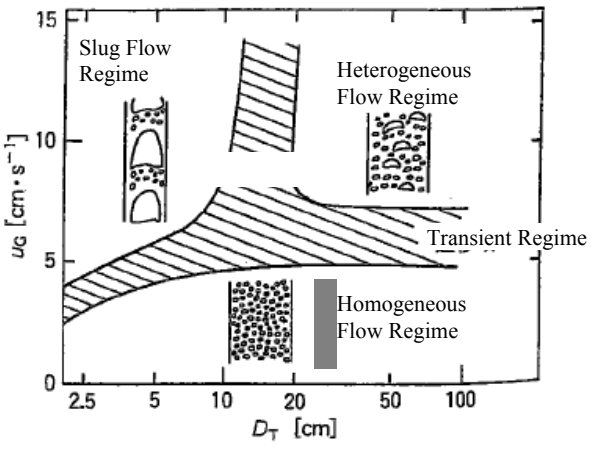

Fig. 3 Flow regime in a bubble column [9]

After a steady state was established, salt and coloring agent were stepwisely injected into the feed water. The salt concentration was 0.07 wt%. Figure 4(a) shows an example of observed tracer motion in Run 1. A conductance meter measured the concentration of salt solution at the outlet (Fig. 4(b)), from which the one-dimensional liquid mixing coefficient D was evaluated using the following equation:

$$\frac{\partial C}{\partial t} + U_{\mathrm{L}} \frac{\partial C}{\partial z} = D \frac{\partial^2 C}{\partial z^2} \tag{1}$$

where t is the time, C the salt concentration, U_{L} the liquid superficial velocity and z the axial coordinate. Measured values of C were substituted into Eq. (1), and Eq. (1) was solved for D [10]. The Euler explicit method was used for the time difference, and QUICK[11] and the central difference schemes were used for convection and diffusion terms, respectively.

Bubble size distributions in the column were also measured. A high speed video camera (Photoron, FASTCAM-512PCI) was used to obtain close-up images of bubbles. Figure 5(a) shows the effect of the superficial gas velocity U_{G} on bubbles. The peripheral length and area of each bubble were measured, from which the Sauter mean diameter was obtained by assuming spheroidal bubble shapes. Figure 5(b) and Table 2 show the measured size distributions. These data were used in the simulations described below.

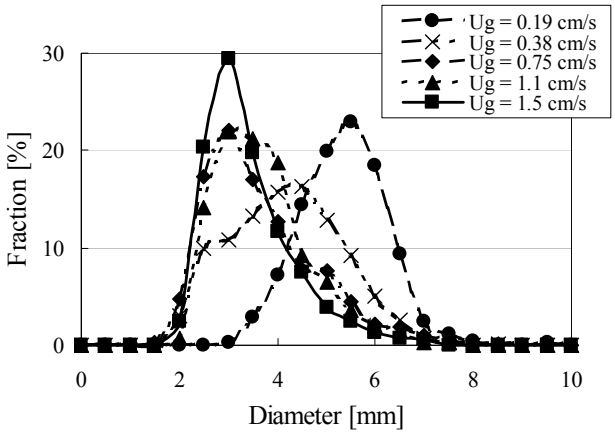
(a) Snapshots in the column (U_{G}: Superficial Gas Velocity)

OUTLINE OF NP2-3D

The hybrid method, NP2-3D, which is based on the combination of multi-fluid and interface tracking methods [7], was used to simulate the flow. This model classifies the phases in a flow into N+2 groups: one continuous gas phase (G), one continuous liquid phase (L) and N dispersed bubble groups (B_m, m = 0, 1, ..., N). When the length scale of a gas-liquid interface is much larger than the cell size Δx, the two phases separated by the interface are regarded as continuous gas and liquid fields. Bubbles smaller than or comparable to Δx are classified into N groups in terms of their sizes. The volume fraction α of each phase field satisfies

$$\alpha_{\mathrm{G}} + \alpha_{\mathrm{L}} + \sum_{m=1}^{N} \alpha_{\mathrm{B}m} = 1 \tag{2}$$



(b) Bubble diameter distribution

Fig. 5 Bubble behavior in a column

Table 2 Bubble group in each case

Run	Superficial velocity of liquid [cm/s]	Gas flow rate		Bubble diameter[mm]/fraction[%]		
		Upper/Total ratio [%]	Total superficial velocity [cm/s]	1	2	3
1	1.0	50	1.50	3.2/33.8	4.7/37.4	6.4/28.8
2	0.5	50	0.75	3.7/39.0	5.0/37.2	6.1/23.8
3	1.0	50	3.00	3.1/48.5	4.6/35.1	6.2/16.4
4	1.0	50	2.25	3.3/39.0	4.6/40.7	6.2/20.3
5	1.0	50	0.75	3.7/39.0	5.0/37.2	6.1/23.8
6	1.0	50	0.38	4.5/27.5	5.5/46.6	6.6/25.9
7	1.0	25	1.50	3.4/20.5(upper) /45.3(lower)	4.7/55.7(upper) /31.8(lower)	4.7/23.8(upper) /22.9(lower)
8	1.0	75	1.50	3.4/45.3(upper) /20.5(lower)	4.7/31.8(upper) /55.7(lower)	4.7/22.9(upper) /23.8(lower)

For simplicity, the gas and liquid phases are assumed to be incompressible Newtonian fluids without phase change, and viscous and turbulent diffusion in the dispersed phases is postulated to be negligible. The cell-volume averaged mass and momentum equations are then given by

$$\frac{\partial \alpha_{\mathrm{B}m}}{\partial t}+\nabla\cdot\left(\alpha_{\mathrm{B}m}\boldsymbol{V}_{\mathrm{B}m}\right)=\frac{1}{\rho_{\mathrm{B}m}}\left(\sum_{m'=1}^{N}\Gamma^{\mathrm{CB}}_{\mathrm{B}m\mathrm{B}m'}-\Gamma^{\mathrm{CB}}_{\mathrm{GB}m}\right) \tag{3}$$

$$\frac{\partial \alpha_{\mathrm{G}}}{\partial t}+\nabla\cdot\left(\alpha_{\mathrm{G}}\boldsymbol{V}_{\mathrm{C}}\right)=\frac{1}{\rho_{\mathrm{G}}}\sum_{m=1}^{N}\Gamma^{\mathrm{CB}}_{\mathrm{GB}m} \tag{4}$$

$$\frac{\partial \alpha_{\mathrm{L}}}{\partial t}+\nabla\cdot\left(\alpha_{\mathrm{L}}\boldsymbol{V}_{\mathrm{C}}\right)=0 \tag{5}$$

$$\frac{\partial \boldsymbol{V}_{\mathrm{B}m}}{\partial t}+\boldsymbol{V}_{\mathrm{B}m}\cdot\nabla\boldsymbol{V}_{\mathrm{B}m}=-\frac{1}{\rho_{\mathrm{B}m}}\nabla P+\boldsymbol{g}-\frac{1}{\rho_{\mathrm{B}m}\alpha_{\mathrm{B}m}}\left(\boldsymbol{M}^{\mathrm{F}}_{\mathrm{LB}m}+\boldsymbol{M}^{\Gamma}_{\mathrm{LB}m}\right) \tag{6}$$

$$\frac{\partial \boldsymbol{V}_{\mathrm{C}}}{\partial t}+\boldsymbol{V}_{\mathrm{C}}\cdot\nabla\boldsymbol{V}_{\mathrm{C}}=-\frac{1}{\rho_{\mathrm{C}}}\nabla P+\boldsymbol{F}^{\mu}+\boldsymbol{F}^{\mathrm{S}}+\boldsymbol{g}+\frac{1}{\rho_{\mathrm{C}}\alpha_{\mathrm{C}}}\sum_{m=1}^{N}\left(\boldsymbol{M}^{\mathrm{F}}_{\mathrm{LB}m}+\boldsymbol{M}^{\Gamma}_{\mathrm{LB}m}\right) \tag{7}$$

where $\boldsymbol{V}$ is the velocity, ρ the density, $\Gamma^{\mathrm{CB}}_{\mathrm{GB}m}$ the gas volume transfer from the bubble group m to the continuous gas phase, $\Gamma^{\mathrm{CB}}_{\mathrm{B}m\mathrm{B}m'}$ the gas volume transfer to the group m due to bubble coalescence and breakup, P the pressure, $\boldsymbol{g}$ the gravity, $\boldsymbol{M}^{\mathrm{F}}_{\mathrm{LB}m}$ the interfacial momentum transfer between the bubble group m and the liquid phase, $\boldsymbol{M}^{\Gamma}_{\mathrm{LB}m}$ the momentum transfer associated with the mass transfer $\Gamma_{\mathrm{GB}m}$,

$\boldsymbol{F}^{\mu}$ the viscous diffusion, and $\boldsymbol{F}^{S}$ the surface tension force. Note that we do not need two momentum equations for the two continuous phases because NP2-3D is based on the one-field approximation for the two continuous phases. Hence the volume fraction α_{C} in equation (7) is defined by $\alpha_{\mathrm{C}} = \alpha_{\mathrm{G}} + \alpha_{\mathrm{L}}$, and ρ_{C} is defined by

$$\rho_{\mathrm{C}} = \frac{\rho_{\mathrm{L}}\alpha_{\mathrm{L}} + \rho_{\mathrm{G}}\alpha_{\mathrm{G}}}{\alpha_{\mathrm{L}} + \alpha_{\mathrm{G}}} \tag{8}$$

When no dispersed phases are present, i.e. when $N = 0$, Eqs. (2)-(8) reduce to the field equations for interface tracking methods (ITM). On the other hand, they reduce to the (N+1)-fluid model (MFM; [8]) when $\alpha_{\mathrm{G}} = 0$. Thus NP2-3D includes ITM and MFM as subsets.

The interfacial momentum transfer term $\boldsymbol{M}^{\mathrm{F}}_{\mathrm{LB}m}$ is given by:

$$\begin{aligned}\boldsymbol{M}^{\mathrm{F}}_{\mathrm{LB}m} &= \boldsymbol{M}_{\mathrm{D}m} + \boldsymbol{M}_{\mathrm{VM}m} + \boldsymbol{M}_{\mathrm{LF}m} + \boldsymbol{M}_{\mathrm{TD}m} \\ &= \frac{1}{8} a_{\mathrm{int}\,m} C_{\mathrm{D}m} \rho_{\mathrm{L}} \left|\boldsymbol{V}_{\mathrm{B}m} - \boldsymbol{V}_{\mathrm{C}}\right| \left(\boldsymbol{V}_{\mathrm{B}m} - \boldsymbol{V}_{\mathrm{C}}\right) + \alpha_{\mathrm{B}m} C_{\mathrm{VM}m} \rho_{\mathrm{L}} \left[\frac{D_{\mathrm{B}m}\boldsymbol{V}_{\mathrm{B}m}}{Dt} - \frac{D_{\mathrm{C}}\boldsymbol{V}_{\mathrm{C}}}{Dt}\right] \\ &\quad + \alpha_{\mathrm{B}m} C_{\mathrm{LF}m} \rho_{\mathrm{L}} \left(\boldsymbol{V}_{\mathrm{B}m} - \boldsymbol{V}_{\mathrm{C}}\right) \times \nabla \times \boldsymbol{V}_{\mathrm{C}} + C_{\mathrm{TD}m} \rho_{\mathrm{L}} k_{\mathrm{L}m} \nabla \alpha_{\mathrm{B}m}\end{aligned} \tag{9}$$

where a_{int} is the interfacial area concentration, $\boldsymbol{M}_{\mathrm{D}}$ the drag force, $\boldsymbol{M}_{\mathrm{VM}}$ the virtual mass force, $\boldsymbol{M}_{\mathrm{LF}}$ the lift force, $\boldsymbol{M}_{\mathrm{TD}}$ the turbulent dispersion force, C_{D} the drag coefficient, C_{VM} the virtual mass coefficient, D/Dt the substantial derivative, C_{L} the lift coefficient, C_{TD} the turbulent dispersion coefficient, and k_L the turbulence kinetic energy. The viscous diffusion is given by

$$\begin{aligned}\boldsymbol{F}^{\mu} &= \nabla \cdot \left[\alpha_{\mathrm{C}} \mu_{\mathrm{C}} \left\{\nabla \boldsymbol{V}_{\mathrm{C}} + \left(\nabla \boldsymbol{V}_{\mathrm{C}}\right)^{\mathrm{T}}\right\}\right] \\ \mu_{\mathrm{C}} &= \frac{\mu_{\mathrm{L}}\alpha_{\mathrm{L}} + \mu_{\mathrm{G}}\alpha_{\mathrm{G}}}{\alpha_{\mathrm{L}} + \alpha_{\mathrm{G}}}\end{aligned} \tag{11}$$

where μ_{L} and μ_{G} are the viscosities of the continuous liquid and gas phases, respectively. Details on closure relations and solution procedure can be found in [4,7].

The viscosity μ_{C} of the continuous liquid must be accurately modeled for good predictions of the liquid mixing in the column. The liquid viscosity μ_{L} can be estimated by

$$\mu_{\mathrm{L}} = \mu^{\mathrm{Re}} + \mu^{\mathrm{M}}$$

where μ^{M} and μ^{Re} are the molecular and turbulent eddy viscosities, respectively.

Lopez de Bertodano *et al*. [12] proposed a two-phase turbulence model based on a linear superposition of bubble-induced turbulence (BI) and shear-induced turbulence (SI). In this model, μ^{Re} is given by

$$\mu^{\mathrm{Re}} = \mu^{\mathrm{BI}} + \mu^{\mathrm{SI}}$$

Hereafter, this model is referred to as “Model A”. Then, a model which accounts for only shear-induced turbulence is called “Model B”:

$$\mu^{\mathrm{Re}} = \mu^{\mathrm{BI}}$$

Equation (14) is based on the intuition that the effects of walls in a bubble column are much smaller than those in pipe flows.

The bubble-induced and shear-induced turbulences were calculated using Sato's model [13] and the k-ε model [14], respectively:

$$\mu_{\mathrm{BI}} = C_{\mu\mathrm{B}} \sum_{m=1}^{N} \alpha_{\mathrm{B}m} d_{Bm} \rho_{\mathrm{L}} \left(\boldsymbol{V}_{\mathrm{B}m} - \boldsymbol{V}_{\mathrm{C}} \right) \tag{15}$$

$$\mu_{\mathrm{SI}} = \rho_{\mathrm{C}} C_{\mu} \frac{k_{\mathrm{SI}}^2}{\varepsilon} \tag{16}$$

$$\alpha_{\mathrm{c}} \frac{D}{Dt} k_{\mathrm{SI}} = \nabla \cdot \alpha_{\mathrm{c}} \left(\frac{\nu_{\mathrm{cL}}}{\sigma_{\mathrm{k}}} \nabla k_{\mathrm{SI}} \right) + \alpha_{\mathrm{c}} \left(p_{\mathrm{k}} - \varepsilon \right) \tag{17}$$

$$\alpha_{\mathrm{c}} \frac{D}{Dt} \varepsilon = \nabla \cdot \alpha_{\mathrm{c}} \left(\frac{\nu_{\mathrm{cL}}}{\sigma_{\varepsilon}} \nabla \varepsilon \right) + \alpha_{\mathrm{c}} \left(C_{\varepsilon 1} \frac{\varepsilon p_{\mathrm{k}}}{k_{\mathrm{SI}}} - C_{\varepsilon 2} \frac{\varepsilon^2}{k_{\mathrm{SI}}} \right) \tag{18}$$

$$p_{\mathrm{k}} = \nu_{\mathrm{cL}} \left(\nabla \boldsymbol{V}_{\mathrm{C}} + \nabla \boldsymbol{V}_{\mathrm{C}}^{\mathrm{T}} \right) : \nabla \boldsymbol{V}_{\mathrm{C}} \tag{19}$$

where k_{SI} is the turbulence energy, p_{k} the production term, and ε the turbulent dissipation rate. The recommended parameters are used in Eqs. (15)-(19): $C_{\mu} = 0.09$, $C_{\mu\mathrm{B}} = 0.6$, $\sigma_{\mathrm{k}} = 1.0$, $\sigma_{\varepsilon} = 1.3$, $C_{\varepsilon 1} = 1.44$, $C_{\varepsilon 2} = 1.92$. The tracer concentration is computed using the following transport equation:

$$\frac{\partial C}{\partial t} + \nabla \cdot \left(C \boldsymbol{V}_{C} \right) = 0 \tag{20}$$

COMPARISON AND DISCUSSION OF TURBULENCE MODEL

Simulations were compared with the experiments to verify the models. The grid size was $\Delta x = \Delta y = \Delta z = 0.02$ m. The total number of cells was 19×19×55=19855. Our previous studies confirmed that good predictions of void fraction distributions can be obtained using a grid size less than 0.1 m (eg. [4]). After 150 sec from the start of gas and liquid injection, the steady state was established. Then tracers (C = 1) were introduced from the liquid inlet. Calculation for t = 650 sec required about 11 hours using a personal computer (CPU: Xeon 3.0 GHz, Memory: 2GB).

Figure 6 shows comparisons between measured and predicted D. The effects of U_{L} and U_{G} on D were investigated. In addition, the effect of the ratio γ of the gas flow rate from the upper sparger to that from the lower one,

$$\gamma = \frac{Q_{\mathrm{G\,upper}}}{Q_{\mathrm{Gtotal}}} = \frac{Q_{\mathrm{G\,upper}}}{Q_{\mathrm{Gupper}} + Q_{\mathrm{Glower}}} \tag{21}$$

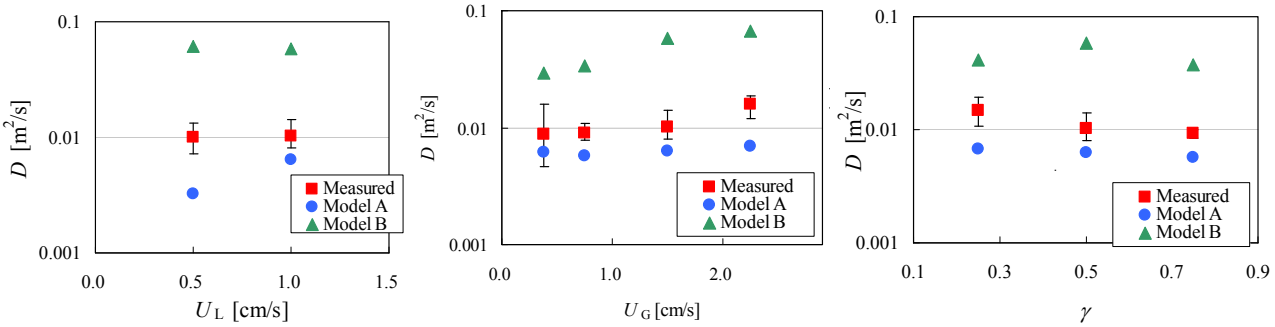
was also examined. Here Q_{Gupper} is the gas flow rate from the upper sparger, Q_{Gtotal} the total gas flow rate, and Q_{Glower} the gas flow rate from the lower sparger.

The experimental data show that (1) the effect of U on D is small, (2) D increases with U_{G}, (3) D depends on γ at constant Q_{Gtotal}. The Model A prediction was 30-50% lower than the measured D. This means Model A overestimates μ^{Re}, which has been also pointed out by Sokolichin and Eigenberger [15]. On the other hand, Model B underestimates μ^{Re}. Menzel [16] has pointed out that there are convex distributions of liquid velocity in the cross section even at U_{L}=0 cm/s. This indicates that shear-induced turbulence is not negligible even at low U_{L}.

To examine the contribution of shear-induced turbulence, we tested the turbulence eddy viscosity μ^{Re} given by

$$\mu^{\mathrm{Re}} = \mu^{\mathrm{BI}} + \phi\mu^{\mathrm{SI}} \tag{22}$$

where ϕ ($0 \le \phi \le 1$)is a parameter representing the contribution of SI.



(a) Effect of U_{L} (b) Effect of U_{G} (c) Effect of γ

Fig. 6 Comparison with available models

Figure 7(a) shows the tracer motion predicted by using $\phi = 0.1$, which is close to Fig. 4(a). Figure 7(b) shows a comparison of the tracer concentration at the outlet. Figure 8 shows comparisons of D by taking U_{L}, U_{G} and γ as parameters. These comparisons clearly show that $\phi = 0.1$ gives good predictions.

As a result, we could confirm that the liquid mixing in a given bubble column can be well predicted, provided that we can find an appropriate value of ϕ in Eq. (22) for the given column.

This kind of information is of great use in the column design. In addition to the liquid mixing, the gas hold up, gas absorption rate, temperature and so on are also obtained in the simulation. Further studies should be, however, indispensable to make the method as a reliable engineering tool, especially on sparger design, column diameter, internal structure, and so on.

CONCLUSION

A one-dimensional liquid mixing coefficient has been measured using a tracer detection method and compared with numerical simulations using a multi-fluid model. A parameter ϕ, which determines the contribution of shear-induced turbulence, was adopted in a two-phase turbulence model based on a linear superposition of bubble-induced turbulence and shear-induced turbulence. Good predictions were obtained for a wide range of gas superficial velocity and liquid superficial velocity by adding 10% contribution of shear-induced turbulence to bubble-induced turbulence, i.e. by setting ϕ = 0.1. This means that the degree of liquid mixing in a given bubble column can be well predicted by taking into account an appropriate amount of contribution of shear-induced turbulence.

THE STRUCTURE OF VELOCITY AND VORTICITY FLOW FIELDS IN THE NEAR WAKE REGION OF A COROTATING VORTEX PAIR

A. Romeos, D. Triantafyllidou, T. Panidis*
Laboratory of Applied Thermodynamics, University of Patras, Patras, Greece

ABSTRACT. The formation-interaction field of a pair of corotating vortices, generated by a split wing configuration, with equal and opposite angles of attack has been studied experimentally, using an in-house designed and constructed 12-sensor hotwire vorticity probe. Simultaneous measurements of all three components of the velocity and vorticity vectors were conducted for Re_c = 133,000, on a cross plane grid, at a distance of 0.3 wing cord lengths, *c,* behind the trailing edge. Due to the proximity of the wings the two streams, which fold around the tips to generate the vortices, collide creating on the cross plane flow a stagnation point and an "impermeable" line joining the two vortex centres. Along this line fluid is directed towards the two vortices, expanding their cores and increasing their separation distance. Vortices' cores are characterised by the presence of a dipole of opposite sign streamwise mean vorticity and a significant streamwise velocity deficit. The turbulent flow field is the result of fluctuations of the intensity of formation and wandering effects.

Keywords: *vortex pair, co-rotating vortices, multisensor hot wire anemometry,*

INTRODUCTION

Vortices generated at the wing tips of an aircraft, constitute a probable hazard affecting the capacity, the safety and the environmental impact of the air transport system. They also represent an intriguing challenge for modern fluid dynamics since they represent distinctive unit coherent structures. The importance of tip vortices has motivated many research efforts during the last decades. Understanding the interaction and merging process of counter and co-rotating vortices is an important element in the study of the vortex system of an aircraft. The interaction of co–rotating vortices generated by aircraft wings is characterized by turbulence that influences the lifetime of the wake. The vortex pairing process, in most of the cases, leads to the formation of a single, stable and significantly larger vortex.

Regarding the interaction and merging process for a pair of corotating vortices, Cerretelli & Williamson [1] suggested a mechanism incorporating four phases, namely: i) an initial stage of diffusive growth, ii) a convective merging phase, iii) a second diffusive stage in which vorticity is reorganized and iv) a final stage where the merged vortex diffuses. Initially, the two cores move away from each other until a critical growth of their radius. The rotational velocity field around each core induces a rotational velocity to the other core and thus the two cores are converging, developing a braid of spiralling vortices, which finally merges to a new stable linear vortex (Devenport et al. [2], Chen et al. [3]).

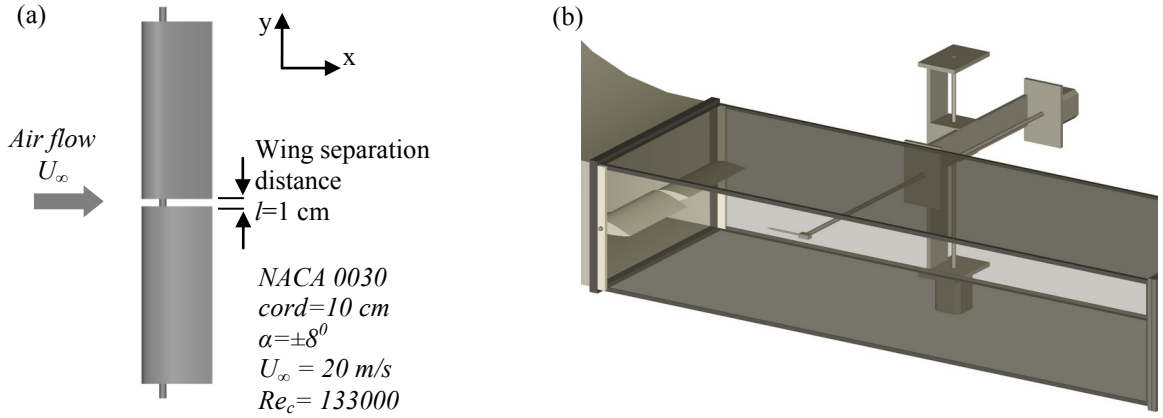

Figure 1. (a) Split-wing arrangement, (b) Wings and hotwire probe placed at the test section

As vortices start to interact, the two cores lose their symmetry and obtain an elliptical formation. Previous studies on two-dimensional vortex interaction attributed the distortion of the vortex cores into an ellipse to the existence of strain rate field of one vortex action upon the other (Moore & Saffman [4], Melander et al. [5, 6]).

In case of three – dimensional vortex interaction, the viscous phase before merging lasts long enough and a three – dimensional short – wavelength elliptic instability is developed (Meunier & Leweke [7], Dizes & Verga [8], Jacquin et al. [9]). This significant feature of corotating vortex interaction plays dominant role in the total flow evolution. This instability is different compared with Crow's [10] long-wavelength elliptic instability, which develops in counter rotating vortices and controls the vortex cores deformation. Furthermore, as proved by Jimenez [11], Crow's instability is not active in corotating vortex systems. Important aspects, as well as open issues, on the physics of trailing vortices have been presented and discussed in several review papers (Rossow [12], Spalart [13]).

The present work is part of ongoing research on corotating vortex interaction (Romeos et al. [14]) and provides experimental information on particular aspects associated with the formation and initial interaction of a pair of corotating vortices produced by a split wing configuration. These phenomena are encountered between vortices generated at wing tips and flaps or fuselage and also on many wake vortex alleviation devices. The flow field is characterized by a number of significant mechanisms that appear to determine the formation of the vortex pair flow field as well as the life expectancy of the vortical scheme. Most of the previous research has been focused on the interaction of vortices produced and formed almost independently with a considerable distance between the wing tips, whereas in the present study a small clearance between the differential wings was used. Detailed 3-D velocity and vorticity experimental measurements providing the mean and statistical characteristics of the interacting vortex–pair flow field were conducted by using an in-house developed and constructed 12-sensor hotwire probe.

EXPERIMENTAL APPARATUS

An open-circuit, subsonic, wind tunnel, with a test section of dimensions 30cm x 50cm x 300 cm, a maximum velocity of 20 m/s and turbulence level <0.2% was used as the experimental test bed. Vortices were generated, using two half-wings placed at the entrance of the test section (Figure 1). Both wings had a rectangular planform with NACA 0030 profile. The length of the cord was c=0.1 m with an effective half span of b=24.5 cm. The half–wings were placed at angles of attack α=±8

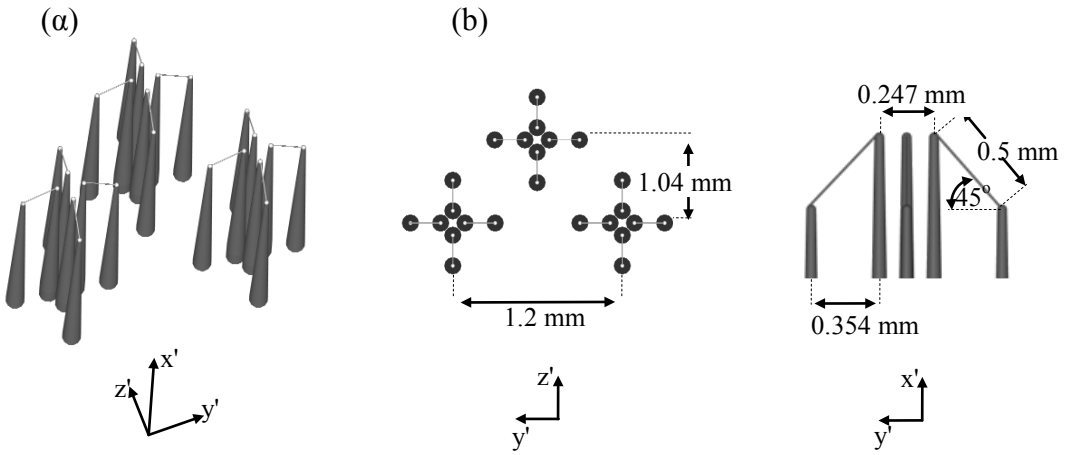

Figure 2. In-house manufactured, 12-hotwire vorticity probe, (a) 3-D view, (b) Probe dimensions

degrees, connected with a circular cylinder of diameter d=1cm at a wing separation distance l=0.1c (1cm). All measurements were made at a cord based Reynolds number, Re_c=133000 corresponding to a free – stream velocity, U_∞, of 20 m/s. Based on initial circulation, Γ_o, the Reynolds number was estimated as, $Re_{\Gamma o}$=58400.

