Preface

This Conference CD-ROM Proceedings contains the papers presented at the seventh World Conference on Experimental Heat Transfer, Fluid Mechanics and Thermodynamics (ExHFT-7) held in Krakow, Poland from 28 June – 03 July 2009.

The World Conferences on Experimental Heat Transfer, Fluid Mechanics and Thermodynamics have been taking place since 1988, a full twenty years. This year's Follows successful conferences in Dubrovnik (1988, 1991), Honolulu (1993), Brussels (1997), Thessaloniki (2001), and Matsushima (2005).

ExHFT-7 is being organized under the auspices of the Assembly of World Conferences on Experimental Heat Transfer, Fluid Mechanics and Thermodynamics. The goal of this conference is to provide a forum for the exposure and exchange of ideas, methods and results in heat transfer, fluid mechanics and thermodynamics.

Conference topics include, but are not limited to: Fundamentals: Heat and Mass Transfer, Fluid Mechanics, Thermodynamics, Measurement Techniques, Interdisciplinary Areas in Heat and Fluid Flow, Reaction and Combustion, and Turbulence, Applications: Aerospace Technology, Advanced Energy Systems, Advanced Environmental Systems, Biotechnology and Medical Systems, Cryogenics, Education, Fuel Cell Systems, Interactive Computational and Experimental Methodologies, Manufacturing Processes, Material Processing, Micro Electronic Equipment, Micro-Electro-Mechanical Systems, Miniaturized Systems for Chemistry and Life Sciences, Nanotechnology.

Within the general subjects of this conference three mini-symposia are organized. The topics include: Biological Systems, Fuel Cell Systems, and Micro- and Nano-scale Systems.

Twelve state-of-the-art keynote papers are delivered by world leading experts and two lectures by Nusselt-Reynolds Prize winners.

All contributed papers were peer reviewed. Recommendations were received from Lead Scientists and the Advisory Board. Accordingly, of the 398 eligible extended abstracts submitted 350 contributions were invited to prepare full papers. Through a review process by International Scientific Committee, 270 papers were selected for presentation at ExHFT-7. All contributions were prepared by the authors in a camera ready form. The total number of submitted and accepted papers for this year's conference represents a significant increase over previous ExHFT conferences, which speaks to the great vitality of experimental heat transfer, fluid mechanics and thermodynamics.

We hope that this proceedings will be used not only as a document of the event but also to assess achievements and new paths to be taken in heat transfer, fluid mechanics and thermodynamics research.

Finally, we would like to congratulate the winners of the 2009 Nusselt-Reynolds Prize, Professors Dimos Poulikakos and Katepalli R. Sreenivasan.

Janusz S. Szmyd

Tomasz A. Kowalewski

Acknowledgments

We would like to express our thanks to our colleagues from the Assembly of World Conferences on Experimental Heat Transfer, Fluid Mechanics and Thermodynamics, as well as from International Scientific Committee i.e. Lead Scientists and the Advisory Board.
Their advice and efforts have helped us to overcome the problems normally associated with organising international meetings.

Special thanks goes to Lead Scientists for their work in encouraging the submission of papers and the subsequent review of all papers. Their contribution cannot be overestimated.

The ExHFT-7 Conference was organised by the AGH University of Science and Technology and Jagiellonian University. The demanding work involved could not have been done without the contribution of so many individuals from both institutions as well as numerous external co-workers. Without their extremely valuable help such a meeting would be impossible. Thank you all so much!

Nusselt- Reynolds Prize Lectures

ON EMERGING MICRO- AND NANOSCALE TECHNOLOGIES FOR ENERGY APPLICATIONS

Dimos Poulikakos
Laboratory of Thermodynamics in Emerging Technologies
Mechanical and Process Engineering Department
ETH Zurich

ABSTRACT. This paper highlights the main points of my keynote lecture for the 2009 Nusselt-Reynolds Prize and contains examples of experimental aspects of my current research in heat transfer and transport phenomena at the interface of energy applications and micro- and nanoscale technologies. It is not the scope of this paper to present an exhaustive account of all current and past activities related to its title. It is rather an account of current research in my laboratory in this area, containing both the underlying scientific challenges as well as the hoped final outcome in terms of applications. To this end, examples from the areas of energy conversion, as well as energy transport will be discussed. In the area of energy conversion an original, deformable, direct methanol micro-fuel cell will be presented made of lightweight, flexible, polymer-based materials. A basic understanding and control of two-phase flows (in this case methanol and carbon dioxide) in microchannels as well as novel materials processing and microfabrication methods are directly related to the performance of such energy conversion devices. In the area of energy conservation and reuse, examples from the information technology will be employed. Specifically, new concepts of liquid (water) cooling of chips reaching heat removal rates in excess of 700 W/cm^2 in domains with restricted heights of the order of one mm will be presented. These concepts include optimized, nature-inspired microchannel designs for liquid transport, combined with ultra-high heat flux impinging micro-jet cooling. One additional advantage of using water to cool high density electronics is energy reuse, due to the potentially much higher exergy content of the coolant compared to toady's air cooled technologies. The last part of the paper focuses on the employment of functional nanostructures such as carbon nanotubes and nanowires of conductive and semi-conductive materials for the efficient transport of electricity and heat and the need for the development of novel technologies for the manufacturing, characterisation as well as handling of such nanostructures.

Keywords: *energy, micro-fuel cells, electronics cooling, nanotechnology, carbon nanotubes*

INTRODUCTION

Energy has emerged as arguably the most important challenge facing humanity in the 21st century (see for example the list in Fig. 1). This fact has reinvigorated the energy debate and research worldwide, bringing to the forefront the multifaceted nature of the scientific and social problems involved, resulting from a rapidly growing, energy hungry world population. At the outset of the scientific debate and depending on its context, a number of basic facts have to be understood. For the energy-engineering scientist, the following are of paramount importance:

-The issue of *quality* is essential in understanding e-The continuous scientific challenge is the *conversion* of various forms of "lower" quality energy (thermal, chemical, nuclear, solar, etc.), to the "highest" quality mechanical or electrical energy.

-Every time we convert we lose in overall quality (2nd Law of Thermodynamics). Hence, we must convert as efficiently and as little as possible (conservation) with due respect to the environment.

Thermal engineering is at the center of just about every energy activity, because thermal energy, its production, transfer, harvesting, control, and storage are necessary steps on the way to conversion to electrical or mechanical energy. In addition, thermal energy is often used directly in a large variety of heating and cooling applications, related or not related to conversion or utilization of other forms of energy.

10. POPULATION (Could go to 10 Billion in the 21st Century ~ 6.4B people in 2004)

Figure 1. Humanity's Top Ten Grand Challenges in the 21st Century (List by R. E Smalley).

It is therefore a natural consequence that the areas of thermodynamics, heat transfer and related fluid dynamics have been at the center of intellectual activity in engineering sciences and have produced a plethora of advances that have served humanity for many years, including those of pioneers in the field such as Wilhelm Nusselt and Osborn Reynolds in the past century.

In this lecture I will attempt to give some examples of current heat transfer research as we enter the 21st century that are directly related to the issue of energy as I described it above. These examples stem from my own activities as well as those of my scientific collaborators. At the beginning of the 21st century we are fortunate to have at our disposal tools and technologies, which the pioneers in the field of heat transfer could not even dream about. To this end, the issue of enabling micro- and nanotechnology for energy applications is central to all the topics I will cover in this lecture. Today, we are able, for example, to analyse and control transport of fluids and heat in channels that are not only smaller than the human hair, but they are beyond the realm of continuity, going down to diameters of molecular dimensions. We can investigate and quantify the transport of heat through the interface between two materials from the atomic viewpoint. Such developments create a new perspective and can give birth to new ideas to confront the energy challenge.

The paper and the lecture are structured as follows: Starting with the area of microscale energy conversion, a deformable, direct methanol micro-fuel cell will be presented, made of lightweight, flexible, polymer-based materials. The importance and control of two-phase flows (methanol and carbon dioxide) in the microchannels of the anode of the fuel cell is directly related to the performance of such energy conversion devices. Next, the area of ultra high heat flux cooling in small spaces will be discussed as well as its implications in energy conservation, in particular as it relates to information technology. Specific concepts include optimized, nature-inspired microchannel designs for liquid transport, combined with ultra-high heat flux impinging micro-jet cooling. One additional advantage of

using water to cool high density electronics is energy reuse, due to the potentially much higher exergy content of the coolant compared to toady's air cooled technologies. The last part of the paper focuses on the employment of nanostructures for novel energy applications, such as, carbon nanotubes and nanowires of conductive and semi-conductive materials for the efficient transport of electricity and heat and the need for the development of novel technologies for the characterisation as well as handling of such nanostructures.

ENERGY CONVERSION: A DEFORMABLE, DIRECT METHANOL MICRO- FUEL CELL

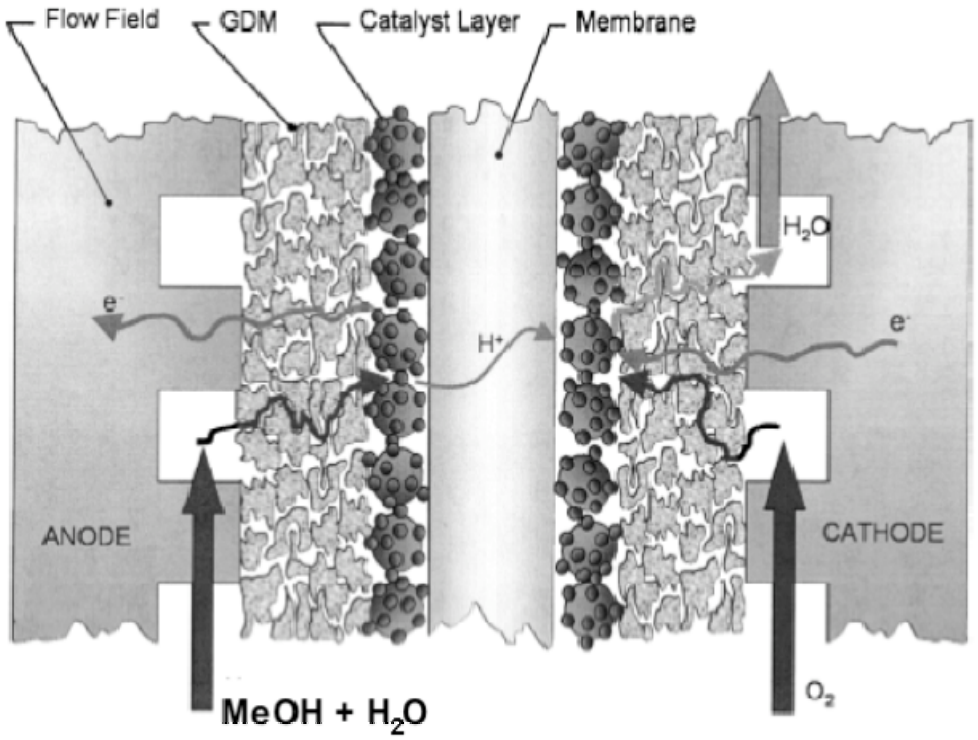

Figure 2. Operating Principle of a direct Methanol Fuel Cell

The schematic in Fig. 2 above shows the operating principle of a direct methanol fuel cell (DMFC). While progress has been made toward the realization of such transportable devices with traditional materials, there is a need for the integration of devices in personal, also wearable environments that are non-flat, undergo deformations and prefer to carry only a limited weight. This gave impetus for the creation of the flexible direct methanol fuel cell shown in Figure 3.

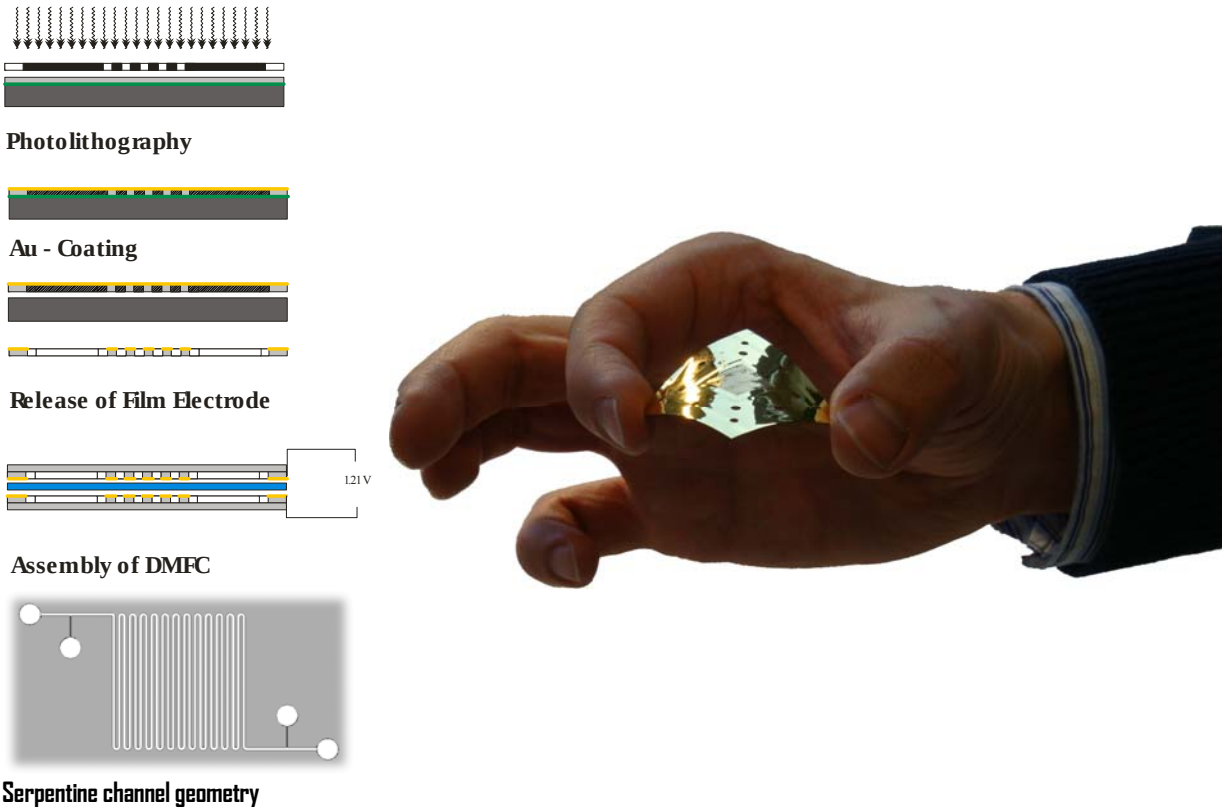

Figure 3. Assembly and photograph of a flexible, small-scale fuel cell on polymer based materials, showing also the serpentine channel geometry for the anode and cathode.

The critical point in the manufacturing of such a device is the combination of metals (gold) and polymers required for the cell anode and cathode see Ref. [1]. A standard microfabrication/MEMS technique [2], based on photolithography was applied to manufacture micro-sized channel networks, see the fabrication steps in Figure 3. In a first step, a 500 ± 25 µm thick, p-doped, double side polished, 4" silicon wafer with a resistivity of up to 30 ohm · cm was coated with at 10 µm thick layer of a negative photoresist (AZ® 4562, MicroChem). In the subsequent photolithographic procesS step (MA6, Süss Micro Tec), the mask polarity of the deployed high resolution quartz mask (ML&C) patterns the photoresist during the UV exposure. A dry etching procedure was performed using an inductive coupled plasma system (ICP, Surface Technology Systems) resulting in a rectangular shaped channel cross-section with a depth and width of 200 µm.

The surface roughness of the channel walls is defined by the cycle length of the involved "Bosch process" and the mask resolution, and does not exceed 1 µm. By the iteration of the abovementioned steps at the backside of the silicon wafer, fluid inlets, outlets and pressure ports are incorporated. After dicing the wafer into predefined microchannel chips, PEEK (Upchurch Scientific®) fluid connectors were sealed to the inlet, outlet and pressure tubes by epoxy. After the anode and cathode of the fuel cell were manufactured in the abovementioned manner, they were processed together sandwiching in between a standard polymer electrolyte membrane, on one side of which an appropriate catalyst was layered. An example of the performance of the resulting fuel cell is shown in Fig. 4. The corresponding flow fields in the fuel cell anode microchannels are shown in Fig. 5, Refs. [1,3]. The darker areas denote gas regions (carbon dioxide). It is clear that the presence of gas disrupts the electrical performance of the fuel cell and may strongly reduce the produced power [1,3] (compare Figs. 4 and 5).

THERMAL ENERGY TRANSFER: MICROCHANNEL ULTRA HIGH HEAT FLUX COOLING DEVICES FOR ELECTRONICS

The past few decades have seen a rapid growth in the computational power of processor chips, which may continue as predicted by Moore's law. The exponential increase in transistor density and storage density as well as the faster clock speed, however, cause serious problems in the thermal management of microelectronic devices. The miniaturization trend renders the thermal management challenging, especially when strict limitation of space and operating costs are applied. Until now the CPUs are cooled using large air heat sinks, but this will not be sufficient for cooling the next generation of microchips [4,5], particularly in compact multichip modules and 3-D microelectronic packages. Hence, novel cooling methods with thin form factors and high cooling performance are needed urgently.

We demonstrated an ultra thin heat sink for electronics, combining optimized impinging slot-jets, micro-channels and manifolds for efficient cooling. The design is optimized for a 2 x 2 cm^2 chip and provides a total thermal resistance of 0.087 cm^2K/W for flow rates < 1 l/min and an overall

pressure drop < 0.1 bar**.** This results in a maximum cooling capacity of 750 W/cm^2 for a temperature difference between fluid inlet and chip of 65K.

No previous studies in the literature considered the influence of the manifold on the hydrodynamic and thermal performance of the heat sink. This simplification is appropriate if there are no size restrictions in the third dimension. With denser packages, there is a demand for thin and efficient heat sinks with only lateral access for fluid supply and return. For these systems the optimum choice of design parameters can only be determined by combined analysis of the performance of a unit cell of the heat transfer structure and the design of the manifold.

We have demonstrated through modelling and experiments, [6,7], that combining heat transfer micro-channels containing slot-jets structures bringing coolant to the hot surface with manifold channels for the coolant transport, allows the optimization of an overall heat sink performance (Figure 6). First, we introduced a three-dimensional model of a unit cell of the heat transfer structure to solve the conjugate heat transfer problem for the micro-channel/jet flow. We then studied the basic physical phenomena of a unit cell and its dependency on the volumetric flow rate. We varied the length, channel width, fin thickness to channel width ratio and inlet/outlet width for a constant volumetric flow rate to determine the sensitivity of the heat sink to the individual design variables. In a second step we constructed a three-dimensional model considering the flow in the manifold channels and the heat transfer structure [6]. This model is applied to study the capability of the manifold to uniformly distribute the liquid coolant and to demonstrate that a design with tapered inlet and expanding outlet manifold channels provides uniform fluid distribution. The model results were confirmed by experiments [7].

The design consists of a manifold system with lateral fluid supply-and-return, which feeds an array of parallel micro-channels where the heat transfer is performed (Figure 6). Fluid enters the inlet manifold channels from the side. Along the inlet manifold channels the flow uniformly branches into the subsequent heat transfer structures through slit nozzles at the bottom wall of the manifold channels. The parallel micro-channels are orthogonal to the manifold channels. Hence, the flow direction after impingement on the hot surface at the bottom of the heat transfer channels is perpendicular to the one of the manifold system. While travelling along the heat transfer micro-channels, the fluid removes the heat, leaves the heat transfer micro-channel structure upwards through slit nozzles and merges into the outlet manifold channels, which guide the fluid to a lateral return (see Figure 6). The entire chip area can be cooled by just one of these systems, comparable from a manufacturing standpoint to a parallel channel network with a lateral manifold system as it was studied in one of our earlier papers [5]. It is possible that many of these systems are arranged in parallel to reduce the overall pressure drop and bulk thermal resistance of the heat sink.

Figure 7a shows streamlines starting from points equally spaced over the inlet surface. The flow enters the heat transfer structure through the inlet nozzle and impinges on the channel bottom wall where it undergoes a 90 deg. change of momentum. The vorticity with its axis transverse to the flow in the streamwise direction generates recirculation near the inner corner at the channel entrance, where the fluid velocity is much slower (Figure 7b). As the fluid flows along the channel, a hydrodynamic boundary layer develops. Towards the end of the channel the fluid is drained to the outlet nozzle with a stagnation zone formed in the channel region opposite to the outlet nozzle.

Figure 7c shows the static pressure contours at the center-plane of the heat transfer unit cell. From this Figure it becomes obvious that the hydrodynamic performance of the unit cell is dominated by the pressure drop across the inlet and outlet nozzles and not by the pressure drop along the channel.