An in–house manufactured, 12–hotwire vorticity probe, consisting of three closely separated orthogonal 4–hotwire velocity arrays (Figure 2), measures simultaneously the three dimensional velocity vector at three locations on a cross plane of the flow field. The design of the probe as well as the data reduction techniques rely upon the work of Lemonis [15], Lemonis & Dracos [16] and have been further improved and refined at the University of Patras. Probe's wires are made of Pt-Rh 10% alloy and are oriented at 45 degrees to the downstream direction. Their length is l_w =0.5 mm with a diameter, d_w =2.5 μm, giving a length/diameter ratio of about 200. Each sensing wire is welded on two separate prongs, uniformly tapered to ~20 μm at the tip, to overcome cross talking and thermal interference effects of previous common prong constructions (Kastrinakis et al. [17]).

Spatial resolution criteria indicate that the sensor length has to be in the range of 2-4 Kolmogorov length scales, η, in order to be able to ideally resolve the flow scales, whereas a similar criterion with the same range is suggested for the separation of sensor arrays in relation to velocity gradients estimation (Vukoslavčević et al. [18], Klewicki & Falco [19], Antonia et al. [20]). The minimum Kolmogorov scale of the present flow was estimated to be η=0.09 mm, in the core region where the dissipation rate attains maximum values. Thus the sensor length to the Kolmogorov length scale ratio deviates marginally from the suggested range only in a small area in the vortex cores where it attains a maximum value of 5.5. The spacing between sensor array centres, over which the velocity gradients are estimated, is 1.04 and 1.2 mm or in relation to the smallest Kolmogorov length scale 11.5η and 13.2η. Thus the probe is expected to almost fully resolve the velocity fluctuations field, whereas spatial filtering of the smallest flow scales in the velocity derivatives estimation within the vortex cores is expected to result in the attenuation of vorticity rms by 15% in the average (Honkan & Andreopoulos [21]).

Probe calibration is performed in-situ in the core of a round jet. The jet is rotatable about the pitch and yaw directions with an accuracy of better than 0.01 deg. Analysis of measurement data is based on the approximation of the calibration response of the wires by three dimensional B-splines and the solution of non-linear, three equations system to determine the components of the velocity vectors at the location of each 4-hot-wire array. Cross plane spatial velocity derivatives are

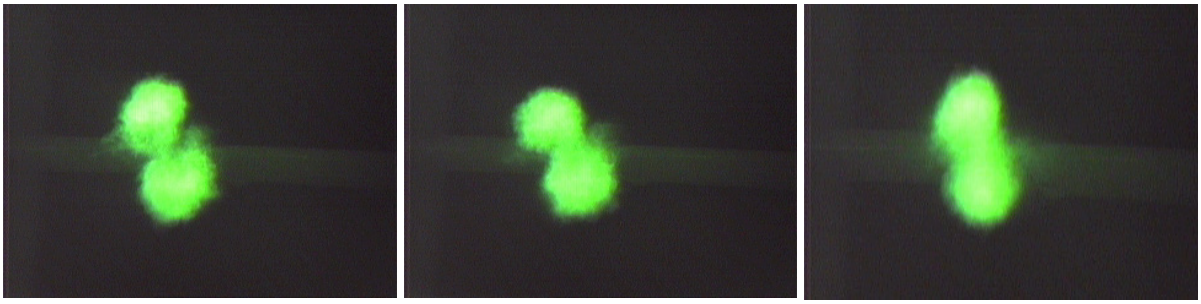

Figure 3. Characteristics visualization pictures of corotating vortex interaction at a cross plane

estimated using a forward scheme of first order accuracy. The streamwise velocity derivatives are obtained making use of Taylor's hypothesis of frozen turbulence using the local average velocity as the convection velocity. The uniqueness domain of a similar probe in combination with the present data reduction method has been assessed by Lemonis & Dracos [16]. Using reverse computations of calibration data they were able to recover correctly all data within a cone of pitch and yaw angles in the range $\pm 40^{o}$. In the present study the corresponding vectors never exceeded 30 degrees.

Flow visualization experiments (Figure 3) were used prior to the measurements to qualitatively characterise the formation and the interaction processes between the co-rotating vortices towards merging and select suitable configurations and measurements' locations. Measurements were obtained at several points, forming a closely spaced grid covering the area occupied by the vortices on a cross plane. At every point 80000 samples of each wire signal were recorded at a rate of 10 kHz, over a total sampling time of about 8 sec. Present results were obtained on a cross plane 3 cm (x/c=0.3) from the trailing edge. All data presented in this work, refer to a right hand Cartesian coordinate system (x, y, z) with corresponding velocities U, V and W (Figure 1).

MEAN FLOW FIELD

The mean velocity flow field, as measured by the 12-wire vorticity probe is presented in Figure 4. The streamwise velocity component, U, clearly depicts the form of two vortices with a characteristic velocity deficit reaching 50% of U_{∞} at the core centres (defined as the rotational centres of the flow field, see Figure 5). Contour lines of elliptical shape surround the vortex centres, illustrating the distortion of the vortex cores which can be attributed to the strain rate field of one vortex action upon the other (Melander et al. [5, 6]). The two transverse mean velocity components,

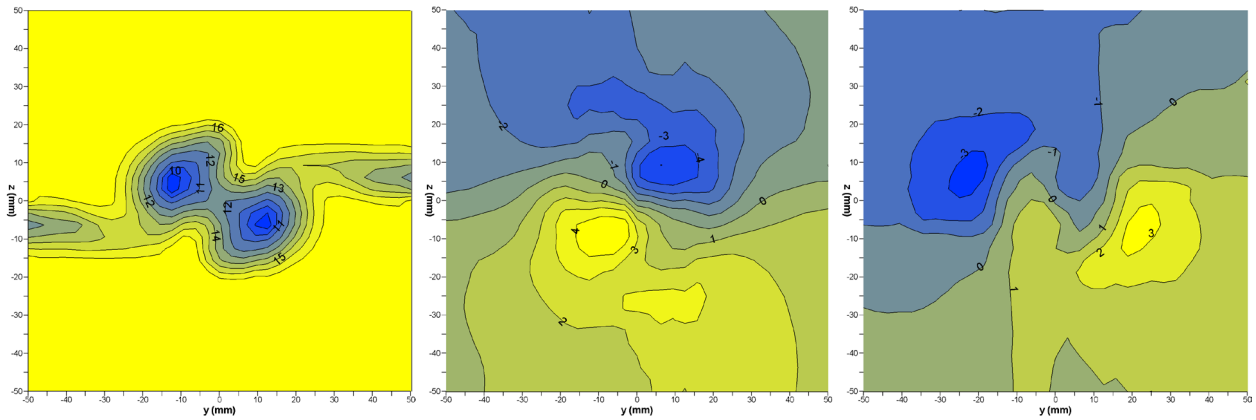

Figure 4. Mean velocity components, U(m/s), V(m/s), W(m/s), measured by 12-wire sensor

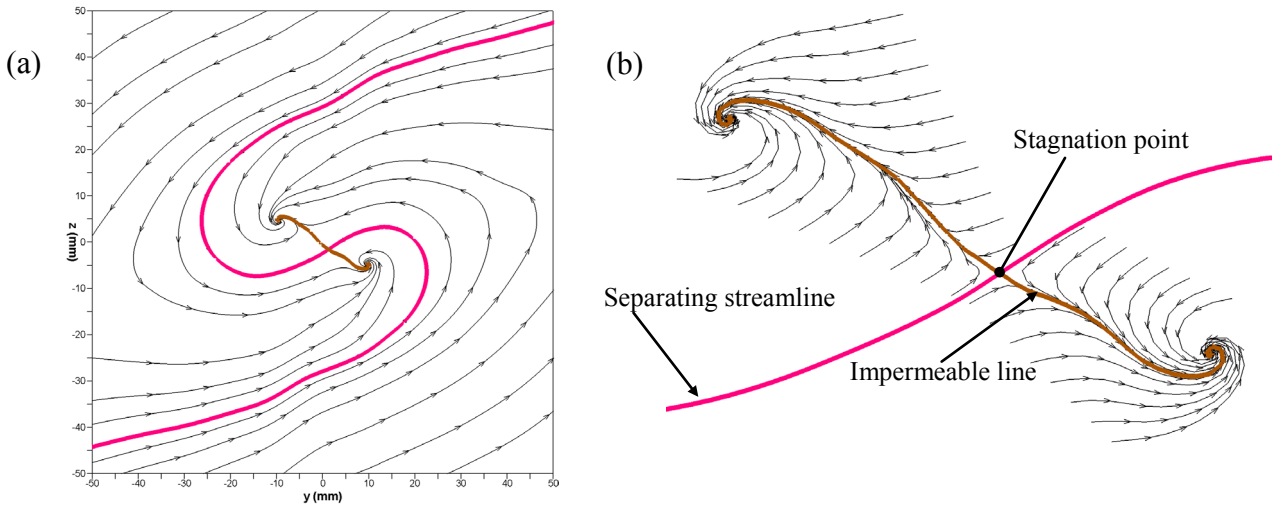

Figure 5. Streamlines and flow topology, (a) cross plane field, (b) enlargement vortex centers area

V, *W*, indicate the rotational character of the cross plane flow field, clearly demonstrated in the "streamline" plot based on the cross plane velocity components (Figure 5). The thick (red) "*S*" curve dividing the flow field in two similar antisymmetric parts represents segments of four limiting streamlines. Fluid travelling on the two sides of these curves will eventually reach a stagnation point at the middle of the "*S*" curve and diverge towards different vortex centres. Therefore, the "*S*" curve is dividing the flow field in two areas, each one comprising fluid which is directed to a different vortex centre. The limiting streamlines reaching the stagnation point continue towards the centres of the two vortices along an "impermeable" line formed between the centres (thick line, brown).

The mean vorticity flow field measured by the 12-wire sensor is presented by contour plots in Figure 6. The distribution of the streamwise mean vorticity component, Ω_x, is characterized by a dipole of positive and negative vorticity in the region of each vortex. The cores' centres are located in an area between the two maxima. Since the measurement technique assumes zero mean velocity gradients in the streamwise direction, both lateral components of mean vorticity are solely determined by the streamwise velocity gradients in the corresponding lateral directions.

The mean flow field indicates the presence of two flow streams, rolling up due to the pressure

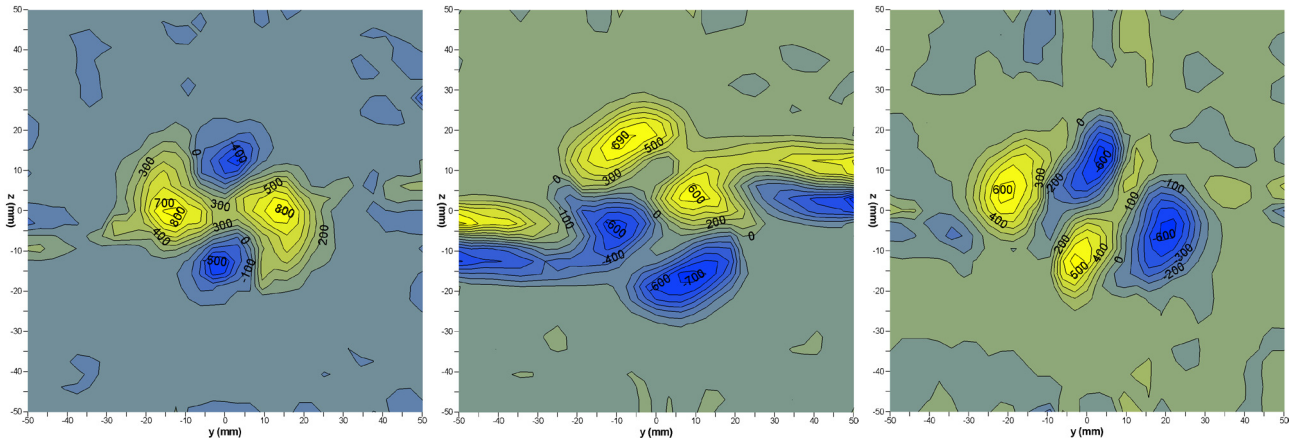

Figure 6. Mean vorticity components, Ω_x(1/s), Ω_y(1/s), Ω_z(1/s), measured by 12-wire sensor

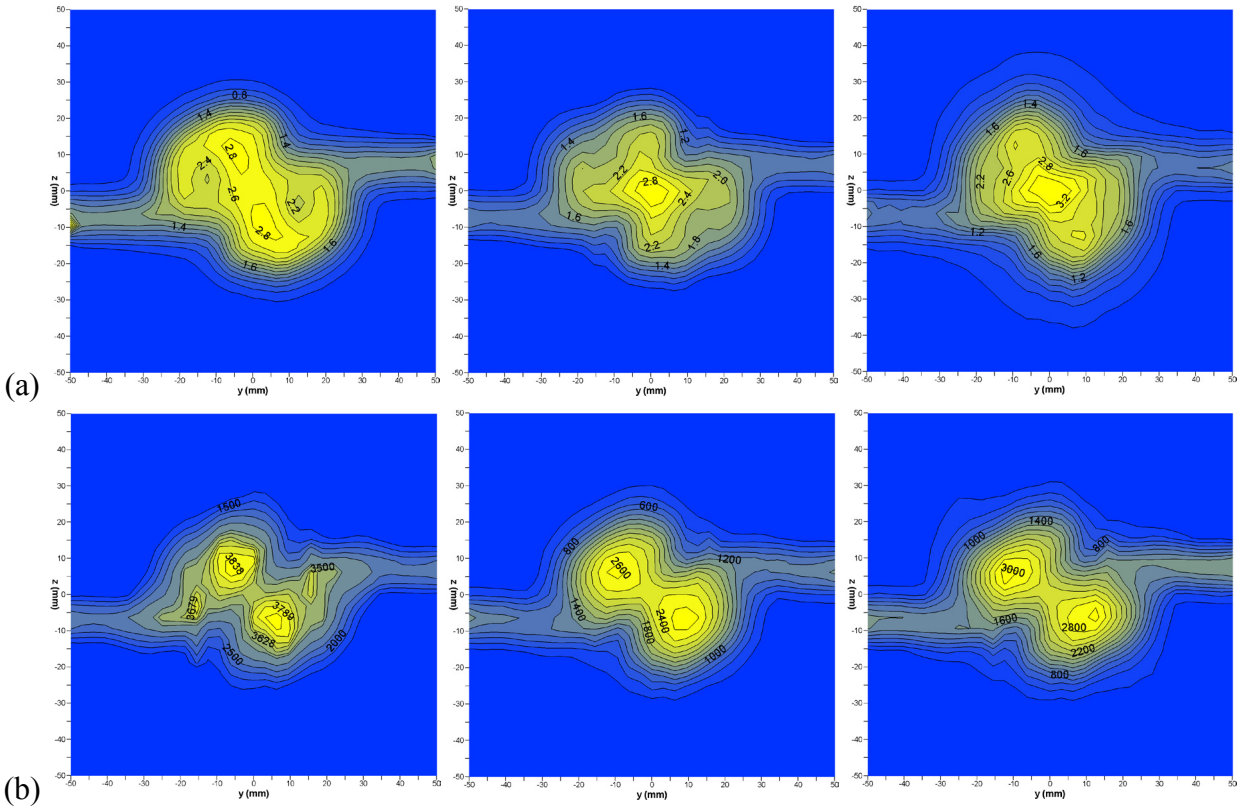

Figure 7. Rms values of (a) velocity fluctuations, $\sqrt{u^2}\ (m/s)$, $\sqrt{v^2}\ (m/s)$, $\sqrt{w^2}\ (m/s)$, (b) vorticity fluctuations, $\sqrt{\omega_x{}^2}\ (1/s)$, $\sqrt{\omega_y{}^2}\ (1/s)$, $\sqrt{\omega_z{}^2}\ (1/s)$

difference at the wing tips. These streams are led to a head on collision at the "impermeable" line. Along this line fluid is travelling towards the vortex centres leading to the expansion of the vortex centres and the increase of their separation. This motion in the absence of an external flow would have generated a counter rotating mushroom type vortex pair. The shear of the external rotational flow enhances the corotating vortex of the pair but eliminates the counter rotating one. Remnants of the counter rotating vortex are the existence of corresponding negative vorticity. This counter rotating vorticity can be also associated with the evolution of a secondary vortex during the formation of a single tip vortex on the wing observed by several investigators (Ghias et al. [22]) and considered as important for the development of the vortex.

TURBULENT FLOW FIELD

Contour plots of the Root Mean Square (RMS) of velocity and vorticity fluctuations are shown in Figure 7. Each vortex is characterized by a significant peak in streamwise velocity rms, $\sqrt{u^2}$, reaching 15% of the mean undisturbed velocity, U_∞. Vortex centres are surrounded by a band of high rms contour lines while a local minimum is observed within them. Cross stream rms velocity components, $\sqrt{v^2}$, $\sqrt{w^2}$, attain highest values, of the same order as the streamwise component, at the centre of the flow field, at the location of the stagnation point. The large values of all normal stresses inside the core region do not necessarily indicate intense turbulent mixing, but may result from inactive motions as it is buffeted by surrounding turbulence (Devenport et al. [2]). All the distributions are affected by the elliptic shape of the vortices and seemingly by specific characteristics of the mean field as for example the location of the mean streamwise vorticity peaks.

Vorticity fluctuations attain very high values, reaching more than 300% of the corresponding mean values. The streamwise component, $\sqrt{\overline{\omega_x^2}}$, also presents two peaks in each vortex, having the vortex centre in between them. The peaks on the clockwise side of vortex centres corresponding to the negative mean vorticity area are broader and higher, whereas those on the counter – clockwise side corresponding to the positive mean vorticity peaks are lower and more concentrated. Cross stream vorticity components' fluctuations rms, $\sqrt{\overline{\omega_y^2}}$, $\sqrt{\overline{\omega_z^2}}$, present one peak in each vortex, on or very close to the vortices' centres. The shape of the vortices and the wing wakes' regions can also be inferred from all vorticity fluctuations plots.

CONCLUSIONS

Simultaneous measurements of the mean and turbulent characteristics of the three-dimensional velocity and vorticity fields of a mutually interacting turbulent corotating vortex-pair have been conducted, using an in-house manufactured 12-hotwire probe. The flow field is characterized by a substantial streamwise velocity deficit at the vortex cores. The formation of the vortices seems to be dominated by the head on collision of the two rolling up flow streams generated due to the pressure difference at the wings' tips. This process results in the development of a dipole of counter-rotating vorticity at each vortex core. Visualization experiments show that the instantaneous flow field of the vortices preserves at all times the structural characteristics of the mean flow field. The vortices are continuously formed close to the wing tips and the fluctuating flow field depicted in the measurements is the result of changes in the intensity of the formation or changes in the position of the cores.

ABSTRACT. Experimental investigation on the turbulent drag reduction with blowing polymer solution from the channel wall was performed. Measurement of the drag reduction has been carried out with changing condition of blowing polymer solution (e.g. blowing rate and concentration) and Reynolds number based on the channel height and bulk mean velocity ranging from 20000 to 50000. The obvious drag reduction was obtained with blowing polymer solution and the maximum drag reduction rate achieved about 20 %. In addition, it seems that there is close relationship between the drag reduction rate and the mass flux of polymer. The drag reduction rate as the function of the mass flux has asymptotic curve limiting the maximum drag reduction. Because it is the merit of wall blowing that polymer can exist in the whole near-wall region, we discussed the difference between our results (wall blowing) and the effect of slot injection. Based on these results, the effect of wall blowing polymer solution on the heterogeneous drag reduction was discussed.

Keywords: *Drag Reduction, Polymer Solution, Wall Blowing*

INTRODUCTION

Adding dilute polymer solution or surfactant to turbulent wall-bounded flow can show obvious reduction in the skin frictional drag compared with the turbulent water at the same Reynolds number. This phenomenon is well known as Toms effect[1]. The drag reduction by additives can be classified into homogeneous drag reduction and heterogeneous drag reduction.

In the homogeneous drag reduction, Virk[2] reviewed the drag reduction by dilute polymer solutions in turbulent pipe flow and obtained 75 % drag reduction comparing with the solvent. Although several studies by polymer solution[3] and surfactant additives[4] have been performed for more than 50 years, the interaction of polymer solution with the near-wall turbulence and coherent structure in turbulent wall-bounded flow are still unclear.

On the other hand, as the heterogeneous drag reduction is the most efficient for applications to the external flow, it becomes remarkable theme in the recent. This heterogeneous drag reduction with injecting polymer solution into the boundary layer can be classified into the drag reduction in the pipe or in the channel. In case of injection into pipe flow, the most successful application of heterogeneous drag reduction by polymer solution is used in the Trans-Alaska-Pipeline. Adding the polymer solution to the crude oil in this pipeline, the desired discharge of 2 million barrels per day could be achieved.

In this study, we focused on the heterogeneous drag reduction with injecting polymer solution into the boundary layer of the channel flow. There are also many studies about heterogeneous drag reduction with injecting polymer solution into the boundary layer from the slot on the channel wall.

(a) Slot injection (b) Wall blowing

Figure 1. Schematic image for the distribution of near-wall polymer concentration: (a) slot injection and (b) wall blowing.

Walker and Tiederman[5] measured the profiles of the instantaneous polymer concentration in turbulent water channel flow with injecting polymer solution from the slot. They examined the action of polymer solution in the turbulent flow, but there were no discussions the relation between the polymer concentration and drag reduction. Winkel et al.[6] measured the drag reduction and near-wall polymer concentration with injecting polymer solution from the slot. They investigated the relation between the local drag reduction and the polymer concentration. Hou et al.[7] employed the PIV measurement to study the relation between the drag reduction and the near-wall polymer concentration.

It is revealed that the polymer in near-wall region is effective to reduce the skin frictional drag. However, the injected polymer from the slot is diffused into the boundary layer and drag reduction does not sustain for long region in the downstream of the slot as shown in Figure 1(a). More effective injection method is dissolving or blowing the polymer solution from the wall because the polymer will remain near the wall before it is diffused into the bulk flow and the polymer additive is expected to interact with the coherent structure near the wall as shown in Figure 1(b). If we can apply this effect to industrial applications such as ship bottom paint, it has great benefit of savings of fuel, cost of marine transportation and travel time. Actually, we are developing a new concept ship bottom paint applying this effect.

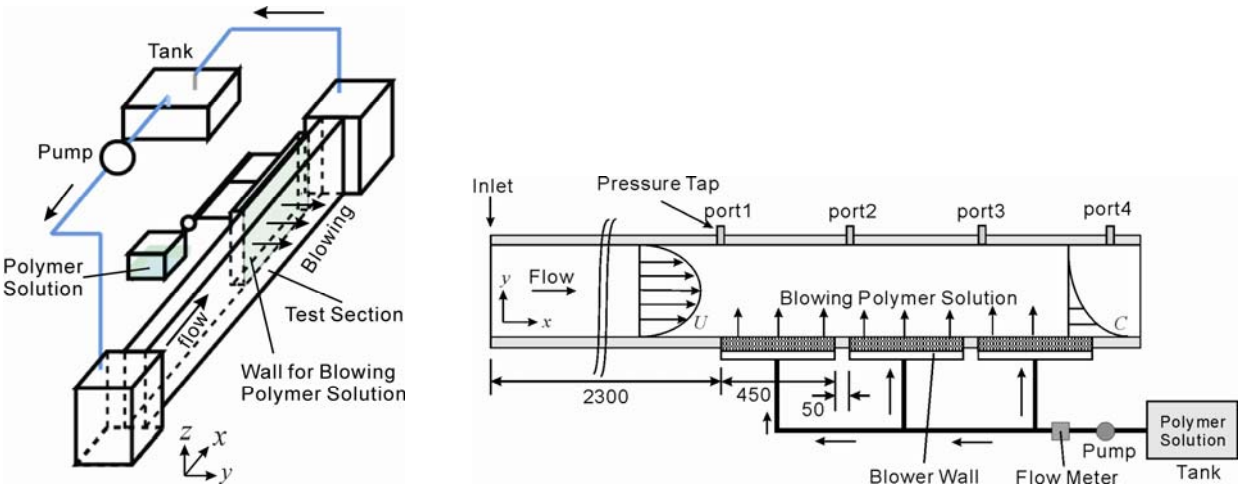
In this paper, as the first step of the development of ship bottom paint with polymer diffusion, we evaluated the drag reduction in the skin friction with blowing polymer solution from the permeable blower wall attached on the channel wall. Based on these results, the relation between the blowing mass flux of polymer and the drag reduction was discussed.

EXPERIMENT

Experimental Facility

Figure 2 shows experimental facilities including (a)flow system and (b)cross section of the channel with blower wall. Flow system consists of a closed-circuit water loop with two-dimensional channel test section. This test section is made of transparent acrylic resin, having 6.0 m in length, 0.04 m in inner height (H) and 0.5 m in spanwise width. There is a honeycomb rectifier with 0.15 m length at the channel entrance for removing large eddies. An electromagnetic flow meter with uncertainty of ±0.01 m^3/min is installed upstream of the channel. Storage tank of the flow loop contained a heater and an agitator to adjust a temperature of flowing fluid. The temperature of fluid is stabled at 25 °C.

The wall for blowing polymer solution is made of sintered metal, having 0.45m × 0.45m in size. Three blower walls are attached to one side of the channel. Polymer solution is oozing from whole surfaces of these walls. The blowing rate of polymer can be adjusted by the pump and the flow meter for polymer solution as shown in Figure 1(b). The blowing velocity normal to the wall is less than 0.09 mm/s.



(a) Flow system (b) Cross section of the test section

Figure 2. Experimental facility: (a) Flow system and (b) Cross section of the test section.

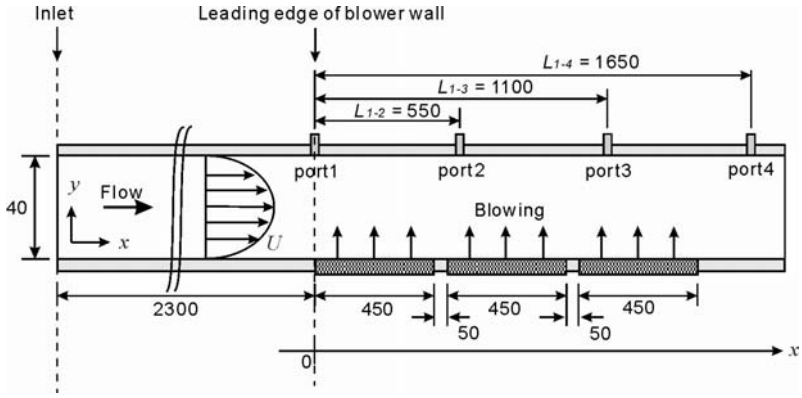


Figure 3. Detailed structure of the test section.

Reynolds number based on the kinematic viscosity of the solvent (ν), the channel height (H) and bulk mean velocity (U_b) is defined as $\mathrm{Re}=U_bH/\nu$. Re can be varied ranging from 20000 to 50000.

Detailed structure of the test section. Figure 3 shows the detailed structure of the test section. We defined the position of the leading edge of the blower wall as x=0. There are four pressure taps at the wall opposite side of the blower wall. These taps located x=0 (pressure port1), x=550 mm (port2), x=1100 mm (port3) and x=1650 mm (port4) at the downstream from the edge. The wall shear stress of between the ports1-2 ($\tau_{1\text{-}2}$), ports1-3 ($\tau_{1\text{-}3}$) and ports1-4 ($\tau_{1\text{-}4}$) can be calculated from static pressure gradient based on port1. Drag reduction rate (DR%) is defined by $(\tau_{water}-\tau_{blowing})/\tau_{water}\times 100$, where $\tau_{blowing}$ and τ_{water} are the wall shear stress of the water flow with and without blowing polymer solution, respectively. We can estimate the drag reduction rate at port 2, port 3 and port 4 based on port 1.

Polymer Solution

The polymer solution used in this experiment is Polyox WSR-205, produced by the Dow Chemical Company, dissolving in pure water. Major component of WSR-205 is 0.6 million in molecular weight water-soluble polyethylene oxide (PEO). This polymer is known to have large drag reduction ability in aqueous solution by other experiment. We prepared following weight concentration of polymer solution: 5, 10, 25, 50 and 100 ppm.