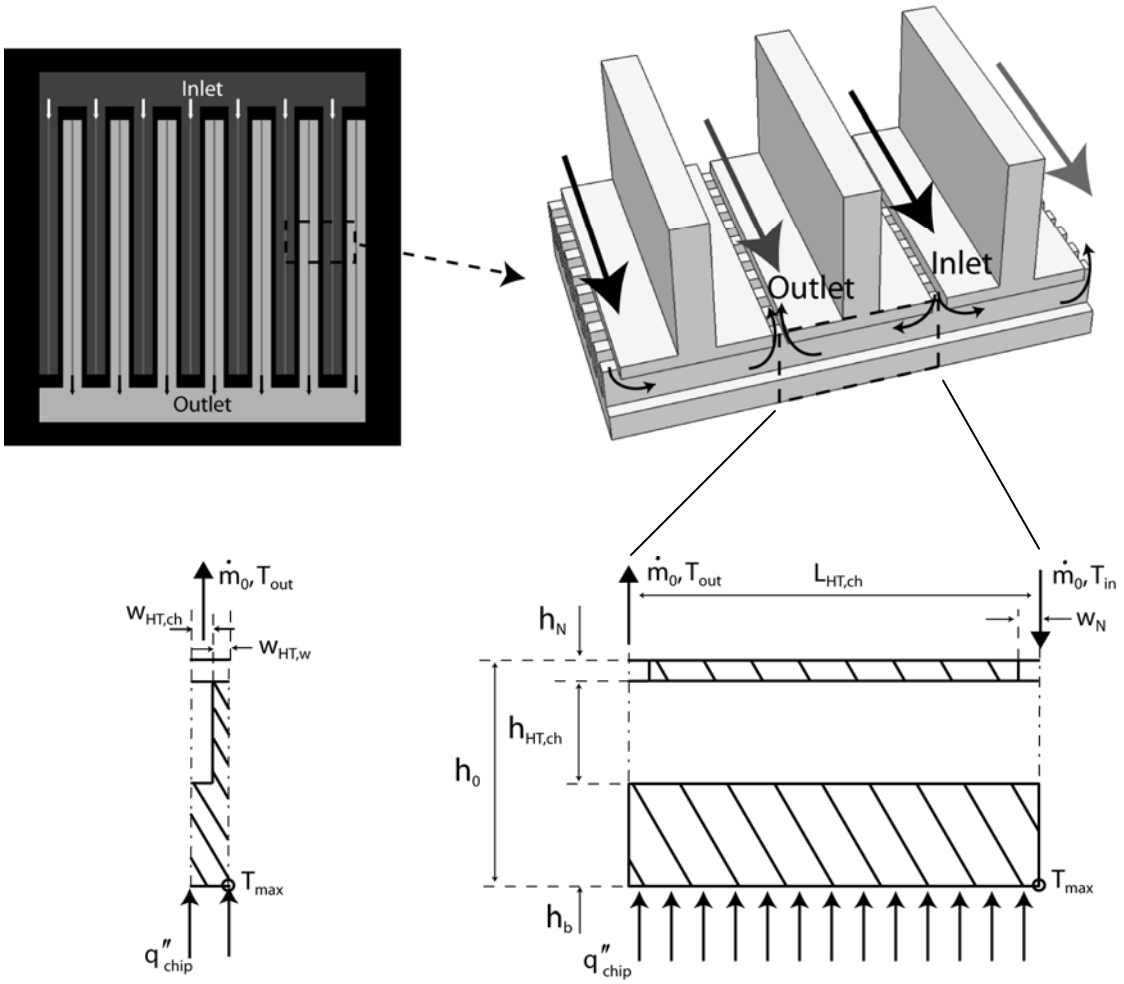

Figure 6. Schematic of a manifold micro-channel heat sink a) top view on manifold, b) isometric section view c) unit cell of the heat transfer structure side view d) unit cell of the heat transfer structure front view. From Ref. [6].

In order to analyze the thermal performance further, we present temperature contours in the solid and the fluid domains at the center-plane of the heat transfer unit cell in Figure 7d. Cold fluid enters the heat transfer structure through the inlet nozzle and impinges on the bottom channel face opposite to the inlet nozzle. The impinging jet inhibits the growth of hydrodynamic and thermal boundary layers, resulting in a small diffusion length from the solid wall to the convective flow and thus in an enhanced heat transfer rate.

Many more details on the performance of this ultra-high heat flux heat sink can be found in [6, 7]. In the following, we compare the efficiency of the different heat sink designs. The efficiency of a heat sink is defined by the ratio of the removed heat flux for a certain invested pumping power. The ability to remove a certain heat flux scales directly with the total thermal resistance of the system. For this reason we compare in Fig. 8 the total thermal resistance of the different designs as a function of idealized pumping power, *P*, which is defined as

$$P = \Delta p \dot{V}_{tot} . \qquad (1)$$

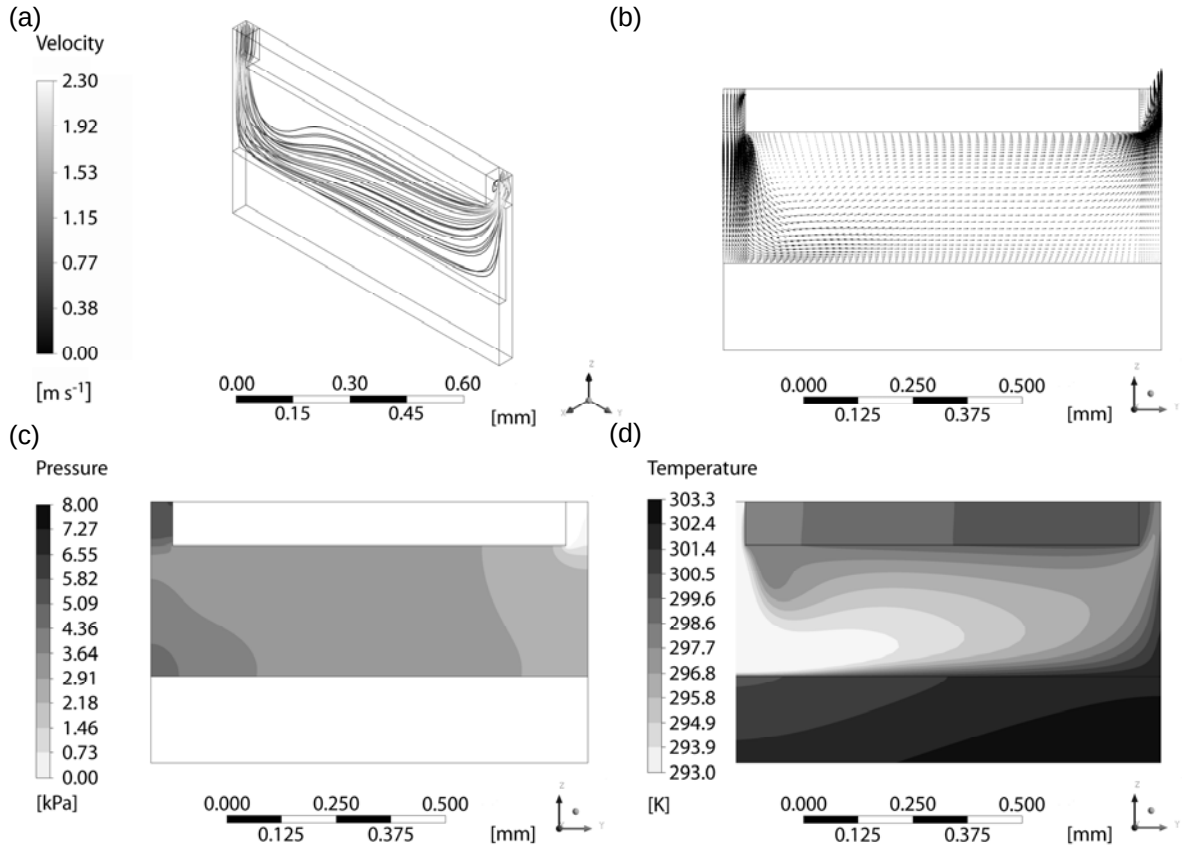

Figure 7: Spatial visualization of basic physical phenomena for a representative case at the center XZ-plane – a) streamlines starting from points being equally distributed over the inlet surface, b) velocity vectors, c) pressure contours and d) temperature contours – computed by means of three-dimensional model of the unit cell of the heat transfer structure. From Ref. [6].

In the case of high pumping powers and correspondingly high volumetric flow rates, the design with the smallest channel width of the heat transfer structure namely $w_{HT,ch}$ = 25 μm performed most efficient, although it had the highest hydrodynamic resistance (Fig. 8). At a constant pumping power, the volumetric flow rate was lower for the test-vehicle with $w_{HT,ch}$ = 25 μm than for the other two with larger channels and consequently it provided a higher bulk thermal resistance. However, due to the lower convective thermal resistance of this test-vehicle, the available thermal mass flux was used more efficiently resulting in higher outlet temperatures for a constant heat flux. When the pumping power was reduced, the increase of total thermal resistance of the test-vehicle with $w_{HT,ch}$ = 25 μm was more pronounced compared to the other two devices. Since its convective thermal resistance was lower than that of the other devices, the transition at which the bulk thermal resistance became the dominant part in the resistance chain occurred at higher volumetric flow rates and, consequently, at higher pumping powers.

In all, the total thermal resistance of the test-vehicle with $w_{HT,ch}$ = 25 μm showed a stronger dependence on the pumping power. For pumping powers below 0.06 W it would be beneficial to increase the channel width of the heat transfer structure from $w_{HT,ch}$ = 25 μm to $w_{HT,ch}$ = 50 μm in order to reduce the hydrodynamic resistance and at the same time the bulk thermal resistance. At this point the increase of the convective thermal resistance due to an enlargement of the channel width would be compensated by the reduction of the bulk thermal resistance [7].

Further, we demonstrate the potential of the heat sink design to be used in combination with elevated inlet temperatures to reduce the datacenter energy costs and to allow energy reuse. We studied the influence of increased fluid inlet temperatures on the performance of the best performing test-vehicle with a channel width of $w_{HT,ch}$ = 25 µm. Figure 9a depicts the pressure drop and the total thermal resistance of this device as a function of fluid inlet temperature at a constant volumetric flow rate of 1 l/min and a constant heat flux density of 100W/cm^2. An increase of fluid inlet temperature from 20°C to 70°C lowered the pressure drop across the heat sink about 40% due to a 60% reduction of the dynamic viscosity of water.

The pressure drop reduction was not linear as the dynamic viscosity of water decays exponentially with temperature. On the other hand, the total thermal resistance of the heat sink was increased by about 12%, being mainly attributed to a 20% reduction of the silicon's thermal conductivity. A reduction of the thermal conductivity of silicon contributed to an increase of the conduction thermal resistance of the silicon base causing a 6% increase of total thermal resistance [7]. In addition, the fin efficiency was decreased causing a reduction of the convective thermal resistance. On the other hand, the fluid thermal conductivity was increased by about 10% resulting in an increased convective heat transfer. However, the total thermal resistance of the heat sink was only slightly affected by the convective thermal resistance as the latter has only a share of 20% in the chain of thermal resistances. The volumetric heat capacity of the fluid decreased by about 2%, which directly affected the bulk thermal resistance of the system.

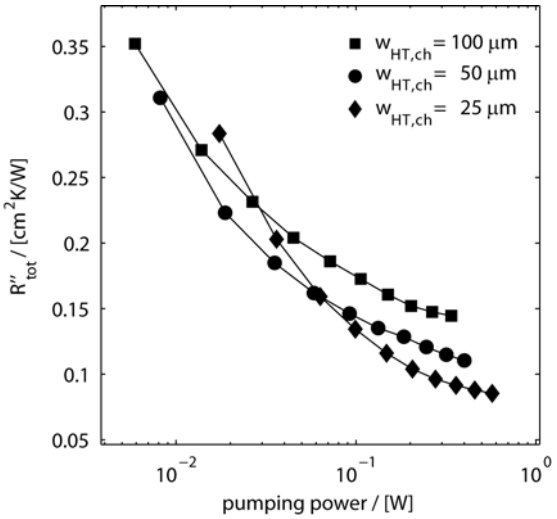

Figure 8. Maximum total thermal resistance as a function of pumping power for varying channel width $w_{HT,ch}$. From Ref. [7].

To evaluate the enhancement in efficiency of the heat sink due to elevated inlet temperatures we determined the relative coefficient of performance, COP, being normalized to the COP at 20°C [7]. The coefficient of performance is defined by the ratio of the removed heat for an invested pumping power. Hence, we write the relative coefficient of performance for a constant maximum temperature difference between heater and fluid inlet as (the symbols are self explanatory, P stands for power and R for thermal resistance)

$$\frac{COP}{COP_{20}} = \frac{\dot{q}_{heater}}{P}\frac{P_{20}}{\dot{q}_{heater,20}} = \frac{P_{20}}{P}\frac{R''_{tot,20}\Delta T_{\max}}{R''_{tot}\Delta T_{\max,20}} = \frac{P_{20}}{P}\frac{R''_{tot,20}}{R''_{tot}} \qquad (1)$$

Figure 9b depicts the relative enhancement in COP as a function of fluid inlet temperature. Due to the nonlinear behaviour of the pressure drop as a function of inlet temperature (Fig. 9a) we

observed a saturation behaviour for the COP. At inlet temperatures above 60°C, the pumping power reduction and the increase of total thermal resistance were balanced. Hence, a further rise of the inlet temperature did not influence the efficiency of the heat sink. Concluding, the performance of the heat sink could be enhanced by more than 40% for a 50°C rise of the fluid inlet temperature (compared to an inlet temperature of 20°C), resulting in a maximum heater temperature of 81°C for a fluid inlet temperature of 70°C.

NANOTECHNOLOGY FOR THE EFFICIENT TRANSPORT OF ENERGY: NANOENGINEERING WITH CARBON BASED ELECTRONICS

A very important part of the energy challenge in the 21st century is energy transport in the form of electricity including the related heat transfer issues. Nanotechnology has a lot to offer here, in particular in terms of nanoengineered materials and interfaces between different materials featuring desired properties, far superior to those of bulk materials. To this end, novel characterization methods need to be developed in parallel, for the accurate determination of the properties of such nanomaterials. In this lecture, I will focus on the topic of determination of the thermal conductivity of a very promising multifunctional kind of nanomaterial, namely, the carbon nanotube [8,9].

Theories and experiments showed that carbon nanotubes have remarkable thermal properties. However, both the experimental data and the theoretical predictions are scattered over 1 order of magnitude. In recent experiments, the reported thermal conductivities for multiwall carbon nanotubes at room temperature are in the range 400- 3000 W/mK, likely depending on the type and size of carbon nanotubes (CNTs) utilized, which give rise to different mean free paths of the energy carriers.

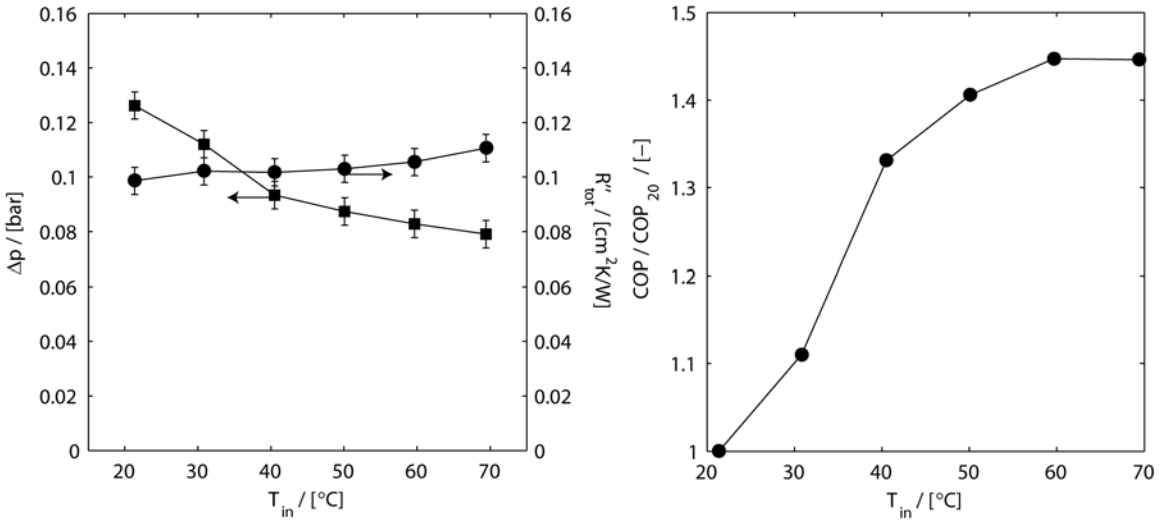

Figure 9: (a) total pressure drop and maximum total thermal resistance and (b) relative COP as a function of fluid inlet temperature for $w_{\mathrm{HT,ch}} = 25\mu m$, $\dot{q}''_{\mathrm{heater}} = 100 W/cm^2$ and $\dot{V} = 1 l/\mathrm{min}$. From Ref. [7].

There is still a need for a reliable and reproducible measurement technique to test the theoretical predictions and to provide fundamental thermophysical data for an efficient design of carbon nanotube based nanoelectronics. To fully understand the fundamental heat transport characteristics in the mesoscopic scale, reliable data of thermal conductivity for various sizes of nanotubes should

be collected in a reasonably precise manner. To this end, we developed a novel measurement technique based on the four-point-probe third-harmonic (3-ω) method with assistance of a focused ion beam (FIB) source for the fabrication of the needed experimental device [8,9].

We have employed the four-point 3-ω method for a carbon nanotube. However, the proposed method can be easily implemented to other nanosystems. With this method, the contact resistance was eliminated and spurious signals caused by it could be avoided. Hence, the contact contribution can be neglected in both the electrical and the thermal network. To construct a four-wire connection, a simple nanofabrication process was developed in which FIB milling was performed on a prefabricated microdevice (Fig. 10). The control of individual carbon nanotubes was realized by dielectrophoresis (Fig. 10). By applying a constant amplitude ac current through the carbon nanotube, we could generate a temperature rise fluctuating at the second harmonic and measure the 3-ω signal, which is used to compute the thermal conductivity. The multiwalled carbon nanotube used in this study shows a dissipative nature. MWCNTs are diffusive conductors. As a consequence, the one-dimensional heat diffusive equation along the nanotube suspended between two metal electrodes can be utilized to obtain a closed form solution of the third harmonic response [8,9].

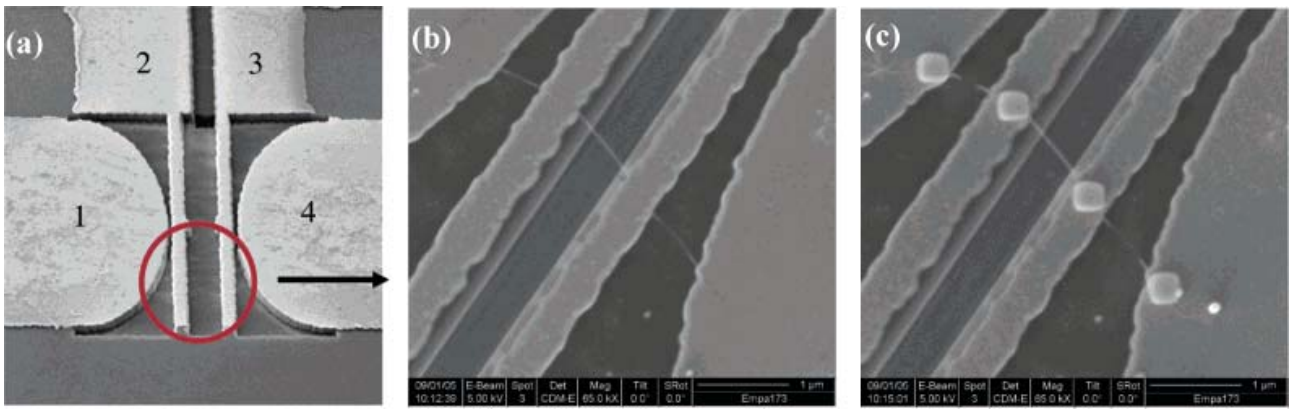

Figure 10. A series of pictures of a four-point-probe 3-ö experiment: (a) four-wire construction by focused ion beam milling; (b) selective deposition of single CNT by dielectrophoresis; (c) electron beam soldering at four contacts. From Ref. [8].

The measured value for the CNTs investigated in [8] is 300 W/mK. The dissipative nature of phonon transport has been verified with the measurement of 3-ω signal, which follows the third power law [8,9].

CLOSING REMARKS

Energy is arguably the most important technical and scientific challenge facing humanity as we enter the 21st century. Significant progress is required in all areas of energy conversion, energy transport and energy storage and conservation. Due to our increasingly mobile society, the capability of decentralized, transportable and personal power generation is becoming a major driver for emerging energy technologies. All the above must be achieved with a great sensitivity to the environmental impact of energy technologies, as the warning signals of the harmful impact of human activities on the environment have reached the danger level. Micro- and Nanotechnologies can significantly contribute to the emergence of the next generation of energy devices in particular

through the enabling of manufacturing of devices and materials with superior performance. Examples of such devices and materials were shown in the course of the lecture. Significant advances in experimental heat transfer and the related thermodynamics are central issues in many novel energy applications and in combination with the great potential of nanotechnology, they can surely be a major contributor to overcoming the energy challenge in years to come.

NUSSELT AND REYNOLDS NUMBERS IN THERMAL CONVECTION AT VERY HIGH RAYLEIGH NUMBERS

K.R. Sreenivasan
International Centre for Theoretical Physics
Trieste, Italy

ABSTRACT. By taking advantage of the unique properties of cryogenic helium gas, a concerted experimental effort has been made to study thermal convection over eleven decades of the Rayleigh numbers upwards of a million. The Nusselt and Reynolds numbers have been measured. The measurements are compared with theoretical results wherever possible. The results of these investigations will be discussed. Some aspects of quantized vorticity below the lambda point in liquid helium will also be presented. The talk will not assume any special knowledge of cryogenic helium.

Keynote Lectures

REALIZATION OF FUSION AS THE ULTIMATE ENGERGY SOURCE FOR HUMANITY

M. A. Abdou
Center for Energy Science and Technology Advanced Research (CESTAR), Los Angeles, USA
University of California-Los Angeles, Los Angeles, California, U.S.A.

ABSTRACT. Fusion promises to be the ultimate energy source for mankind, but the scientific and technological challenges are enormous. ITER, now being constructed in France is a major step in fusion research. But the most challenging stage of fusion development still lies ahead: the development of Fusion Nuclear Science and Technology (FNST). This stage will aim at developing the nuclear components surrounding the plasma, which are exposed to an extreme environment of high surface and volumetric heating, intense radiation fluxes, strong 3-component magnetic field, and many thermal/chemical/mechanical/electromagnetic interactions. The presence of these multi-function components in the unique and complex fusion environment leads to many new multi-physics, multi-scale phenomena and synergistic effects that require extensive worldwide R&D programs to understand and predict. A facility for development of FNST is required in addition to ITER.

Keywords: *Fusion, FNST, ITER, CTF, DEMO*

INTRODUCTION

Fusion has great potential to be a sustainable energy source with no emission of greenhouse or other polluting gases. However, fusion development has taken a relatively long time. When the viability, practicality, and economic competitiveness of fusion will be demonstrated is an open question. Our success in realizing practical fusion in the 21st century will depend in large measure on our understanding of the enormous engineering challenges that a fusion energy system involves and addressing them in an extensive R&D program, including the construction and operation of the appropriate facilities in a timely manner.

Fusion development from 1950 until today can be characterized as “exploring the physics of plasmas.” Fusion is now entering a new phase that can be generally called “exploring the physics of fusion.” This phase may take about 20 years with the primary research activities focused on the construction and operation of ITER, under construction by an international consortium in Cadarache, France, and the

Email : abdou@fusion.ucla.edu

National Ignition Facility (NIF) being constructed by the US in Livermore, California. ITER and NIF will investigate the physics of burning fusion plasmas in magnetic and inertial fusion, respectively.

The most challenging phase of fusion development will most likely be the R&D on Fusion Nuclear Science and Technology (FNST). This phase will aim at developing the nuclear components surrounding the plasma, which are exposed to an extreme environment of high surface and volumetric heating, intense radiation fluxes, strong 3-component magnetic field, and many thermal/chemical/mechanical/electromagnetic interactions. Nuclear components are located inside the vacuum vessel where tolerance for failure is low.

There are five pillars of a fusion energy system: *1-Confined and Controlled Burning Plasma, 2-Tritium Fuel Self-Sufficiency, 3-Efficient Heat Extraction and Conversion, 4-Safe and Environmentally Advantageous, 5-Reliable System Operation.* FNST plays the key role in all the last four pillars, i.e. 2-5. Yet, FNST has not yet received the priority and the resources needed in the world fusion program. The blanket is a central component of FNST. Yet, no fusion blanket has ever been built or tested. There exist no facilities that provide the necessary environment for meaningful testing of the fusion nuclear components.

ITER will provide the first fusion nuclear environment in which blankets can be tested and data relevant to FNST obtained. While testing in ITER provides very important information on FNST, it is severely limited. Development of FNST will require a new facility designed specifically to test and develop fusion nuclear components. This type of facility for fusion nuclear science and technology is often called CTF (Component Testing Facility) or VNS (Volumetric Nuclear Source).

WHAT IS FUSION NUCLEAR TECHNOLOGY?

Fusion Nuclear Technology (FNT) includes all components from the edge of the plasma to the toroidal field coils, i.e. First Wall/Blanket, vacuum vessel and shield components, and other plasma interactive/high heat flux components (divertor, r.f. antennas/launchers/waveguides, diagnostics). These components are illustrated in a vertical cross section of a tokamak reactor in Fig.1. Other components coupled to and affected by the nuclear environment include Tritium Processing Systems, Instrumentation and Control Systems, Remote Maintenance Components, and Heat Transport and Power Conversion Systems. Many technical areas are essential to FNT; for example, neutronics, materials, thermomechanics, thermofluids, magnetohydrodynamics, safety, solid mechanics, radiation effects and chemistry.

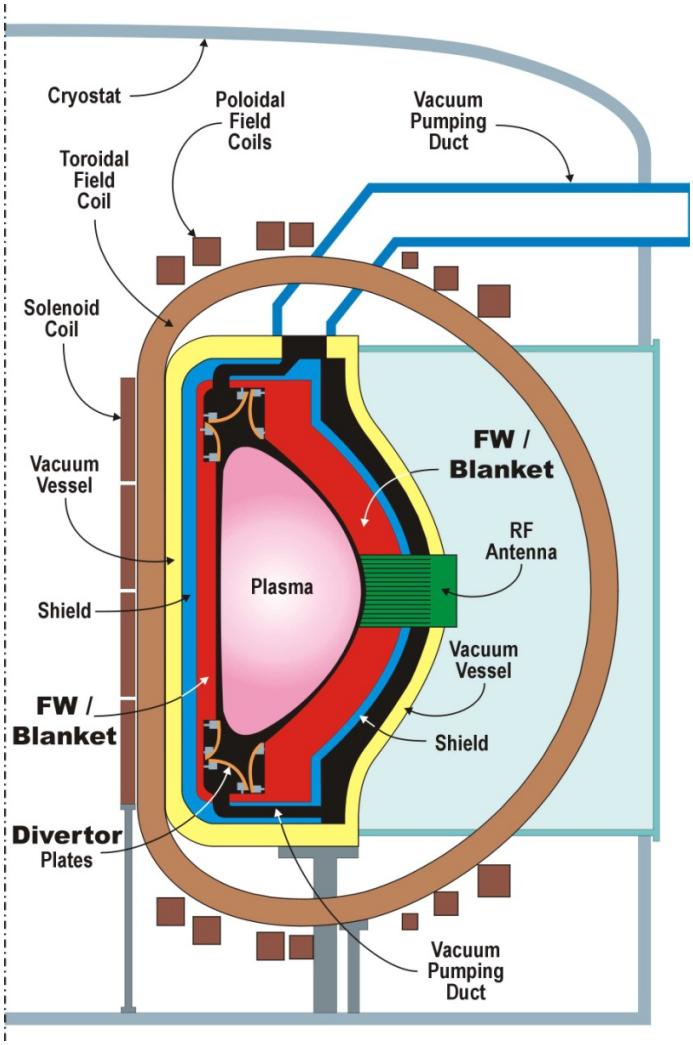

Figure 1**.** Vertical Section of a Tokamak Reactor that shows the fusion nuclear components

FNT components, particularly the blanket/first wall/divertor must operate safely and reliably in a harsh environment. Yet, no fusion blanket has ever been built or tested. Blanket systems have many possible designs, materials, and configurations. Many blanket concepts have been proposed worldwide, see Table 1, each having its own balance of feasibility and attractiveness issues. Only after stages of fusion environment testing can an informed down-selection be made. The large number of concepts and wide range of issues are best screened by utilizing the resources and the ingenuity of the world's FNT programs.

ITER AND TEST BLANKET MODULE (TBM)

ITER is a tokamak, in which strong magnetic fields confine a torus-shaped fusion plasma. It will be the first fusion reactor to create more energy than it uses. The objectives set out for ITER are basically two: 1) programmatically, to demonstrate the scientific and technological feasibility of fusion energy for peaceful purposes; and 2) technically, to demonstrate extended burn of DT plasmas, with steady state as the ultimate goal; to Integrate and test all essential fusion power reactor technologies and components, and to demonstrate safety and environmental acceptability of fusion. Breeding blankets represent one of the major technological breakthroughs required from passing from ITER to the next step, usually called DEMO, a demonstration reactor able to furnish electric power to the grid. For this reason, among the technical objectives of ITER it is specifically stated that "*ITER should test tritium breeding module concepts that would lead in a future reactor to tritium self-sufficiency and to the extraction of high-grade heat and electricity production.*"

Test Blanket Modules (TBMs) inserted in ITER represent a principal strategy by which ITER will provide the first experimental data on the potential of fusion as an energy source. TBMs are essential to answering two critical questions about fusion as an energy source: "*Can tritium be produced in the blanket at a rate sufficient to supply tritium to fuel the plasma?"* and *"Can heat be extracted from the blanket, simultaneously with tritium breeding, at temperatures high enough for efficient electricity generation?"* This is why successful TBM experiments in ITER represent an essential step on the path to DEMO in all the ITER Parties' fusion development plans. A *principal mission* of the ITER Test Blanket Module (TBM) Program is to develop, deploy, and operate ITER TBM experiments that provide unique experimental data on, and operational experience with, the integrated function of blanket and first wall (FW) components and materials in a true fusion environment. This data is essential for validation of the scientific understanding and predictive capabilities; demonstration of the principles of tritium self-sufficiency in *practical* systems; development of the technology necessary to install breeding capabilities in next-step machines; and providing the first integrated experimental results on reliability, safety, environmental impact, and efficiency of fusion energy extraction systems.

The overall ITER operational plan through the first ~10 years is preceded by one year of integrated commissioning of in-vessel components. The 10-year plan includes 2.5 years of initial H-H operation; a brief D-D phase; and an approximately six-year-long D-T phase. During the D-T phase, typical operating conditions for the TBMs include an average FW surface heat flux of 0.27 MW/m^2 (during a plasma pulse), a neutron wall load of 0.78 MW/m^2 (during a plasma pulse), and a pulse length of 400 s (or longer) with a duty cycle of 22% (or higher). These parameters are used in the conceptual designs of Parties' TBMs. Other important conditions of ITER that allow for meaningful integrated testing of blanket components and material systems include a strong magnetic field (~ 5 T) of the same order as in power plants, and off-normal plasma events such as disruptions, ELMs, VDEs, *etc*.

Three 1.75 m wide × 2.2 m high equatorial ports have been allocated by ITER for TBM testing. Test modules must be recessed 50 mm from the nominal surface of the first wall of the ITER shielding blanket in order to reduce plasma-wall interaction effects, including the maximum disruption energy load (0.55 MJ/m^2 over 1-10 ms). Correspondingly, a 2 mm beryllium protection layer on the FW is requested.

Each TBM is supported by a water-cooled steel frame that has a thickness of 200 mm on each side of the TBM and a backside shield behind each TBM. The TBM is inserted from the plasma side into the frame and supported from behind by attachment to the backside shield block with flexible supports. Each frame can hold two vertically or horizontally oriented TBM backside shield pairs. This combined unit is known as the TBM port plug, and provides a standardized interface with the ITER basic

structure, including thermal insulation of the basic machine from the TBM. The port plug is inserted though the bioshield and into the port as a single unit.

Each TBM system includes several associated sub-systems, such as coolant loops, tritium management equipment, a liquid breeder loop (in liquid breeder TBMs), instrumentation packages and control systems, and safety systems. These sub-systems will need to interface with the ITER facility and services, including remote handling equipment, the hot cell facility, the ITER standard cooling system, the HVAC, diagnostic, and control and safety systems, each with its corresponding operational procedures and limitations. Any equipment and interfaces necessary for a particular TBM will have to match the space and services available at each test port. Three blanket options, in which liquid metal MHD plays an important role in determining blanket performance, have been proposed for testing in ITER. They are a helium-cooled PbLi (HCLL), a dual-cooled PbLi (DCLL), and a dual-function PbLi (DFLL) blanket concept. The common MHD problems among the three concepts relate to the MHD flow distribution for complex flow elements including toroidal manifold flow distribution, contractions/expansions in poloidal plane, and MHD velocity profile in electrically-coupled multiple ducts. In the HCLL blanket, liquid metal circulation is primarily required for tritium removal. Larger flow rates are desirable in order to keep the tritium permeation losses low. A specific MHD question on the HCLL concept addresses the coupled effect of the MHD velocity magnitude and profile on alleviating the tritium permeation problem. The basic idea of the DCLL blanket is to use helium to remove all heat deposited in the blanket structure (including the surface heat flux on the first wall), and a flowing, self-cooled, PbLi alloy breeder to remove nuclear heat generated in the breeding zone – at a high temperature for efficient power conversion. The DCLL concept consists of PbLi channels contained within a helium-cooled structure made of reduced activation ferritic steel (RAFS). A unique MHD problem for this particular concept relates to the effect of natural convection on the MHD flow and temperature distributions. Both DCLL and DFLL concepts require the use of an insulator such as SiC/SiC flow channel insert (FCI) for pressure drop and thermal loss control. Such a FCI performs two important functions: (a) the FCI thermally insulates the PbLi so that its temperature can be considerably higher than the surrounding structure, and (b) the FCI also provides electrical insulation between the PbLi flow and the thick, load-bearing RAFS walls to reduce the MHD pressure drop to a manageable level, even in high magnetic field regions. MHD related R&Ds have been identified under the IEA collaborative efforts, including toroidal expansion and toroidal manifold MHD experiments.

In addition, it is necessary to ensure that the TBMs are compatible with the tokamak operation. Several issues driven by the interaction of the test blanket module and the magnetic field that must be characterized and investigated during the hydrogen plasma operation phase including:

- interference of the test modules with plasma confinement, including the effects of ferritic/martensitic steels on the ITER magnetic confinement fields;
- operation of the test modules, diagnostics, and supplementary equipment in a strong magnetic field;
- test module structural loads and corresponding responses owing to surface heat flux on the test module first wall during normal plasma discharges, and including spatially non-uniform heat fluxes, for instance, from plasma MARFEs;
- test module structural loads and corresponding responses during tokamak startup and shutdown, including transient events like plasma disruptions; and
- material erosion and transport from the test module first wall and the necessity of using a beryllium protective layer (current requirement is for a 2 mm Be layer).

These issues also present challenging opportunities for the PAMIR Community.

FRAMEWORK FOR FNT DEVELOPMENT

The technical foundations for the fusion nuclear technology development path to DEMO are based on many previous technical studies led by the US and other countries over three decades. Examples of references that provide the technical basis are References [1], [2], and [3]. These comprehensive studies concluded that blanket development is one of the key components on the critical path to DEMO. The major elements of the proposed blanket development path to DEMO are illustrated in Fig. 2. They are:

Base R&D activities with nuclear and non-nuclear experiments in *non-fusion* facilities; and modeling and computer simulations

Testing Blanket Modules (TBM) in ITER during Phase 1 of operation

Continuous transfer of information from ITER TBM and base R&D into the refinement of blanket designs and the construction of blanket test modules, and possibly breeding blankets, in CTF

Testing in CTF that addresses the engineering development and reliability growth of blankets to a level sufficient to design, construct and operate full breeding blankets in DEMO.

It is important to understand the relationship and incremental role of each of these elements. A detailed description is given in reference 6.

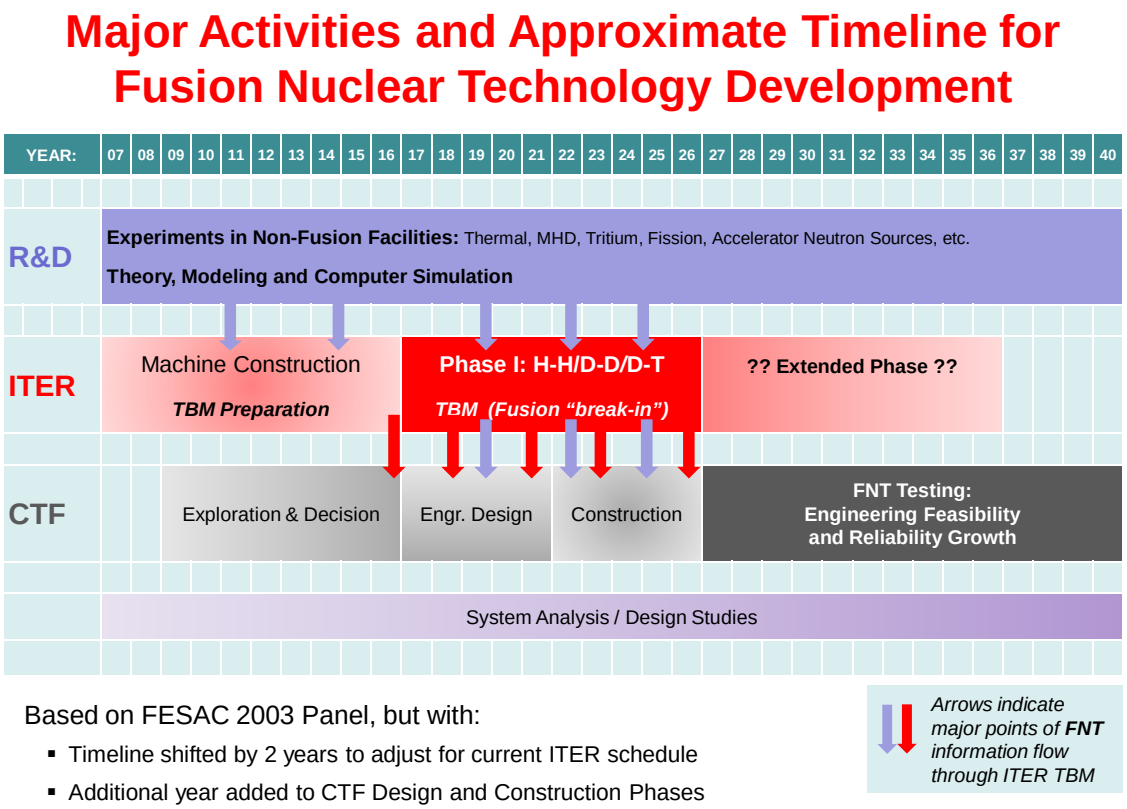

Figure 2. Major Activities and Approximate Timeline for FNT Development

These main FNT development path elements are made up of many progressive R&D activities, as illustrated in Fig. 3. Note that tests in non-fusion facilities are limited to single-effect and some multiple-interaction tests. Fusion tests are needed to cover several multiple-interaction tests, integrated tests, and component tests.

In partial analogy to experience from technology development in other fields, we propose that testing and development of FNT (primarily the blanket) in fusion facilities proceed in three stages: (I) initial fusion environment "break-in"; (II) engineering feasibility and performance verification; and (III) component engineering development and reliability growth, as illustrated in Fig.4.

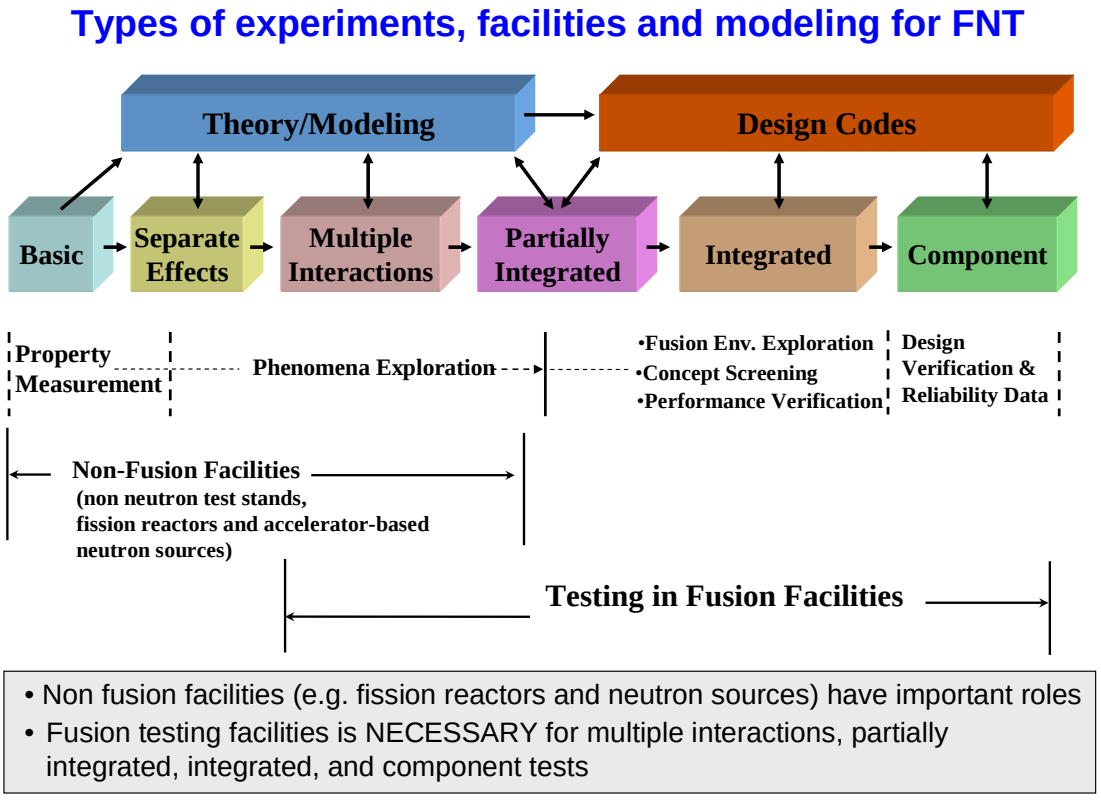

Figure 3. Types of Experiments, Facilities, and Modeling for FNT

We note again that FNT components such as the blanket have never been tested before in any fusion facility. Therefore, the Stage I testing should be focused on calibration and exploration of the fusion environment, including uncovering unexpected synergistic effects and testing experimental techniques and diagnostic tools (e.g. how to measure and collect data, interpret and extrapolate results, and include the effects of the fusion environment on instrumentation tools). Part of the Stage I fusion environment exploration is screening a number of candidate design concepts. Only a limited number of concepts are tested in Stage II, which aims at engineering feasibility and performance verification. Modules with a representative size should be used in this stage to ensure that all the key aspects of subsystem interactions are tested. Results of tests in Stage II should permit selection of a very small number of concepts, but selection of a single concept is too risky, prior to performing reliability growth tests in

Stage III. Stage III tests focus on true engineering development where actual prototypical components are tested and an aggressive design/test/fix iterative program is instituted. The extensive reliability testing required to achieve blanket availability goals is one of the primary reasons why blanket testing determines the critical path for FNT development.