Table 1
Blowing Mass Flux $\dot{m}$ each Blowing Rate and Polymer Concentration.

	C ppm				
	5	10	25	50	100
Q L/min	$\dot{m}$ mg/(min ·m^2)				
0.5	4.1	8.2	20.5	41.0	82.0
1.0	8.2	16.4	41.0	82.0	164.0
1.5	12.3	24.6	61.5	123.0	246.0
2.0	16.1	32.8	82.0	164.0	328.0
2.5	20.5	41.0	102.5	205.0	410.0

Blowing Rate of Polymer Solution

As mentioned above, the polymer solution is blowing from the blower wall in this experiment. The blowing rate Q can be adjusted 0.5 L/min to 2.5 L/min. The blowing mass flux of polymer $\dot{m}$ can be calculated as follows:

$$\dot{m} = \frac{CQ}{S} \tag{1}$$

where, S is the total area of the blower wall (0.45m×0.45m×3) and C is weight concentration of polymer solution for blowing. The blowing mass flux of polymer $\dot{m}$ each Q and C is shown in Table1.

RESULTS AND DISCUSSION

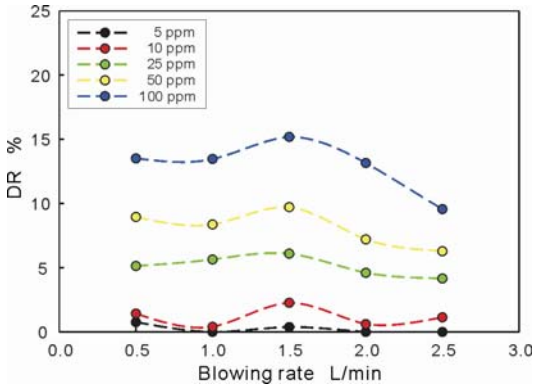
Blowing Condition Dependence on the Drag Reduction

Figure 4 shows the polymer concentration dependence on the drag reduction evaluated between the ports 1 and 4 for Re=(a)20000, (b)40000 and (c)50000. These figures indicate that the obvious drag reduction is obtained with blowing polymer solution from the wall. The drag reduction for Re= 40000 is larger than that for Re=20000. However, comparing Re=40000 with 50000, the drag reduction rate is almost same and the profiles are similar. Moreover, the drag reduction becomes large in blowing condensed polymer for Re=20000, but it seems that there is saturation of the drag reduction in 50ppm for Re=40000 and 50000. About 20% of maximum drag reduction was obtained.

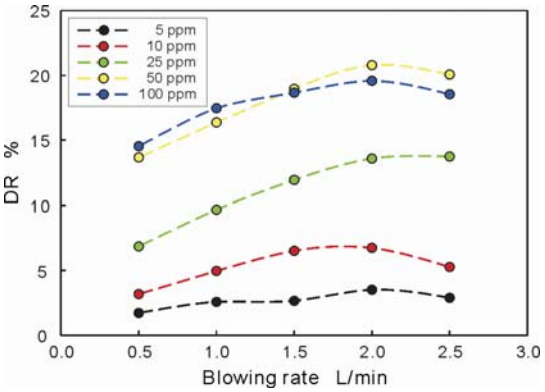
The blowing rate dependence on the drag reduction rate evaluated between ports 1 and 4 for Re=(a)20000, (b)40000 and (c)50000 are shown in Figure 5. As the blowing rate of polymer solution increases, the drag reduction rate becomes large and also saturates at 2.0 L/min of blowing rate for Re=40000 and 50000. Thus, the drag reduction rate saturates with the polymer concentration and the blowing rate as shown in Figure 4(c) and 5(c). These saturation behaviours were also observed in the slot injection study. It is believed that the drag reduction rate is determined by the local polymer concentration at the buffer layer. Therefore, though the blowing condition is different between Re=40000 and 50000, almost same amount of polymer seems to be existence at the buffer layer. Then once the polymer suppresses the turbulence, the surplus of polymer cannot work any more and the polymer diffuses to the logarithmic layer. As a result of this polymer behaviour, almost same drag reduction rate was obtained.

Streamwise Development of Drag Reduction

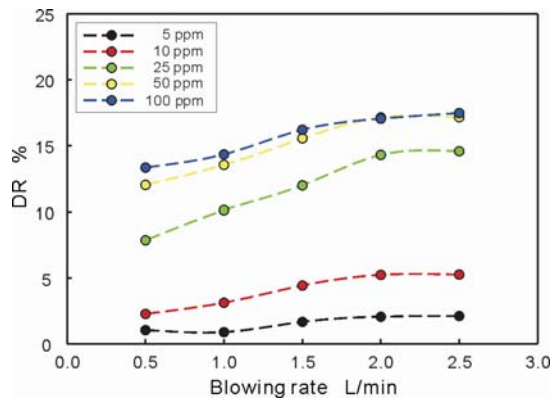
Figure 6 shows the drag reduction rate evaluated between ports1-2 (550 mm), ports1-3 (1100 mm) and ports1-4 (1650 mm) for Re=(a)40000 and (b)50000. The blowing rate is 0.5 L/min. This figure indicates that the drag reduction rate develops at the downstream from the leading edge of the blower wall. Though the drag reduction becomes large in blowing condensed polymer, this rate saturates in 50 ppm similar to Figure 4(b) and (c). The track of the change of drag reduction is similar between



(a) Re=20000

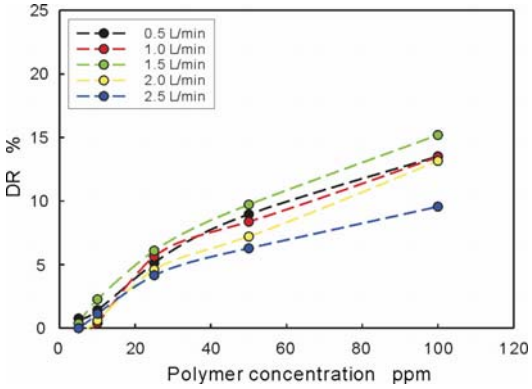


(b) Re=40000

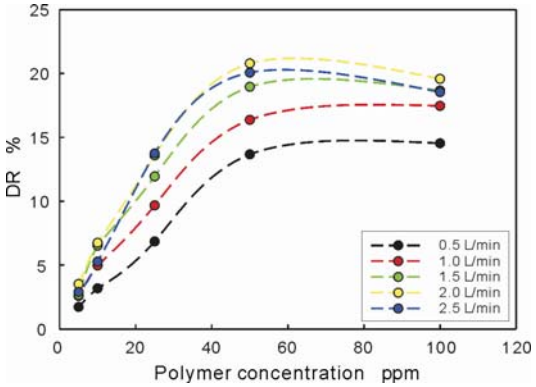


(c) Re=50000

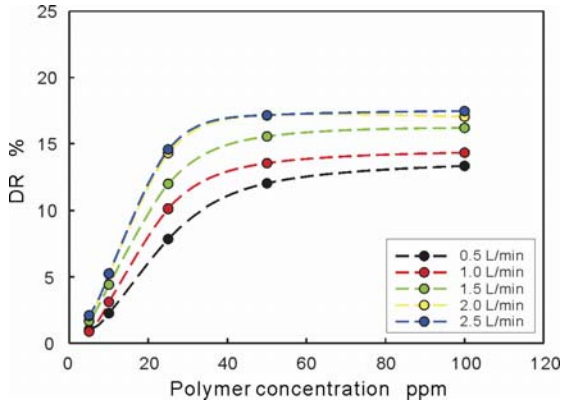
Figure 4. Polymer concentration dependence on the drag reduction rate: Re=(a)20000, (b) 40000 and (c)50000.



(a) Re=20000



(b) Re=40000

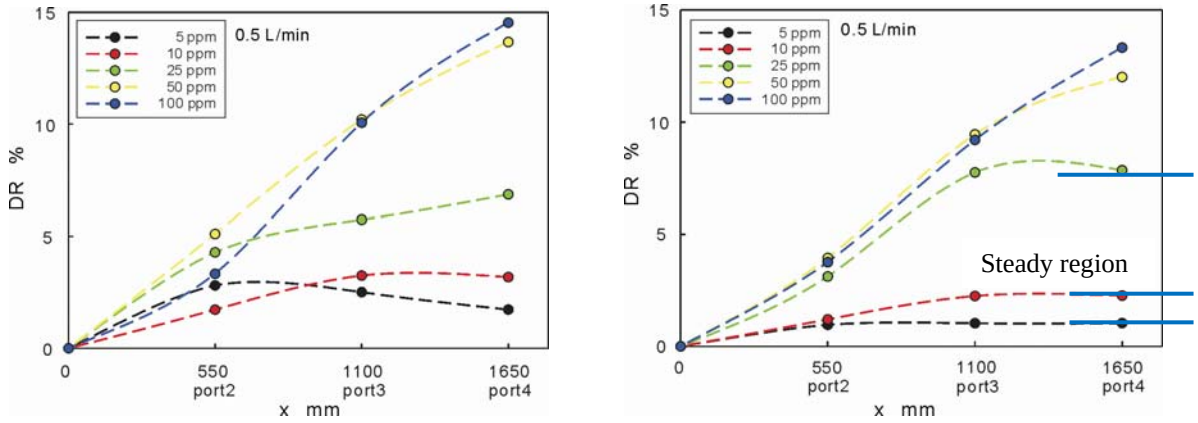


(c) Re=50000

Figure 5. Blowing rate dependence on the drag reduction rate: Re=(a)20000, (b)40000 and (c)50000.

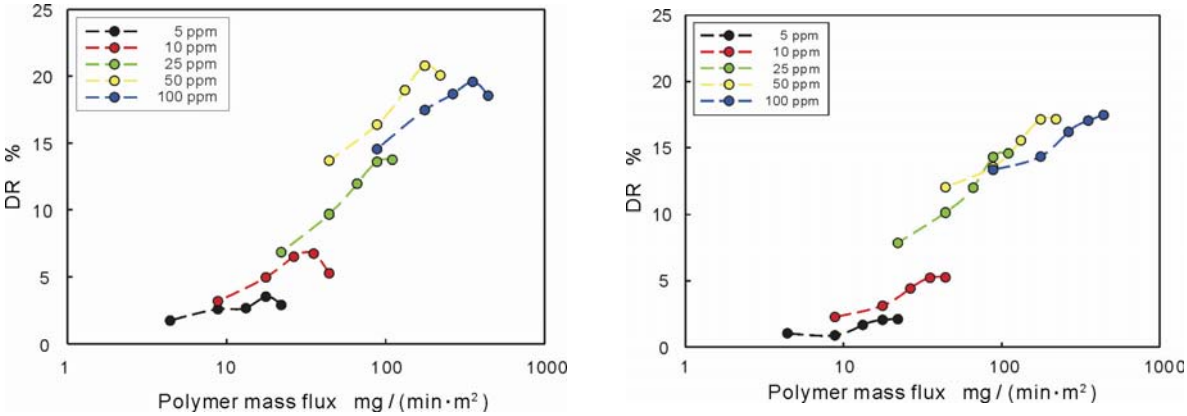
Re=40000 and 50000, and about 15 % of maximum drag reduction was obtained in this blowing condition. If we experiment with large blowing rate or large polymer concentration, about 20 % of maximum drag reduction can be expected.

There appeared the region where the drag reduction rate is kept at a constant level toward downstream. We call this region as “Steady region” in this study. This steady region is obtained remarkably for 5, 10 and 25 ppm at Re=50000. If the blower wall is longer, the steady region can be observed for 50 and 100 ppm. In this region, the polymer seems to be provided continuously at the buffer layer. As a result, the same drag reduction can be kept to the downstream.



(a) Re=40000 (b)Re=50000

Figure 6. Streamwise development of the drag reduction: Re=(a)40000 and (b)50000.



(a)Re=40000 (b)Re=50000

Figure 7. Relation between the blowing mass flux of polymer and the drag reduction: Re=(a)40000 and (b)50000.

In comparing with the slot injection[6,7], the steady region is also obtained, but it is necessary to inject very high concentration of polymer solution (e.g. 1000 ppm or 500 ppm). Moreover, the steady region cannot be kept to the downstream, the drag reduction decreases immediately at the downstream of the slot. As mentioned above, in the wall blowing, the steady region can be obtained with blowing low concentration of polymer solution and kept to the downstream. This ability to keep the drag reduction is one of the merits of wall blowing.

Relation between Mass Flux and Drag Reduction

Figure 7 shows the relation between the blowing mass flux of polymer and the drag reduction rate for Re=(a)40000 and (b)50000. This figure indicates that the amount of blown polymer has close relationship with the drag reduction. The tendency of results is similar between Re=40000 and 50000. It seems that the drag reduction rate as the function of the mass flux has asymptotic curve with limiting the maximum drag reduction 20%.

The profiles of the relation between the mass flux and drag reduction rate for each Re are shown in Figure 8. Though the profiles of Re=40000 and 50000 is observed in similar tendency, the profiles of Re=20000 shift to the right region. Because the wall shear stress for Re=20000 is smaller than that for Re=40000, the effect of polymer is lower relatively at Re=20000 and the profiles are observed at the right region. However, there is limitation in the effect of polymer and the tendency of result becomes similar for Re=40000 and 50000.

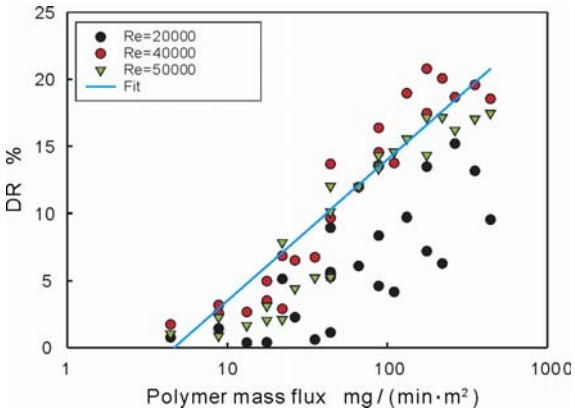


Figure 8. Relation between the blowing mass flux of polymer and the drag reduction.

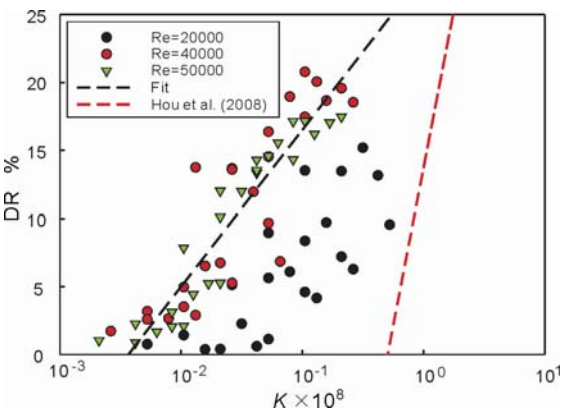

Figure 9. Relation between the *K* plot and drag reduction.

The solid line in Figure 8 is a fit to left side of these profiles. This line seems to represent the effective amount of blown polymer for getting the target drag reduction. However, the drag reduction rate has a limitation of 20 %. Eventually, the drag reduction is depend on the blowing mass flux of polymer $\dot{m}$ as a function of polymer concentration C and blowing rate Q represented by Equation (1) having limitation.

Comparison with Slot Injection

About K parameter. The drag reduction rate with slot injection can be plotted as a function of the *K* parameter developed by Vdovin and Smol'yakov[8]. It is useful to relate the amount of injected polymer from the slot and the drag reduction rate. This *K* parameter is defined as

$$K = \frac{Q_i C}{\rho X_i U_b} \tag{2}$$

where, Q_i is volumetric injection rate per unit span, C is the weight concentration of polymer solution, ρ is the density of the solvent (water), X_i is the downstream distance and U_b is the bulk mean velocity. The drag reduction rate is observed to be linearly proportional to $\log_{10}(K)$ and reaches maximum drag reduction.

Comparison with slot injection by K parameter. Figure 8 shows the profiles of the relation between $K\times10^8$ and the drag reduction rate. The black broken line is a linear fit to the experimental data with following equation:

$$\mathrm{DR} = 11.5\times\log_{10}(K\times10^8) + 28 \tag{3}$$

On the other hand, the red broken line is obtained by Hou et al.[7] This line is represented as:

$$\mathrm{DR} = 46.3\times\log_{10}(K\times10^8) + 13.7 \tag{4}$$

As mentioned above, there are two methods of diffusing polymer, wall blowing (our experiment) and slot injection (Hou et al.[7]). Equations (3) and (4) refer to the effective condition of blowing polymer from the wall and injecting polymer from the slot, respectively. The profiles of *K* for the wall blowing exist in the region where the value of *K* is smaller than that for the slot injection representing in Equation (4). This result indicates that the method of wall blowing can obtain the large drag reduction with blowing small amount of polymer in comparison with the slot injection. This ability is the excellent merit of wall blowing. However, the maximum drag reduction for wall blowing is smaller than that for slot injection.

CONCLUSIONS

We carried out precise measurement of a drag reduction rate with blowing polymer solution from the permeable blower wall attached on the channel wall. Measurements have been conducted with changing condition of blowing polymer and Reynolds number based on the channel height and bulk mean velocity ranging from 20000 to 50000. The main conclusions were drawn as follows:

1. Obvious drag reduction was obtained with blowing polymer solution from whole surface of the wall. The drag reduction becomes large in blowing condensed polymer. However, it seems that there is saturation of drag reduction in 50 ppm of polymer weight concentration and 2.0 L/min of the blowing rate. Maximum drag reduction is 20 % in this experiment.
2. The drag reduction rate develops at the downstream from the leading edge of the blower wall. The "Steady region" where the drag reduction can be kept at a constant level was observed. This steady region was obtained remarkably for 5, 10 and 25 ppm at Re=50000. In the slot injection, this steady region cannot be obtained with injecting low concentration polymer and the drag reduction rate decreases to the downstream. It is one of the merits of wall blowing that the drag reduction rate can be kept at the same level toward the downstream.
3. The drag reduction rate is dependent of the blowing mass flux of polymer. The drag reduction rate as the function of the mass flux has asymptotic curve with limiting the maximum drag reduction 20%.
4. In comparison wall blowing (our experiment) with slot injection, though the maximum drag reduction with wall blowing is smaller than that with slot injection, wall blowing can obtain the large drag reduction with blowing small amount of polymer comparing with the slot injection.

ACKNOWLEDGMENT

This study was carried out under the support of research project of the New Energy and Industrial Technology Development Organization (NEDO). We would like to thank Dr. L.Q. Kang, Mr. T. Ikegami and Mr. T. Satou of the Tokyo University of Science and Mr. E. Yoshikawa of the Chugoku Marine Paints, Ltd. for the supporting in this study.

ANALYSIS OF MOMENTUM AND HEAT TRANSFER IN COUNTER – CURRENT JETS

B. Wojciechowska[1,*], P. Domagała[1], S. Drobniak[1]
[1]Częstochowa University of Technology, Częstochowa, Poland

ABSTRACT. The paper presents the results of experimental analysis of the flowfield in isothermal and non-isothermal countercurrent round jets. The velocity measurements were carried out by means of a hot-wire anemometry and Laser Doppler Anemometry. The instantaneous signals collected during the experiment were digitally processed and used to determine the statistics and spectra of velocity fields and the distributions of turbulence scales. The results revealed, that both the fluid aspiration at the jet periphery and the density ratio between the inner and outer jet significantly influence mixing and entrainment in the flow considered.

Keywords: *countercurrent jets, turbulence intensity, turbulence scales, coherent structures*

INTRODUCTION

The countercurrent jet is the subject of a number of publications which appeared mostly during the recent decade. The reason for this interest is twofold, i.e. the applicability of this type of flow in many practical technologies and the appearance of interesting flow phenomena like absolute instability. The motivation for research in counter-current jets was initiated by the experiment of Strykowski and Niccum [1], which revealed the great potential of that way of flow stimulation in terms of an intensification of transport processes. The phenomenon had local character, i.e. intensive mixing took place in limited space of the flow only, and was accompanied by flow "laminarisation" (i.e. damping of turbulent fluctuations) in the remaining jet regions. Another motivation for investigations of counter-current jets is the appearance of absolute instability, found experimentally in heated jets by Monkewitz et al [2] and in helium jets by Kyle and Sreenivasan [3]. The theoretical justification for absolute instability triggered by external counter flowing jet was shown theoretically by Jendoubi and Strykowski [9], but so far no convincing experimental evidence was found for the existence of this phenomenon in countercurrent jets. Presented study resulted from the research performed at ITM CzUT within the framework of TIMECOP A.E. project, devoted to modelling of liquid fuel atomization and combustion in jet engines. The counter-current jet was selected as the test flow for investigations of fuel droplets evaporation [4] due to possibility of changing the structure of turbulence at the given point by changing the velocity ratio between the inner and outer jets. The results concerning the influence at suction velocity in outer jet upon the flow characteristic in isothermal jet was presented recently in [5, 8] but the problem of mixing enhancement in non – isothermal jets still needs clarification which was the main motivation for the present study.

EXPERIMENTAL FACILITY AND CONDITIONS

α	7°

the first one along the symmetry axis of the jet (denoted "a") and the second located along the edge of the inner jet (denoted "j – e"), as can be seen in Figure 2. From this sketch one may observe that the spreading rate of main stream may be changed by the aspiration parameter I, which is defined as the ratio of the inner to outer velocity. When aspiration is applied, the spreading rate of the inner jet increases and in all points of the flow the mean and fluctuating parameters are changed.

One of main components of the test rig is an inner nozzle which is made of brass. This nozzle generates air stream with low turbulence level and "flat" profile of mean velocity at the exit. The key parameter for this type of outflow is the roughness of inner surface of the nozzle. For this reason the inner surface has been done as turn surface. Additionally to reduce influence of backflow on the velocity field in the channel between inner and outer nozzle a profiled collar has been mounted at the inner nozzle.

The extension collars with different lengths L have been used to change the exit boundary layer thickness δ, because there is experimental evidence [7] that the ratio δ / D_1 may appear important in further investigations. The key parameter for the outer nozzle is also the inner surface, because its shape determines the shape of the reversed flow channel. Additionally, the design of the outer nozzle allows for change of orifices which determine the inlet width of the suction channel. The outer nozzle and orifices are made of aluminium.

Instrumentation of Test Rig and Measured Quantities

The flow rate of the inner jet was controlled by measurement of static pressure at the nozzle. Since the inner jet was heated the static pressure readings were corrected for air temperature measured with thermocouples. The flow rate of the outer jet was measured with a set of rotameters, which could be connected in parallel in order to cover the entire range of flow rates.

The temperature of the fluid flow was measured with type K thermocouple with uncovered joint. This thermocouple was introduced to the main flow only for controlling the airflow temperature. During measurements of the velocity profile at the nozzle exit this thermocouple was removed to avoid

flow disturbances. Detailed information about design of test rig and previous test conditions can be found in [7, 8].

The isothermal jet measurements were carried out with the use of DANTEC single channel hot-wire anemometer, the details of the setup are shown schematically in Figure 4. Constant temperature anemometer was used to recover the instantaneous velocity of flow. Velocity measurements were performed with DANTEC gold-plated wire probe 55P05. Instantaneous voltage signals of CTA were sent to the signal conditioners and data analysis system. In order to enable the continuous monitoring of the experiment, all signals were visualized by oscilloscopes and their average values were controlled by mean voltage meters. Signal processing, i.e. recovering the instantaneous velocity value U as well as the evaluation of the statistical moments and spectral density functions, was performed digitally by HP signal analyzer.

The measurements of velocity field for the cold jet were performed along the jet radius in several control planes covering the area $x/D_1 = 0 \div 11D_1$ as well as along the inner jet axis (line "a") and along the line being the extension of the edge of the inner nozzle (line "j-e"). The spreading rate of main stream could be changed by the parameter I, which was defined as the ratio of the inner to outer velocity. The main flow parameters of the reported experiment Reynolds number $Re = U_1D_1/\nu$ was 10000 and 20000, aspiration intensity expressed as the ratio of the mean velocities of the reverse flow and main stream was varied in the range $I = U_2/U_1 = 0 \div 0.4$.

The hot jet measurements were carried out with the use of DANTEC 2D Laser Doppler Anemometry in backscatter mode, equipped with Ar–Ion laser which generated two beams i.e. green (515nm) and blue (488nm) with total power 300mW, the details of the set up are shown schematically in Figure 5. Velocity measurements were performed with 2D DANTEC LDA probe with focal length 310mm. Instantaneous LDA signals were sent to FVA/BSA processor and then they were recorded on PC. For the case with overheat of the inner jet the experiment was performed for Re = 10000, the test conditions were controlled by aspiration ratio, and the overheat of the inner jet described by the density ratio "s" between the inner jet and the ambient fluid. The mean velocity, its gradient and turbulence intensity, as well as mean and temperature fluctuations were measured, furthermore the scales of turbulence and spectra of velocity and temperature were investigated for the following test conditions:

- Reynolds number Re = 10000, 20000
- Aspiration ratio $I = U_2/U_1 = 0 \div 0.4$
- Dimension ratio $L / D_1 = 7$
- Density ratio s = 1.0, 0.7, 0.5

RESULTS

The first stage of the experiment was the comparison of present experimental data for mean velocity and turbulence intensity with literature data [6] for Reynolds number Re = 20000 along the symmetry axis for the isothermal (s = 1.0) jet with no suction (I = 0). The investigations were intended as the verification of the test-rig conditions [6]. Results for mean velocity (Figure 6) are in very good agreement with literature data. Also the data for turbulence intensity (Figure 7) are very similar except for the first region where some differences can be noticed. These differences are most probably due to much lower turbulence intensity at the jet exit obtained during the present experiment, which may be attributed to corrected shape of the nozzle and better selection of gauzes in the plenum chamber. One may conclude therefore, that the inner jet characteristics are in agreement with previous investigations.

The next part of investigation was devoted to the analysis of mixing enhancement due to countercurrent external flow and the overheat of the inner jet. Both countercurrent flow and overheat should create the conditions for the appearance of the absolute instability phenomenon, as it was reported in [2, 3]. These investigations were performed for two values of Reynolds number i.e. Re = 10000 and Re = 20000, the sample results shown in Figures 8 and 9 for Re = 10000 case reveal, that both the decay of the potential core (Figure 8) and the increase of turbulence intensity along the jet symmetry line (Figure 9) caused by suction are visible, these pictures present the measurements obtained in consecutive cross-sections from the jet exit up to normalized distance x/D1 = 11D_1. Both the mean velocity and RMS of velocity fluctuations have been normalized with inner jet velocity $\bar{U}_0$ at the exit. The influence of suction is not monotonous, the smallest value of suction parameter I = 0.1 causes faster decay of potential core and bigger increase of turbulence intensity than for I = 0.2, for larger values of I the faster decay of mean velocity and increase of Tu is restored, for all values of I the maximum of Tu moves upstream. One may see that due to change of variable I flow parameters change considerably at every point located at the jet axis. One may conclude therefore, that the results presented here is in full agreement with previous investigations [5] and confirms that external counter flow is effective way of mixing enhancement.

Consecutive Figures 10 and 11 present the comparison of the isothermal (s = 1.0) and non-isothermal (s = 0.5 and 0.7) jet when the counter flow was absent i.e. for the ratio I = 0. The distance x and velocity U are again normalized by jet diameter D_1 and inner jet velocity at the exit $\bar{U}_0$.

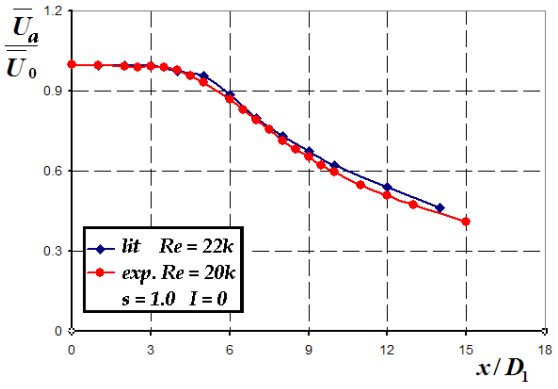

Figure 6. The comparison of present experimental data for turbulence intensity with literature [6] (measurements along the jet axis)

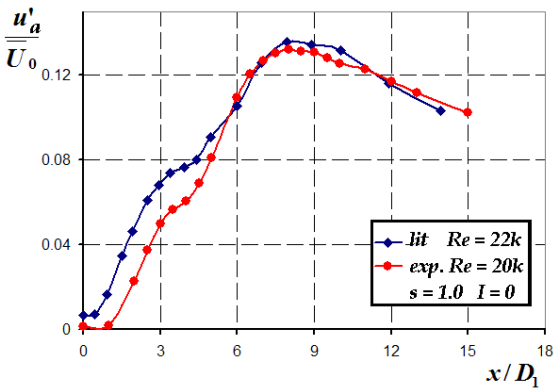

Figure 7. The comparison of present experimental data for mean velocity with literature [6] (measurements along the jet axis)

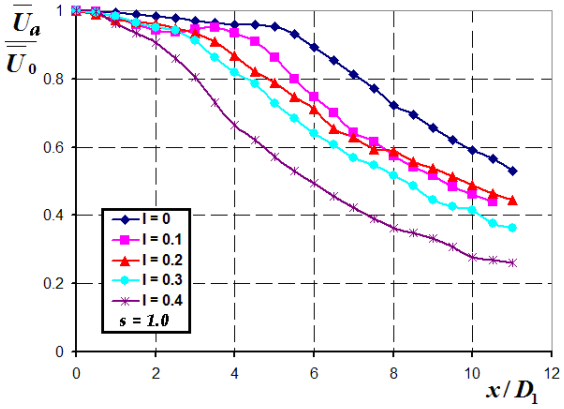

Figure 8. The decay of the potential core for Re = 10000 for various ratios of suction intensity I

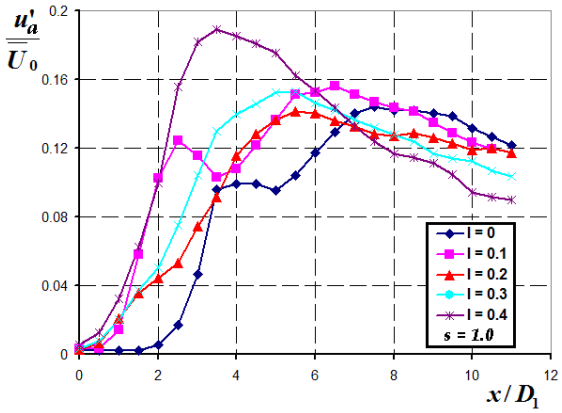

Figure 9. Turbulence intensity evolution for Re = 10000 for various ratios of suction intensity I

The decay of potential core (Figure 10) and the increase of turbulence intensity (Figure 11) behave differently, then before i.e. for smaller overheat s = 0.7 the decay of mean velocity is slower, while for s = 0.5 the decay of mean velocity along the jet axis is faster than isothermal flow. This behaviour is consistent with the data for turbulence intensity (Figure 11), which reveals slower increase rate for s = 0.7 and faster increase for s = 0.5. It may be observed, that contrary to counter flow the jet overheat influences the flow behaviour in complex and first of all not monotonous way. The measurements in non – isothermal flow required the application of LDA, and to the optical probe limitations the measurements could not be performed at the outlet plane (see Figures 10 and 11). The final stage at the investigations was the joint application of both counter flow and overheat.

This series of measurements was performed for Re = 10000 and for two values of overheat ratio i.e. s = 0.7 and s = 0.5,the suction ratio was varied in the range I = 0 ÷ 0.4. Sample results for s = 0.5 and s = 0.7 given in Figures 12 and 13 reveal, that the both mean and fluctuating velocity fields react to countercurrent flow but this reaction is the less effective the higher is the inner jet overheat. It may suggest that new phenomenon appears in this type of flow, that requires more elaborate investigations.

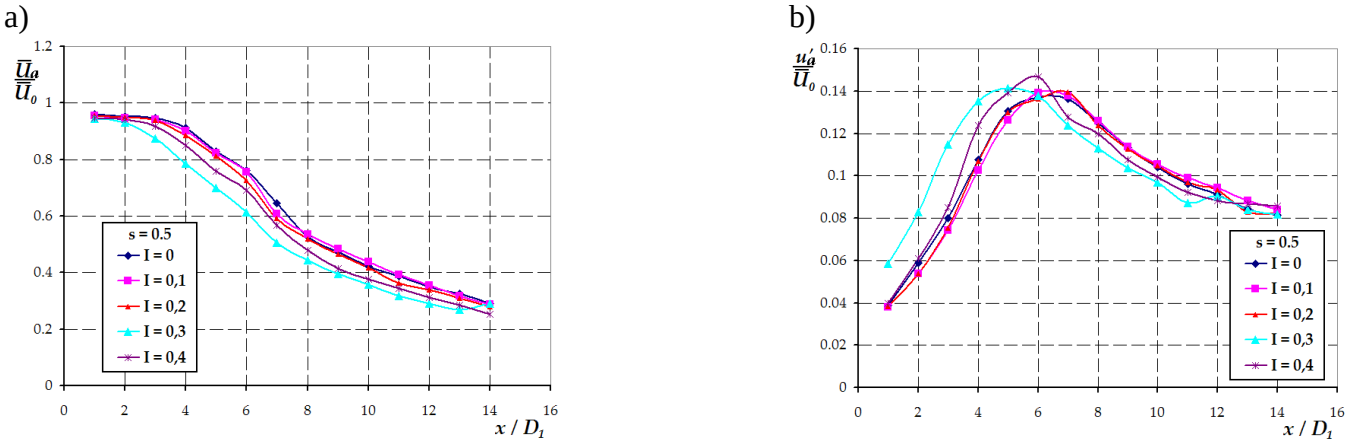

Figure 13. The influence of suction intensity upon the mean a) and fluctuating b) velocity along the jet axis for countercurrent jet with density ratio s = 0.5

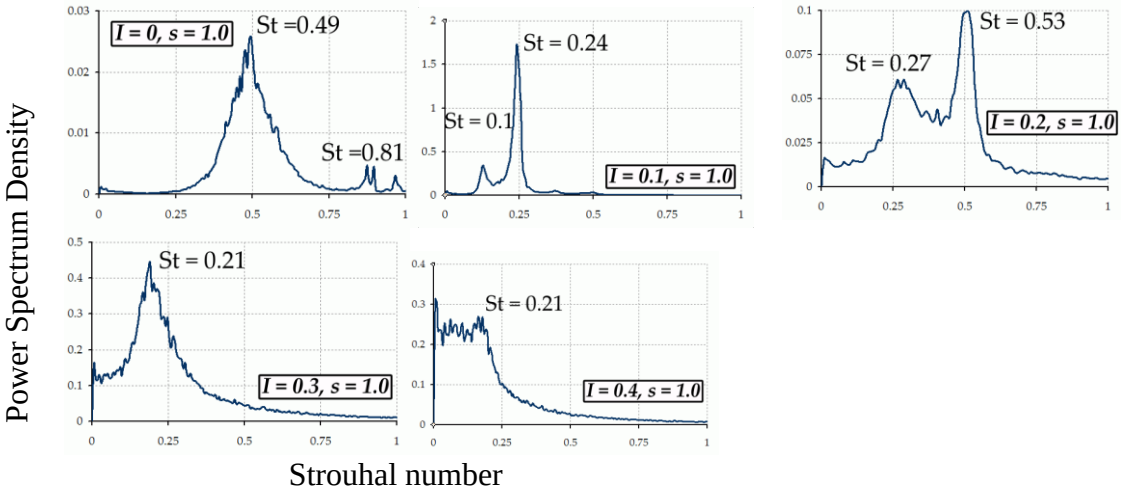

Figure 14. The evolution of the power spectrum density function of velocity fluctuation at the axial location $x/D_1 = 3$ for various ratios of suction intensity I

Since the pioneering paper of Crow & Champagne [10] it is a well established fact that the dynamics of a free jet is mainly governed by the large – scale vortices, which first are characterized by

the dominant frequency and then are transformed during pairing phenomenon when they travel downstream. Consecutive stages of pairing create more coherent structures which in turn contribute to larger amplitudes of periodic velocity oscillations. Vortex phenomena may be most precisely investigated by spectral analysis and that is why these measurements have been performed in the present research. The sample results in Figure 14 present power density spectra (*psd*) of velocity fluctuations recorded at the isothermal jet (s = 1.0) centreline at the distance $x / D_1 = 3$ from the nozzle exit, that for isothermal jet corresponds to the end of potential core. Figure 14 presents the centreline spectra measured at $x / D_1 = 3$ for all the values of aspiration ratio "I". These plots were expressed in terms of Strouhal number.

One may notice that for undisturbed jet (I = 0) the *psd* plot obtained at the end of potential core reveals the presence of peak for $St \approx 0.8$, that corresponds to the first stage of formation of column mode vortex rings. The lowest level of aspiration ratio (I =0.1) leads to the appearance of well established column vortex rings with the typical frequency $St \approx 0.24$, one may also notice the presence of pairing phenomenon, that leads to the formation of peak at half the dominant frequency ($St \approx 0.2$). Application of higher aspiration ratio (I=0.2) intensifies the vortex pairing phenomenon as it is indicated by the growing amplitude of the peak corresponding to half the dominant frequency. One should notice however, that for I= 0.2 aspiration ratio the dominant frequency was slightly shifted towards higher frequencies, as it is indicated by the $St \approx 0.5$ value of the dominant peak for I=0.2 (instead of $St \approx 0.24$ observed for I=0.1). This phenomenon may result from the change of exit boundary layer thickness, but the more convincing explanation requires more elaborate studies. The increase of aspiration ratio to I=0.2 leads to the formation of peak at half the column mode dominant frequency ($St \approx 0.2$), while further increase of aspiration (I=0.4) leads to the *psd* shape, which is characteristic for fully developed turbulence (see that only slight trace of $St \approx 0.2$ peak is visible at Fig. 14 for I=0.4). One may conclude therefore, that aspiration ratio I acts as an effective means of vortex dynamics control in a free jet, and the changes in spectra of velocity fluctuations due to the increase of I are identical as the psd transformation observed in undisturbed jet when the measuring point is moved downstream along the jet axis. A similar analysis was performed for the non – isothermal counter – current jet but this discussion is beyond the scope of the paper.

SUMMARY

The paper presents the experimental study describing of flow field characteristics in isothermal countercurrent round jets. The experiment confirmed that both the reverse outer flow and the overheat of the inner jet may substantially change the flow pattern of inner jet, proving that it can be utilised for the active flow control. In particular, the results obtained prove that these parameters affect the process of coherent vortex rings formation that in turn intensifies the momentum and heat transport in the flow considered.

NOMENCLATURE

δ – the thickness of boundary layer

v – kinematic viscosity coefficient

CTA – Constant Temperature Anemometer

D_1 – diameter of inner jet

D_2 – diameter of outer jet

I – the ratio of the outer to inner velocity [$I = \overline{U}_2 / \overline{U}_1$]

L – extension collar length

LDA – Laser Doppler Anemometer

Re – Reynolds number based on D_1

s – the density ratio between the jet and the ambient fluid

St – Strouhal number [$St = fD_1 / \overline{U}_1$]

$u'/\overline{U}$ – turbulence intensity

$\overline{U}_1$ – mean velocity of main (inner) jet

$\overline{U}_2$ – aspirated reverse (outer) mean velocity

$\overline{U}_0$ – mean reference velocity at the exit of the inner nozzle

$\overline{U}$ – local mean velocity

u' – turbulence component of $\overline{U}_1$ (RMS)

EDDY GENERATION AND HEAT-TRANSFER CONTROL IN RIBBED SYSTEMS COMPOSED OF SEVERAL STREAMLINED RIBS

Ya.I. Smulsky, V.I. Terekhov*, N.I. Yarygina
Kutateladze Institute of Thermophysics SB RAS,
Novosibirsk, Russia

ABSTRACT. In the present work, experimental data are reported concerning the development of turbulent separated flow and heat transfer in systems of several transverse or inclined ribs at different levels of free-stream turbulence. Visualization data and data on pressure and heat-transfer coefficients are presented. It is shown that there is the extremely unstable vortex formation in the second inter-rib cell under condition of natural turbulence of main stream, but high external turbulence stabilizes flow. The approximately identical promoting action of high turbulence on pressure coefficients and heat transfer coefficients is demonstrated. It was obtained that the secondary flows caused by the inclined ribs create a significant spanwise variation of heat transfer coefficients with appreciable increase of heat transfer on the part of a sharp angle at the ward side. Average on heated surface heat transfer coefficients slightly depend on ribs orientation. The maximal values of heat transfer intensity take place at an inclination angle of 60 degrees.

Keywords: *experiment, flow, separated flow, turbulence, heat transfer*

INTRODUCTION

In the present work, experimental data are reported concerning the development of turbulent flow and heat transfer in systems of several ribs at different levels of free-stream turbulence. On the one hand, this problem is related with the necessity of developing advanced heat transfer intensification methods providing simultaneously for an acceptable level of hydraulic losses in heat-and-power plant applications. On the other hand, this study is aimed at the development of physical foundations for heat and mass-transfer processes in high-turbulent flows with separation.

Rib turbulators are frequently in the form of rectangular cross-sectional bars mounted along the surface, which are often angled with respect to the bulk flow direction. Because they protrude into the flow, they act to trip the flow, mix the flow, and also generate vortices and three-dimensional velocity gradients. Today, many reported studies are available in which the flow structure and heat transfer in ribbed channels were examined [1-9]. Nonetheless, the multiparameter nature of the problem and the action of such factors as initial conditions, high flow turbulence, mutual influence of flows separated from obstacles, etc., did not allow a reliable calculation procedure to be developed for predicting heat transfer intensification in ribbed channels.

In our previous studies [10-13], the vortex-formation pattern and heat transfer behind a transverse rib streamlined by turbulent flow were thoroughly examined. The rib height and the free-stream turbulence were found to be parameters permitting an efficient control of the separated flow and heat transfer intensification. The separated flows behind steps [10] and flows in transverse cavities [14] are flows even more sensitive to external conditions, including the free-stream

turbulence. According to [15], the flow pattern in an inter-rib cell differs substantially from the flow pattern in a similarly sized rectangular cavity. Unfortunately, reported studies of the flow structure and heat transfer over the initial length of flow in system of cross-flow ribs are few in number. Over this length, a most pronounced influence of external conditions on the separated flow is exerted, defining the formation of downstream flow features throughout the surface. Considering the evolution of the flow, establishing the conditions that make the flow over the ribbed surface self-similar also seems to be an important matter.

In the present work, we experimentally examined the dynamic and thermal characteristics of the separated flow in systems of two to five flat flow-normal ribs and oblique to flow direction ribs. The vortex formation patterns, and the fields of temperature, pressure and heat transfer coefficients, were investigated. Visualization data, and also data on pressure and heat transfer coefficients, are reported. The effect due to free-stream turbulence is analyzed.

EXPERIMENTAL SETUP

The tests were carried out in the subsonic flow of the wind tunnel of the Institute of Thermophysics SB RAS with rectangular working channel 1000 mm long, 200 mm wide and 200 mm high. A 600-mm long model was installed at a height of 600 mm over the lower wall. The step nose of the model, of length 100 mm, was used to produce on the surface a 1/7-power-law turbulent boundary layer about 10 mm thick [10].

In measuring the dynamic and thermal characteristics, identically sized models were used. Both models were made of 20-mm thick textolite. The dynamic model was provided with pressure taps located in five longitudinal cross-sections across the channel, spaced 5 mm apart over the initial length of 300 mm and 10 mm apart on the remaining part of the plate. The 500-mm thermal model was heated ohmically in the regime q_w = const with the help of a ribbon heater made of 20-μm thick aluminum foil which covered the entire surface of the model. In the central longitudinal cross-section, twenty thermocouples were provided, mounted flush with the surface. The heat leaks by thermal conduction were determined from the temperature drop across the model. The distribution of temperature over the entire heat-exchanging surface was examined thermographically, with the help of a THERMO TRACER TH7102 IR imager (Japan). The gained temperature fields were digitized using reference thermocouples and special software.

To visualize the surface flow pattern in the ribbed system by the soot-oil film method, we used another similar-sized model coated with 3-mm thick Plexiglas. The visualizing mixture was a mixture of offset black and lamp oil.

A system of two to five ribs, sufficiently wide to completely span the channel, was mounted on the model surface; the first rib was installed 50 mm from the leading edge of the model. The ribs were made of Plexiglas, the rib height being H = 60 мм, and were 4 mm thick. Like the rib height, the spacing between the ribs was 60 mm; the used cells were therefore square. In the systems of oblique ribs, the rib height was 3, 6 and 10 mm. In the majority of experiments, the free-stream velocity U_0 = 20 m/s. The Reynolds number for this velocity calculated from the rib height was $1.2 \cdot 10^5$.

The experiments were carried out at two, a low and a high, free-stream turbulence levels $Tu_0 = \sqrt{\overline{u'^2}}/U_0$ = 1.5 and 15 %. The high turbulence level was achieved by tripping the flow with a flag turbulence generator installed 330 mm upstream of the first rib. The polyethylene flags were fastened to a perforated grid with 20-mm diameter holes. This grid completely spanned the channel.

EXPERIMENTAL DATA

Flow visualization. The visualized patterns of the flow at the bottom of inter-rib cells were obtained for all ribbed systems comprising one to five ribs. A typical picture for the systems of four and five ribs at the low and high level of free-stream turbulence is shown in Fig. 1. In the figure, the

flow is directed from the left to the right. The vortex-formation pattern observed in the first cell at Tu_0 = 1.5 % closely resembles the pattern observed in a rectangular cavity [14].

Near the trailing wall of the cell a most intense eddy forms, with a secondary eddy registered near the leading wall. Similar patterns were also registered in the third and fourth cells, the flow in these cells being more stable. The flow in the second cell was very unstable because of the development of a reverse flow directed against the mainstream flow and moving out of the third cell into the second cell. This effect was reported previously in our early studies (see [15]). Flow instability in the second cell was also observed in the systems of three and four ribs. In these systems, the flow behind the last rib always resembled the flow behind a single rib. Under the action of the external turbulence, the flow in the second cell gets stabilized to become a flow most stable among all cells. Flow instability was also registered in the first cell; accordingly, a reverse flow, yet less intense compared to the low-turbulence case, was observed in the region over the second rib. An appreciable reconstruction of the vortex structure was exhibited by the secondary flow in the third and fourth cells.

Figure 1. Vortex-formation pattern at the bottom surface in the system of five ribs
a) Tu_0 = 1.5 %; b) Tu_0 = 15

Distribution of pressure coefficients. Our experiments showed that the distributions of pressure measured inside inter-rib cells in different cross-sections of the channel were almost identical.

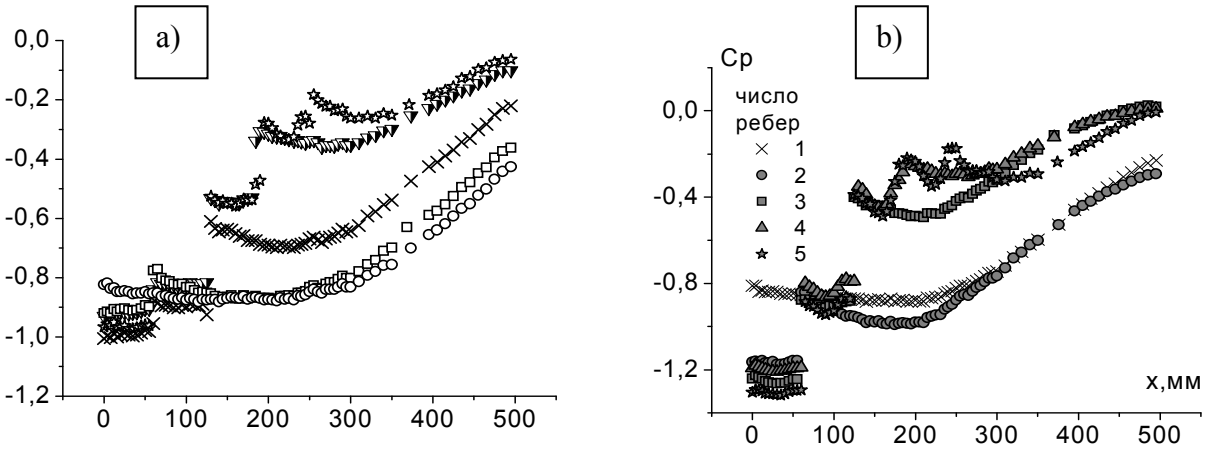

Figure 2. Distribution of pressure coefficient in inter-rib cells in systems with different number of ribs a) - Tu_0 = 1.5 %; b) - Tu_0 = 15 %

The distributions of the pressure coefficients $C_p=2(p_i - p_0)/\rho U_0^{\,2}$ at the bottom of inter-rib cells are shown in Fig. 2. Here, p_i is the wall pressure, and p_0 and U_0 are the reference pressure and the flow-core velocity un the region over a rib. In the downstream region of the last rib, a characteristic distribution of pressure is observed that closely resembles the similar distribution behind a single rib. Behind the last rib, the pressure recovers over a length of 14 calibers [5]. As it follows from Fig. 2, with each additional rib installed in the system the pressure recovers more and more rapidly. In the system of four or five ribs the pressure recovery lengths are identical, extending to a distance of nine calibers from the leading wall of the first rib. In the tripped flow, a decrease in the absolute value of C_p in the downstream region of the last rib is observed, especially in systems made up by small number of ribs, and also in the second cell of the system comprising three ribs, this finding being indicative of some reconstruction of the flow.

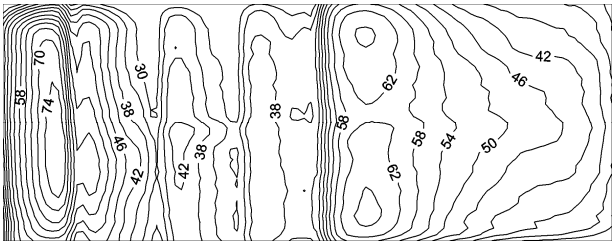

Figure 3. Isotherms of the bottom surface under heating the bottom in the system of five ribs

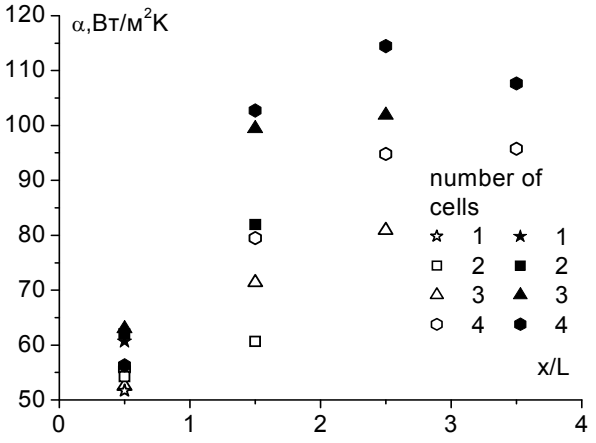

Figure 4. Distribution of cell surface-average heat transfer coefficient α in the systems of two to five ribs (open symbols - Tu_0 = 1.5%, full symbols - Tu_0 = 15 %)

Heat transfer. The temperature field revealed thermographically at the natural turbulence level in the system of five ribs and in the downstream region of the last rib is shown in Fig. 3. The flow instability in the second inter-rib cell is seen to have a most pronounced influence on the distribution of temperature in this cell. The temperature field in the second cell is symmetric with respect to the temperature field in the first cell. A weak reconstruction of temperature distributions is also observed in the third and fourth cells, the isotherm distribution behind the last rib being the same as behind a single rib.

The gained temperature fields were used to calculate the local heat transfer coefficients α. The longitudinal distributions of the lengthwise-local values of α obtained in systems with different numbers of ribs showed that, for both turbulence levels, a considerable growth of heat transfer in the second cell is observed, most pronounced in the system of five ribs. In subsequent cells, the growth of heat transfer coefficients somewhat weakens. In the low-turbulence flow over the system of five ribs the rate of heat transfer attains its highest in the two last cells. This observation is also confirmed by Fig. 4, which shows the surface-average heat transfer coefficients for each cell. In compliance with the vortex-formation pattern, the most pronounced heat transfer intensification due to the external turbulence (up to 30 %) is observed in the second cell.

The visualization tests performed with systems of low-height (6 mm) oblique ribs inclined at angles of 45, 60, and 75° to the flow proved the temperature and thermal fields to differ from the fields observed in systems of flow-normal ribs. Figure 5 shows visualization data for 60° angled ribs represented in the form of distributions of local heat transfer coefficients.

It is seen from Fig. 5 that, compared to systems of flow-normal ribs, the heat transfer coefficient in systems of oblique ribs are substantially redistributed in the spanwise direction with markedly enhanced heat transfer behind ribs on the acute-angle side.

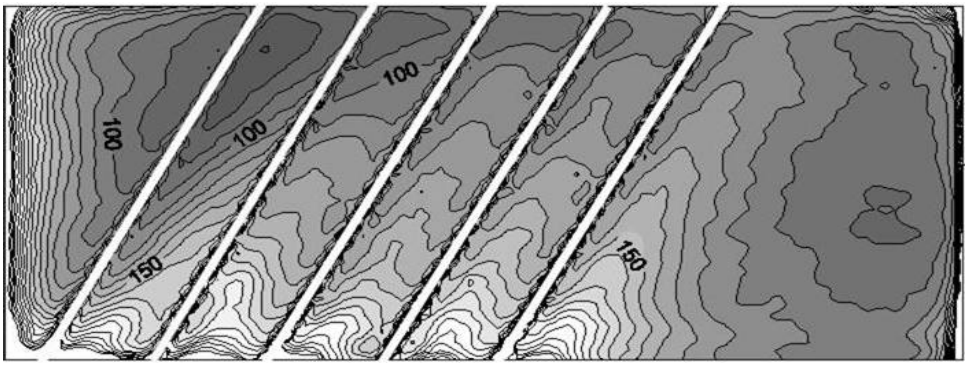

Figure 5. Distribution of local heat transfer coefficients in the system of 60° angled ribs

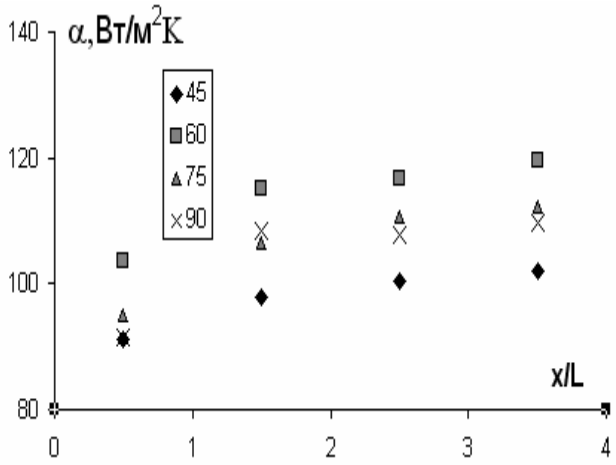

Figure 6. Distribution of cell surface-average heat transfer coefficient in the system of ribs with different inclination angles

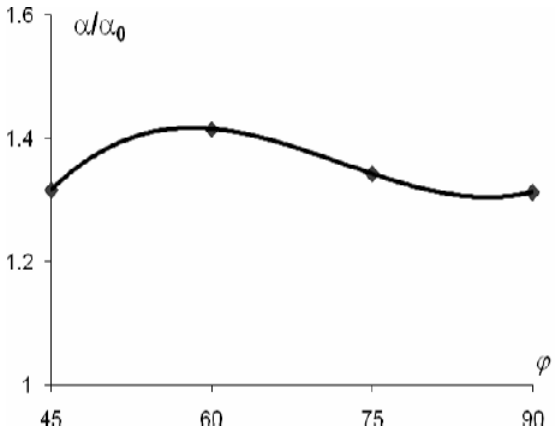

Figure 7. All heated surface-average heat transfer coefficient normalized to the same coefficient on a flat plate for four angular configurations of the system of five ribs

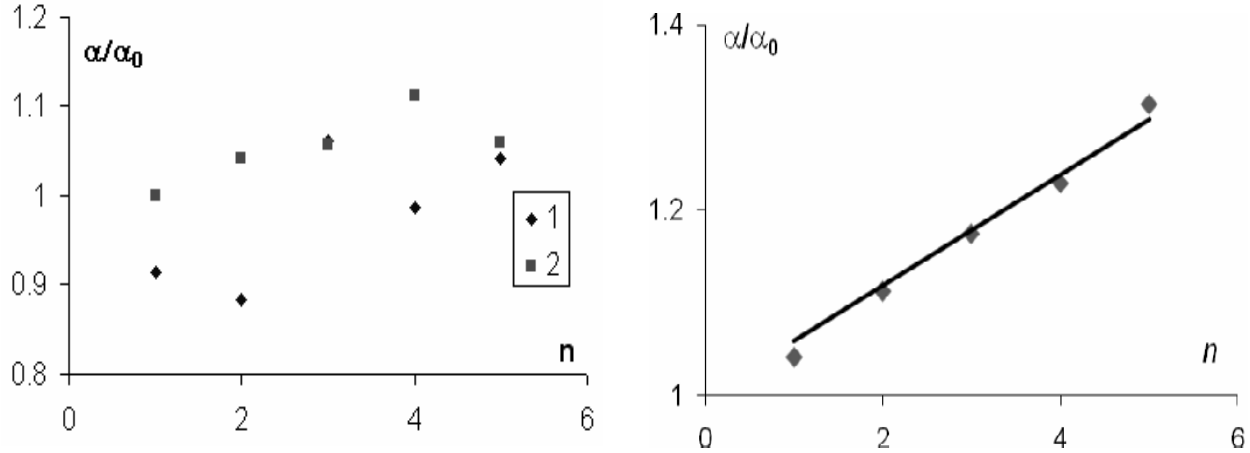
Overall picture of heat transfer distribution in each cell is similar. For all angular configurations the first cell has the least heat transfer augmentation in comparison with the subsequent cells that Fig. 6 proves to be true. However the level of heat transfer for various angles of a ribs orientation is slightly differs. According to Fig. 7, the surface-average heat transfer coefficients in the system of five ribs also depend, although insignificantly, on the rib angle φ. All data, including those for flow-normal ribs, were obtained for 6-mm high obstacles. A maximum values of α_{mean} was observed at φ=60°.