The role of ITER TBM is to provide the Stage I testing needs, while the CTF mission is to perform the testing required in Stages II and III.

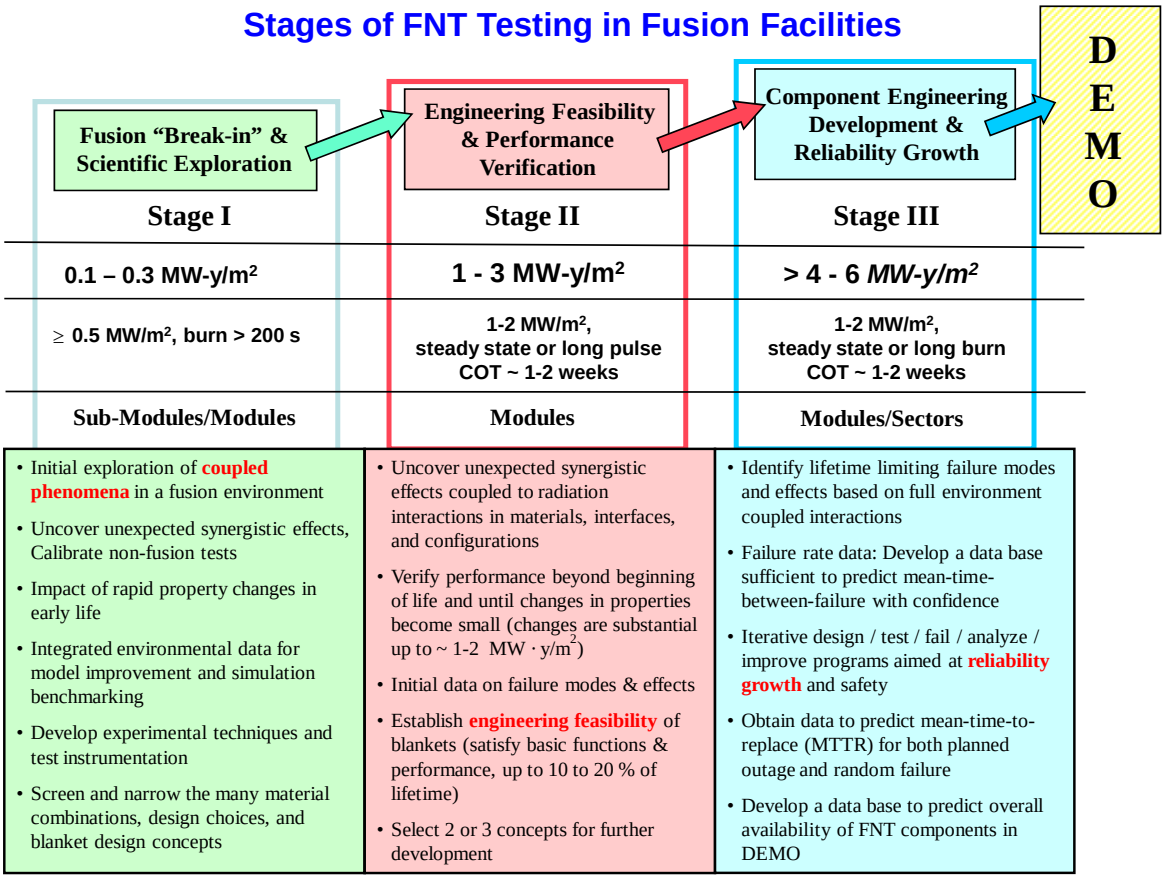

Figure 4. Stages of FNT Testing in Fusion Facilities

DEMO GOALS

DEMO requirements are a strong driver for the need for such an FNT development path, as described above. Previous system and planning studies provide general goals and features of DEMO. All studies and planning activities conclude that the DEMO must achieve tritium self-sufficiency. Another conclusion is that at least one option must be validated for each component prior to construction of DEMO. The goal of fusion R&D plans around the world is the operation of a demonstration power plant (Demo), which will enable the commercialization of fusion energy. The target date is typically 20-40 years from now. Early in its operation the Demo will show net electric power production, and ultimately it will demonstrate the commercial practicality of fusion power. It is anticipated that several such fusion demonstration devices will be built around the world. In order for a future fusion industry to be competitive, the Demo must:

a) achieve tritium self sufficiency; b) be safe and environmentally attractive;
c) extrapolate to competitive cost for electricity; d) use the same physics and technology as the first generation of competitive commercial power plants to follow; and
e) achieve availability of ~ 50%, and extrapolate to commercially practical levels.

The most difficult and time consuming stage in FNT development is expected to be the "reliability growth phase." Prior studies, *e.g.* Refs. [1] and [4], have shown that the availability of the blanket system must be higher than 88% to meet a Demo target availability goal of 50%. Since the time to replace blankets is long (weeks), the Mean-Time-Between Failures (MTBF) must be long to achieve such a high availability target goal. Current assessments, again see *e.g.* Ref. 1, show that (A) the MTBF for a single blanket module must be considerably longer than its fluence lifetime, and (B) the required blanket system MTBF is longer than what is achievable based on extrapolations from other technologies. Therefore, an aggressive reliability growth program needs to be pursued for the blanket, which will require a large testing area and long testing time to achieve a reasonable confidence level. This is one of the major objectives of CTF. Early data from R&D and ITER TBM should help screen blanket concepts in order to allow CTF to focus quickly on engineering development and reliability growth testing of a very small number of blanket concepts (preferably two).

CONCLUSIONS

Fusion nuclear components must operate safely and reliably in a harsh environment. No fusion blanket has ever been built or tested. Hence, their integrated function and reliability are by no means assured. ITER presents the first opportunity to test blanket materials and components in an actual fusion environment after many years of research, development and design in domestic programs. ITER test blanket module (TBM) testing represents a critical step toward establishing the principles of tritium self-sufficiency and energy extraction – on which the feasibility of deuterium-tritium fusion energy production relies. The role of ITER TBM is to provide the Stage I Fusion Break-in testing needs. The CTF mission is to perform the testing required in Stages II and III.

Fusion Nuclear Science and Technology (FNST) development is the most difficult challenge remaining in the practical realization of fusion as a practical energy system. The cost of R&D and the time to DEMO and commercialization of fusion energy will be determined largely by FNST.

Solar Hydrogen Production

H. Müller-Steinhagen*, M. Neises, M. Roeb, C. Sattler
Deutsches Zentrum für Luft- und Raumfahrt e.V. (DLR)
Institute of Technical Thermodynamics, Germany

Abstract. The potential of hydrogen to become the energy carrier of the future is widely accepted. Today more than 90% of hydrogen is produced from fossil sources, mainly by steam reforming of natural gas and by coal gasification. To finally benefit from hydrogen as a fuel, it has to be produced in large quantities without emission of greenhouse gases. Solar thermal processes have the potential to be the most efficient technologies for large scale hydrogen production in the future. Therefore, high temperature solar technologies are under development for the different steps on the way to renewable hydrogen. This paper discusses the general research strategy for a spectrum of solar processes incorporating carbonaceous materials as well as splitting of pure water.

Keywords: *solar, hydrogen, thermochemical cycles, CSP, steam methane reforming*

INTRODUCTION

The potential of hydrogen to become the energy carrier of the future is widely accepted. At present, about 50 million tonnes of hydrogen are produced per year, with an annual increase of about 6 % [12]. More than 90% of this amount is produced from fossil sources, the other 10% mainly by electrolysis using power from the grid. 95 % of the hydrogen is directly used in chemical industry for the production of ammonia, methanol, and for refining.

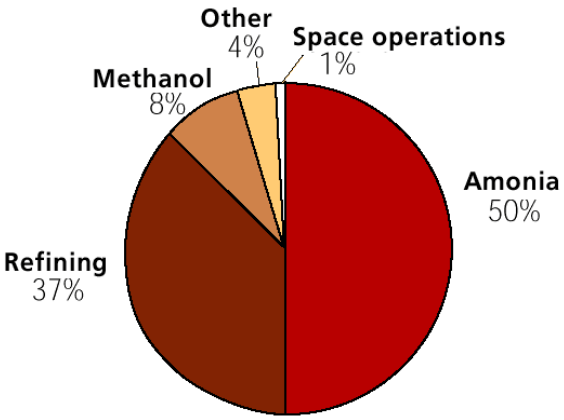

Figure 1: Use of hydrogen in 2002 [1].

Today the only energetic use of hydrogen worth mentioning is as a propellant in space operations for example in rocket engines like the Vulcain of the Ariane-5 [3,4].

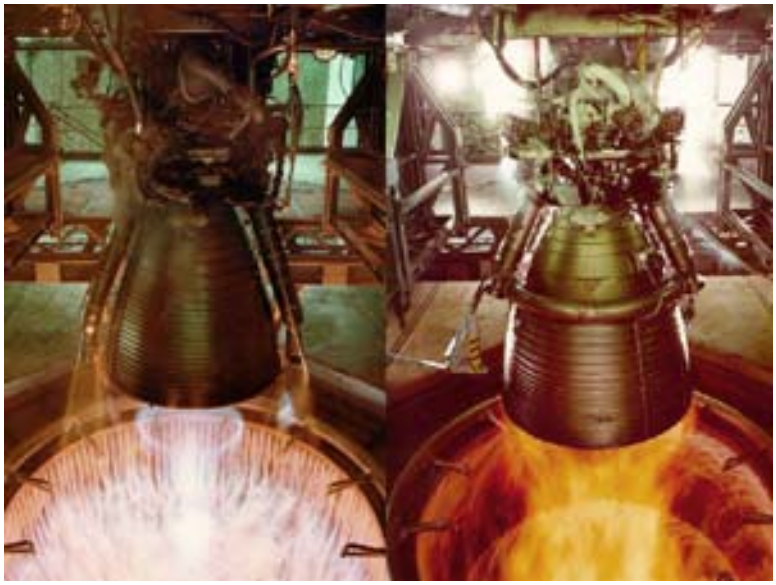

Figure 2: Vulcain-1 (left) and Vulcain-2 (right) rocket engines heat-up test at DLR Lampoldshausen, Germany.

Therefore, the change to a hydrogen based energy economy which is worldwide supported and already prepared by international initiatives such as the International Partnership for the Hydrogen Economy, IPHE [5,6], the International Energy Agency, IEA [7], or the European Hydrogen and Fuel Cell platform and the Joint Technology Initiative [8,9,10,11,12] will be very challenging. To finally benefit from hydrogen as an energy carrier, especially for transport sector, it has to be produced without greenhouse gas emission. To become accepted by users, it will initially have to become desirable and available for niche applications, and then affordable to reach the mass market. Also, the basic supply infrastructure will have to be established.

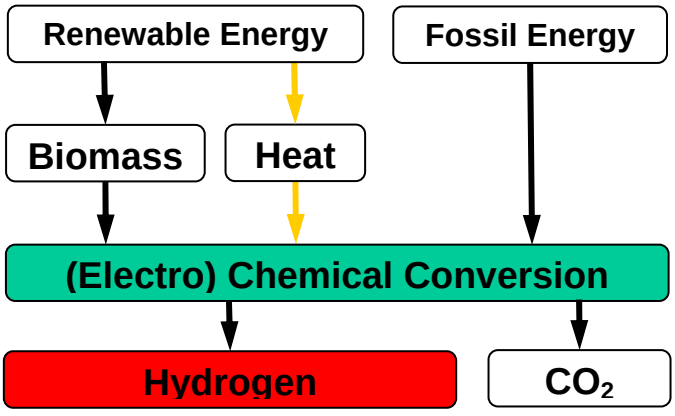

Figure 3: Hydrogen production routes.

These criteria have to be connected by a strategy incorporating transition steps. The efficiency and applicability of the chosen production processes as well as technologies for storage and conversion are the most important conditions for a successful implementation of a hydrogen economy. On this pathway, the focus will move from desirable, available and applicable to efficient, affordable, and sustainable.

In the present paper, cost estimates from many different sources for industrial scale production of hydrogen are provided. Most of the prices are based on models and theoretical studies. Therefore,

they are neither consistent nor real values. Nevertheless, they indicate that numerous authors care about market introduction of hydrogen as an energy carrier, and demonstrate the importance of the harmonization of the calculation procedures.

CURRENT INDUSTRIAL HYDROGEN PRODUCTION

Steam methane reforming (SMR)

SMR is currently the least expensive and most common method for hydrogen production. The feedstock is mainly natural gas (NG), which is primarily composed of methane mixed with some heavier hydrocarbons and CO_2 as well as some impurities which need to be removed [13].

Initially, NG is hydrogenated at 350-450 °C to convert sulphur impurities into H_2S which is removed over a ZnO bed forming ZnS and H_2O. Upon preheating at 450 to 650 °C NG is injected into the reforming reactor together steam in excess of stoichiometry. The reactor pressure varies from 2 to 3 MPa and its temperature from 850 to 950 °C. Most of the industrial SMR is done in externally heated tubular reactors using catalysts.

The reforming reaction never reaches completion. It yields a gas mixture of H_2, CO, H_2O, CH_4, and CO_2. This has to be processed over several steps to obtain sufficiently pure H_2. The first step is the water gas shift (WGS) reaction where CO is converted into CO_2 producing additional H_2, followed by the separation of H_2 and acid gases (CO_2 and remaining H_2S).

(1) $$CO + H_2O \rightarrow CO_2 + H_2$$

Classical regenerative chemical or physical absorption techniques are used for this purpose. The final step allows the separation of the remaining impurities from H_2 using a Pressure Swing Adsorption (PSA) unit. This PSA works at 2 to 2.5 MPa based on the selective adsorption on a molecular sieve. Three to four columns are used for continuous hydrogen production, working in alternative mode: while one is adsorbing and purifying the gas, the others are regenerated (depressurization, rinsing, pressurization). Standard PSA units achieve H_2 purities above 99.9 %.

Depending on the plants and their optimization levels (gases recirculation loop, heat exchangers), the thermal efficiency varies from 65 to 75 % [1]. The production of 1 kg H_2 by means of SMR yields 9.42 kg of CO_2 emissions [14]. The production cost of hydrogen is between 5.97 and 7.46 $/GJ (0.57 and 0.74 €/kg) [15].

Coal gasification

The oldest technology for hydrogen production is coal gasification. Here, coal is introduced into a gasifier at temperatures between 750 and 1500 °C, depending on reactor type, with air or oxygen as reactants and steam as temperature moderator. Three types of reactors are commonly used:

- fixed bed (Lurgi)
- fluidized bed (Winkler/Lurgi)
- entrained flow (Koppers-Totzek, Texaco)

These reactors work under different operating pressures:

- atmospheric (Koppers-Totzek – 1480 °C)
- up to 10 MPa (Texaco at 4.2 MPa – 1350/1450 °C)

[1] Thermal efficiencies for steam methane reforming and coal gasification have been calculated using data extracted from the *E3 Database* (software tool to create energy chains for individual processes, used in the project HYWAYS), which provides an assessment of consumables for a given plant, in particular natural gas consumption in kWh per kWh of produced hydrogen.

The produced syngas consists primarily of H_2, CO, CH_4 and CO_2. After several separation and purification steps, technically pure hydrogen is obtained. Industrial plants have thermal efficiencies ranging from 45 % to 60 % [1] depending on the requirement of coal crushing, O_2 supply and/or gas compression units. For Koppers-Totzek (58%) and Texaco (63%) more precise values are available [45]. Typical amounts of CO_2 emissions are about 23 kg CO_2 / kg H_2 [16]. Hydrogen cost for a coal gasification plant with a production of 2.8 million Nm³/day amounts to 11.57 $/GJ H_2 (1.15 €/kg), the underlying coal price in this case is unknown [15]. Today, there are large coal gasification plants in Europe, South Africa and the USA, and technologies for gasification of coal are the subject of significant R & D efforts by the coal industry.

The Lurgi Process (Fixed-Bed)

Different descriptions of the Lurgi Process are reported. For example, the reactor has been described as fixed-bed and as well as moving bed. The present authors decided to use the more plausible fixed bed option. The original Lurgi gasifier was developed in 1936. In a vertical water cooled pressure vessel coal is intermittently charged from above through a lock-hopper. The coal movement is controlled by a distributor. Steam and O_2 (or air) are injected through a rotary bottom grate, which is also used for the extraction of the residual dry-ash. The Lurgi gasifier requires large quantities of steam to reduce the combustion zone temperature below the ash fusion temperature. The temperature is about 1000 °C near the bottom and about 500 °C near the top. Because of the low temperature and the lack of O_2 in the devolatilization zone, the product gas contains a high content of hydrocarbon liquids which are separated by cooling. A standard Lurgi unit is 4 m in diameter and has a nominal dry gas capacity of 55,000 m³/h (= 600 t/d moisture ash free coal) [17].

The Winkler Process (Fluidized-Bed)

Fluidized bed systems are operated between 800 and 1100 °C, depending on the coal reactivity, to avoid ash fusion in the gasifier. At these temperatures, the coal is converted primarily into CO, H_2 and CO_2 and small amounts of CH_4. The coal is supplied as a powder and maintained in a suspended state of continuous random motion, by the gasified agent [17].

Due to the fact that gasifier exhaust temperatures match hot gas clean-up and purification temperatures, these systems have a better overall efficiency than entrained flow systems, which require cooling before clean-up. In comparison to moving bed reactors, fluidized bed units have higher coal mass flow rate, thus reducing the size and the cost of the unit. Low temperature and high pressure fluidized bed gasification processes produce more CH_4 and synthesis gas, thus requiring less O_2 and having an increased efficiency. However, there are also several disadvantages such as narrow particle size distribution, agglomeration of feed coal which lowers the gasification rate, and high dust content of the raw gas due to the grading effect of the gas stream [17].

A typical Winkler gasifier is 5.5 m in diameter and 23 m high. It can gasify approximately 1100 t/d of coal under atmospheric pressure [17].

The Koppers-Totzek Process (Entrained-Bed)

Coal is first pulverized then gasified in a mixture of steam and air (or O_2). The products must be cooled down before purification, which reduces the thermal efficiency. These entrained flow systems produce only little CH_4, are relatively compact, and have short reaction times because of their high operating temperatures (1040 – 1540 °C). The gasifiers are insensitive to almost all pulverized coal with a certain particle size. Due to the requirement of a high temperature and therefore a high O_2 consumption, the process has a lower thermal efficiency than fluidized and moving bed systems. The synthesis gas is relatively free of tars, hydrocarbons heavier than CH_4 and nitrogen compounds.

Most of the Koppers-Totzek gasifiers are using two burner heads. They have an internal diameter of up to 3.5 m, a height of about 7.5 m, and an internal volume of approximately 28 m³. Their nominal

dry gas capacity is 17000 m³/h (= 210 t/d of moisture-ash-free coal. Additionally, four-burner-head models with 56 m³ are in operation and a six–burner gasifier is being developed [17].

IMPLEMENTING CONCENTRATED SOLAR ENERGY

The success of a hydrogen economy is dependent on the availability of the energy carrier H_2. Since the present infrastructure is mainly based on (non-renewable) fossil resources, it may be logical to start from this point. Sequestration of CO_2 is a widely discussed opportunity to reduce greenhouse gas emissions (GHG) but research is at the very beginning. Concentrated solar technologies on the other hand are in operation and under further development for since several decades. Hence, it is advantageous to combine the established production processes with (renewable) solar energy to firstly reduce GHG emissions. This initial application of solar technology will foster the possibility to develop processes that ultimately are based on water splitting, only.

At present some fossil/solar hybrid processes are already under development.

Solar Tower Power Plants

The basis for using solar thermal technologies in bulk conversion technologies is their ability to provide heat at a temperature level of at least 900 °C in the multi MW range.

Figure 4: First commercial solar tower power plants PS-10 in operation and PS-20 under construction (Seville, Spain).

All solar technologies described in the following are based on technology derived from solar tower (or central receiver) power plants. The inauguration of the first commercial solar tower power plant PS-10 in June 2007 near Seville, Spain, demonstrated that this technology has the potential to generate electricity in large-scale facilities. It now has to show that it can also be integrated into more complex processes.

CARBON BASED TRANSITION PROCESSES

Since SMR is the most common process for hydrogen production it is obvious that the first intermediate technology to be worked on was the solar steam reforming of methane-rich gas. This technology is already on a several 100 kW scale. It combines the economical efficiency of SMR with solar thermal heat leading to partially renewable hydrogen production with reduced CO_2 emissions. Besides NG, other fossil resources like coal or petcoke are also under investigation for solar thermal conversion. A further step will be the decomposition of methane into hydrogen and carbon. With this, less resource intensive hydrogen is produced and the carbon remains as a solid which may either be used or stored. Solid storage is much easier than the sequestration of gaseous CO_2. The use of biomass as feedstock may enhance the sustainability of all hybrid processes.