Figure 8 shows the surface-average heat transfer coefficients in the low-turbulent flow normalized to the flat-plate heat transfer coefficients versus the total number of installed ribs. High flow-normal ribs are seen to be good heat transfer intensifiers only in the high-turbulent flow due to the high level of free-stream turbulence. In the case of low-height ribs installed obliquely to the flow (Fig.8 b), the rate of heat transfer increases with increasing number of such ribs.



a) b)

Figure 8. Cell surface-average heat transfer coefficient versus the total number of installed ribs
a) H = 60 mm, 1 - φ = 90°, Tu_0 = 1.5%; 2 - φ = 90°, Tu_0 = 15%;
b) H = 6 mm, φ = 45°, Tu_0 = 1.5%.

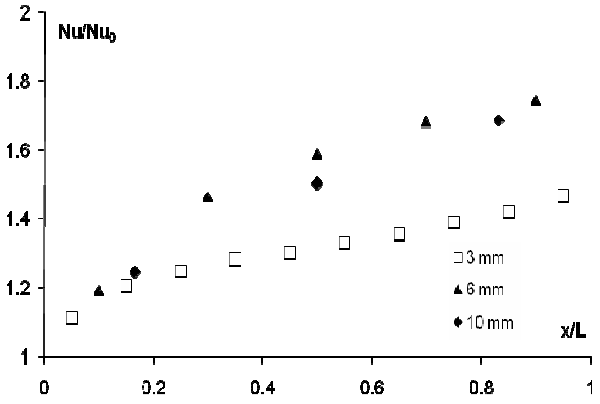


Figure 9. Cell surface-average Nusselt number normalized to the same coefficient on a flat plate for φ = 60°

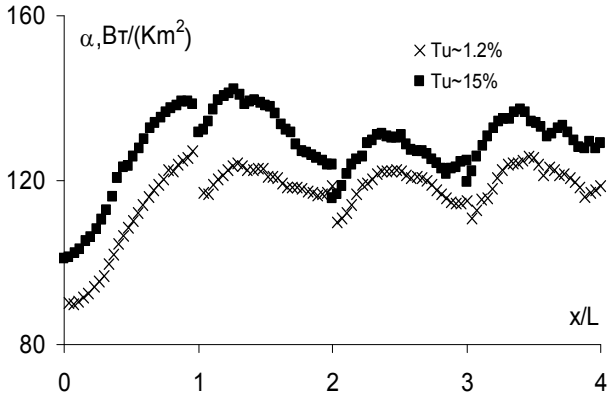

Figure 10. Distribution of local heat transfer coefficient in the system of 45° angled ribs at two turbulence levels

Distribution of average heat transfer coefficient calculated on the area of a cell of for system of ribs with an attack angle of 60° is submitted at three values of height of a rib in Fig. 9. The system has consisted of 4 ribs with step of 100 mm at height of rib H=10 mm on heat-release surfaces, from 6 ribs with step of 60 mm at height H=6 mm and from 11 ribs with step of 30 mm at H=3 mm. In Fig. 9, Nusselt number grows with increase in height for ribs of small height.

Distribution of local coefficient α along an axis of symmetry of model (at φ =45° and H=6 mm, Fig. 10) differs from distribution local heat transfer in system of direct ribs (Fig. 4) a little. There is influence of external turbulence upon α up to 30 % in the system of 45° angled ribs the same as in system of direct ribs. As a whole it is shown, that the augmentation of heat transfer in separated

flows behind obstacle such as ribs can be effectively control both change of orientation of a main stream and a level of turbulence in the external flow.

CONCLUSIONS

An experimental study was performed to examine the formation of the vortex structure, and also the pressure and temperature fields, in inter-rib cells of ribbed systems at two turbulence numbers, 1.5 % and 15 %.

The visualization tests showed that in the low-turbulent flow over a system of three or more ribs a very unstable flow forms in the second cell, related with the rarefaction induced mass suction behind the second rib and with the development of a reverse flow in the region over the third rib. Under conditions of high free-stream turbulence, this instability was found to be displaced into the first cell.

With each additional rib installed in the system, the flow separation region behind the last rib and the pressure recovery region become less extended in the downstream direction, and the coordinate at which the pressure attains its maximum, decreases.

A sharp increase in the rate of heat transfer in the second inter-rib cell was identified. The rate of heat transfer in the flow over a system of five ribs under the low-turbulence conditions attains its highest in the third cell, at a distance of three calibers over the rib height, whereas in the flow over a single rib this distance amounts to 15 calibers. High free-stream turbulence intensifies heat transfer. In the second cell, the heat transfer intensification amounts to 30 %.

In the systems of oblique ribs, some redistribution of temperature profiles is observed, most pronounced for obliquely ribbed systems with $\varphi = 60°$. Unlike systems with high ribs, under natural-turbulence conditions low-height ribbed systems ($H \leq 10$ mm) serve good heat transfer intensifiers.

This work was partly supported by the Russian Foundation for Basic Research (Grant No. 09-08-00076).

Abstract. Aerodynamic forces are function of the relative velocity between the air and the body model. In a wind tunnel, this relative velocity is achieved moving the air over a stationary model. In the past years, several wind tunnels are being designed and built to measure aerodynamic forces and moments. It is observed that, even with the recent computational advances, wind tunnels are still an essential tool to the study of the aerodynamics. This paper presents a comparison between numerical and experimental data in the test section of a low speed wind tunnel. Numerical results were obtained for three turbulence models, namely the k-ε, *RNG k-ε and* shear stress transport *SST* models. The simulation results were compared with the mean time experimental velocity profiles as a function of several values of inlet mass flow rate, as well as with the experimental turbulent kinetic energy.

Keywords: *wind tunnel, hot wire anemometry, CFD*

INTRODUCTION

A wind tunnel is a research tool used to help the study of the effects of air moving over or around a body. Geometrical shapes or models (such as cars or plane wings) are mounted inside a duct and air is blown or sucked through this duct, creating a relative movement between the air and the object. Although the first wind tunnels predated the advent of aeroplanes, with Wenham in 1871, the wind tunnel was developed along with the aeronautical industry, between 1900 and 1960. In this period, the wind tunnel was seen as an essentially research tool. Between 1960 and 1980, it became a reliable and robust tool for commercial design purposes. From 1980, there have been significant advances in wind tunnel testing techniques, particularly in terms of instrumentation [1]. Even with the computational advances, wind tunnels still represent an essential tool to aerodynamic studies. Wind tunnel measurements are being used to validate Computational Fluid Dynamics (CFD) calculations, and CFD can be used as a tool to support wind tunnel design, wind tunnel testing and the interpretation of the test results [2].

Several reports of experiments performed in wind tunnels are available in literature. Wind tunnels are used to evaluate the drag and lift forces in objects [3, 4, 5], to investigate mean and fluctuating wind loads on buildings and atmospheric boundary layers [6, 7, 8] and to investigate turbulent boundary layers [9], among other studies.

With the improvement of computational capabilities, CFD techniques have been used to predict the behaviour of the airflow over and around solid bodies and to predict the acting forces and moments over them. Experiments in wind tunnels are performed to validate the numerical models [10, 11].

This paper presents numerical and experimental investigations of the airflow inside an open wind tunnel. The wind tunnel tests were carried out in the test section of a low-speed wind tunnel. Velocity and pressure were measured in an array of points in the test section. The instantaneous velocity and turbulent intensity were measured in the central point of the exit region of test section. The numerical predictions were performed using three turbulence models: the standard k-ε, the *RNG* k-ε and the *SST* model (see next section).

2.1 Numerical Methodology

A Computational Fluid Dynamics (CFD) technique comprehends the numerical solution of the governing flow equations. In the analysis, the solution domain is divided into a large number of infinitesimal control volumes and the governing equations are solved for each of them. The main governing equations of fluid flow are mass conservation, momentum conservation and energy conservation.

For turbulent flows, it is necessary to take into account the effects of turbulence. In this paper it is done through application of turbulence models. Three turbulence models were evaluated: k-ε model [12], the *RNG* k-ε model [13] and the *SST* model. The *SST* model was proposed by [14] from the k-ω turbulence model, initially formulated by [15]. The models are presented in the above-mentioned order, considering only the main equations used in the numerical simulations. Models constants are also introduced. It is important to note that are presented the model definitions and formulation used in [16], since the numerical simulations were performed with this commercial code. The main interest is to study how different models can lead to different computational results only considering the defaults definition of each model, including the default boundary conditions.

The mass conservation and momentum conservation equations are used in the same form for all the models evaluated.
Mass conservation:

$$\frac{\partial \rho}{\partial t} + \vec{\nabla} \cdot (\rho \boldsymbol{U}) = 0 \tag{1}$$

Momentum conservation:

$$\frac{\partial (\rho U)}{\partial t} + \vec{\nabla} \cdot (\rho U \otimes U) = -\vec{\nabla} p + \vec{\nabla}\left(\mu (\vec{\nabla} U)\right) + B \tag{2}$$

where B is the sum of body forces, μ_{eff} is the effective viscosity accounting for turbulence, and p' is the modified pressure. μ_{eff} and p' are given respectively by:

$$\mu_{eff} = \mu + \mu_t \tag{3}$$

$$p' = p + \frac{2}{3}\rho k \tag{4}$$

2.2 Standard k-ε model

The k-ε model uses the eddy viscosity concept, assuming that the turbulence viscosity μ_t is computed by:

$$\mu_t = C_\mu \rho \frac{k^2}{\varepsilon} \tag{5}$$

where C_μ is a model constant.

The standard k-ε model [17] introduces two new variables into the equation system: the turbulent kinetic energy, k, m^2/s^2; and the turbulence eddy dissipation,ε, m^2/s^3. The new variables are obtained through the solution of transport equations, given by:

$$\frac{\partial(\rho \boldsymbol{k})}{\partial t} + \vec{\nabla} \cdot (\rho \boldsymbol{U} k) = \vec{\nabla} \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_{\boldsymbol{k}}} \right) \vec{\nabla} k \right] + \boldsymbol{P_k} - \rho\varepsilon \tag{6}$$

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \vec{\nabla} \cdot (\rho \boldsymbol{U} \varepsilon) = \vec{\nabla} \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon} \right) \vec{\nabla} \varepsilon \right] + \frac{\varepsilon}{k} \left(C_{\varepsilon 1} \boldsymbol{P_k} - C_{\varepsilon 2} \rho\varepsilon \right) \tag{7}$$

In the equations, $C_{\varepsilon 1}$, $C_{\varepsilon 2}$, σ_k and σ_e are the model constants and P_k is the turbulence production tensor due to viscous forces. The buoyancy forces are not considered in the present work.

The *RNG* k-ε model is based on renormalization group analysis of the Navier-Stokes equations. The transport equations for turbulence generation and dissipation are the same as those for the standard k-ε model, but the model constants differ. The equations for the momentum and continuity are also the same.

The other two-equation turbulence model refers to the Shear Stress Transport model taken from [12]. This model was proposed by [14], and grew from the denominated baseline k-ω model in [12]. The baseline k-ω model makes use of the k-ε model in regions far away from the walls and the k-ω Wilcox model (cf. [15]) near the surface. The *SST* model is an improvement of the baseline k-ω model, taking into account the transport of the turbulent shear stress by a limitation of the eddy viscosity ν_t by the following equation:

$$\nu_t = \frac{a_1 k}{\max(a_1 w, SF_2)} \tag{8}$$

where: $\nu_t = \mu_t / \rho$ and S represents an invariant measure of the strain rate. F_2 is a blending function, which restricts the limiter to the wall layer computed by:

$$F_2 = \tanh(\arg_2^2) \tag{9}$$

with:

$$\arg_2 = \max\left(\frac{2\sqrt{k}}{\beta' \omega y'} \frac{500\nu}{y^2 \omega} \right) \tag{10}$$

3. Experimental setup

The experiments were conducted in an open wind tunnel type shown in Figure 1. This setup has a square cross-sectional test section of 200 mm wide and 790 mm of extension. Before the test

section removable grids can be installed to homogenize the flow turbulence. The rotation speed of the fan is controlled to modify the mass airflow inside the wind tunnel. The tests were carried out for several values of rotation speeds, ranging from 1800 rpm up to 3200 rpm.

In order to measure the mean time axial velocity a Pitot-static probe was used in several points of the exit test section region. Considering that [18] establishes a minimum of 25 measurement points, 36 measurement points were used to characterize the velocity profile in the exit of the test section. These points are shown in Figure 2, where (0,0) corresponds to the centre of the section and the values are in mm.

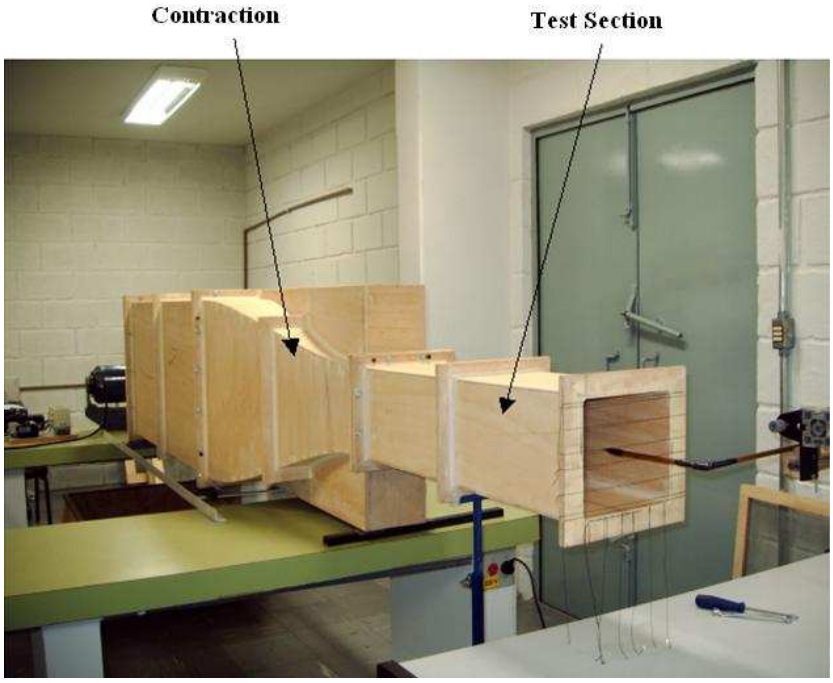

Figure 1. Wind tunnel[19]

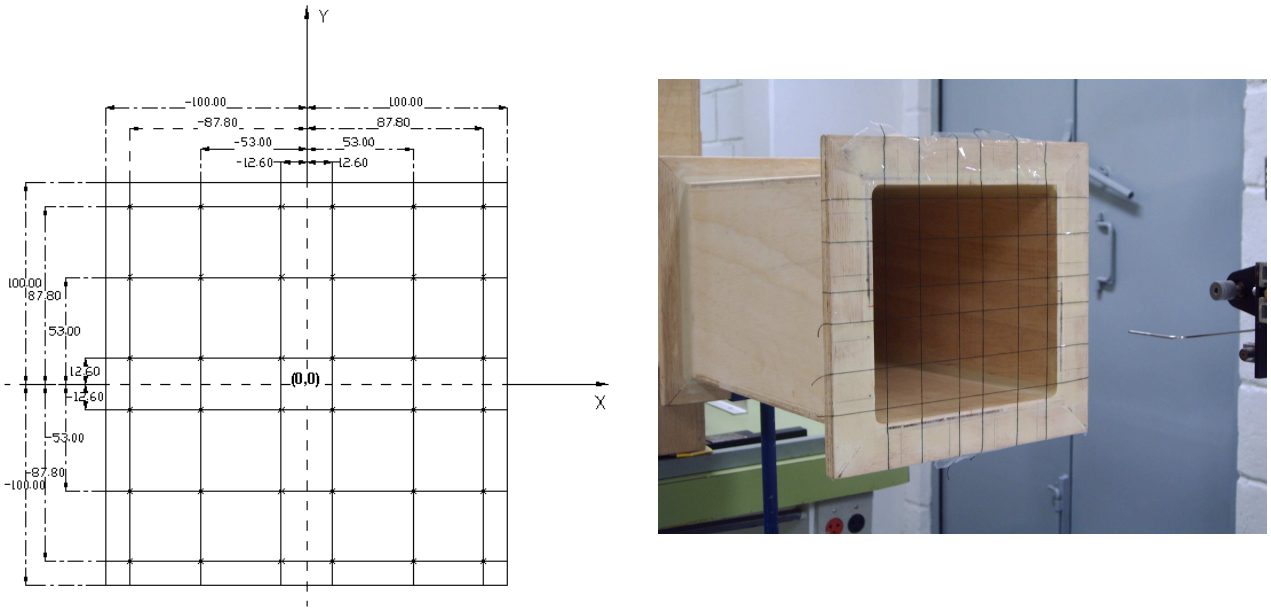

Figure 2. Velocity measurement points at the exit of the test section [19].

A hot wire anemometer was placed in the centre of the test section (0,0 coordinates) to evaluate the instantaneous velocity and the intensity of turbulence of the airflow at this point. In the experiments, the room temperature was 294 K and the atmospheric pressure was 0,906 bar.

RESULTS AND DISCUSSIONS

The employed computational domain (see Figures 5 and 6) includes the wind tunnel test section and additional region, after the wind tunnel exit, which was used in order to guarantee a zero value of the relative pressure. In all the simulations was employed a computational mesh with a total number of elements and nodes equals to 1386313 and 339286, respectively. A mass flow rate, obtained from experimental results, was used as inlet boundary condition. The outlet region (additional region in Figures 5 and 6) considered a zero value of the relative pressure in all outlet surfaces and was set out as an opening condition in the CFX code. This condition allows a mass flow across the outlet surfaces. A no slip condition was considered for the wind tunnel test section walls. The flow was considered as isothermal with a temperature value of 293 K. For the necessary turbulent quantities at boundaries were employed the CFX default boundary conditions assumed for each turbulence model. The models constants also were assumed as the default values considered in the CFX code.

Figure 3 shows the numerical results and experimental data of the cross-sectional mean time axial velocity profiles at position ($x = 0.1126$ m, $0 \leq y \leq 0.2$ m) in the exit plane of the wind-tunnel test section. In terms of the mean time axial velocity, it is not observed significant differences in the numerical results obtained for each turbulence model and each fan rotational speed. In the present case this behaviour is expected because the flow does not present a strong adverse pressure gradient at the exit region, which commonly lead to unsatisfactory results when the k-ε and *RNG* k-ε models are used (see [14] for more details).

Comparing with the experimental data, the major differences are observed in the regions near the tunnel walls, especially in the left side. This behaviour can be explained to small distortions of the wood wind tunnel walls; which produce an asymmetry of the experimental velocity profiles.

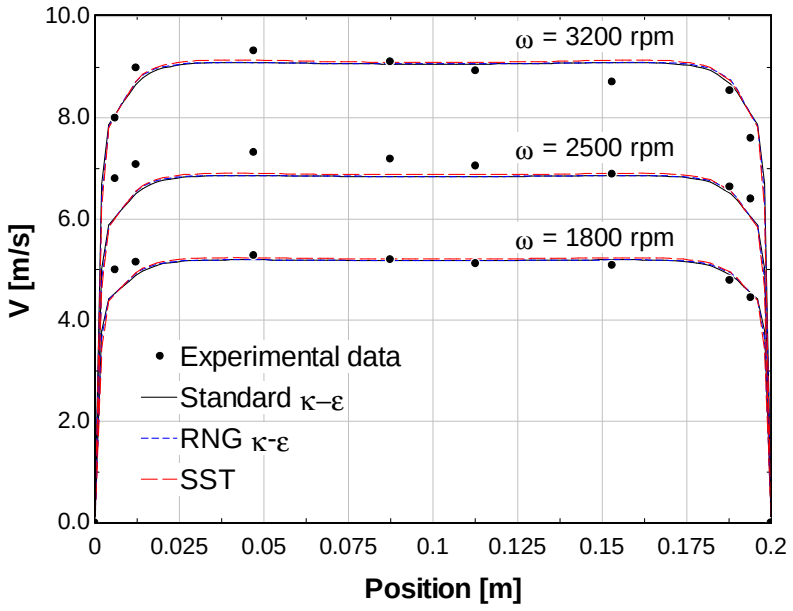

Figure 3. Velocity profile versus position at exit wind tunnel section.

The turbulent kinetic energy profiles for the three turbulence models are shown in Figure 4. The experimental data was obtained in the centre of the tunnel using the hot wire anemometer sensor. The turbulent kinetic energy is associated with the rms velocity fluctuations. Laufer [20] using a hot wire anemoter showed that the rms fluctuations in a turbulent developed pipe flow are small in the

regions near walls and have a sharp maximums near the edges of the laminar sublayers, existing a strong movement of kinetic energy away from this point (laminar sublayer). This behavior was obtained only with the *SST* turbulence model, as shown in Figure 4. The *k-ε* and *RNG k-ε* models were not able to predict this feature. Considering the experimental value of the turbulent kinetic energy in the tunnel centre it is also noted that the best prediction was obtained with the *SST* model.

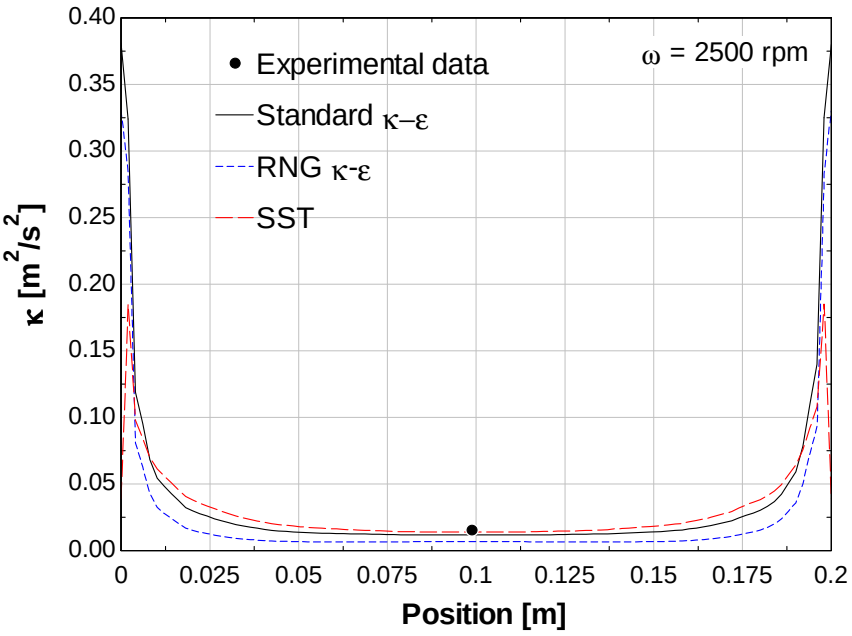

Figure 4. Turbulent kinetic energy versus position at exit section.

Figure 5 shows the numerical velocity field in the test section of a wind tunnel. It can be seen a free jet and a recirculation region in the outlet section after the test section, properly of this type of flow. The maximum velocity equals to 9.18 m/s, in accordance with experimental data.

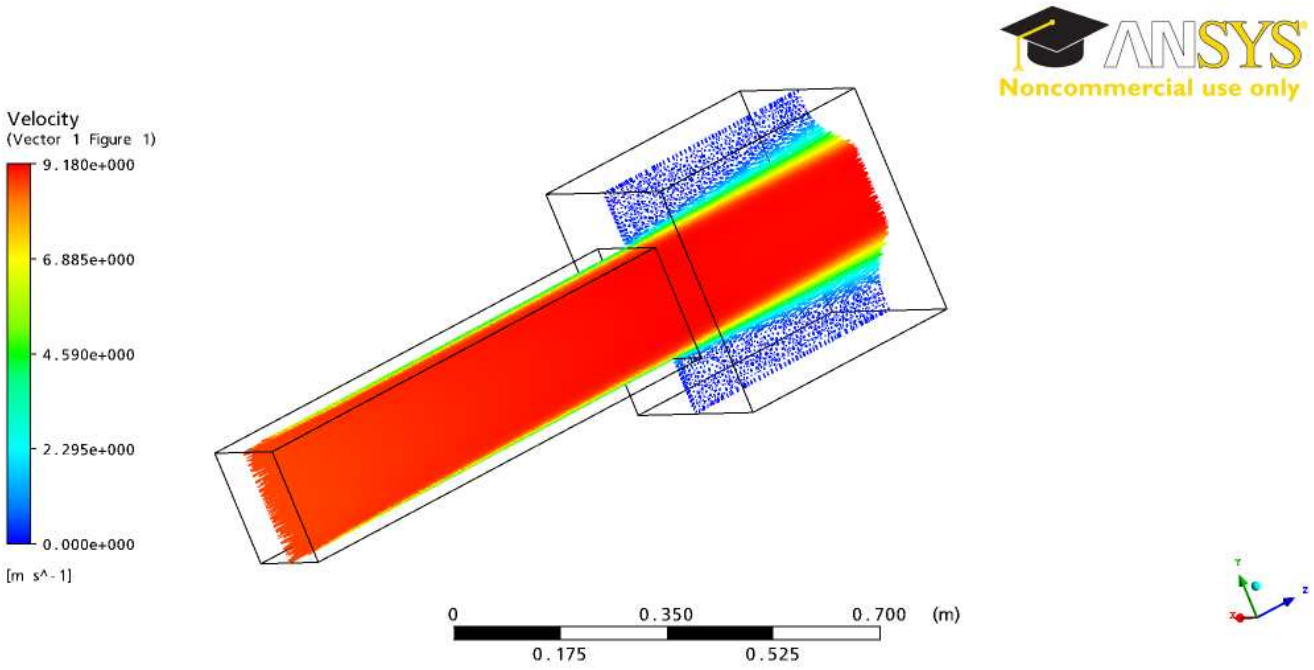

Figure 5. Numerical results of velocity field section (w= 3200 rpm)

Figure 6 shows the numerical pressure field in the test section of wind tunnel. It can be seen that the highest relative pressure is at the inlet of the test section, decreasing towards the exit region, as expected. It should be observed that the present turbulent flow is characterized by very small pressure gradient and pressure values, which was not possible to measure experimentally with the available measurement devices. However, the displayed pressure gradient seems to be physically correct, and will be validated in future works.

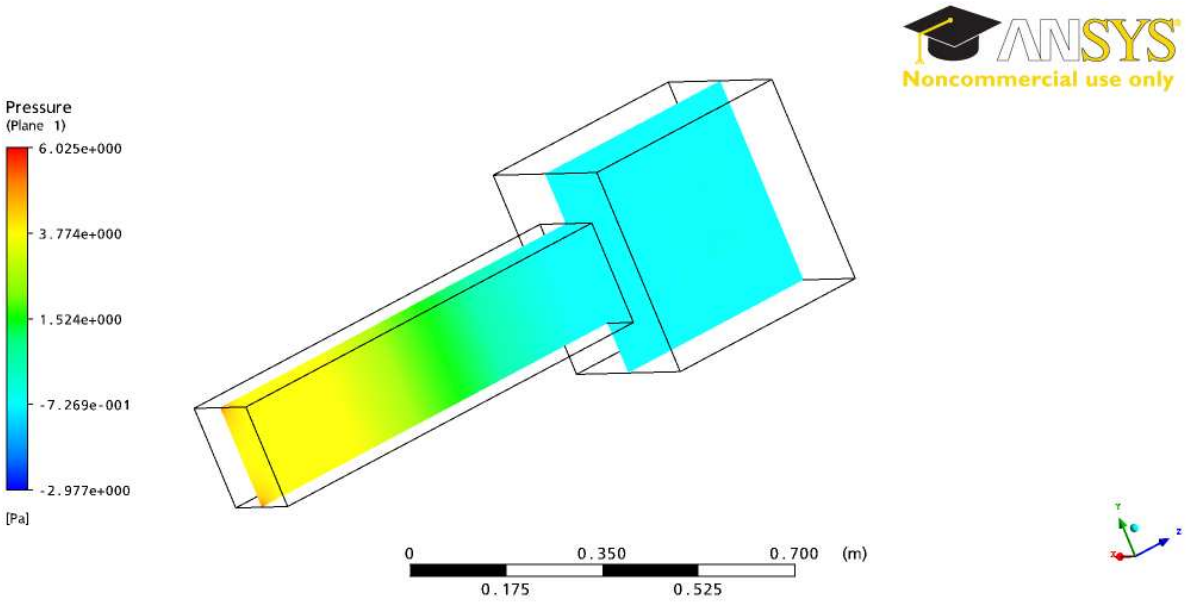

Figure 6. Numerical results of pressure field section (w= 3200 rpm)

CONCLUSIONS

This paper presents a comparison between numerical and experimental data in the test section of a low speed wind tunnel. Detailed Pitot tube and hot wire anemometry measurements were made to examine the flow behavior in the exit region of a wind tunnel build from wood. Numerical results were obtained for three turbulence models, namely the *k-ε, RNG k-ε and* shear stress transport *SST* models. The simulation results were compared with the mean time experimental velocity profiles as a function of three values of inlet mass flow rate, as well as with the experimental turbulent kinetic energy in the centre of the exit region of wind tunnel. The comparison of the numerical and experimental data showed that the *SST* model appears to be the one that produces the best results. More advances studies must be carried on to confirm the present observations.