Solar Reforming of Natural Gas

Using a solar thermal reactor, many of the required unit operations are similar to industrial SMR. Natural gas is converted using concentrated solar energy to generate a hydrogen rich gas. Afterwards, the WGS-reaction is applied. The reforming of natural gas using solar energy has been investigated since the 1980s. Reformer efficiencies from 85-90 % are reported. Basic solar plant costs have been estimated at 1322 €/kW_e for a 100 MW_e central receiver gas turbine plant. Solar heat is delivered at 0.0164 \$/kWh_{th} (0.0135 €/kWh_{th}) which finally results in H_2 production costs of 0.0264 \$/kWh_{th} (0.73 €/kg) [18]. These numbers are very optimistic compared to the industrial process, but show that the gap between fossil and fossil/solar hybrid is quite small.

The technical feasibility of solar reforming with LPG as feed stock and combustion of the product gases in a gas turbine to generate electricity was successfully demonstrated in the SOLASYS project. During the solar reforming test period, the solar reformer was operated in the power range 100-220 kW producing synthesis gas at 8.5 bar and 760 °C [19,20]. Currently, within the European project SOLREF, this process is further developed.

Recently, the 400 kW_{th} SOLREF reactor was installed on the solar tower of the Weizmann Institute of Science (WIS), Rehovot Israel. The plant is designed to be very close to an industrial installation. Forthcoming test campaigns will demonstrate how such installations can be operated under semi-industrial conditions.

Figure 5: The SOLREF reactor installed on the WIS solar tower.

Solar Gasification and Reforming of Petcoke

Solar reforming of petcoke uses fossil fuels that are not suitable for conventional refining. Upgrading with concentrated solar power as energy source may make large carbon resources accessible. The gasification process strongly depends on its temperature, pressure and C/O_2 ratio. The chemical product of the process is synthesis gas. Above 1000 °C, gasification yields a pure gas phase containing H_2 and CO. Solar energy acts as carbon saver since 50% of feedstock is substituted.

Solar and simulated solar heated gasification of petcoke samples from the Orinoco Basin was successfully performed at laboratory scale and at 5 kW solar furnace scale by ETH Zurich, CIEMAT, and PDVSA [21]. The hydrogen generation cost are estimated to about 2.1 €/kg H_2 [22].

Solar-assisted Coal Gasification

Solar-assisted coal gasification is closely related to the conventional process, but the use of solar energy results in a significant contribution of about 30 % renewable energy to the products. Unlike SMR, coal gasification involves solid materials, and thus the design of a solar-driven coal gasification reactor is much more technically challenging [23].

Some small-scale R&D work has been done by the Research Centre for Carbon Recycling and Utilization at the Tokyo Institute of Technology. In their experiments, molten salts provide a thermal storage system that allows the reaction to proceed in a stable manner under the conditions of intermittent solar energy supply. These conditions have been studied at laboratory scale. Due to the utilization of molten salt and the better contacting of CO_2 with the coal particles in the melt, higher reaction rates have been achieved [23].

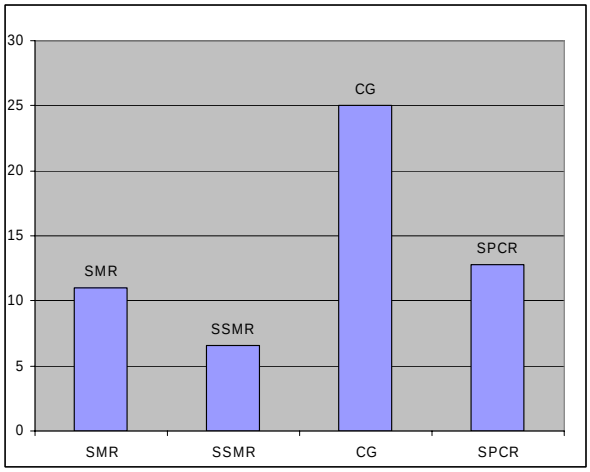

Figure 6: CO_2 production in carbon containing processes [kg CO_2 /kg H_2].

WATER BASED PROCESSES

Long term technologies should be solely based on the water splitting reaction.

(2) $$H_2O \rightarrow H_2 + 1/2\,O_2$$

Electrolysis powered by renewable (or nuclear) energy seems to be the way since it is an established technology. However, since the 1970s extensive work was done on thermal processes because they are predicted to have higher efficiencies and lower cost. The easiest reaction for the production of hydrogen is the thermal decomposition of water (eq. 2) which directly yields pure hydrogen [24]. However because of unfavourable thermodynamics, relevant yields can only be achieved at very high temperatures above 2500 °C, resulting in tremendous technological problems with materials selection and the attempt to incorporate solar energy as the driving energy for the reaction [25].

Especially in the 1970s to 1990s significant work was done on this problem [26, 27, 28, 29, 30, 31, 32, 33]. The feasibility of water-splitting was demonstrated experimentally at the Weizmann Institute of Science in Israel [33] and in France [34].

Current efforts on the solar chemistry for water splitting and hydrogen production are focused on processes for water splitting at lower temperatures [35].

Metal/Metal oxide Thermochemical Cycles

From all technological possibilities the most interesting is the thermochemical two-step water splitting process using redox systems. According to this idea, during the first step (water splitting)

the reduced and therefore activated material (usually a metal oxide) is oxidized by taking oxygen from water and producing hydrogen according to the reaction:

(3) $$MO_{reduced} + H_2O \rightarrow MO_{oxidized} + H_2$$

During the second step (re-generation) the material is reduced to be used again, delivering some of the oxygen of its lattice according to the reaction:

(4) $$MO_{oxidized} \rightarrow MO_{reduced} + O_2$$

The advantage of this process is the production of pure hydrogen without having to separate hydrogen and oxygen. The challenge is the realisation of a two-step process consisting of a splitting and a regeneration step. The redox materials that have been evaluated consist of oxide pairs of multivalent metals (Fe_3O_4/FeO [36], Mn_3O_4/MnO [37, 38]) or systems of metal oxide/metal (e.g. ZnO/Zn [39, 40]). Water splitting is taking place at temperatures below 900K while the reduction of the metal oxide, i.e. the regeneration, takes place at much higher temperatures. Using solar concentrated energy at temperatures above 1600 °C, Fe_3O_4 can be transformed into FeO. This is followed by the exothermic reaction of FeO and H_2O at much lower temperatures where H_2 and Fe_3O_4 are generated. The concept has been proven experimentally [41 , 42]; however the regeneration temperatures are still high, imposing a barrier to the integration of two-step water splitting processes a concentrating solar systems. Also, knowledge gaps in chemical thermodynamics and their impact on reactor design and process performance exist for these extreme conditions [36].

With an activated redox system, the reaction temperature for the two-step water-splitting process can be reduced. Within the scope of the EU-funded HYDROSOL project, the H_2 production was proven at experimental scale [43]. The reactor system works on a level of 15 kW_{th} in a quasi-continuous way. It consists of two reactors in which both reaction steps are carried out in parallel.

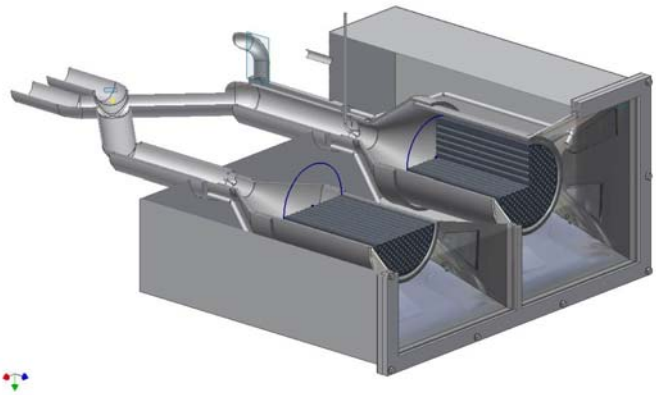

Figure 7: Reactor for quasi continuous H_2 production.

In a test campaign using the solar furnace at DLR Cologne (see Fig. 8), the reactor efficiency η_r of the research reactor and the efficiency related to the higher heating value of the produced hydrogen η_{HHV} were determined.

(5) $\eta_r = Q / P_s$

(6) $\eta_{HHV} = Q_H / P_s$

$Q = \Sigma H_{products,\ reactor\ exit} - \Sigma H_{educts,\ reactor\ entry}$
Q_H = higher heating value of H_2 produced
Ps = radiation power

For η_r for the whole process 24 % were achieved over one day. The efficiency of the production of hydrogen (related to the higher heating value) η_r was 4.4 %. This is a good starting point for the

improvement of this process, considering that the reactor is of very small scale and neither the reactor nor the redox system is optimized as yet. In addition, Kolb et al [44] predicted the potential of such technology when implemented in a multi-Megawatt solar tower system. According to their analysis annual solar-to-hydrogen efficiencies are 5-7 percentage-points higher than those of a comparable solar plant producing electricity and applying alkaline electrolysis for hydrogen production.

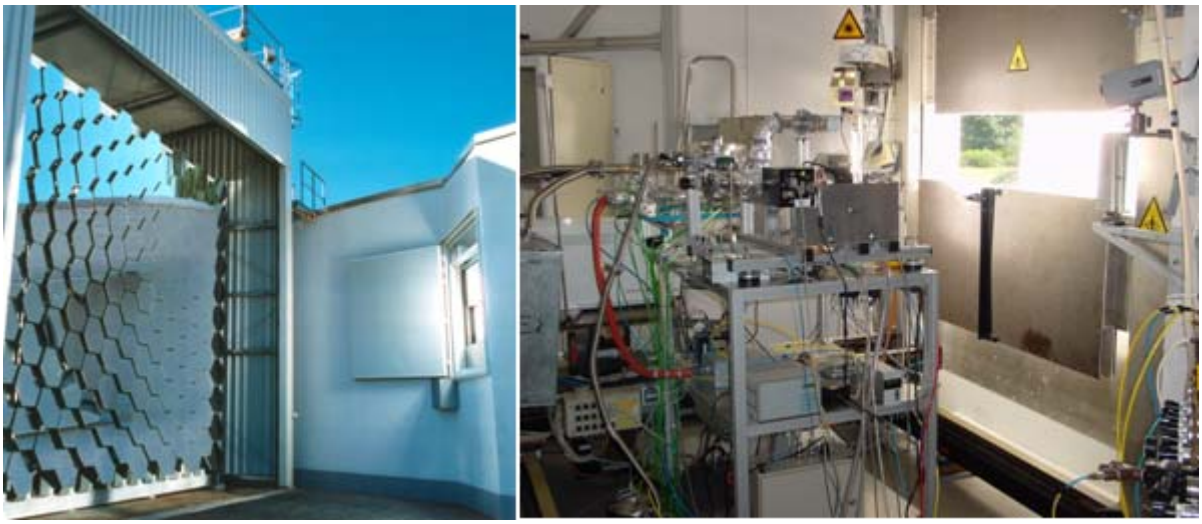

Figure 8: Hydrogen production in the DLR solar furnace, Cologne Germany.

Based on the prototype reactor tested in the solar furnace a scale-up step has been carried out. A 100 KW_{th} pilot plant has been developed and built. It was installed and inaugurated in March 2008 at the Small-Solar-Power-System (SSPS) on the Plataforma Solar de Almería (PSA), Spain (**Figure 9**).

Figure 9: Pilot plant for two-step water splitting during test operation.

In summer 2008 a detailed thermal qualification campaign of the pilot plant took place, using uncoated ceramic honeycombs as absorbers. Some main aspects of these tests were the development and validation of operational and measurement strategies, the gain of knowledge on the dynamics of the system, in particular during thermal cycling, the determination of the controllability of the whole system, and the validation of the control concept. The thermal tests allowed to improve, refine and finally demonstrate the process strategy and showed the feasibility of the implemented control concept. It could be shown that rapid change-over between the modules is a central benefit for the performance of the process. This reduces the time period with lower hydrogen production or ineffective regeneration of the modules. To achieve a faster switching of the temperature levels, the

number of heliostats changing in focus should be as high as possible until the target temperatures are reached. **Figure 10** shows the temperature progression over some cycles and the number of heliostats necessary to keep and adjust the two different temperature levels in both chambers of the reactor.

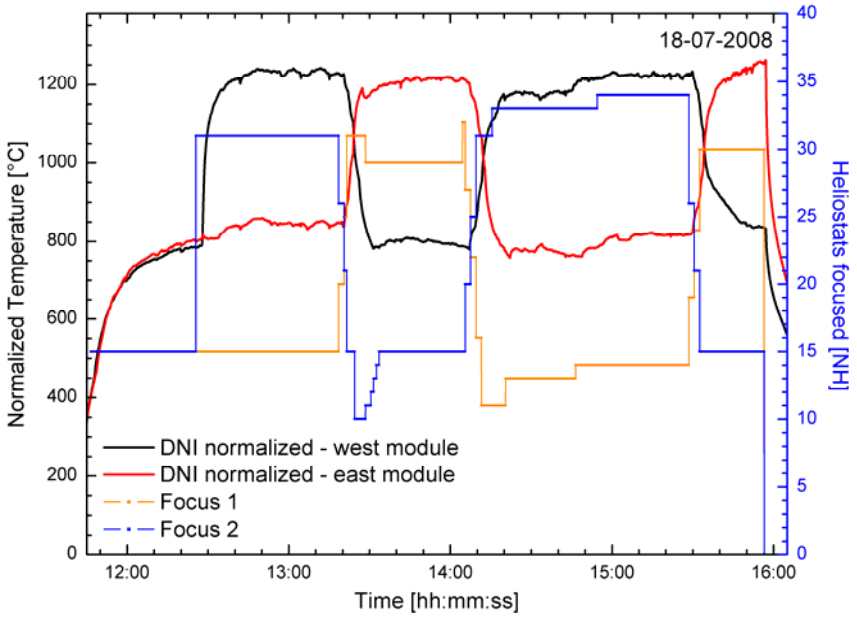

Figure 10: Thermal cycling of the reactor and number of heliostats needed to power and control the process.

In November 2008 the absorber was replaced and honeycombs coated with redox material were installed. This allowed carrying out first tests of hydrogen production by water splitting. The tests were successful – some first cycles could be run without problems. Significant amounts of hydrogen were produced with a conversion of steam of up to 30 %.

Extensive work has also been carried out on the Zn/ZnO cycle. Its first step is the thermal dissociation of ZnO into Zn and O_2 at about 2000 °C. In the second step Zn is hydrolysed at 450 °C generating H_2 and ZnO. The Zn/ZnO cycle can reach a maximum exergy conversion efficiency of 29% and a solar thermal efficiency of 40% [39]. A study for a 90 MW solar reactor operated at 2000 °C was reported by Fahrni [45]. Solar H_2 production costs for this large scale plant with an annual production rate of 61 million kWh_{th} were estimated between 0.13 and 0.15 $/$kWh_{th}$ (3.58-4.12 €/kg). If electric energy generated by fuel cells would be used the price would be 0.33 $/$kWh_{th}$ (9.08 €/kg).

Sulfur Cycle Family

Many of the promising thermochemical cycles for water splitting use sulphur based systems. Much of work was done in the European Joint Research Centre in Ispra, Italy, which focused on the use of nuclear heat [46]. Since the sulphuric acid decomposition process is carried out at the maximum temperature level of high temperature reactors and in a corrosive atmosphere, it constitutes the main problem in the coupling. Since nuclear heat is and will be limited to temperatures below 950°C which might be possible with a GEN IV reactor, concentrated solar energy is able to perform these processes much more efficiently. The reason for this is an exponential rise of the reaction rate with increasing temperature [47]. Industrially the process is carried out in several steps, between 300 and 1000 °C. One option to carry out this process by solar radiation is the Solar CRISTINA Process [48]. Basically, carbon steel and refractory bricks can be used for the equipment. Energy is transferred by direct contact between the hot air vector and the reactants; thus direct contact heat transfer equipment can conveniently be used. Since the solar heat source is intermittent and

thermochemical processes are conceived to operate continuously, it will be necessary to provide continuity by storing thermal energy, chemical energy, chemicals, etc.

Hybrid Sulfuric Acid Cycle (Westinghouse, ISPRA Mark 11)

The Westinghouse cycle is a hybrid electrochemical thermochemical cycle consisting of two steps [49]. Catalysts are available for accelerating the rate of SO_3 reduction coupled to a nuclear heat source at a temperature level of 850 °C. As described above, the use of catalysts may not be necessary if higher temperatures can be provided by concentrated solar radiation. Electrical power is required for the electrolysis. Nevertheless, the overall process is calculated to be more efficient than direct water electrolysis [50]. For SO_2 electrolysis, carbon-supported platinum catalysts were employed to prepare the electrodes [51]. Ceramics such as silicon carbide, silicon nitrite, and cermets possess excellent resistance to H_2SO_4 corrosion at ambient temperature and at low acid concentration [52].

(7) $2\ H_2O + SO_2 \rightarrow H_2SO_4 + H_2$ electrolysis, 80°C

(8a) $H_2SO_4 \rightarrow H_2O + SO_3$ > 450°C

(8b) $SO_3 \rightarrow SO_2 + ½\ O_2$ >800°C

The cycle has the potential for achieving high thermal efficiencies above 40 % while using common and inexpensive chemicals. The material selection for the decomposition of the H_2SO_4 is the main challenge of the process [49,50].

Conceptual designs and cost estimates indicate that the product gas separation can be done conventionally and economically [50]. The H_2 production costs were calculated alternatively at 0.0596 \$/Nm³ H_2 (0.55 €/kg) [52] or 8.4\$/GJ H_2 (0.83 €/kg) [53].

Sulfur-Iodine Cycle (General Atomics, ISPRA Mark 16)

The sulphur-iodine (IS) process also known as the ISPRA Mark 16 and General Atomics (GA) process is a “pure” thermochemical cycle [39,46,54]. Originally it was intended to couple the cycle to a nuclear heat source, but more recently the coupling to a solar thermal plant was designed because of higher efficiencies at temperatures above 1000 °C [49,55,56,57].

The three reactions are performed in separate sections of the apparatus, the Bunsen reaction and the sulphuric acid decomposition run in parallel to avoid SO_2 storage [58]. The IS feasibility was successfully demonstrated in a glass, quartz and Teflon laboratory-scale apparatus [49], on the solar power tower of the Georgia Institute of Technology [59], and within the European HYTHEC project in the solar furnace of DLR in Cologne, Germany [60,61].

For large scale application, heat generation by a 2400 MW_t modular helium reactor (H2-MHR) which should be able to provide temperatures up to 900 °C was proposed. The overall efficiency for this reactor was calculated to 42 % at 850 °C. It is assumed that efficiencies up to 52 % may be achievable with a reactor outlet temperature of 950 °C [59]. The decomposition of H_2SO_4 and HI was found to be a challenging procedure causing severe corrosion problems [49]. The experimental problems and the less promising results of the economic calculations led to abandoning the activities on the Mark 16 cycle by GA. Recently it is again in the focus of intensive research.

Within the EU funded project HYTHEC sulphuric acid splitting could be shown in a continuously working solar receiver reactor in the solar furnace of DLR over a time period of 75 hours. Complete vaporisation of concentrated sulphuric acid in and at a porous absorber made of SiSiC was achieved at temperatures between 1000 °C and 1250 °C. Sulphuric acid was homogeneously decomposed without the use of catalysts with conversions between 20 and 55 % at different operating points confirming the positive influence of increased temperatures. The throughput of the solar reactor was limited by the capacity of the vaporiser used. No visible corrosion occurred in the reaction zone of the reactor [61].

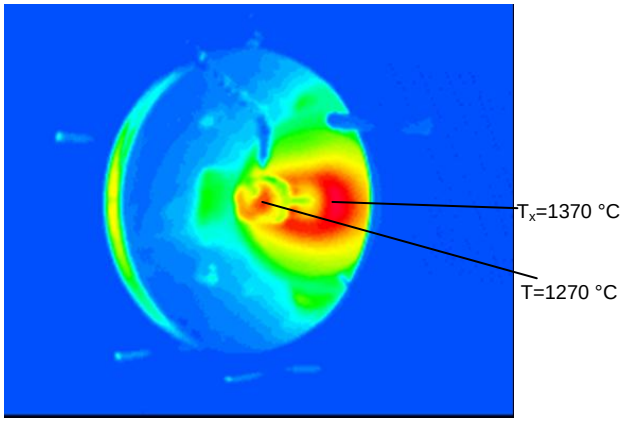

Figure 11: Solar H_2SO_4 splitting in a volumetric reactor in the DLR solar furnace, Cologne, Germany.

The hydrogen production costs by a solar driven IS process are calculated at 45.7 $/GJ (4.53 €/kg). The solar heat costs were estimated at 260 $/$MW_{th}$ (215 €/MW_{th}) [57]. The coupling to the H2-MHR would result in H_2 production cost between 11.84 and 16.75 $/GJ (1.17-1.66 €/kg) depending on the kind of installation [59].