NUMERICAL SIMULATION OF COMBUSTION INSTABILITIES FROM THE METASTABLE STATE TO THE LIMIT CYCLE

H. J. Kim, H. D. Shin*
Korea Advanced Institute of Science and Technology, Daejon, Korea

ABSTRACT. This paper describes the dynamic behaviours of the limit cycle for combustion instability. The time evolution of pressure oscillations usually demonstrates growth and saturation behaviours when combustion instability occurs. This saturation behaviour is known as limit cycle behaviour and it occurs due to nonlinear oscillations. Until now, the limit cycle behaviour was usually determined by the time evolution of pressure oscillation. However, the total disturbance equation was derived from the linearization of governing equations in 1965 instead of the acoustic energy equation which was derived under isentropic assumption. The total disturbance equation includes three main variables: pressure, velocity and entropy. In this study, numerical simulation was performed for combustion instabilities from the metastable state to the limit cycle. The limit cycle region was redefined as a fixed trajectory of pressure, velocity and entropy in three-dimensional phase space. In conclusion, considering entropy oscillation, in addition to pressure and velocity oscillations, may be important when determining the time step in which the limit cycle starts.

Keywords: *Combustion Instability, Meta Stable State, Limit Cycle*

INTRODUCTION

Combustion instabilities have caused serious problems in industrial applications such as the use of gas turbines for electricity and in high performance propulsion systems including liquid rocket and scramjet. The most serious problems resulted from large pressure oscillations and damage to the combustor by detonation. Researchers have tried to reduce combustion instabilities for a long time, because many industrial applications and propulsion systems can not endure large pressure oscillations. The instability mechanisms in combustion are categorized into acoustic, shock and fluid dynamics [1, 2]. Many studies have been conducted to experimentally or theoretically determine the relationship between acoustics and heat releases [3-9].

Numerical simulation is based on the pioneering works of Benelli (1990) [10], who first simulated unsteady combustion using FLUENT v2.97 software and Vax 8530 hardware. The main objective of his experiment was to observe the time evolution of turbulence, mixing rates and reaction rates under acoustic perturbation. Benelli et al. (1993)[11] observed combustion instability under the oscillations of a turbulent reaction rate. It was initially believed that the turbulent reaction rate determined the combustion rate. However, the experiment revealed that the velocity oscillation caused by acoustic waves led to fluctuation in the turbulence. The reaction rate oscillation occurred as a result of the oscillations of the turbulent variables. Hantschk and Vortmeyer (1999)[12] studied thermoacoustic instability in a Rijke tube using the FLUENT commercial code. They simulated combustion instability in a combustor and studied the time evolution of pressure oscillation, time-lag variables and the pressure oscillation frequencies in 2002 [8]. In 2000, Steele et al. performed

numerical simulation for two-dimensional geometry using CFD-ACE+ software. The axial distance from the fuel injection was an important factor in creating unstable combustion. The predicted frequency value was similar to the measured value and the predicted stable operating conditions were in agreement with the experimental range for stable combustion. The three-dimensional Large Eddy Simulation (LES), three-dimensional Unsteady Reynolds-Averaged Navier-Stokes (URANS) and two-dimensional URANS were simulated and compared by Cannon et al. Their predicted results of the frequency and pressure histories for the three cases were nearly identical to the measured values despite the different frequencies. These studies indicated that the time evolution of pressure reached the limit cycle, the oscillations of variables were delayed on the time axis and the resonant frequencies were predicted by unsteady calculation.

The time evolution of pressure oscillation normally shows growth and saturation behaviour when combustion instability occurs. This saturation dynamic occurs due to nonlinear oscillation and is called limit cycle behaviour. Previously, limit cycle behaviour was characterized by the time evolution of pressure oscillation [8, 13]. However, the total disturbance energy equation was derived by Chu [14] and rederived by Nicoud and Poinsot (2005)[15] based on Chu's results from the linearization of governing equations instead of the acoustic density equation that is typically derived under the isentropic assumption. The total disturbance energy equation is composed of three main variables: pressure, velocity and entropy. The left-hand side of the resulting equation ($e_{tot}= \rho_0 \mathbf{u}_1^2/2+p_1^2/2\rho_0 c_{sound,0}^2+p_0 s_1^2/2Rc_p$) indicates that pressure, velocity and entropy are very important in the non-isentropic method. Although the total disturbance energy equation was derived from linear analysis, the time evolutions of the three variables need to be examined further. In addition, the entropy oscillation portion of the equation was numerically investigated because it was difficult to measure directly.

In this study, the dynamic behaviours of combustion instabilities were analysed using numerical simulation from the metastable state to the limit cycle. The limit cycle region was also redefined as a periodic trajectory of pressure, velocity and entropy oscillations in the three-dimensional phase space. The time evolutions of the three variables were observed and their trajectories were investigated in phase space. In conclusion, the time step in which the limit cycle began was redefined through the investigation of the trajectories in three-dimensional phase space.

EXPERIMENTAL AND NUMERICAL METHODS

Numerical Models

The Favre-averaged conservation equations for mass, momentum and energy can be readily found in the literature [16, 17]. It is important to simulate the interaction between the turbulence and chemical reactions. The Direct Numerical Simulation (DNS), LES and RANS are all models for turbulence treatment. The RANS method generally costs less than the other methods. Furthermore, the 2-dimensional URANS and the 3-Dimensional LES and URANS were simulated and compared by Cannon et al.[18] Their results showed that the three cases followed the same pressure histories. Therefore, the standard k-ε turbulent model was used in this study because the URANS provided similar results to the other models despite its low cost.

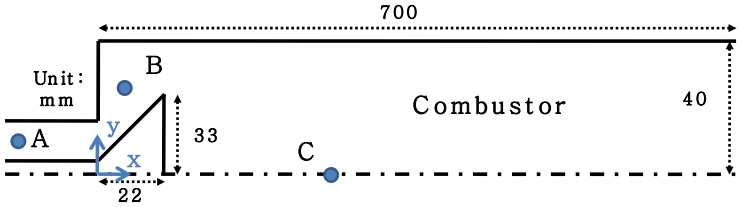

Figure 1. The position for data acquisition; (A) position A, (B) position B and (C) position C

Combustion models are based on statistical methods and turbulent mixing. The statistical method refers to the technique using probability density function (PDF) and the turbulent mixing model indicates combustion that is dominated by the turbulent time scale. Therefore, the latter model has stronger physical meaning. Particularly in the case of the latter, the eddy dissipation model (EDM) is the simplest model to simulate turbulent flames. This model was developed by Magnussen and Hjertager [19] and assumes that combustion occurs immediately when fuel and oxidizer meet. The chemical reaction for turbulent reacting flow does not occur that quickly. For example, the turbulence effect on combustion is not dominant enough that the turbulent mixing and kinetically controlled reaction effects should simultaneously be considered. For numerical simulation, the kinetically controlled reaction rate is a function of the Arrhenius rate coefficient and mass fraction, and the turbulence controlled reaction rate is a function of the turbulent time scale and mass fraction. Furthermore, the minimum values of the reaction rate representing the above two effects should be applied to the computational domain. This method is usually referred to as the hybrid model (eddy dissipation model and kinetically controlled model) [16]. Hantschk and Vortmeyer [8] investigated combustion instabilities using this model and found that the predicted frequency was in agreement with the measured value.

Experimental and Numerical Method

In this study, axisymmetric geometry was applied to the combustor, which was the same type of combustor as that used by Hong [20]. This geometry prevented the flame from lifting off and reduced the calculation cost, because the geometry could be treated as a two-dimensional model for numerical simulation using a bluff-body burner instead of a swirl burner. Liquefied petroleum gas (LPG; approximately 98% C_3H_8) was used for fuel and was injected from a 0.3 mm diameter hole pierced at an interval of 90° and x=-0.285 m based on the distance from the dump plane to the mixing pipe for air flow. The bluff-body burner was lozenge shaped and had a diameter of 66 mm at the y-axis and 22 mm at the x-axis. Therefore, the flame could exist in the vicinity of the burner without swirl flow, because the flame had such a radial flow structure that the resident time was extended at the upstream field of the flame. The height of the combustion chamber was fixed at 700 mm, which was designed for the dominant longitudinal mode. The pressure was measured with a piezoelectric pressure sensor (PCB Model 106B) installed under the dump plane and surrounded with a water jacket to protect it from the high temperature.

Numerical simulation was performed by FLUENT. The combustion chamber was made of quartz and had a diameter of 80 mm. The exit pressure of the combustion chamber was set to the pressure boundary condition. The overall grid was a non-uniform, hexagonal grid of 145012, which was refined in the vicinity of the injection hole. In order to investigate the grid dependency of the solution, the number of grids was increased twice and an error of less than 1% was computed from steady calculations. Therefore, the grid dependency was negligible. After obtaining the steady solutions, unsteady simulation was completed on them with a small pressure perturbation and the sinusoidal function was used in the simulation for 2 ms. Then self-excited pressure oscillations evolved from the metastable state to the limit cycle.

Figure 1 shows the positions for data acquisition. The position A is at x=-40 and y= 12 mm, position B is at x=10 and y=30 mm and position C is at x=300 and y=0 mm in the dump plane.

VALIDATION AND TRAJECTORY ANALYSIS

Frequency Spectra Result

Figure 2 shows the frequency spectra of the calculated pressure plotted from 0.2 sec to 0.3 sec. The values obtained by the pressure sensor for the pressure amplitude (peak-to-peak $\Delta p \approx 10$kPa) and frequency (~256Hz) were nearly identical to the first harmonic value (~244Hz) predicted by

numerical simulation. The reaction zone was positioned near the downward plane of the bluff body and the upward plane of position B where the chemical reaction was dominant, however it did not exist in positions A and C.

The Trajectories Near The Meta Stable State

Figure 3 shows the trajectories near the metastable state at each position. The pressure oscillation in the time domain appeared with different growth constants (*k)* for each position. The value of *k* (exponential function e^{kt}) was approximately 173.3 for position A, 187.6 for position B and 184.2 for position C. The pressure oscillation was higher at position A and therefore it started at approximately 900 Pa in Fig. 3 (A-1), while it started at approximately 0 Pa in Fig. 3 (B-1) and Fig. 3 (C-1). The history of pressure oscillation in Fig. 3 (A-1), (B-1) and (C-1) exhibited identical behaviour in respect to the linear growth rate.

Figure 3 (A-2), (B-2) and (C-2) showed the trajectories near the metastable state in two-dimensional phase space (pressure and axial velocity). The linear behaviour was observed for 2 ms due to the forced sinusoidal pressure oscillation and the trajectories gradually shifted far away from the metastable state because of self-excited dynamic behaviour. All of the trajectories appeared to have a spiral structure in each position. Their behaviours were identical, including their movement counter-clockwise in two-dimensional phase space.

The trajectories are shown in Figure 3 (A-3), (B-3) and (C-3) in two-dimensional phase space (pressure and entropy) near the metastable state. These trajectories had spiral structures and were not near the metastable state. They moved clockwise in Fig. 3 (A-3) and (B-3), while they moved counter-clockwise in Fig. 3 (C-3).

The trajectories between axial velocity and entropy are shown in Figure 3 (A-4), (B-4) and (C-4) near the metastable state. Dynamic behaviours in Fig. 3 (A-4) and (C-4) moved counter-clockwise, while the one in Fig. 3 (B-4) moved in the reverse direction. Noisy trajectories in Fig. 3 (A-3) and (A-4) seemed to be caused by the smallest entropy oscillation.

The trajectories of three variables (pressure, axial velocity and entropy) appeared to have a spiral pattern in three dimensional phase space in Fig. 3 (A-5), (B-5) and (C-5). It was difficult to characterize the pattern of the trajectory found in Fig. 3 (A-5), because the entropy changed with little fluctuation. The other trajectories in Fig. 3 (B-5) and (C-5) clearly exhibited their identical patterns (spiral structure).

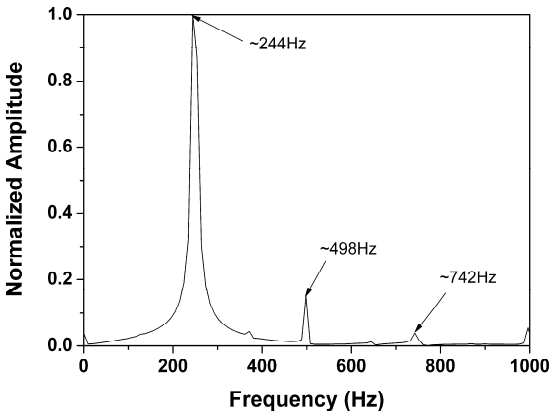

Figure 2. Frequency spectra of the calculated pressure from 0.2 sec to 0.3 sec (at the limit cycle region)

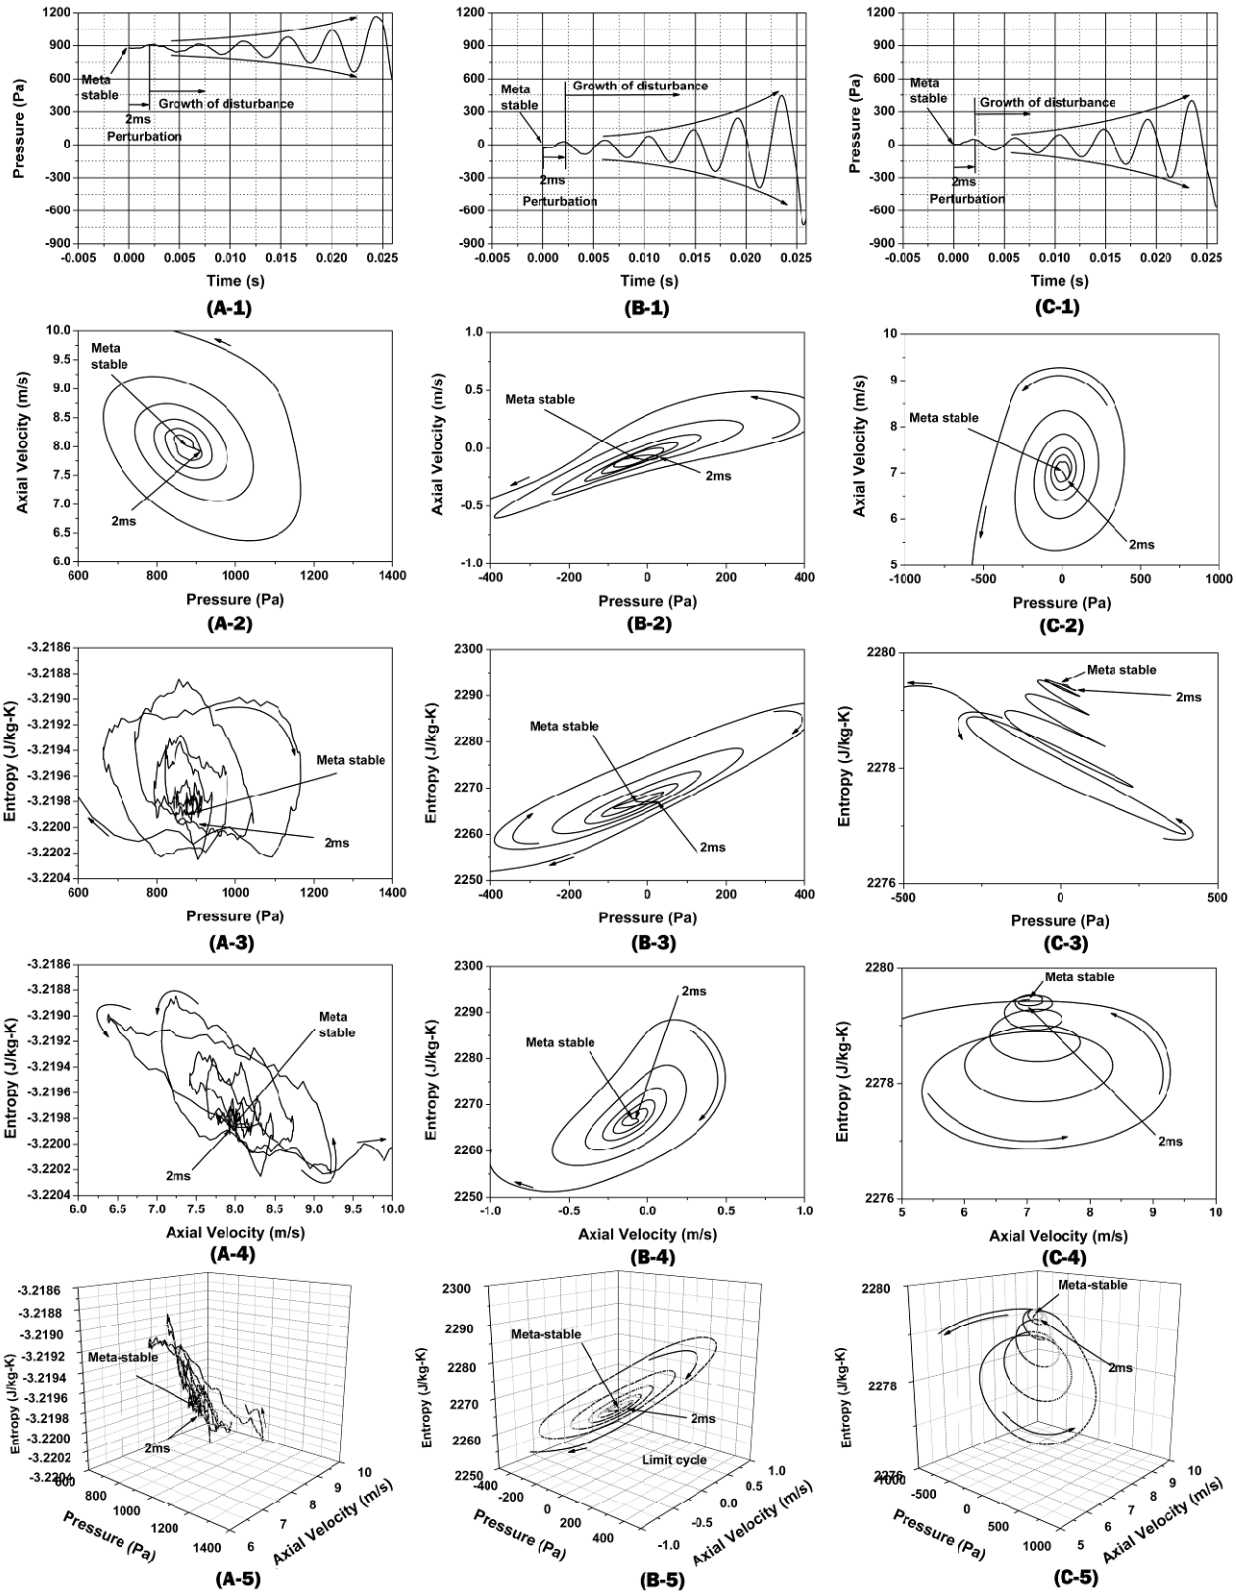

Figure 3. The time evolution of the pressure oscillations (A-1), (B-1) and (C-1); the trajectories in two–dimensional phase space, which consisted of pressure-axial velocity: (A-2), (B-2) and (C-2), pressure-entropy: (A-3), (B-3) and (C-3) and axial velocity-entropy: (A-4), (B-4) and (C-4); and the trajectories in three–dimensional phase space (A-5), (B-5) and (C-5). All graphs were plotted near metastable states for 0.025 seconds.

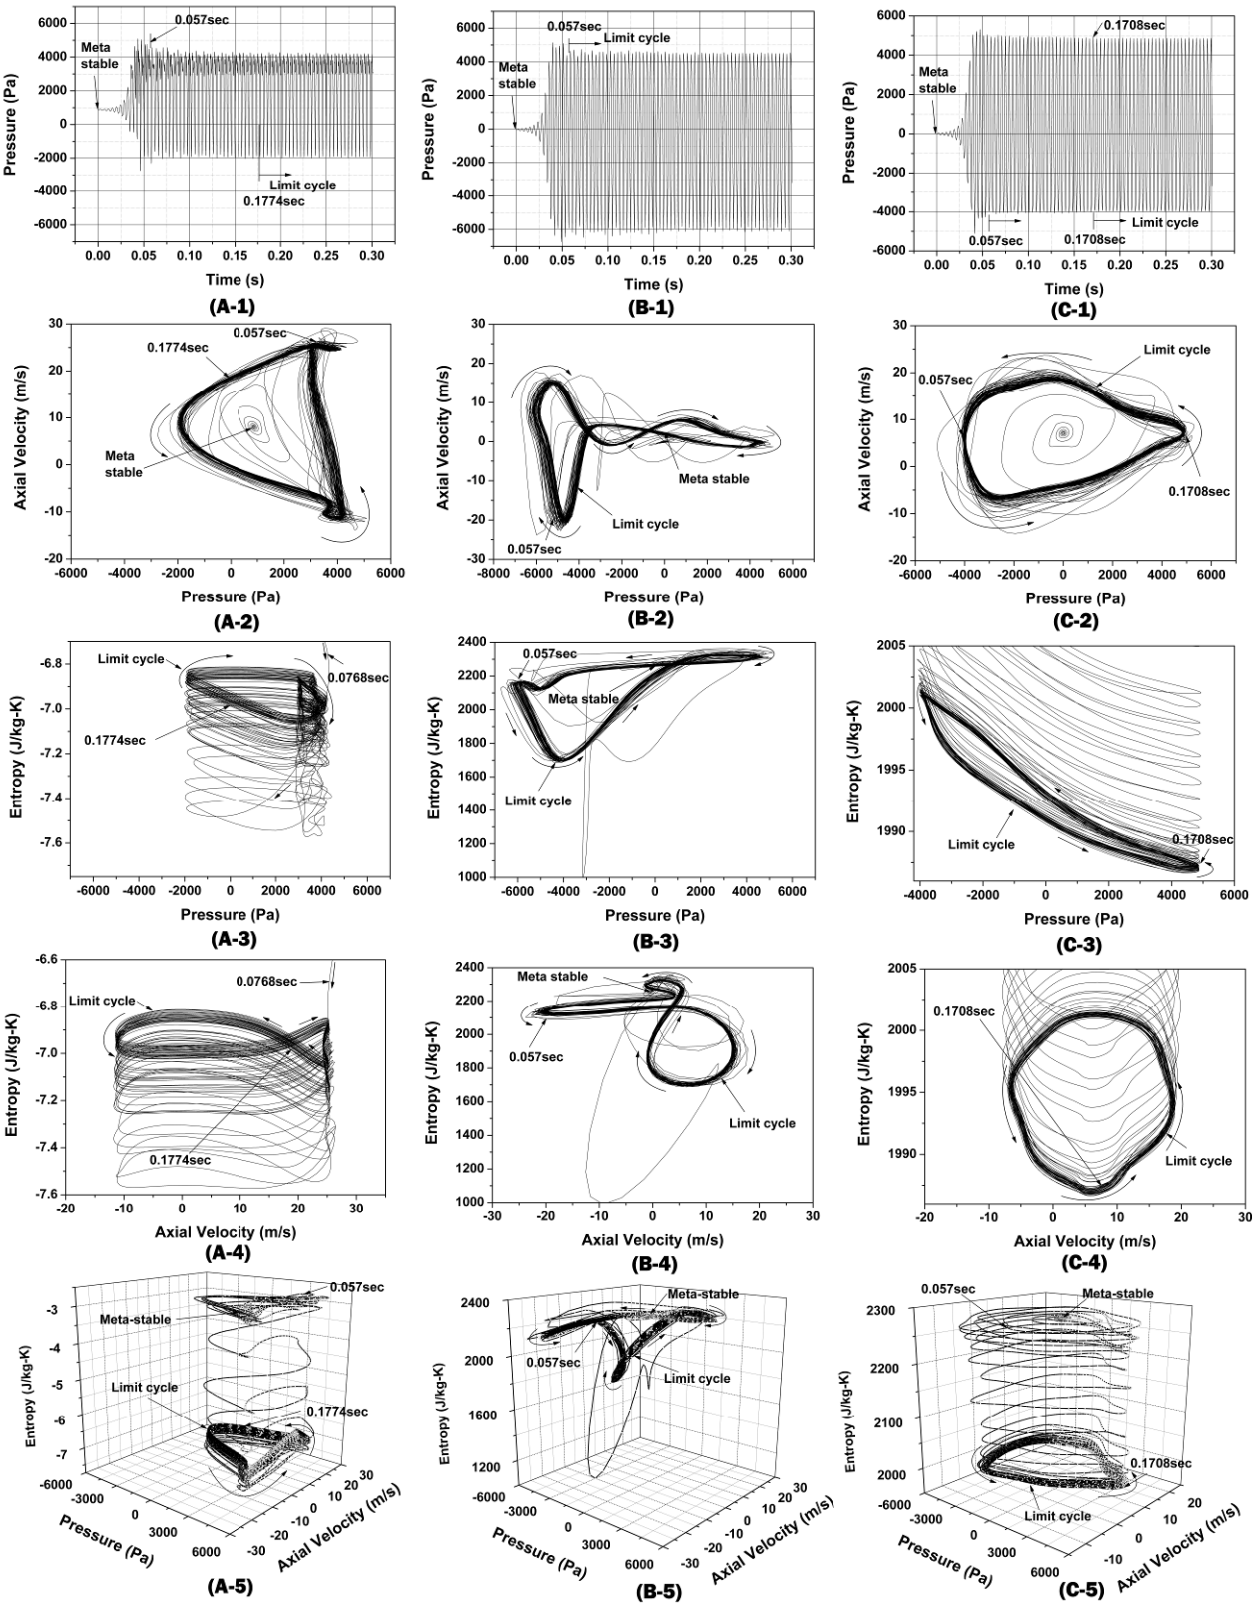

Figure 4. The time evolution of the pressure oscillations (A-1), (B-1) and (C-1); the trajectories in two–dimensional phase space which consisted of pressure-axial velocity (A-2), (B-2) and (C-2), pressure-entropy (A-3), (B-3) and (C-3) and axial velocity-entropy (A-4), (B-4) and (C-4); the trajectories in three–dimensional phase space (A-5), (B-5) and (C-5). All graphs were plotted on limit cycle regions for 0.3 seconds.

The Trajectories Near The Limit Cycle Region

Figure 4 shows the full trajectories to the limit cycle state at each position. The time evolution of the pressure oscillation, which changed from the metastable state to the limit cycle, was identical for all positions. It appeared that the pressure oscillation at all positions reached the limit cycle region after nearly 0.057 seconds. Until now, the limit cycle had been defined as the saturation behaviour of the pressure oscillation's time evolution in Fig. 4 (A-1), (B-1) and (C-1). However, the starting point of the limit cycle needed to be changed through investigation of the dynamic movement, including entropy fluctuation, in the phase space as shown in Fig. 4 (A through C, 3 through 5).

To investigate the starting point of the limit cycle in detail, the trajectories were observed in two dimensional and three dimensional phase space in Fig. 4 (A through C, 2 through 5). The trajectories evolved to the limit cycle in three and two-dimensional phase space, and they moved around a fixed trajectory after reaching the limit cycle region. The trajectories at the limit cycle region appeared as bold curves which were amassed as a periodic trajectory in phase space. Therefore, the limit cycle could have been defined as the point when the time evolution of the three variables reached periodic trajectory in the phase space.

The starting point of the limit cycle in Fig. 4 (A-2), (B-2) and (C-2) was nearly the same as that after 0.057 seconds in Fig. 4 (A-1), (B-1) and (C-1). The overall trajectories near the limit cycle region moved counter-clockwise in Fig. 4 (A-2) and (C-2) and clockwise in Fig. 4 (B-2), although their intersection occurred in the border of the limit cycle. However, the trajectories in the phase space which included the entropy variable had a different starting point of the limit cycle as shown in Fig. 4 (A and B, 3 through 5). The trajectories of the variables in the phase space reached the limit cycle in approximately 0.1774 and 0.1708 seconds in Fig. 4 (A-3 through 5) and (C-3 through 5), respectively, and the trajectories reached the limit cycle in approximately 0.057 seconds in Fig. 4 (B-3 through 5) similar to the timing in Fig. 4 (A-, B- and C-, 1 and 2). Consequently, the trajectories in the phase space not including entropy reached the limit cycle earlier than those that included entropy in the position where the flame didn't exist. Those trajectories that did not include entropy appeared to have the same starting point for the limit cycle as those including entropy in the flame position, because the flame produced the entropy and only existed at position B.

CONCLUSIONS

The frequency value that was obtained by the pressure sensor was compared to that calculated by numerical simulation, and the values were in good agreement. The time step in which the limit cycle starts in the time evolution of the pressure oscillation was the same as that in two-dimensional phase space (pressure-axial velocity). The starting point of the limit cycle in the time evolution of the pressure oscillation was the same as that in the phase space in the flame position where the entropy was produced. The starting point of the limit cycle in the phase space including entropy differed from that in the time evolution of the pressure oscillation and in two-dimensional phase space (pressure-axial velocity) in the positions where the flame didn't exist. The method that was used to determine the limit cycle region from the time evolution of pressure oscillation and the trajectories in the phase space which consisted of pressure and velocity could not produce accurate results for determining the starting point of the limit cycle. Therefore, it is necessary that the starting point of the limit cycle is determined in the phase space including entropy.

DATA ASSESSMENT ON TWO ERCOFTAC TRANSITION MODELLING TEST CASES FOR CFD VALIDATION

D. Di Pasquale[*1], A. Rona[1]

[1] Department of Engineering, University of Leicester, Leicester, UK

ABSTRACT. This paper aims to demonstrate the use of the Ercoftac database to validate a 2D CFD code, giving more details of the approach adopted, and how to use the Ercoftac experimental data to generate the inflow condition, and in doing so to inform the community on the consistency of the information in this dataset by testing it for the known trend in the mean velocity components and their statistical fluctuations. The objectives are to expose some limitations of the dataset and to evaluate the performance of the RANS transition model implemented in the in-house code Cosmic. Velocity measurements from two boundary layer test cases under zero pressure gradient are considered.

Keywords: *Ercoftac, transition, intermittency, boundary layer, CFD*

INTODUCTION

Transition is a complex phenomenon, defined as the whole process of change from laminar to turbulent flow. The origin of turbulence and the accompanying transition from laminar to turbulent regime, as often happens, for example, on aircraft wings or past turbine blades, is of fundamental importance for the whole science of fluid mechanics. The European Research Community on Flow, Turbulence and Combustion (ERCOFTAC) is a scientific association of research, education and industry groups in the technology of flow, turbulence and combustion. The Special Interest group of Ercoftac (SIG10) on Transition Modelling is organized into five sub-groups focussing on different aspects of transition modelling. In particular the Sub-group 5 focusing on experimental Real-Flow data in order to provide a sufficiently experimental databases to validate predictive capabilities of transition codes, on the identification of directions for future model developments and applications, and to focus model refinement on the key elements which influence accuracy of predictions under real operating conditions; in addition to establish a fundamental experimental analysis of the flow physics of bypass transition with the aim to build up basic understanding of the phenomenon.

DESCRIPTION OF THE TEST CASES

The Ercoftac test cases T3A- and T3A [1] include both laminar and transitional boundary layers over a 1.7m long flat plate which is 20mm thick and 710mm wide, with the test surface extremely flat that employs a small leading edge radius of 0.75mm. These cases have zero pressure gradient and a nominal air temperature maintained at 20°C±0.1°C The T3A- case has a freestream velocity U_∞=19.8 m/s and a FST level of 0.9%. The second test case, T3A, has U_∞=5.2 m/s and a higher FST level of 3.3%. The wind tunnel used in these experiments is of the closed circuit type. Its major elements include a centrifugal fan blowing through a large plenum fitted with turbulence reducing honeycomb gauzes, a small 2-D contraction, leading to a highly versatile working section, and a

E-mail address: ddp2@le.ac.uk

wide-angle diffuser. The working section is of 2m length, 0.71m width and 0.26m height with full-length perspex sidewalls for good optical access as it is shown in Figure 1.

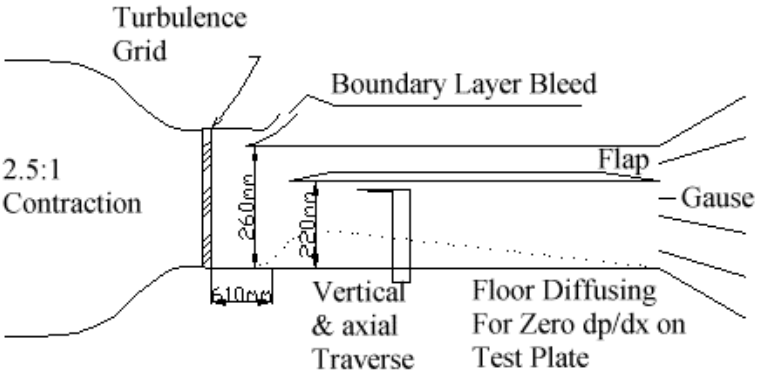

Figure1. Detail of the wind tunnel and test plate

DATABASE INTEGRITY

The database is a valuable tool for the transitional flow community. Still, in both datasets, some discrepancies were found from what is stated in the description of the experiment and in the database information, specifically with respect to the normal velocity component, the turbulence isotropy, and the pressure gradient.

In the Ercoftac database, case T3A, as well as in the case T3A-, the sign of the cross-stream velocity V is negative, as shown in Figure 2(a) and 3(a) respectively. However, V should be positive definite, as the displacement thickness grows monotonically along the flat plate, giving a negative $\partial U/\partial x$ and a positive $\partial V/\partial y$ so that the incompressible continuity equation (1)

$$\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}=0 \tag{1}$$

is satisfied.

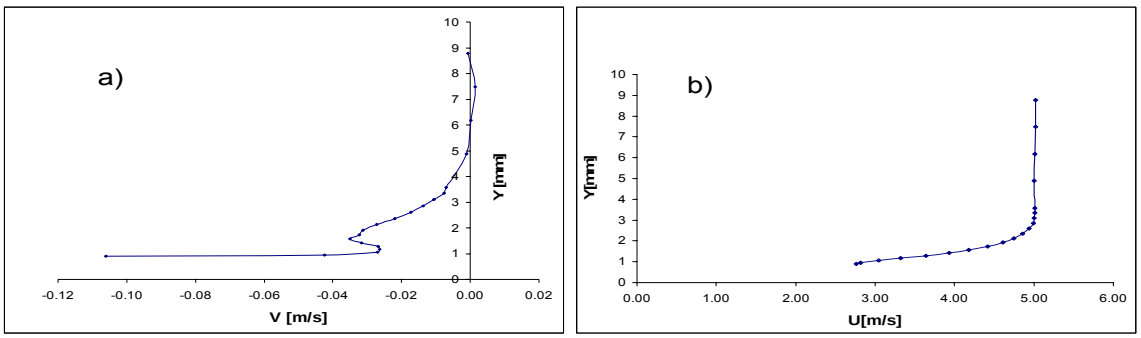

Figure 2. (a) cross-stream and (b) stream-wise velocity measurements. Case T3A.

Moreover, the first data points closest to the wall in Figure 2(a) and 3(a) are suspect; the velocity magnitude above this points decrease monotonically, whereas at these points the trend reverse; it is only possible to assume that the odd behaviour of V near the wall is associated with measurements problems with the hot-wire when this was very close to the flat plate surface. Therefore, they should not be inserted in the dataset.

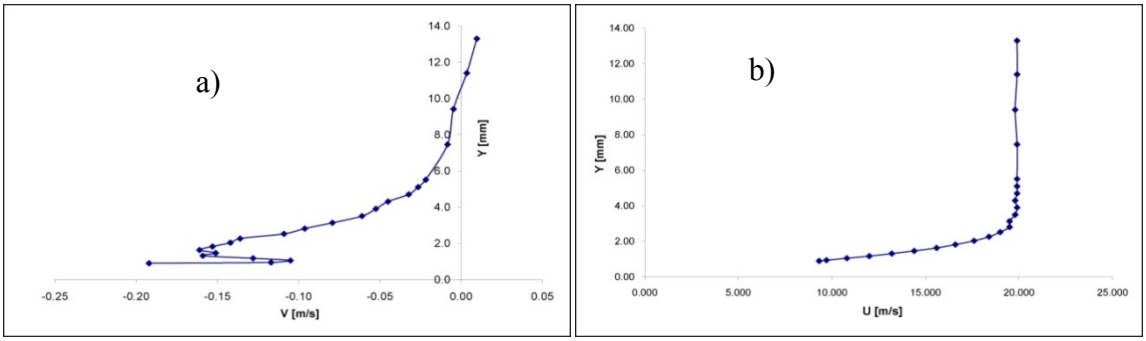

Figure 3. (a) cross-stream and (b) stream-wise velocity measurements. Case T3A-.

As far the free-stream turbulence is concerned, it is found to be not isotropic, contrary what is stated in the Ercoftac explanatory note for this database, which report that the generated turbulence is extremely homogeneous and isotropic with a streamwise-to-normal fluctuating velocity ratio of about 1.005, obtained with a turbulence generating grid located at the entrance plane of the working section, at the downstream end of the 2-D contraction, made of square or round bars and woven wire mesh, and it is positioned 610mm upstream of the test plate leading edge. Table 1 reports the data taken from the database at approximately four δ above the wall. The ratio of the streamwise-to-normal velocity fluctuations, u'/v' and u'/w', are quite far from 1.005.

Table1
Fluctuations of Velocity Components

Test case	x-coord. [mm]	δ (99%) [mm]	y-coord. [mm]	u' [m/s]	v' [m/s]	w' [m/s]	u'/v'	u'/w'
T3A	495	3.33	13	0.130	0.100	0.117	1.300	1.111
T3A-	95	2.71	8.78	0.124	0.101	0.118	1.227	1.051

The next aspect over our attention is focussed on the pressure gradient. In the Ercoftac documentation it is declared possible in the wind tunnel in use inclining both the test plate and the opposite tunnel wall in such a way as to ensure zero pressure gradient over the bulk of the test plate length. But using the database for ρ and T values and making use of the equation of state for ideal gas $P = \rho RT$ it is possible determine a non-constant value of pressure along the flat plate. In fact, the experimental data does not show a constant value of the free-stream velocity along the flat plate, as shown in Figure 4.

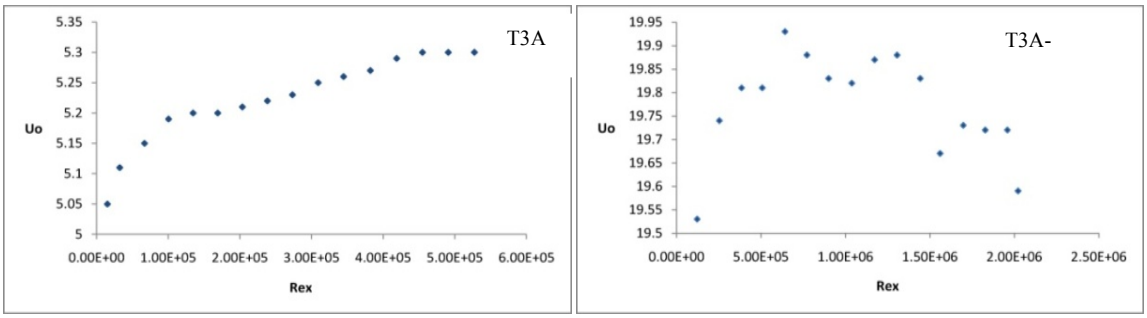

Figure 4. Free-stream velocity along the flat plate for both test cases.

This is also confirmed by applying the Thwaites method as it is shown in Figure 5, an empirical relationship, based on the observation that laminar boundary layer obey the following relationship:

$$\frac{u_e}{\upsilon}\frac{\partial\theta^2}{\partial x} = 0.45 - 6\frac{\theta^2}{\upsilon}\frac{\partial u_e}{\partial x} \tag{2}$$

The above equation (2) may be analytically integrated to find the momentum thickness θ. After θ is found, the following relations (3) and (4) are used to compute the shape factor $H = \delta^*/\theta$

$$H = 2.61 - 3.75\lambda + 5.24\lambda^2 \quad for\ 0 \le \lambda \le 0.1 \tag{3}$$

$$H = 2.472 + \frac{0.0147}{0.107 + \lambda} \qquad for -0.1 \le \lambda \le 0 \tag{4}$$

where, $\lambda = (\theta^2/\upsilon)(\partial U/\partial x)$ is the dimensionless pressure gradient.

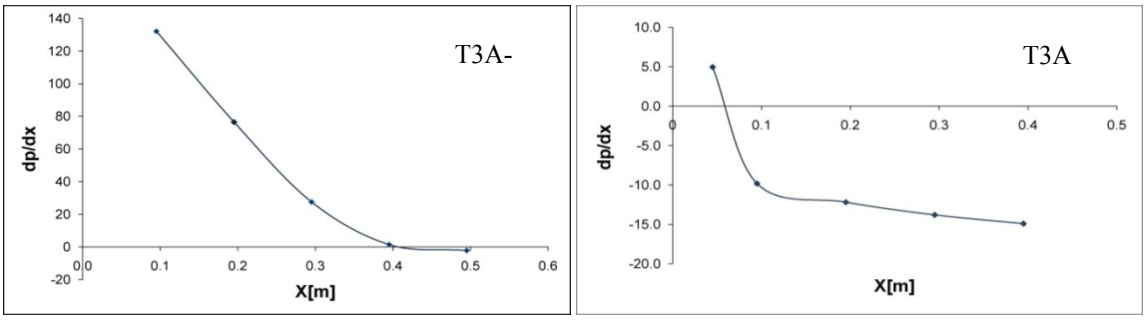

Figure 5. Pressure gradient evaluated with the Thwaites method for both test cases in the laminar part of the boundary layer

The start of transition is taken as the location where the skin friction coefficient starts to deviate from its analytical laminar value.
This is shown to be at $Re_x \approx 1.3*10^5$ in Figure 6(b). In a flow with zero pressure gradient, the shape factor before transition should be constant and equal to 2.61. As it can be seen from Figure 6(a), the shape factor H reduces below the laminar value of 2.61 in the region before the transition starts. This can be explained by a non-zero streamwise pressure gradient in the flow field.

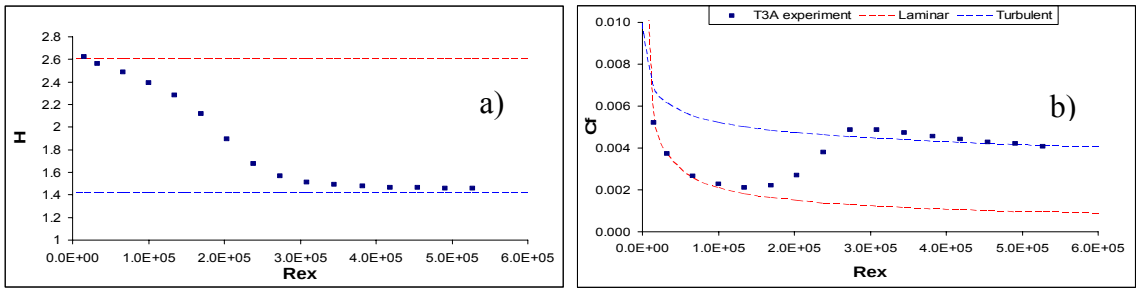

Figure 6. (a) Shape factor and (b) Skin friction coefficient distribution along the flat plate for the T3A test case.

VALIDATION OF RANS 2D TRANSITION CFD MODEL

This project aims to evaluate the performance of the transition RANS transition model implemented

in the in-house code Cosmic. The in-house multi-block finite volume time-resolved RANS scheme is used to compute the seven conservative variables (density, specific momentum, specific stagnation energy, specific turbulent kinetic energy, specific turbulent dissipation rate and intermittency) that define the flow state in the discretized Navier-Stokes equations. The code uses a 2D finite-volume four-point stencil approximate Riemann solver with a Monotone Upstream-centred Scheme for Conservation Laws (MUSCL) interpolation by Van Leer et al. [2] to compute the convective fluxes. This gives up to a third order accurate reconstruction of the spatial gradients in regions of smooth flow. To prevent numerical oscillations in region of rapidly changing flow, the spatial gradients are limited by the introduction of a Total Variation Diminishing Scheme (TVD) by Sweby [3]. The scheme is explicit and a standard multi-stage second-order Runge-Kutta (RK) integration is used to time-march the flow. The turbulent flux vector is estimated using a second order accurate gradient reconstruction method, based on the Gauss divergence theorem.

The creation of a transitional flow solver combining an in-house laminar flow solver and a RANS k-ω solver through incorporating an intermittency transport model into the computation. The intermittency transport model uses empirical correlations that have shown some success in predicting transitional flows past conventional geometries. A two-equation turbulence model was modified to incorporate the varying turbulence intermittency of transitional flow. Further to the flow solver already in place a γ transport equation, balancing its production, destruction, convection and diffusion, was implemented. The flow is governed by the compressible Navier- Stokes equations. These are suitably averaged into time-dependent discrete Navier-Stokes equations, so that in 2D the flow state is described by 7 conservative variables. Seven conservative laws plus algebraic auxiliary equations are solved by the numerical scheme. The implementation of the transition model of Suzen & Huang [4] it is presented. Suzen & Huang developed an intermittency transport model which can produce both the experimentally observed streamwise variation of intermittency and a realistic profile in the cross-stream direction. The model combines the transport equation models of Steelant & Dick [5] and Cho & Chung [6]. Specifically, the transport of intermittency, γ, is given by the following equation (5):

$$\frac{\partial \rho\gamma}{\partial t}+\frac{\partial u_j\gamma}{\partial x_j}=(1-\gamma)\left[(1-F)C_0\rho\sqrt{u_k u_k}\beta(s)+F\left(\frac{C_1\gamma}{k}\tau_{ij}\frac{\partial u_i}{\partial x_j}-C_2\gamma\rho\frac{k^{\frac{3}{2}}}{\varepsilon}\frac{u_j}{(u_k u_k)^{\frac{1}{2}}}\frac{\partial u_i}{\partial x_j}\frac{\partial \gamma}{\partial x_j}\right)\right]+C_3\frac{k^2}{\varepsilon}\frac{\partial \gamma}{\partial x_j}\frac{\partial \gamma}{\partial x_j}+\frac{\partial}{\partial x_j}\left(\left((1-\gamma)\gamma\sigma_{\gamma t}\mu+(1-\gamma)\gamma\sigma_{\gamma t}\mu_t\right)\frac{\partial \gamma}{\partial x_j}\right) \tag{5}$$

Where the modelling constant are: $\sigma_{\gamma t}=1.0$, $C_0=1.0$, $C_1=1.6$, $C_2=0.16$, $C_3=0.15$

Further details of the transport model algorithm are given in Suzen & Huang. Equation has been implemented explicitly in the scheme. The convective and diffusive terms are treated separately. Specifically, the upwind Riemann solver of Roe convects γ around the flow field. The γ-diffusion term has been implemented using the Gauss divergence theorem around cell interfaces. All derivatives in the source terms are discretized by central differencing. The intermittent behaviour of transitional flows is modelled by modifying the eddy viscosity μ_t by the intermittency factor γ. Turbulent quantities are predicted by using the Wilcox [7] two-equation k-ω turbulence model. While the intermittency transport equation defines the intermittency distribution for transitional flows in the simulation, the onset of transition is defined by correlations. The onset of attached flow transition is determined as a function of the turbulence intensity, Tu, for zero pressure gradient. Specifically, for by-pass transition, the Abu-Ghannam & Shaw [8] correlation (6) is used.

$$Re_{\theta t} = 163 + exp(6.91 - Tu) \tag{6}$$

The length of transition region is obtained from the Suzen correlation (7).

$$\hat{n}\sigma = \left(\frac{n\upsilon^2}{U^3}\right)\sigma = 1.8 \cdot 10^{-11} Tu^{\frac{7}{4}} \tag{7}$$

The predicting capabilities of this model have been validated against the ERCOFTAC T3A- and T3A experiments of Roach & Brierley. The computational domain is made up of 260352 rectangular computational cells, with 1357 nodes points in the x-direction and 193 nodes in the y-direction. For accuracy grid points are clustered in regions of large gradients, but spread out elsewhere for economy. The stretching factor has been chosen in order to have a value of $y+ < 0.2$ for the first point away from the wall, and such that the viscous region of the BL ($y+ < 30$) contains more than 40 cells (see Figure 7).

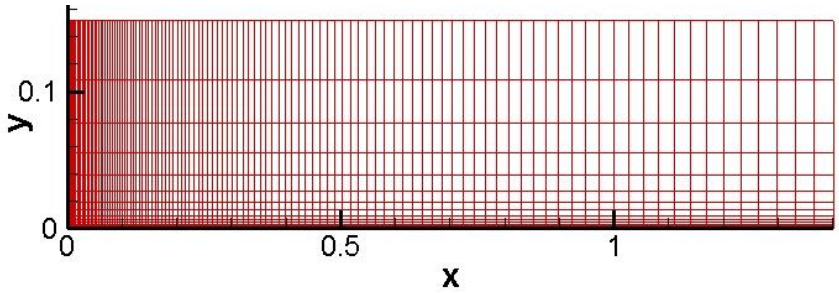

Figure 7. Computational mesh: the total length of the test section is 1.4m. For clarity, one point every 12 in both x and y direction is shown, and the x-axis to y-axis ratio is 0.4

At the streamwise distance of x=495mm and x=95mm, respectively, from the leading edge, a laminar profile (γ=0) is imposed as the inflow of the computational domain. As far as the inflow boundaries in the computation, these are derived from a numerical solution of the Blasius equation that is re-scaled to match the experimental laminar boundary layer parameters, see Table 2, in order to have a turbulent kinetic energy and its specific dissipation rate profiles.

Table2
Boundary layer parameters at inflow (95mm) for T3A case

T3A	C_f	δ^* [mm]	θ [mm]	Re_θ	H
Experimental	0.003723	0.882	0.344	117.4	2.562
Numerical	0.003731	0.918	0.354	118.1	2.593

This has been done, because transition is strongly affected by the decay of turbulence in the free-stream; therefore, it is very important for a correct analysis of the results to assign the appropriate inlet boundary condition. It is not possible starting from experimental initial condition supplied to computors in the form of tabulated hot-wire probe traverse results both for the uncertainty of the experimental data and because it is not easy to estimate the dissipation profile starting from velocity data. The inlet turbulent kinetic energy is fixed according to the freestream turbulence level. Initially gamma is set to zero throughout the flow field. On solid wall boundaries and at the freestream, a zero gradient of gamma is assumed. On outflow boundaries gamma is extrapolated from inside the domain to the outer boundaries. The temperature distribution across the boundary

layer was determined using Crocco's law. Adiabatic wall temperature due to frictional heating was given by the equation (8):

$$T_w = T_\infty \left[1 + \sqrt{P} \frac{\gamma - 1}{2} \left(\frac{\bar{U}}{\sqrt{\gamma R T}} \right)^2 \right] \tag{8}$$

and the wall's one modelled as adiabatic by the use of the temperature recovers factor the square root of Prandlt number. The static pressure was imposed as constant across the boundary layer.
Finally, the computational result for the T3A case is shown in Figure 7. The predicted skin friction coefficients and shape factor variation have been compared with the experimental data. The plot (a) shows the shape factor which indicates the region where the boundary layer tends to be turbulent. A decrease in H implies the transition is about to occurs. As before mentioned the experimental data showed a premature decline of H from the laminar value, on the other hand, the computation showed a pure laminar flow before the transition onset. Also for the skin friction as well as the streamwise velocity profile (see Figure 8), the computational results are in good agreement with the experimental ones.

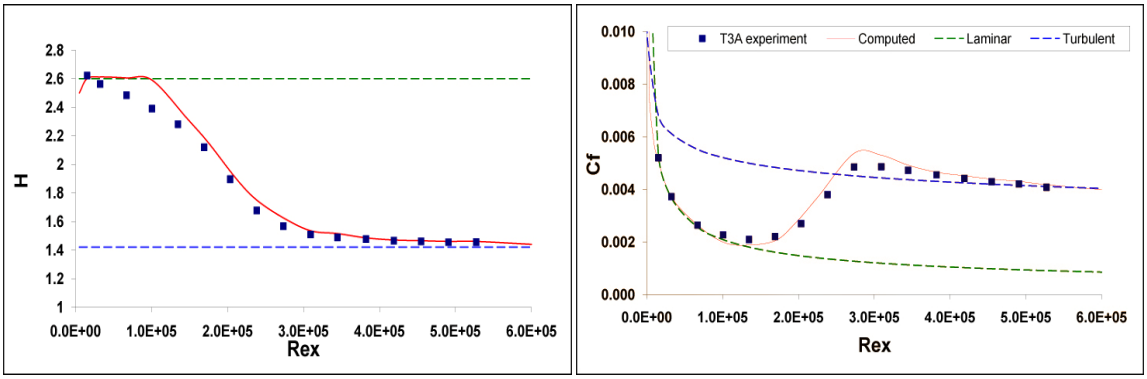

Figure 7. Comparison of the experimental shape factor and skin friction coefficient against computational results for the T3A test case

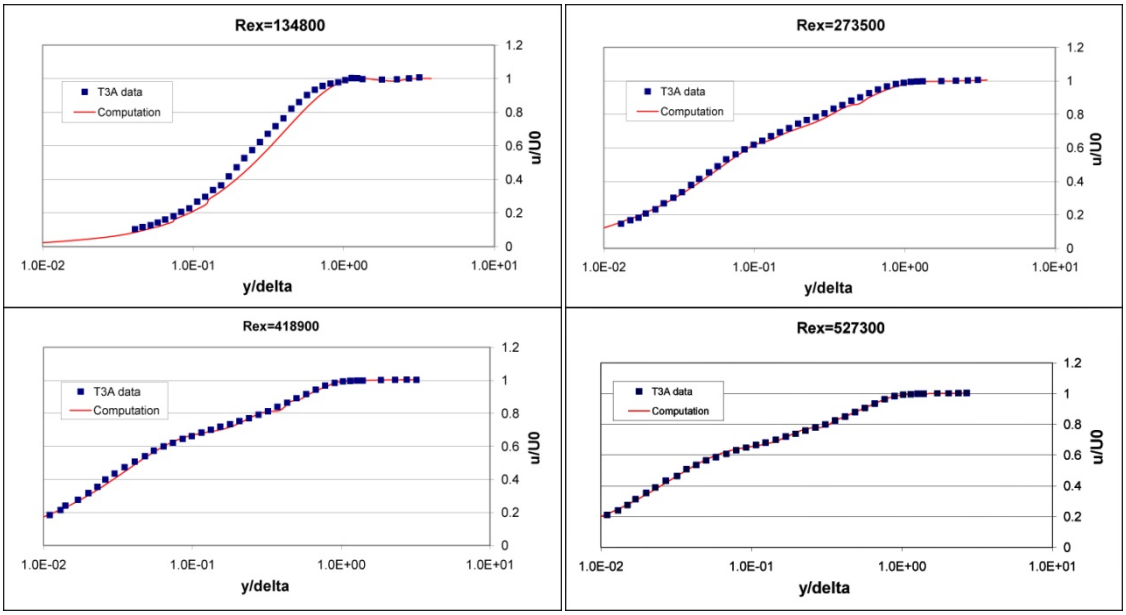

Figure 8. Numerical against experimental stream-wise velocity profile at different location along the flat plate

CONCLUSIONS

The dataset for the two Ercoftac test cases analysed has to be used with care, so the practitioners should be aware of the issue encountered. Perhaps an extension of the explanatory notes accompanying the database should be done. The transition model works well at a moderate FST level and less well at lover FST intensity. This different behaviour is probably due to the different physics of the two transition mechanisms in the two test cases. Possibly in the T3A- test case with a FST level of 0.9% the influence of Tollmien-Schliting waves might be not entirely negligible.

STUDY OF VORTICAL STRUCTURES IN IMPINGING JETS - NEW METHODS AND APPROACHES

V. Tesař [*], **V. Němička**
Institute of Thermomechanics AS CR v.v.i., Praha, Czech Republic

ABSTRACT. Heat transfer characteristics of impinging jets are strongly affected by complex, not yet fully understood vortical structures that develop due to hydrodynamic instability in the outer mixing layer**.** The paper describes the new techniques used in experiments with impinging jets: periodically triggered vortex formation, visualisation by laser light scattered from water mist particles added to the jet, and using advanced processing of image sequences. Particularly interesting is "frozen motion" evaluations of the correlations between frames of a sequence, revealing the investigated structures by using their higher coherence in contrast to the uncorrelated surrounding turbulence.