CONCLUSIONS

The present paper summarizes and compares the available technologies for the production of hydrogen, as well as the related R&D efforts. To optimize and accelerate the availability of environmentally benign hydrogen, it will initially be necessary to combine established technologies like steam-methane reforming with solar energy. Subsequently, further development will proceed successively to renewable hydrogen production without CO_2 emissions. This pathway has to be adapted to comply with geographical, political and economical circumstances. All proposed solar technologies have to be implemented in the sunbelt of the earth. While there will occur regional differences, the technological challenges have to be solved in a joint effort. Considering the scope of the technological challenge and the associated costs, it will be important to pool the efforts presently undertaken all over the world, in order to improve the most promising processes and make them available for the market.

ACKNOWLEDGMENTS

The authors would like to thank the European Commission for funding the projects SOLASYS, SOLREF, SOLHYCARB, HYDROSOL, HYDROSOL 2, HYTHEC, HYCYCLES, and INNOHYP-CA.

BOILING IN MICRO-CHANNELS

G. Hetsroni*
Department of Mechanical Engineering, Technion - Israel Institute of Technology,
32000, Haifa, Israel

ABSTRACT. Boiling heat transfer in micro-channels is a subject of intense academic and practical interest. Though many heat transfer correlations have been proposed, most were empirically formulated from experimental data. However, hydrodynamic and thermal aspects of boiling in micro-channels are not well understood. Moreover, there are only a few theoretical models that link the heat transfer mechanism with flow regimes in micro-channels. Also, there are discrepancies between different sets of published results, and heat transfer coefficients have either well exceeded, or fallen far below, those predicted for conventional channels. Here we consider these problems with regard to micro-channels with hydraulic diameters ranging roughly from 5 μm to 500 μm, to gain a better understanding of the distinct properties of the measurement techniques and uncertainties, the conditions under which the experimental results should be compared to analytical or numerical predictions, boiling phenomenon, as well as different types of micro-channel heat sinks. Two-phase flow maps and heat transfer prediction methods for vaporization in macro-channels are not applicable in micro-channels, because surface tension dominates the phenomena, rather than gravity forces. The models of convection boiling should correlate the frequencies, sizes and velocities of the bubbles and the coalescence processes, which control the flow pattern transitions, together with the heat flux and the mass flux. Therefore, the vapour bubble size distribution must be taken into account. The flow pattern in parallel micro-channels is quite different from that in a single micro-channel. At same values of heat and mass flux, different, time dependent, flow regimes occur in a given micro-channel. At low vapour quality, heat flux causes a sudden release of energy into the vapour bubble, which grows rapidly and occupies the entire channel cross section. The rapid bubble growth pushes the liquid-vapour interface on both caps of the vapour bubble, at the upstream and the downstream ends, and leads to a reverse flow. We term this phenomenon as explosive boiling. One of the limiting operating conditions with flow boiling is the critical heat flux (CHF). The CHF phenomenon is different from that observed in conventional size channels.

Keywords: *micro-channel, boiling, pressure drop, heat transfer, fluctuation*

INTRODUCTION

To achieve higher heat dissipation rates for micro-electronic and optical technologies, the fundamentals of two-phase heat transfer in micro-channels are being studied ever more extensively. Micro-channel heat sinks are devices that provide liquid or two-phase flow through parallel channels of diameter less than, say, 1mm. These systems are ideally suited for devices where high heat flux is dissipated from small surface area of high performance supercomputers, optical devices,

electric vehicles and advanced military avionics. The hydraulic diameter of micro- channels, d_h, is in the range 10- 500 μm, the length, L, is in the range 10-15 mm.

Qu and Mudawar [1] presented and discussed experimental results, which provide physical insight into the unique nature of saturated flow boiling heat transfer in a water-cooled micro- channel heat sink. Contrary to macro- channel the heat transfer coefficient was shown to decrease with increasing thermodynamic equilibrium quality. This unique trend was attributed to appreciable droplet entrainment and onset of annular flow regime. Such a trend was also reported by Hetsroni et al. [2]. On the other hand, Bertsch et al. [3] found that heat transfer coefficient first rises steeply as vapour quality increases from a subcooled value, and again drops sharply with further increases in vapour quality. Agostini et al. [4] presented experimental results on flow boiling of refrigerants R236fa and R245fa in silicon heat sinks. Three significant heat transfer trends were identified: the heat transfer coefficient was independent of the heat flux, increased or decreased with heat flux.

An annular flow model was developed by Qu and Mudawar [5] to predict the saturated flow boiling heat transfer coefficient. Laminar liquid and vapor flow, smooth interface, and strong droplet entrainment and deposition effects were incorporated into the model.

Kandlikar and Balasubramanian [6] presented the flow boiling correlations to transition, laminar and deep laminar flows in micro-channels. The flow boiling correlations for large diameter tubes were modified for flow boiling in micro- channels. It was concluded that boiling was more nucleate dominant for low Reynolds numbers (Re< 100) in micro- channels. Thome et al. [7] proposed a new heat transfer model for evaporation in the elongated- bubble regime in micro- channels. The model describes the transient variation in local heat transfer coefficient during the sequential and cyclic passage of a liquid slug, an evaporating elongated bubble and a vapour slug. The time averaged local heat transfer coefficient calculated using this model was compared by Dupont et al. [8] to 1591 experimental data which cover tube diameters from 0.77 to 3.1 mm. The data were obtained for the following seven fluids: R- 11, R- 12, R- 113, R- 123, R- 134a, R- 141b, and CO_2. The new model predicts 67% of the database to within +- 30%.

Zhang et al. [9] proposed a correlation for flow boiling heat transfer in mini-channels. However, the realistic prediction of flow boiling heat transfer coefficients is possible only for a set of experimental data selected by the authors of these models. For example, the mean relative error of prediction of recent experimental data presented by Agostini et al. [4] by different investigations is: Thome et al. [7] +4%, Kandlikar and Balasubramanian [6]-23%, Lee and Mudawar [10] -609%, Zhang et al. [9] +35%.

An important aspect of flow boiling in micro-channels is the pressure fluctuations, because these fluctuations can lead to instabilities in flow. Pressure fluctuations and corresponding temperature oscillations are associated with boiling in micro- channels to a greater extend than in conventional channels. This is because the flow velocities are very low, and bubble formation can cause a significant disruption of low-quality flow. The periodic wetting and rewetting phenomena were observed by Hetsroni et al. [2, 11, 12, 13], Zhang et al. [14], Steinke and Kandlikar [15]**.** The explosive vaporization and significant pressure drop fluctuations were observed by Hetsroni et al. [2, 12]. Flow pattern, observed in these studies and reported also by Kandlikar [16], revealed a flow reversal in some channels with expanding bubbles pushing the liquid- vapor interface in both upstream and downstream directions. Lee et al. [17, 18] studied experimentally bubble dynamics in a single trapezoid micro-channel and in two parallel micro-channels with a hydraulic diameter of 41.3 μm. Bubble nucleation and growth in parallel micro-channels were observed for some cases with the wall temperature lower than the saturation temperature corresponding to the system pressure. It was reported by Bergles and Kandlikar [19] that CHF in micro-channels under

conditions of low mass flux and low quality may be a result of instabilities rather than conventional dryout mechanism.

The main purpose of the present study is to highlight the dynamics of vapour bubble, and heat transfer coefficient under condition boiling regime in micro-channels.

DYNAMICS OF VAPOR BUBBLE

The bubble dynamics in a confined space, in particular in micro-channels, is quite different from that in unconfined still fluid. In micro-channels the bubble evolution depends on a number of different factors such as existence of solid walls restricting bubble expansion in the transversal direction, a large gradient of the velocity and temperature field, etc. Some of these problems were discussed by Kandlikar [16], and Dhir [20]**.** A detailed experimental study of bubble dynamics in a single and two parallel micro-channels was performed by Lee et al. [21] and Li et al. [22].

Dimensional Analysis. Yarin et al. [23] presented the functional equation for the rate of bubble growth as follows

$$\frac{dr}{dt} = f(q, h_{LG}, \rho_L, \rho_G, \mu_L, k_L, c_{pL}, d_0, d_*, \sigma, \Delta T_S, g, t, U) \tag{1}$$

where dr/dt is the rate of bubble growth, t is the time.

Among the dimensional variables of the problem, five parameters which have independent dimensions may be chosen, and then equation (1) may be written in dimensionless form. Choosing parameters p_L , c_{pL} , U, ΔT_S , d_* and taking into account the π-theorem, equation **(**1) can be represented as:

$$\Pi = \varphi(\Pi_1, \Pi_2, ...\Pi_9) \tag{2}$$

where $\Pi = \frac{\dot{r}}{U}$, $\Pi_1 = \frac{q}{\rho_L U c_{pL} \Delta T_S}$, $\Pi_2 = \frac{h_{LG}}{c_{pL} \Delta T_S}$, $\Pi_3 = \frac{\rho_G}{\rho_L}$, $\Pi_4 = \frac{\mu_L}{\rho U d_*}$, $\Pi_5 = \frac{k_L}{\rho_L c_{pL} U d_*}$, $\Pi_6 = \frac{d_0}{d_*}$,
$\Pi_7 = \frac{\sigma}{\rho U^2 d_*}$, $\Pi_8 = \frac{g d_*}{U^2}$, $\Pi_9 = \frac{\tau U}{d_*}$, $\dot{r} = \frac{dr}{dt}$

Analysis of experimental data presented by Lee et al. [21] revealed that the parameters $\Pi_3 - \Pi_9$ did not change significantly, and the parameter Π_2 depends mainly on the wall access temperature, $\Delta T_S = T_W - T_S$. We assumed that $\Pi_2 \approx$ const. Thus, one can consider Π_1 as the dimensionless parameter that determines the rate of bubble growth in the linear regime:

$$\frac{dr}{dt} = \varphi(\Pi_1) \tag{3}$$

Experimental Data. Single micro-channel. Data by Lee et al. [21] and Li et al. [22] contain the results related to bubble dynamics in a single micro-channel.

In the range of $\Pi_1 = 0.00791 - 0.0260$ linear behavior of the bubble radius was observed, when $\Pi_1 > 0.0260$ exponential bubble growth took place (Figure 1**).**

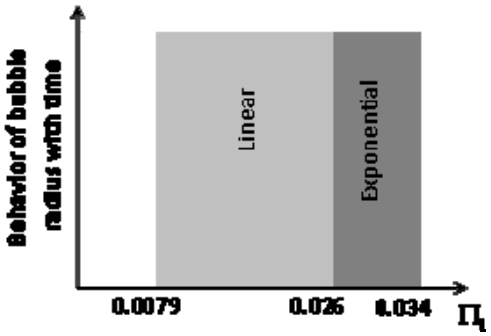

Figure 1. Behaviour of bubble change of radius vs. time. The values of $\prod_1$ were calculated from experimental data.

Parallel micro-channels. The bubble dynamics under conditions corresponding to flow in two parallel trapezoidal micro-channels with hydraulic diameter 47.7 μm was studied by Li et al. [22]. The bubbles in two parallel micro-channels generally grow in a similar way to that in a single micro-channel. The authors also reported the presence of two-phase flow instability.

Hetsroni et al. [11] studied bubble growth in 26 parallel horizontal triangular micro-channels of d_h = 103 μm and length of 10 mm. Temporal variation of bubble size is shown in Figure 2**.** Figures 2a, b show the variation of bubble size in the streamwise direction L_p, and in the spanwise direction L_n, respectively.

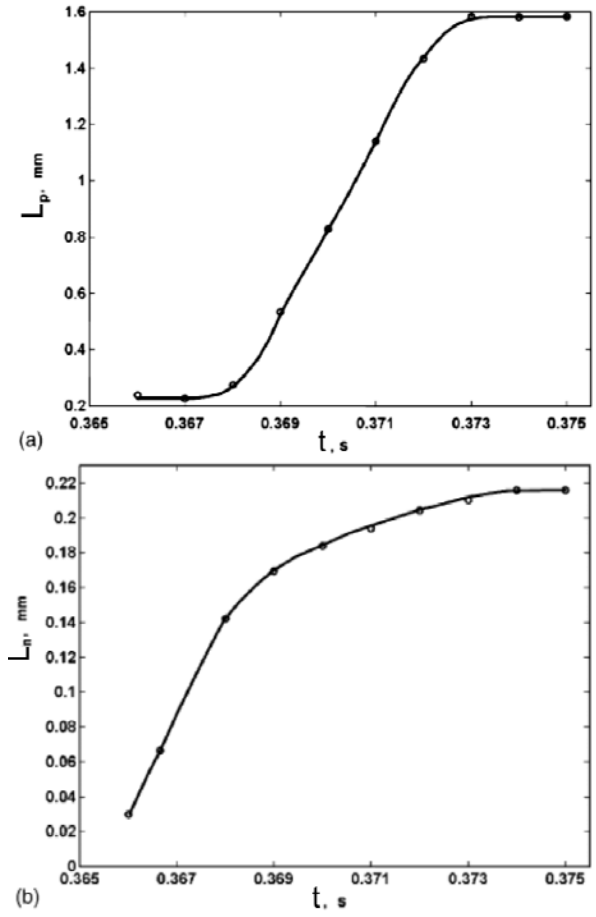

Figure 2. Temporal variation of vapour bubble size: (**a**) streamwise direction, L_p (**b**) spanwise direction, L_n. U_{LS} = 0.046 m/s, q = 8×10^4 w/m^2.

The observed ratio $f = L_p/L_n$, is quite different from that reported for subcooled flow boiling of water in tubes of 17–22 mm inner diameter. Prodanovic et al. [24] reported that this ratio was typically around 0.8 for experiments at 1.05–3 bar.

Bubble velocity. Figure 3 shows the velocity of the displacement of the bubble tail in the streamwise direction U_b (m/s) versus the bubble lifetime t, at fixed conditions as described above, i.e., $q = 8\times10^4$ W/m^2, $U_{LS} = 0.046$ m/s. One may conclude that the velocity of bubble displacement varies, depending on the range of lifetime. In region A of the boiling process, during the period of about 0.005 s from the appearance of the first bubble, ONB, the bubble velocity is equal to the superficial liquid velocity. It should be noted that the term ONB, known as the onset of nucleate boiling, was borrowed from the terminology of subcooled flow boiling in larger tubes. Region B is characterized by a sharp increase in the bubble velocity, namely the bubble is accelerated in the streamwise flow direction. Figure 3 shows that in this region the bubble velocity increases about threefold, during a time interval of about 0.003 s. After the time when U_b reaches maximum value it remains constant, as shown in Figure 3**,** region C.

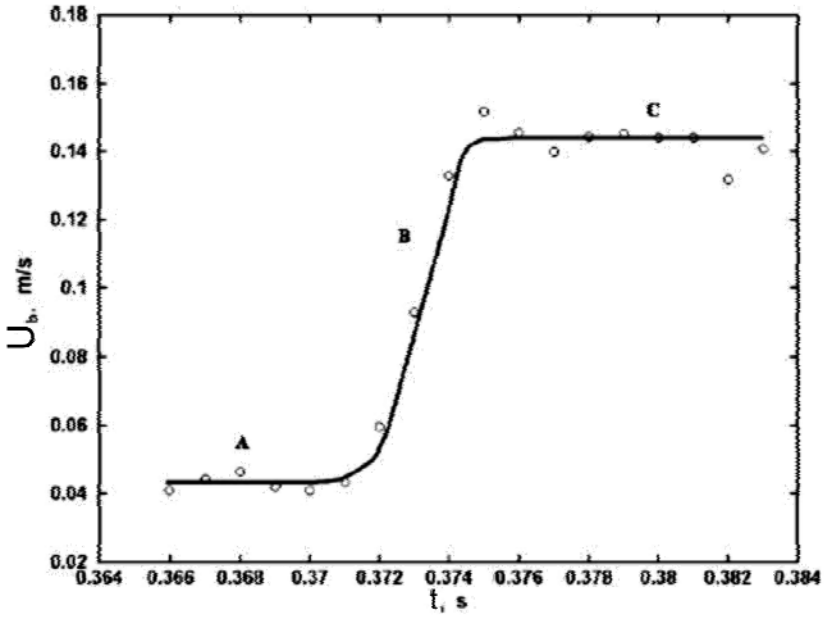

Figure 3. The velocity of bubble displacement. $U_{LS} = 0.046$ m/s, $q = 80$ kW/m^2.

Such a behaviour agrees with results reported by Agostini et al. [25]. The collision of elongated bubble has been studied by Revellin et al. [26] along adiabatic glass micro-channels of 509 and 709 μm internal diameters for refrigerant R-134 a. A model for the collision of elongated bubbles in micro-channels was proposed to predict the bubble length distribution at the exit of the micro-evaporator.

In micro-channels, bubbles cause a significant volume change (relative to the channel size). As a result, pressure fluctuations were observed. The temporal behaviour of the pressure drop is shown in Figure 4.

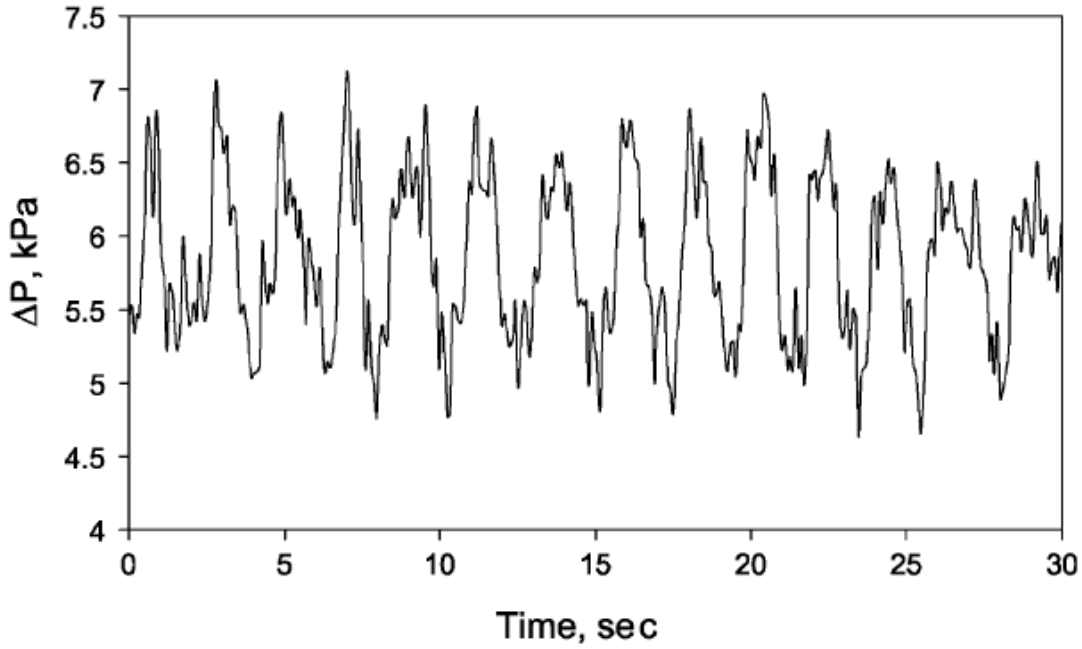

Figure 4. Pressure drop fluctuations. U_{LS} = 0.14 m/s, q = 220 kW/m^2.

The pressure spike introduces a disruption in the flow. Depending on the local conditions, the excess pressure inside the bubble may overcome the inertia of the incoming liquid and the pressure in the inlet manifold, and cause a reverse flow of varying intensity, depending on the local conditions. There are two ways to reduce the flow instabilities: reduce the local liquid superheat at the ONB and introduce a pressure drop element at the entrance of each channel, Kandlikar [27]. Kakac and Bon [28] reported that density-wave oscillations were observed also in conventional size channels. Introduction of additional pressure drop at the inlet (small diameter orifices were employed for this purpose) stabilized the system.

Simultaneous visualizations and measurements were done by Wang et al. [29] to investigate effects of inlet/outlet configurations on flow boiling instabilities in parallel micro-channels having a length of 30 mm and a hydraulic diameter of 186 μm. It was found that nearly steady flow boiling existed in the parallel micro-channels through an inlet restriction.

HEAT TRANSFER

The heat transfer coefficient of boiling flow through a horizontal rectangular channel with low aspect ratio (0.02–0.1) was studied by Lee and Lee [30]**.** The detail experimental study of flow boiling heat transfer in two-phase heat sinks was performed by Qu and Mudawar [5]. It was shown that the saturated flow boiling heat transfer coefficient in a micro-channel heat sink is a strong function of mass velocity and depends only weakly on the heat flux. This result, as well as the results by Lee and Lee [30]**,** indicates that the dominant mechanism for water micro-channel heat sinks is forced convective boiling but not nucleate boiling.

Heat transfer characteristics for saturated boiling were considered by Yen et al. [31]. From this study of convective boiling of HCFC123 and FC72 in micro-tubes with inner diameter 190, 300 and 510 μm one can see that in the saturated boiling regime, the heat transfer coefficient monotonically decreased with increasing vapour quality, but is independent of mass flux.

The convective and nucleate boiling heat transfer coefficient was the subject of experiments by Grohmann [32]. The measurements were performed in micro-tubes of 250 and 500 μm in diameter. Nucleate boiling metastable flow regimes were observed. Heat transfer characteristics at the nucleate and convective boiling in micro-channels with different cross-sections were studied by Yen et al. [33].

Several popular macro-channel correlations, and recently recommended small-channel correlations, were examined by Lee and Mudawar [34]. Predictions were adjusted for the three-sided wall heating and rectangular geometry.