Keywords: *impinging jets, flow visualisation, image processing, vortical structures, turbulence*

INTRODUCTION

Impinging jets, Figure 1, are an especially important case of fluid flows used in heat transfer applications, because they make possible achieving the highest thermal power transfer rates between a fluid and a solid surface – higher than any other known convective transport method [5].

It has been for a long time recognised that impinging jet flowfields, and their resultant heat transfer properties, are strongly influenced by the vortices - as well as by more complex vortical structures that gradually evolve from the initially regular vortex motions – that arise and evolve due to hydrodynamic instability in the mixing layer surrounding the jet core. They are apparent features in the example in Figure 2. All aspects of this influence have not yet been fully elucidated [1]. For example, experimental results obtained with the nozzles positioned at a small relative distance h/d,

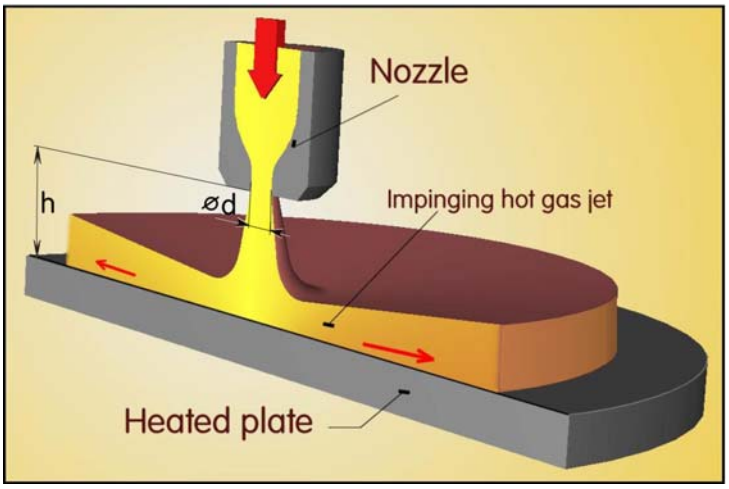

Figure 1. Schematic representation of heating by a hot gas in the impinging jet configuration. The jet issues from a nozzle usually oriented in perpendicular direction towards the heated surface. Reynolds number of the jet is usually high enough for vortical motions, associated with hydrodynamic instability of the flow, developing in the mixing layer on the outer edge of the jet.

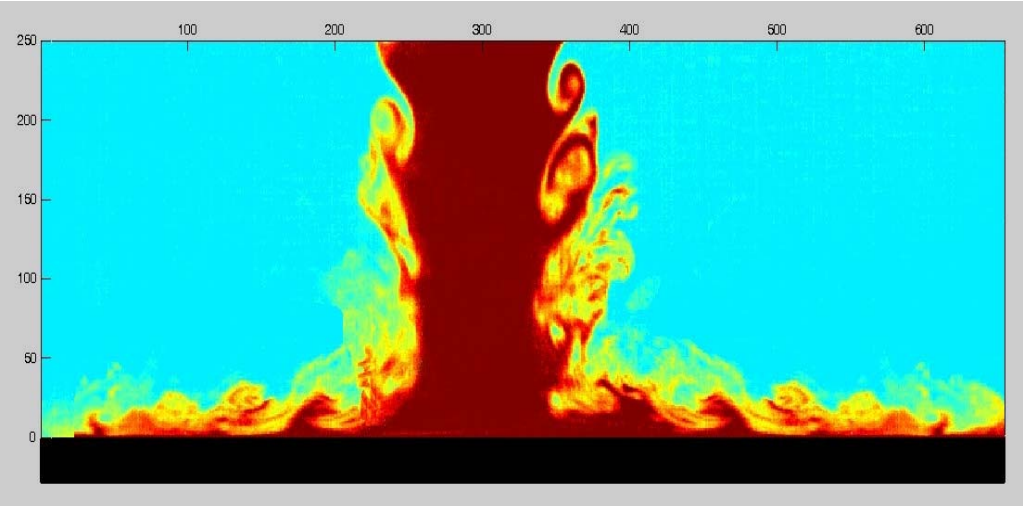

Figure 2. A typical example of a visualised impinging jet at a Reynolds number value typical for heat transfer applications, with prominent vortices initially developing in the mixing layer on the outer edge of the jet, gradually losing the coherence and finally evolving into chaotic turbulence.

(Figure 1) above the impingement wall exhibit strange off-axis transfer rate maxima [2], which are now accepted to be caused by the vortical motions [3, 11, 14], but the details of generating the maxima are not fully understood, especially since the vortices apparently decompose before reaching wall proximity.

The main difficulty encountered in investigations of these vortical objects is their variation in time. They appear with certain periodicity, but with chaotic phase jitter, and are not easy to follow as they are carried with the jet flow. Particularly troublesome problem is the influence of chaotic turbulence by which the structures are surrounded and within which they finally disappear.

The authors made three important steps in eliminating these problems in experimental investigations. First, they applied a periodic triggering action so that the vortices are formed in precisely reproducible periodicity. Second, the triggering of vortex formation was synchronised, at an adjustable phase angle, with the instants at which the camera recorded the frames showing the visualised jet. Finally, the image frames are processed in a novel way making apparent the investigated structures by using their higher coherence property in contrast to the uncorrelated surrounding turbulence.

This paper describes the basic features of these newly developed techniques.

EXPERIMENTS

General features

The investigated flow was a jet of air issuing from a $d = 40$ mm i.d. nozzle. The nozzle properties were studied as described in [6]. It was located in the centre of a large horizontal surface perpendicular to the jet axis. The jet impinged upon a parallel impingement surface positioned at a distance $h = 100$ mm, i.e. at $h/d = 2.5$. The air was supplied by an adjustable-speed blower [7] through a settling chamber provided with sieves. The flow rate was varied so that Reynolds numbers of the jet were of the order $1 .10^3 – 10 .10^3$. The jet was visualised by addition of water mist particles. These scattered the light of an illuminating "laser knife". The images of the scattered light were captured by a digital camera oriented perpendicularly to the light sheet. Essentially, they pro-

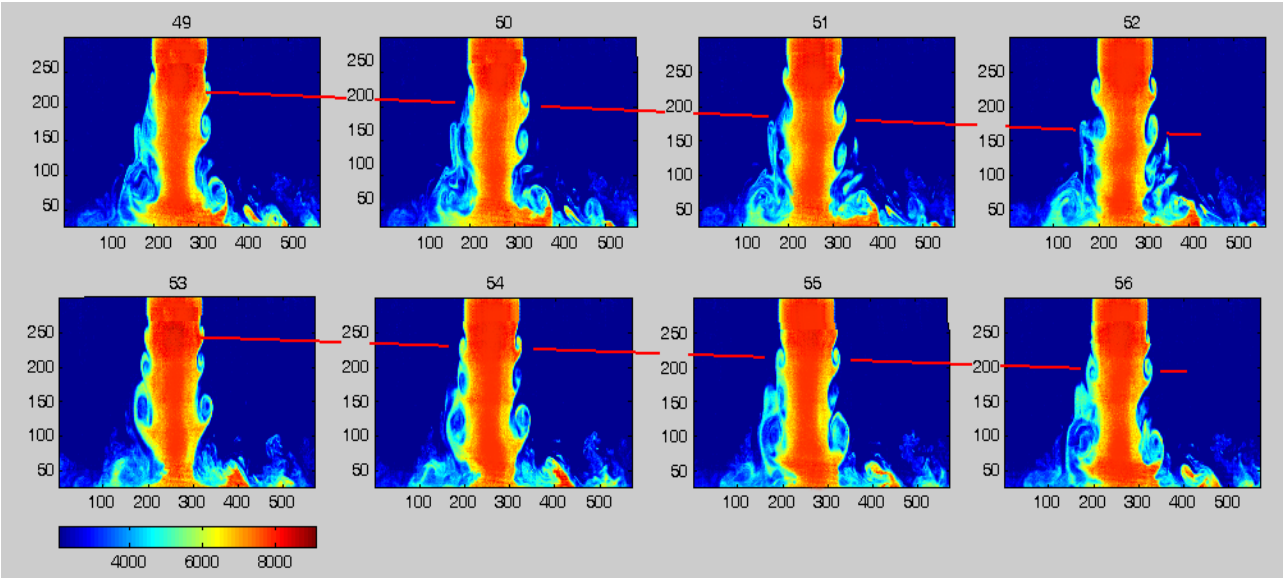

Figure 2. A typical sequence of video frames of an impinging jet visualised by addition of water mist particles and presented using the false-colour mapping that replaced the actually photographed various levels of grey by an arbitrarily assigned colour according to the scale at bottom left. These frames show the vortices as they form in unexcited impinging jet. The red line connects the positions of a particular vortex as it progresses towards the wall.

vided an information on local intensities of the scattered light. The scattering particles were made by evaporating water and passing it through a bed of crushed ice, so that the vapour condensed before it was introduced into the air flow in the entrance into the blower. This placement of the injection ensured homogeneous mixing by the blower blades before the mist containing air entered the nozzle.

The laser used for generating the "*laser light knife*" was a diode-pumped solid state green light (wavelength 532 nm) Nd:YAG laser DPGL-2200L-45 supplied by Shanghai Uniwave Tech-nology Ltd. Its maximum output power is 200 mW; but the power was adjustable and during the experiment the values were usually lower than this maximum. The laser is provided with a cylindrical optics generating the light sheet of fan angle 45^{o} and guaranteed width < 5 mm at 5 m distance. The distance actually used, 700 mm, was shorter so that the sheet thickness was ~0.7 mm.

The camera used was Vision Research Phantom v7.3 with continuously recording 14-bit monochrome SR-CMOS sensors giving 800 x 600 pixels resolution and top speed of 6 688 frames per second – which was not used in the present case. In the unexcited jet pictures in Fig. 2 the data acquisition speed was 100 frames per second while with the excitation the picture taking was synchronised to the excitation frequency. From the images, sequences of 8 frames were chosen and processed. The original pictures presented various levels of grey. The entrained outer air containing no water droplets appeared black and the numerical value stored for the corresponding pixel of the image should be theoretically 0. There is always some inevitable light dispersion inside the test space and also the absorbance of the background (which was black textile) is not perfect, so that the minimum values are higher. On the other hand, no pictures contained the full 14 bit white extreme. Also the camera sensitivity is practically never set so as to utilise the 14 bit resolution. Instead of the theoretical range 0 to 16 384, in practical situations the values were in a more narrow range, which was shifted down to make the lowest value zero. Typically, after the shift, the highest value were typically near to 9 000. This is seen in the colour coding bar in the lower left corner of Figure 2. To facilitate visual inspection of the images, the levels of grey were replaced by a false colour using an assignment function which could be completely arbitrary and has to be presented in the form of the colourbar accompanying the images.

Phase synchronisation

Among the complicating factors that make a closer study of the vortical structures not easy, is their motion from the nozzle towards the impingement wall, as it is clearly seen from the slope of the red connecting line in Figure 2. In our experiment, we managed to virtually "stop" this motion when taking flow visualisation pictures by utilising the stroboscopic effect [8]: the pictures are taken at the same phase of a periodic process. With natural generation of vortices only very roughly periodic, the periodicity was to be secured by triggering the vortex formation. An essential part of the experimental rig used by the authors is an actuator for periodic excitation of the jet flow. It should be stressed that this is no generation of the vortices - the excitation is very weak. Due to the hydrodynamic instability the vortices are ready to appear even if there were no excitation at all so that even the very weak triggering disturbance suffices to start the vortex formation. Because of maintaining a precise excitation frequency, the stroboscopic effect makes the pictures of subsequently appearing vortices to look like if there were permanently only a single, stationary vortex – as is, e.g., the vortex A in Figure 3.

The ultimate target of the planned investigations (not discussed in the present paper) are the rather strange properties of helical instability structures [10]. This is why the chosen excitation mode in the experiments is azimuthal, acting on the jet in the plane of the nozzle exit. It has the form of two waves running, one after another, along the exit circumference. The actuator producing it consists of 8 electro/acoustical transducers - standard commercially available low-frequency woofer loudspeakers ARN-165-01/4. Four neighbouring transducers supplied by harmonic electric current with phase shifting by one quarter of the period generate the first acoustic perturbance. The azimuthal wave coupled with the axial translation of the jet produces a helical object upon leaving the outer part of the nozzle. Similarly, the remaining quartet of the loudspeakers produces another wave, phase shifted by 180 deg. The two waves follow one another and this generates two interleaved helical structure objects in the mixing layer of the jet. It should be noted that because of this arrangement, the Strouhal number values Sh are twice as high than if they were simply computed from the given frequency f.

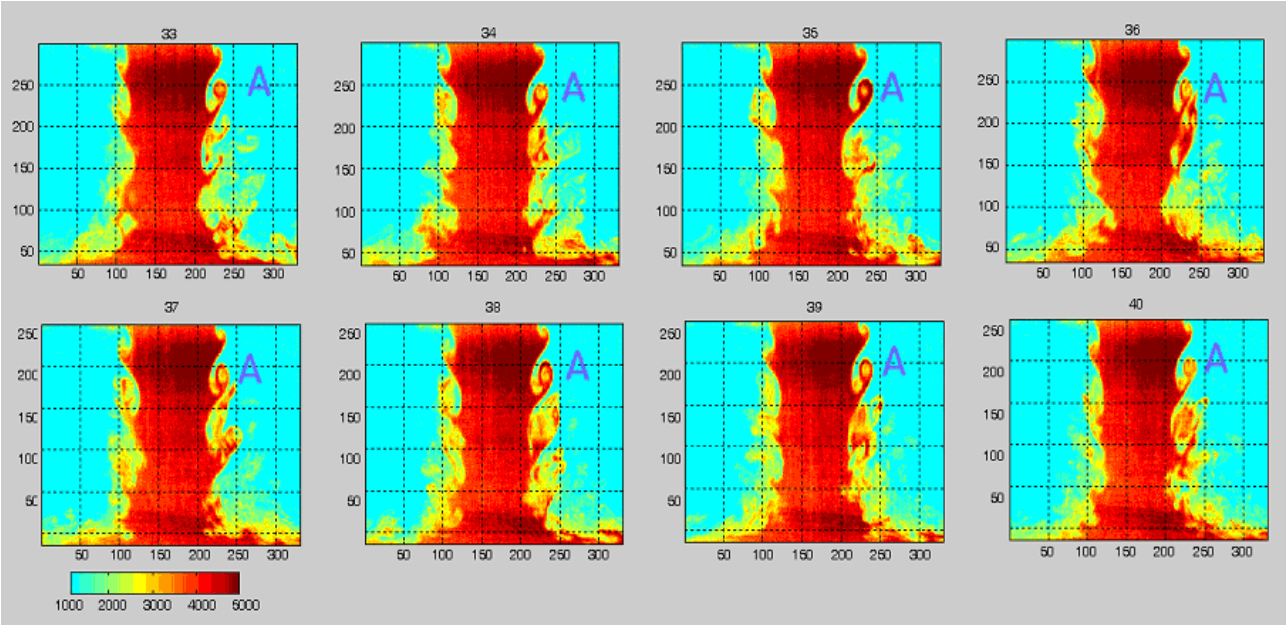

Figure 3. An example of video frames sequence demonstrating the success of the phase synchronisation. The impinging jet, same as in Figure 2, was excited by azimuthal acoustic waves in the nozzle exit plane. Taking of the pictures at a particular phase of the excitation resulted in seeing in each frame the excited jet in the same phase of the excitation. In this case, different subsequently generated vortices A are captured in the same phase of their development so that they seem to be the same stationary object.

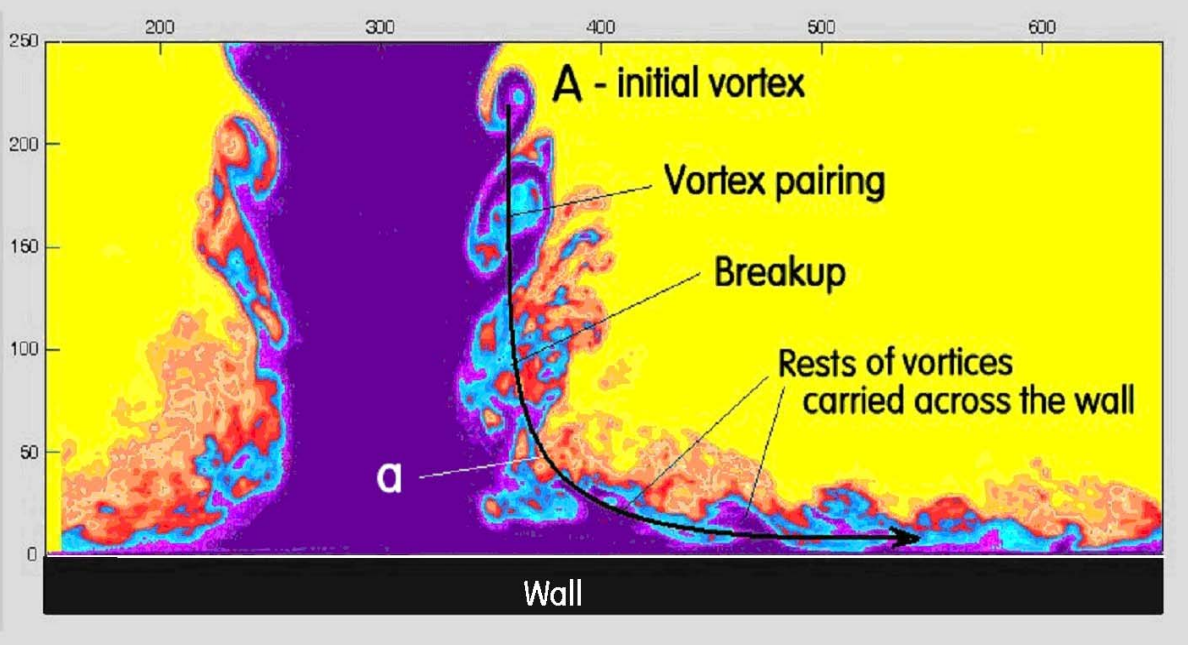

Figure 4. The constant phase processing of video frames – here enhanced by posterisation (reduction of colour palette) makes possible a close study of the development of progressing vortices and their rests remaining in the flowfield after the vortex breakup.

The signal for camera release was derived, by a phase-shifting circuit, from the generator of the excitation signal. This way, taking each picture in the sequence was synchronised with acoustic triggering of vortex generation. As a result, the coherent components of the structures (best seen in the initial stages when the vortices are still coherent — such as is the case of the topmost vortices A in the accompanying Figure 3) became virtually "frozen", non-movable. Further downstream, the vortical structure breaks down and loses its coherence. Because the main periodic component of the motion of the structures keeps them at a particular, virtually steady location in the frame, the pictures make possible evaluating the uncorrelated components of their behaviour – e.g. by statistical processing of the time-mean and fluctuating components of the structures. A single-picture example that demonstrates the possibilities offered for the study of the breaking-up of the vortices by this synchronisation is presented in Figure 4. Of course, these processes are incoherent and the results are therefore different in each frame – as is seen in following further downstream the decomposing vortices in the frames of Figure 3.

Figure 4 also demonstrates one of the simple but useful methods of the image processing – the ***posterisation*** approach used to make better apparent the basic features, as introduced by Tesař and Barker in [11]. The colour palette of the picture is drastically reduced to only a few colours. Also the contours between the different hue areas were traced to make better recognisable the demarcation lines between the coloured areas. The posterisation procedure is somewhat of a psychological paradox. It, in fact, decreases the information contents of the processed image rather than increasing it, yet can make some essential features better recognisable visually. Its certain disadvantage is the considerable degree of subjective aspects in the procedure – the demarcation lines between the coloured areas may be chosen differently by different investigators. Usually, posterisation is not a structure-revealing procedure itself, but may be usefully applied to images processed by some more advanced procedure.

Correlation

More sophisticated and for the visual identification more convincing detection criterion used to identify the instability structures is the use of correlation techniques [4]. This is based on the fact

that the information about the local intensity of the scattered light in a flow visualisation frame is stored in the form of a matrix, e.g. a matrix $\underline{A}$ in one frame and matrix $\underline{B}$ in the following one, the numerical values at a particular element of a matrix being the stored numerical value at the corresponding pixel. There are standard library procedures for computing correlations of two matrices. The procedure admits a considerable degree of freedom in choosing the pixels entering the evaluation. In the accompanying example in Figure 5, for each interrogated pixel the evaluation procedure took the surrounding 5 x 5 pixels in the RoI (Region of Interest). This selection leads to formation of the submatrix

$$\text{sub}\,\underline{A} = \begin{bmatrix} A_{k-2,l-2} & A_{k-2,l-1} & A_{k-2,l} & A_{k-2,l+1} & A_{k-2,l+2} \\ A_{k-1,l-2} & A_{k-1,l-1} & A_{k-1,l} & A_{k-1,l+1} & A_{k-1,l+2} \\ A_{k,l-2} & A_{k,l-1} & A_{k,l} & A_{k,l+1} & A_{k,l+2} \\ A_{k+1,l-2} & A_{k+1,l-1} & A_{k+1,,} & A_{k+1,l+1} & A_{k+1,l+2} \\ A_{k+2,l-2} & A_{k+2,l-1} & A_{k-2,l} & A_{k+2,l+1} & A_{k+2,l+2} \end{bmatrix} \quad \ldots (1)$$

The comparison vector may be then formed from the elements of this submatrix as follows:

$$\mathbf{A} = [\, A_{k-2,l-2},\ A_{k-2,l-1},\ A_{k-2,l},\ A_{k-2,l+1},\ A_{k-2,l+2},\ A_{k-1,l-2},\ A_{k-1,l-1},\ A_{k-1,l},\ A_{k-1,l+1},\ A_{k-1,l+2},\ A_{k,l-2},\ A_{k,l-1},\ A_{k,l},\ A_{k,l+1},$$
$$A_{k,l+2},\ A_{k+1,l-2},\ A_{k+1,l-1},\ A_{k+1,l},\ A_{k+1,l+1},\ A_{k+1,l+2},\ A_{k+2,l-2},\ A_{k+2,l-1},\ A_{k-2,l},\ A_{k+2,l+1},\ A_{k+2,l+2}\,]$$

and analogously in the comparison vector of the second frame there are

$$\mathbf{B} = [\, B_{k-2,l-2},\ B_{k-2,l-1},\ B_{k-2,l},\ B_{k-2,l+1},\ B_{k-2,l+2},\ B_{k-1,l-2},\ B_{k-1,l-1},\ B_{k-1,l},\ B_{k-1,l+1},\ B_{k-1,l+2},\ B_{k,l-2},\ B_{k,l-1},\ B_{k,l},\ B_{k,l+1},$$
$$B_{k,l+2},\ B_{k+1,l-2},\ B_{k+1,l-1},\ B_{k+1,l},\ B_{k+1,l+1},\ B_{k+1,l+2},\ B_{k+2,l-2},\ B_{k+2,l-1},\ B_{k-2,l},\ B_{k+2,l+1},\ B_{k+2,l+2}\,]$$

The correlation coefficient R is then computed as

$$R = \frac{\mathbf{A}\,\mathbf{B}}{|\mathbf{A}||\mathbf{B}|} \quad \ldots (2)$$

The order of the components in the vectors may be selected differently [9] so as to identify the direction of the studied motion changes of the compared vortical structures during their. In principle,

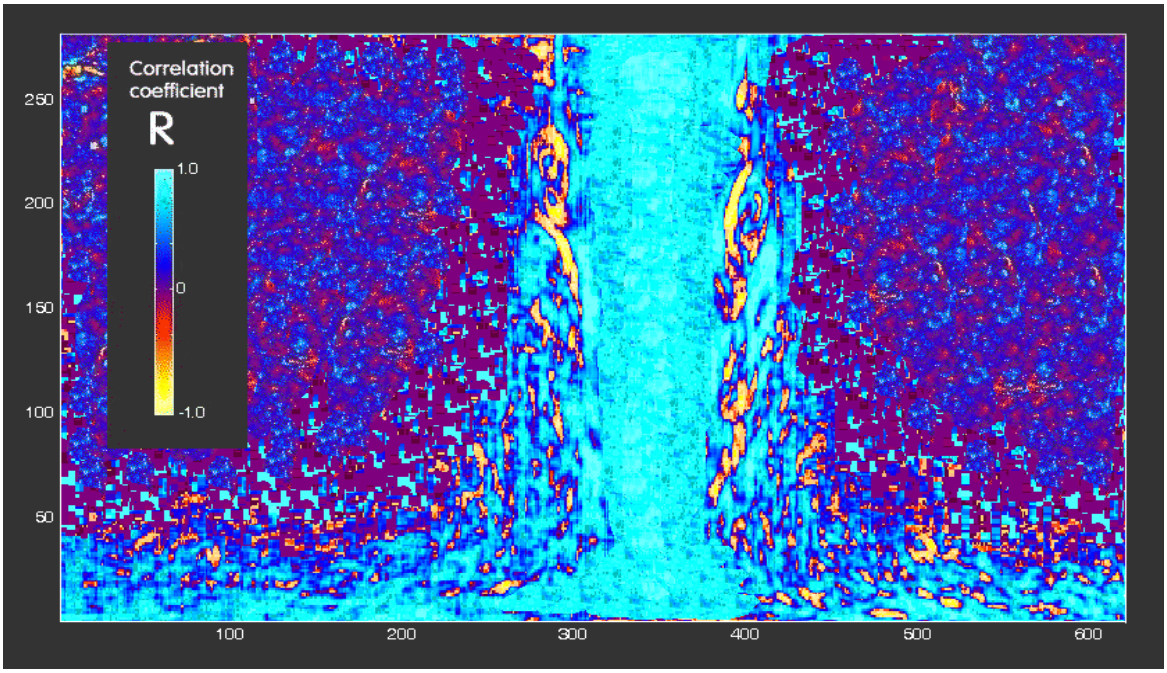

Figure 5. An example of image processed by computing correlations between two frames in a sequence, using the absolute values of the optical intensity data. In the locations coloured light blue the flow features do not change between the instants at which the pictures were taken. Of interest are the yellow coloured areas of large negative correlation coefficient. They are indicative the motions of coherent structures and are mainly found on the structure edges.

the correlation is computed as the normalised scalar product of the vectors [9]. Because of the normalisation, the resultant correlation coefficient may be interpreted geometrically as the cosine of the (multi-dimensional) "angle" between the two vectors. If the two vectors are identical or parallel, their correlation coefficient is $R = 1$. The corresponding area is coloured light blue in Figure 5. If the two vectors have nothing in common at all, or are mutually "perpendicular", the correlation coefficient is zero $R = 0$. The corresponding area should appear black in Figure 5, but the ideal value is rarely attained and the areas are coloured dark blue or dark red. This is the region of uncorrelated turbulence. Most interesting in the present context are the locations in which the comparison vectors from the two frames in the interrogation point are anti-parallel $R = -1$. The corresponding areas should be marked light yellow in the picture. This is usually indicative of movement of instability structures that move coherently. In particular, such a change is mainly found on the structure edges.

By choice of the pixels in the RoI that are used to set up the components of the comparison vectors it is possible to detect the ***direction*** of structure motion between two correlated image frames.

The correlations may be also computed using comparison vectors from the differences with subtracted mean value of a sequence. We store the scattered light intensity data in six matrices A, B, C, D, E, F, each containing an information acquired at a different instant of time. The mean value $M_{k,l}$ at each k and l location is simply evaluated as

$$M_{k,l} = (A_{k,l} + B_{k,l} + C_{k,l} + D_{k,l} + E_{k,l} + F_{k,l}) / 6 \quad \ldots (3)$$

The differences, such as e.g. $A_{k,l} - M_{k,l}$, are particularly sensitive to even small changes taking place during the time interval between which the frames were captured. Evaluating the correlations from these relative values makes in the results particularly apparent the structure evolutions in time and their motion in space.

CONCLUSIONS

The subject of this paper are new techniques introduced by the present authors for detecting instability structures in impinging jet flows and for evaluation of the dynamics of their development. The basic problem is how to extract information about three-dimensional objects – in particular vortical structures – from two-dimensional flow visualisation images. The problem is made more difficult by the objects of interest appearing quasi-periodically (i.e. with large variations in the phase), moving as they are carried away with the flow, and submerged in stochastic turbulence that complicates even their mere identification. Because of the unsteady character of the detected objects, the turbulence cannot be simply filtered out by statistical averaging.

The discussed approach to solving these problems operates with triggering the vortex formation by a periodic signal from which is derived the camera releasing signal. This way one obtains a sequence consisting of a relatively small number of monochrome pictures taken at periodic time intervals, each of them capturing only a section through the object (which makes them insufficient for a tomographic reconstruction). The images are then analysed using as the basic idea the difference in the rates of change of the identified object and of the surrounding chaos. Using subtraction of local mean values and evaluation of correlation coefficients, supplemented by false colour coding and posterisation, can reveal interesting and significant information.