Experiments by Lee and Mudawar [34] reveal the range of parameters at which heat transfer is controlled by nucleate boiling or annular film evaporation. The first of these processes occurs only at low qualities (x< 0.05) corresponding to very low heat fluxes; the second one at moderate (0.05<x<0.55) or high (x>0.55) qualities that correspond to higher heat fluxes. New correlations were suggested by Lee and Mudawar [34]. They are based on the Martinelli parameter X and account for micro-channel effects not represented in the prior correlations.

The work by Steinke and Kandlikar [15] focused on obtaining heat transfer data during flow boiling in micro-channels. An experimental investigation was performed for flow boiling using water in six parallel, horizontal micro-channels with a hydraulic diameter of 207 μm. The ranges of parameters are: mass flux from 157 to 1782 kg/m^{2}s, heat flux from 5 to 930 kW/m^2, inlet temperature of 22°C, quality from sub-cooled to 1.0, and atmospheric pressure at the exit.

$$h_{tp} = 0.6683\,Co^{-0.2}(1-x)^{0.8} f_2 h_L + 1058\,Bo^{0.7}(1-x)^{0.8} F \cdot h_L \tag{4}$$

$$Co = \left(\frac{\rho_G}{\rho_L}\right)^{0.5} \left(\frac{1-x}{x}\right)^{0.8} \tag{5}$$

$$Bo = \frac{q}{G h_{LG}} \tag{6}$$

where Co is the convection number given in equation (5), Bo is the boiling number given in equation (6), f_2 is the multiplier, h_L is the heat transfer coefficient with all liquid flow, and x is the quality. The F number for water is 1.0 and the f_2 is multiplier is 1.0 for micro-channel flow.

The empirical correlation obtained by Steinke and Kandlikar [15] predicts a heat transfer coefficient about twice higher than that measured by Qu and Mudawar [5] during flow boiling of water (x<0.15) and during flow boiling of R-134a (x = 0.4–0.8). This correlation also overpredicts the experimental data obtained by Yen et al. [31] during convective boiling of HCFC123 and FC72 in d=190 μm tubes in the range of x=0.4–0.9.

Critical Heat Flux of Flow Boiling. Zhang et al. [35] proposed a correlation for CHF under condition of saturated boiling:

$$Bo = 0.0352\left[We + 0.0119\left(\frac{L}{d_h}\right)^{2.31}\left(\frac{\rho_G}{\rho_L}\right)^{0.361}\right]^{-0.295} \times \left[\left(\frac{L}{d_h}\right)^{-0.311}\left(2.05\left(\frac{\rho_L}{\rho_L}\right)^{0.170} - x_{in}\right)\right] \tag{7}$$

where $Bo = q_{crit} / (h_{LG} G)$ is the boiling number, $We = (G^2 d_h) / (\sigma \rho_L)$ is the Weber number, q_{crit} is the critical heat flux, h_{LG} is the latent heat of vaporization, G is the mass flux, x_{in} is the thermodynamic equilibrium quality at the inlet, ρ_G and ρ_L are the densities of saturated vapor and liquid, respectively, d_h is the hydraulic diameter, L is the heated length, and σ is the surface tension.

Hall and Mudawar [36] provided a comprehensive review of the current state of knowledge of subcooled CHF for water flow boiling in channels, and proposed a statistical correlation with five parameters based on almost all available subcooled CHF databases in the literature:

$$Bo = \frac{C_1 We^{C_2} (\rho_L / \rho_G)^{C_3} [1 - C_4 (\rho_L / \rho_G)^{C_5} x_{in}]}{1 + 4 C_1 C_4 We^{C_2} (\rho_L / \rho_G)^{C_3 + C_5} (L / d_h)} \tag{8}$$

where the Weber number $We = G^2 d_h / (\rho_L \sigma)$, $C_1 = 0.0722$, $C_2 = -0.312$, $C_3 = -0.644$, $C_4 = 0.900$, and $C_5 = 0.724$. The correlation was developed using a total of 4860 data points and predicted CHF with a rms error of 14.3% in the following parametric ranges: $0.1 < P_0 < 20$ MPa, $0.25 < d_h < 15.0$ mm, $2 < L/d_h < 200$, $300 < G < 30000$ kg/m^2 s, $-2.00 < x_{in} < 0.00$, and $-1.00 < x_{out} < 1.00$.

A theoretical model for the prediction of the critical heat flux of refrigerants flowing in heated, round micro-channels has been developed by Revellin and Thome [26]. The model is based on the two-phase conservation equations and includes the effect of the height of the interfacial waves of the annular film. Validation has been performed by comparing the model with experimental results presented by Wojtan et al. [37], Qu and Mudawar [38], Bowers and Mudawar [39], Lazareck and Black [40]. More than 96% of the data for water and R-113, R-134a, R245fa were predicted within ±20%.

Explosive Boiling of Water in Parallel Micro-Channels. The thermo-hydrodynamic processes of boiling in a micro-channel heat sink were subject to a number of experimental investigations performed during the last decade. Periodic wetting and rewetting phenomena were observed by Hetsroni et al. [11, 12], Zhang et al. [14], Steinke and Kandlikar [15], and Kandlikar and Balasubramanian [6].

Quasi-Periodic Boiling in a Certain Single Micro-Channel of a Heat Sink. The main parameters that affect the explosive boiling oscillations (EBO) in an individual channel of a heat sink such as hydraulic diameter, mass flux, and heat flux were studied by Hetsroni et al. [11-13].

Period between successive events. Figure 5 shows the dependence of the dimensionless period of phase transformations (i.e., the time between bubble venting), t^*, on boiling number Bo ($t^* = t/Ud_h$, $Bo = q/Gh_{LG}$, where t is the period between successive events, U is the mean velocity of single-phase flow in the micro-channel, d_h is the hydraulic diameter of the channel, q is heat flux, m is mass flux, h_{LG} is the latent heat of vaporization). The dependence of t^* on Bo can be approximated, with a standard deviation of 16%, by

$$t^* = 0.000030 \, \mathrm{Bo}^{-2} \tag{9}$$

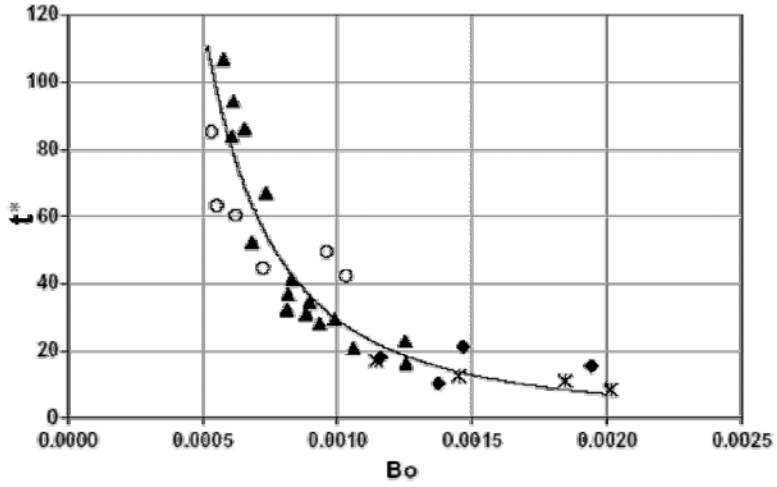

Figure 5. The dependence of the dimensionless time interval between cycles on the boiling number: circles (o) represent d_h=100 μm, water, triangles (▲) represent d_h=130 μm, water, diamonds (♦) represent d_h=220 μm, water, star (∗) represents d_h=220 μm, ethanol.

The Initial Thickness of the Liquid Film. The term initial liquid film thickness is defined as the average thickness of fluid, evenly distributed during the period t, over the surface of the circular micro-channel, after venting of the elongated bubble.

The average liquid thickness δ, can be calculated as:

$$\delta = qt / \rho_L h_{LG} \tag{10}$$

Figure 6 shows the dependence of the dimensionless initial liquid thickness of water and ethanol δ^*, on the boiling number Bo, where $\delta^* = \delta U / \nu$, U is the mean velocity of single-phase flow in the micro-channel, and ν is the kinematic viscosity of the liquid at saturation temperature. The dependence of δ^* on Bo can be approximated, with a standard deviation of 18%, by:

$$\delta^* = 0.00015\ \mathrm{Bo}^{-1.3} \tag{11}$$

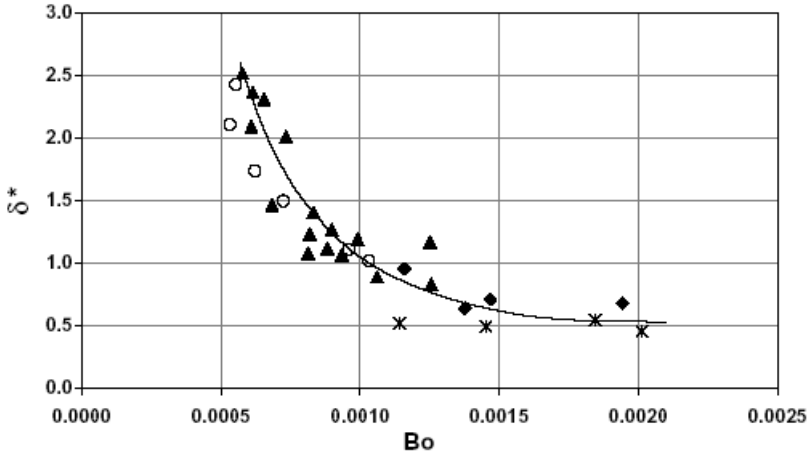

Figure 6 Dependence of the dimensionless initial film thickness on the boiling number: *circles* (o) represent d_h=100 μm, water, *triangles* (▲) represent d_h=130 μm, water, *diamonds* (♦) represent d_h=220 μm, water, *star* (∗) represents d_h=220 μm, ethanol.

The initial thickness of the liquid film is a key parameter of the explosive boiling. The term initial liquid film thickness is defined as the average thickness of fluid, evenly distributed during period *t*, over the surface of the circular micro-channel, after venting of the elongated bubble. This surface is located downstream of the ONB and may be characterized by the heated length and hydraulic diameter. This point may be discussed in some detail with regard to the beginning of the critical heat flux (CHF) regime. The variation of the initial thickness of the film of water versus the heat flux is depicted in Figure 7. For explosive boiling the film thickness decreases with increasing heat flux from 125 to 270 kW/ m^2 from about 8 to 3 μm. This range of values is on the same order of magnitude as those given by Moriyama and Inoue [41] and by Thome et al. [7] for R-113 in small spaces (100–400 μm). Decreasing liquid film thickness with increasing heat flux is a distinct feature of dryout during explosive boiling. Under the conditions at which the instantaneous temperature of the heater surface exceeds 125°C, the value of δ was in the range of 3±0.6 μm. This value may be considered as minimum initial film thickness. If the liquid film reached the minimum initial film thickness δ_{min}, CHF regime occurred. According to Thome et al. [7] δ_{min} is assumed to be on the same order of magnitude as the surface roughness. The values of the minimum initial film thickness calculated by Thome et al. [7] for R-113 at saturation temperature 47.2°C was in the range of 1.5–3.5 μm.

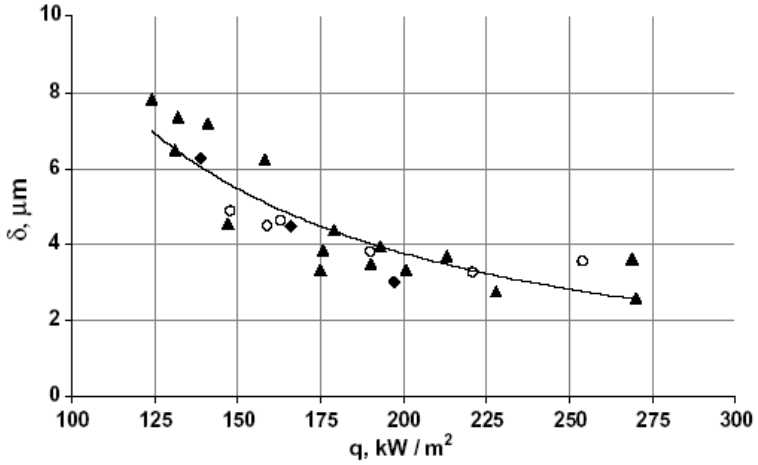

Figure 7 The variation of the initial film thickness for water versus heat flux: *circles* (o) represent d_h=100 μm, water, *triangles* (▲) represent d_h=130 μm, water, *diamonds* (♦) represent d_h=220 μm, water.

System that Contains a Number of Parallel Micro-Channels. Hetsroni et al. [11-13] also studied the effect of EBO in individual channels on the average characteristics of the whole heat sink: total pressure drop and temperature fluctuations on the heater, and the heat transfer coefficient. The high-frequency oscillations in individual micro-channels are superimposed and lead to total low-frequency pressure drop and temperature oscillations of the system.

Fluctuation of pressure drop, fluid and heated wall temperatures. The experimental investigations of boiling instability in parallel micro-channels were carried out by simultaneous measurements of temporal variations of pressure drop, fluid and heater temperatures. The channel-to-channel interactions may affect pressure drop between the inlet and the outlet manifold as well as associated temperature of the fluid in the outlet manifold and heater temperature. Figure 8 illustrates this phenomenon for pressure drop in the heat sink that contains 13 micro-channels of d_h = 220 μm at mass flux G = 93.3 kg/m^2 s and heat flux q = 200 kW/m^2. The temporal behaviour of the pressure drop in the whole boiling system is shown in Figure 8a**.** The considerable oscillations were caused by the flow pattern alternation, that is, by the liquid/two-phase alternating flow in the micro-

channels. The pressure drop FFT is presented in Figure 8b. Under condition of the given experiment, the period of pressure drop fluctuation is about t = 0.36 s.

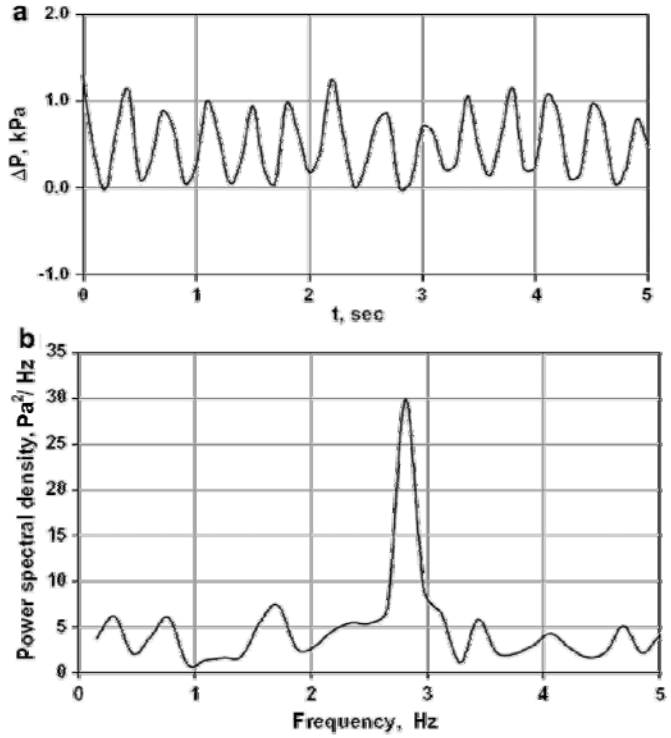

Fig8. Time variation of pressure drop at q = 200 kW/m^2: (**a**) pressure drop fluctuations, (**b**) pressure drop amplitude spectrum.

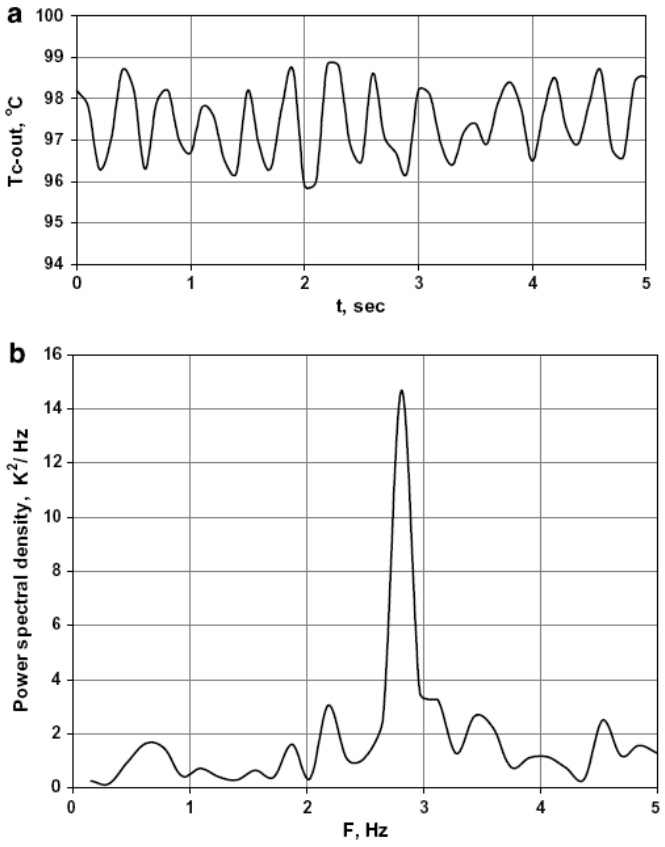

Fig 9. The Time variation of the fluid temperature at the outlet manifold q=200 kW/m^2: (**a**) temperature fluctuations, (**b**) temperature amplitude spectrum**.**

The pressure drop fluctuation provides an insight into the temperature behaviour of the fluid in the outlet manifold. The pressure drop fluctuation frequency represents the oscillations in the system. Figure 9a, b shows the time variation and FFT of the fluctuation component of the fluid temperature. In Figure 9a one can observe that the average fluid temperature at the outlet manifold is less than the saturation temperature. This results in the fact that only single liquid comes to the outlet manifold through some of the parallel micro-channels.

The time variation of the mean and maximum heater temperature is presented in Figure 10. The mean heater temperature (i.e., the average temperature of the whole heater) changed in the range of $\Delta T_{av} = 10$ K. The maximum heater temperature changed in the range of $\Delta T_{max} = 6$ K. Comparison between Figs. 8, and 9, shows that the time period (frequency) is the same for the pressure drop and the fluid temperature at the outlet manifold, and the mean and maximum heater temperature fluctuations. It also allows one to conclude that these fluctuations are in phase. When the heat flux is increased, at constant value of mass flux, the oscillation amplitudes of the pressure drop, the fluid and the heater temperatures also increase.

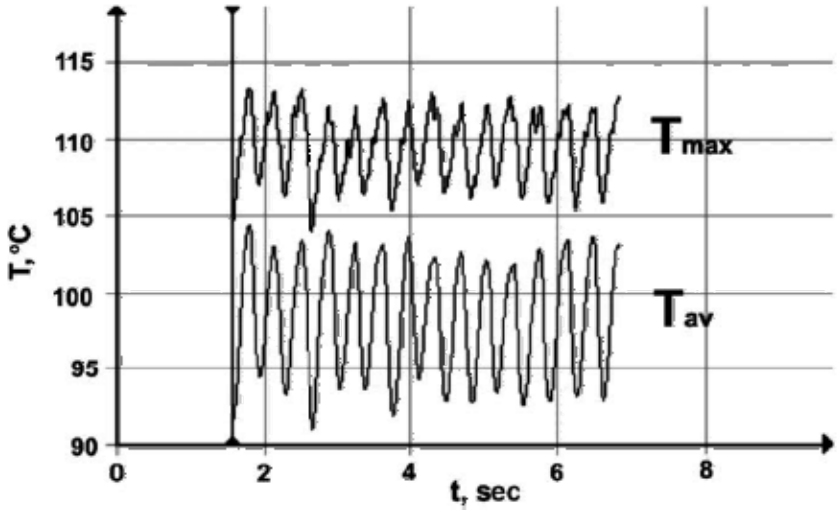

Figure 10. Time variation of average and maximum heater temperature at $q = 200$ kW/m^2.

Average Heat Transfer Coefficient. In the range of quality x=0.01-0.08 it was observed that at the same boiling number and inlet temperature, an increase in diameter shifts the ONB further from the inlet. The region of the local dryout decreases and the average heated surface temperature decreases as well. Under this condition the heat transfer coefficient increases with increased hydraulic diameter. In order to take into account the effect of surface tension and micro-channel hydraulic diameter, we have applied the Eotvos number $Eo = g(\rho_L - \rho_G)d_h^2/\sigma$. Figure 11 shows the dependence of the Nu/Eo on the boiling number Bo, where $Nu = hd_h/k_L$ is the Nusselt number, h is the heat transfer coefficient, and k_L is the thermal conductivity of fluid. All fluid properties are taken at the saturation temperature. This dependence can be approximated, with a standard deviation of 18%, by the relation:

$$Nu/Eo = 0.030\, Bo^{-1.5} \tag{10}$$

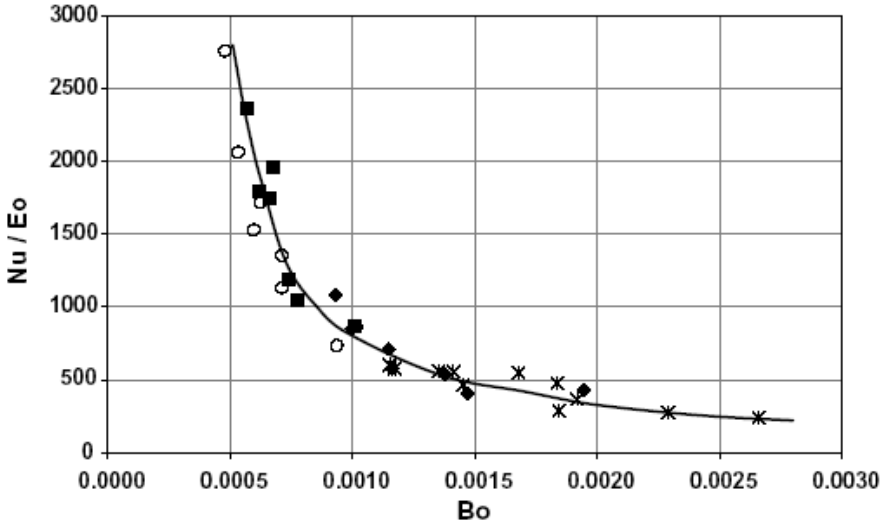

Fig 11. The dependence of *Nu / Eo* on the *Bo*: *circles* (o) represent d_h=100 μm, water, *triangles* (▲) represent d_h=130 μm, water, *diamonds* (♦) represent d_h=220 μm, water, *star* (∗) represents d_h=220 μm, ethanol.

CONCLUSIONS

Bubble dynamics in a confined space. Dimensional analysis shows that the variation of the bubble radius with time depends on the parameter $\Pi = q/(\rho_L U c_{pL} \Delta T_S)$. In the range of Π=0.0079–0.026, linear behaviour was observed, and when Π>0.026 exponential bubble growth took place.

Heat transfer in two-phase flow boiling. The extent to which an incoming liquid will be vaporized is a design variable that depends on the intended application. In micro-scale refrigeration systems, the change in vapour quality may be substantial, on the order of 0.8 for example. In electronics cooling applications, the equilibrium vapour quality may remain at 0, or be very small; in those designs, the aim is to capture the high-heat transfer coefficients of subcooled flow boiling, without the added complexities of net vapour generation (e.g., the need to incorporate a condenser). The distinction between low and high-quality outflow affects heat transfer coefficients. Experiments by Lee and Mudawar [34] revealed the range of parameters at which heat transfer was controlled by nucleate boiling or annular film evaporation. The first of these processes occurred only at low qualities ($x < 0.05$), the second one at moderate ($0.05 < x < 0.55$) or high ($x > 0.55$) qualities. New correlations were suggested by Lee and Mudawar [34]. They are based on the Martinelli parameter and may be used for two-phase flow boiling of water and refrigerant R-134a.
Critical Heat Flux

Several thousand CHF points have been reported in the boiling literature of the past 50 years. Most of these data were obtained with stable flow in single conventional size circular tubes and conventional size channels. The tubes were usually of uniform wall thickness, and direct electrical heating was utilized to simulate the constant heat flux. The correlation suggested by Zhang et al. [35], (equation (7)) gives the best agreement with experimental data on saturated CHF in channels of 0.33–6.22 mm. There is a significant difference between experimental results of CHF obtained in a single micro-channel of d_h = 0.5 mm and in the block that contained twenty-one 0.215 × 0.21 mm channels.

The study of CHF in micro-channels has not received much attention in the literature. Single-tube CHF data are not available for micro-channels with hydraulic diameters less than 0.3 mm. Under

conditions of explosive boiling, Hetsroni et al. [13] suggested that the initial thickness of the liquid film may by considered as a key parameter that affects CHF in the system containing a number of parallel micro-channels of $d_h = 0.1–0.22$ mm. New experiments should be performed to validate the dimensionless groups suggested for the evaporating interface near the heated wall and CHF for single micro-channels, as well as for blocks that contain parallel micro-channels.

Flow instability. The channel-to-channel interactions may affect pressure drop between the inlet and the outlet manifolds, as well as associated temperature of the fluid in the outlet manifold and the temperature of the heater. The frequency and the phase are the same for all these fluctuations. They increase at a constant value of mass flux with increasing heat flux. The large heated wall temperature fluctuations are associated with CHF. As the heat flux approached CHF, the parallel-channel instability, which was moderate over a wide range of heat fluxes, became quite intense and must be associated with maximum temperature fluctuation of the heated surface.

QUANTITATIVE TEMPERATURE AND THERMAL CONDUCTIVITY PROFILING WITH THERMOCOUPLE SCANNING THERMAL MICROSCOPE PROBE

O. M. Kwon[1], J. S. Lee[2*]
[1]Korea University, Seoul, Korea
[2]Seoul National University, Seoul, Korea

ABSTRACT. Quantitative temperature and thermal conductivity profiling technique is presented, which eliminates the influence of heat transfer through the air, and measures the temperature and thermal conductivity of a sample from a tip-sample heat transfer only, operating thermocouple scanning thermal microscope (SThM) probe in both passive and active modes. We describe the principle of the technique through a rigorous theoretical analysis of the heat transfer that occurs during measurement. The spatial resolution of this technique is demonstrated by obtaining the thermal conductivity profile of samples in which a thin silicon oxide layer is sandwiched between single crystal silicon layers. Thermal conductivity distributions are quantitatively profiled for samples with a 1.4 μm-thick silicon oxide layer and a 200 nm-thick oxide layer. For a sample with a 100 nm-thick silicon oxide layer, only the existence of a region with lower thermal conductivity could be identified. Based on our results, the spatial resolution of this technique is estimated to be around 150 nm.

Keywords: *Scanning thermal microscope, thermocouple probe, quantitative profiling, temperature, thermal conductivity*

INTRODUCTION

The scanning thermal microscope (SThM) is a type of scanning probe microscope (SPM) that maps out the temperature and/or the thermal property of a sample surface by scanning a sharp SThM probe with a temperature sensor at the tip. The tip-sample contact force is controlled by an atomic force microscope (AFM) [1, 2]. Since a SThM can measure temperature and thermal properties with the highest known spatial resolution, it has been used for such diverse applications as the detection of the failure of electronic devices [3], locating a hot spot in an operating metal-oxide semiconductor field effect transistor [4], imaging the phonon temperature distribution of electrically-heated carbon nanotube (CN) circuits [5], imaging the temperature distribution inside a vertical-cavity surface-emitting laser [6], polymer light-emitting diodes [7], thermal conductivity distribution of biological samples [8], and nondestructive evaluation of subsurface microelectronic structures [9].

Despite the high spatial resolution of SThM, its usefulness has been limited because of its lack of quantitative measurement. In an effort to improve quantitative temperature measurement, Luo *et al.* developed a resistance network model based on the assumption that when a probe makes contact with a sample surface, heat transfers from the sample to the base of the cantilever without any leakage to the surrounding air [10]. According to this model, if the thermal resistance of the SThM probe cantilever and tip-sample contact are measured correctly, a quantitative temperature

profile of the sample can be obtained from the temperature distribution measured by the thermocouple junction at the end of the SThM probe tip.

However, Shi *et al.* observed experimentally that the temperature measured by the thermocouple junction of a SThM probe depends on the size of the sample, even if the temperature of the sample is the same [11]. This is because most of the heat transfers not through the tip-sample contact, but through the air gap between the sample and the SThM probe. Hence, it became clear that merely by multiplying a certain proportionality constant by the temperature distribution measured by the thermocouple of the SThM probe, a correct quantitative temperature profile of the sample cannot be obtained.

Conventionally, thermocouple SThM probes have been used mostly for temperature imaging, whereas thermo-resistive SThM probes are used for thermal property imaging. However, both thermocouple and thermo-resistive probes can be operated in either a passive mode or an active mode. Hence, in principle, both probes can measure either temperature or thermal properties.

Recently, Roh *et al.* developed a technique, named the 2ω method [12, 13], that can image a local thermal property by taking advantage of a thermocouple SThM probe that had already shown a spatial resolution of around 100 nm in local temperature measurement [14]. The 2ω method can map out the local thermal property by monitoring the amplitude of the 2ω signal from the thermocouple junction of a probe heated by an alternating current (ac) with a frequency of 1ω. The spatial resolution of this technique is around 200 nm. However, the spatial resolution of the 2ω method is severely limited by heat transfer through the air gap between the probe and sample, which turned out to be much larger than the heat transfer through the contact between the probe tip and the sample. Moreover, heat transfer through the air prevents quantitative interpretation of the measured data.

Therefore, for the quantitative profiling of temperature or thermal properties, the influence of air should be carefully removed. A direct approach would be to carry out the measurement in a vacuum. However, measurement in vacuum can entail several problems. First, it might reduce measurement sensitivity since, in a vacuum, the water film that enhances the heat transfer through the tip-sample contact in an atmospheric environment disappears. Second, a new position control mechanism for the SThM probe should be employed, since the laser beam deflection technique widely used for SThM probe position control in an atmospheric environment would not be effective in a vacuum due to significant heating caused by the laser beam. Third, for measurement in a vacuum, the necessary equipment and the measurement process are more expensive.

However, if the sensitivity of the SThM probe is sufficiently improved to detect even the smallest signal generated by heat transfer through the tip-sample solid-solid contact, then measurement in a vacuum can have the following advantages: first, the spatial resolution might be improved further, since the diameter of the tip-sample contact would be significantly reduced without the water film; and second, measurement in a vacuum would allow differentiation of the energy transport through the solid-solid contact from energy transport through solid-liquid-solid contact. Therefore, a vacuum measurement using SThM can potentially be a scientifically useful tool.

For quantitative local thermal conductivity measurements, thermo-resistive probes have been used. The thermo-resistive probe can be operated in either ac or direct current (dc) mode. In dc mode, the thermal conductivity of the sample is obtained from the amount of the power estimated to be transferred to the sample, while the SThM probe is operated in constant temperature mode. Ruiz *et al.* argued the power transferred to the sample is the difference between the power required to maintain the temperature of the thermo-resistive element at a predetermined constant value in contact with the sample, and the power out of contact [15]. Introducing a generalized thermal conductivity approach, Tsukruk *et al.* refined the model suggested by Ruiz *et al.* [16]. Through analytical and numerical thermal modelling of the tip and sample, Lefevre *et al.* showed that a major portion of the power (~ 66 %) goes to the silver coating of the probe wire [17]. However, the method proposed by Ruiz *et al.* has been used without much modification.

For the ac mode of measurement, unlike the dc mode of measurement that requires calibration for the particular probe used, it is supposed to be an advantage that the thermal conductivity of a sample can be extracted from a certain functional relation existing between the heating frequency and the amplitude of temperature oscillation without any calibration of the probe being used. Fiege *et al.* reported that the 3ω method was applied in SThM with a resistive probe for quantitative measurement of the thermal conductivity of gold, silver, and a CVD diamond film with a spatial resolution of approximately 30 nm [18]. However, Lefevre *et al.* later argued with a thermal modelling of the SThM set up that the conventional 3ω method cannot be applied to the SThM setup [19]. Anyway, any other experimental results that can reverse this argument are hard to find ever since.

Since thermo-resistive SThM probes, especially the Wollaston wire probe, are very robust and can be operated in both passive and active modes, they have been used widely for the characterization of thermal properties. However, if the size of the thermo-resistive element of the probe were reduced to improve its spatial resolution, its sensitivity would decrease because a thermo-resistive SThM probe is a line sensor based on a line-heating and line-sensing scheme. In addition, in order to keep the electrical resistance of the lead line smaller than that of thermo-resistive element, the metal lead line should remain thick enough, but this prevents proper thermal insulation of the sensing thermo-resistive element. The thermal sensor should be thermally insulated to the greatest extent possible to enhance its sensitivity: without adequate sensitivity, spatial resolution cannot be improved.

Since the thermocouple SThM probe is, in principle, a point sensor, the size of its sensing part can be reduced without sacrificing sensitivity. The size of the sensing part of the current thermocouple SThM probe is already quite small, and the thermal insulation of the thermocouple junction is good--it is located at the end of the silicon oxide tip whose thermal conductivity is about 1.4 W/m-K. With the rapid evolution of nanofabrication techniques, the thermocouple junction at the end of the tip will become sharper and smaller, and this would enhance sensitivity and spatial resolution even further.

In this study, we suggest a quantitative temperature and thermal conductivity profiling technique with the thermocouple SThM probe, which has advantages in spatial resolution and sensitivity, by removing the influence of air in the environment while operating the probe in both passive and active modes.

PRINCIPLE OF QUANTITATIVE MEASUREMENT

Recently, Kim *et al.* demonstrated, both theoretically and experimentally, a double scan technique that can profile temperature only from the heat transfer through the tip-sample contact by the subtraction of the signal due to the heat transfer through the air [20]. In this study, we demonstrate theoretically and experimentally that this technique can be extended to quantitative thermal conductivity profiling. For a rigorous description of the measurement principle, the heat transfer between a thermocouple SThM probe and a sample is schematically shown in Figure 1. The principle of the technique is as follows.

First, the topography of the sample and the dc thermoelectric signal from the thermocouple junction are measured simultaneously by scanning the probe on the sample surface in controlled force-contact mode. The dc thermoelectric signal measured at this time, as shown schematically in Figure 1, is the signal due to both the heat transfer through the tip-sample contact and the heat transfer through the air. In contact mode, the governing equation for the temperature distribution in the probe is

$$\frac{d}{d\xi}\left[\sum A_i(\xi)k_i\frac{dT_c(\xi)}{d\xi}\right]-p(\xi)h_{eff}(\xi)[T_c(\xi)-T_{sub}(\xi)]+g\left(\xi\right)=0 \tag{1}$$

where ξ represents a position in the probe, T_c is the local temperature in the probe in contact mode, A_i is the cross section of each material in the probe, k_i is the thermal conductivity of each material, p

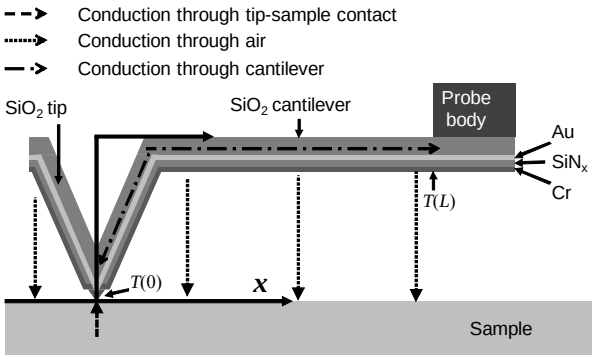

Figure 1. SThM probe in contact with sample and various heat transfer paths around the probe.

is the perimeter of the probe related to the surface exchanging heat flux with the sample, h_{eff} is the effective heat transfer coefficient between the probe and the sample, T_{sub} is the local temperature of the sample, and g is the heat generation per unit length of probe. During passive mode operation for temperature profiling, g=0, but during active mode operation for thermal conductivity, profiling g would be nonzero in the active mode. The boundary condition for equation (1) is

$$\sum A_i k_i \frac{dT_c(0)}{d\xi} = Q_{ts} = G_{ts}(T_c(0) - T_{sub}(0)),\ T_c(L) = T_b \tag{2}$$

where Q_{ts} is the heat flux through the tip-sample contact, G_{ts} is the tip-sample conductance, and T_b is the temperature at the cantilever base contacting the silicon body.

Second, the SThM probe is scanned along the same line as the first scan at a constant height above the sample surface using the topography data obtained from the first scan. The thermoelectric signal measured at this time is due to the heat transfer through the air only, because the tip is not in contact with the sample in the lift mode. In lift mode, the governing equation is

$$\frac{d}{d\xi}\left[\sum A_i(\xi) k_i \frac{dT_l(\xi)}{d\xi}\right] - p(\xi) h_{eff}(\xi)[T_l(\xi) - T_{sub}(\xi)] + g(\xi) = 0 \tag{3}$$

where T_l is the local temperature in the probe in lift mode. The value of h_{eff} in equation (3) is assumed to be the same as that in equation (1). Since the tip is not in contact with the sample, by definition there is no heat transfer through the tip-sample contact. Therefore, the boundary condition of equation (3) is

$$\sum A_i k_i \frac{dT_l(0)}{d\xi} = 0,\ T_l(L) = T_b \tag{4}$$

Then, the difference between the thermoelectric signal obtained in the first scan by contact mode and the signal in the second scan by lift mode is the signal due to the heat transfer through the tip-sample contact only. The equation governing the difference between the temperature in contact mode and the temperature in lift mode can be obtained by subtracting equation (3) from equation (1):

$$\frac{d}{d\xi}\left[\sum A_i(\xi) k_i \frac{dT_{cl}(\xi)}{d\xi}\right] - p(\xi) h_{eff}(\xi) T_{cl}(\xi) = 0 \tag{5}$$

where T_{cl} is T_c - T_l. The boundary condition of this equation is obtained by subtracting equation (4) from equation (2):

$$\sum A_i k_i \frac{dT_{cl}(0)}{d\xi} = Q_{ts} = G_{ts}(T_c(0) - T_{sub}(0)),\ T_{cl}(L) = 0 \tag{6}$$

Unlike equations (1) and (3), equation (5) is homogeneous. Therefore, its solution $T_{cl}(\xi)$ is linearly proportional to Q_{ts} in the whole domain. This linear relationship also holds at the end of the tip (ξ = 0), where the nano-thermocouple junction is located. Hence,

$$Q_{ts} = C\left(T_l(0) - T_c(0)\right) \tag{7}$$

where C is a proportionality constant whose dimension is [W/K]. From equations (2) and (7), the local temperature of the sample T_{sub} is

$$T_{sub}(0) = T_c(0) + \frac{C}{G_{ts}}\left(T_c(0) - T_l(0)\right) \tag{8}$$

Since equation (8) holds regardless of the location of the tip-sample contact x, the temperature profile of the sample is

$$T_{sub}(x) = T_c(x) + \varphi\left(T_c(x) - T_l(x)\right) \tag{9}$$

where φ is a dimensionless constant defined as C/G_{ts}, $T_{sub}(x)$ is the local temperature of the sample, and $T_{c,l}(x)$ is the temperature of the probe at the end of the tip ($\xi = 0$) in contact or lift mode when the tip-sample contact is made at x.

The derivation leading up to equation (9) is exact except for one assumption: that the value of h_{eff} in equation (3) is the same as that in equation (1). One possible approach to minimizing the error caused by this assumption is to keep the height for the lift mode scan as small as possible. However, this approach makes the measurement quite difficult, and cannot remove the error completely.

Another more effective approach can be explained using Figure 2. As a heater line used as a sample moves closer to the end of the SThM tip, the temperature measured by the thermocouple probe rises almost linearly until the sample makes contact with the end of the SThM tip. Therefore, the temperature that would be measured at the height of zero just before the tip-sample contact is made can be obtained from the simple extrapolation of the temperatures measured at two different heights. Thus, we have

$$T_l(x) = T_{l_1} + \frac{\left[T_{l_1}(x) - T_{l_2}(x)\right] l_1}{l_2 - l_1} \tag{10}$$

where T_l is the local temperature just before the tip-sample contact is made, and T_{l1} and T_{l2} are the temperatures measured at lift heights l_1 and l_2, respectively.

Next, the local thermal conductivity of the sample can be obtained as follows. According to the theory of scanning spreading resistance microscopy [21], which is commonly used to measure the local electrical conductivity of semiconductors, the following relation is satisfied:

$$I = \frac{1}{R_{elec}}(V_{sub} - V_{ground}), \quad R_{elec} = \frac{1}{4a\sigma} \tag{11}$$

where I represents the electrical current through the tip-sample contact, R_{elec} is the electrical spreading resistance, V_{sub} is the voltage of the sample at the contact, V_{ground} is the ground voltage, a is the radius of the contact, and σ is the local electrical conductivity of the sample. As the driving potential of electrical current is voltage, the driving potential of heat flux is temperature. From this analogy, we see that the following relation is also satisfied:

$$Q_{ts} = \frac{1}{R_{th}}(T_{sub} - T_\infty), \quad R_{th} = \frac{1}{4ak} \tag{12}$$

where Q_{ts} represents the heat flux through the tip-sample contact, R_{th} is the thermal spreading resistance, T_{sub} is the temperature of the sample at the contact, T_∞ is the temperature of the surroundings, a is the radius of the contact, and k is the local thermal conductivity of the sample.

Hence, from equations (7), (9), and (12), we obtain

$$\frac{1}{k} = \frac{4a}{C}\left[\frac{T_c - T_\infty}{T_l - T_c} - \frac{C}{G_{ts}}\right] \tag{13}$$

In terms of the thermoelectric voltage measured from the SThM probe, equation (13) can be rewritten as

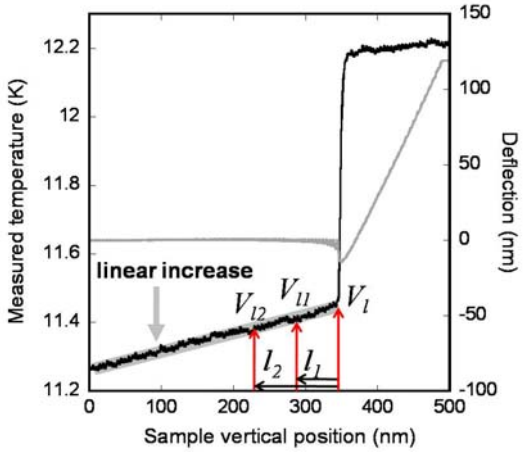

Figure 2. Cantilever deflection and temperature measured by SThM probe as a function of the vertical position of a heater line used as a sample.

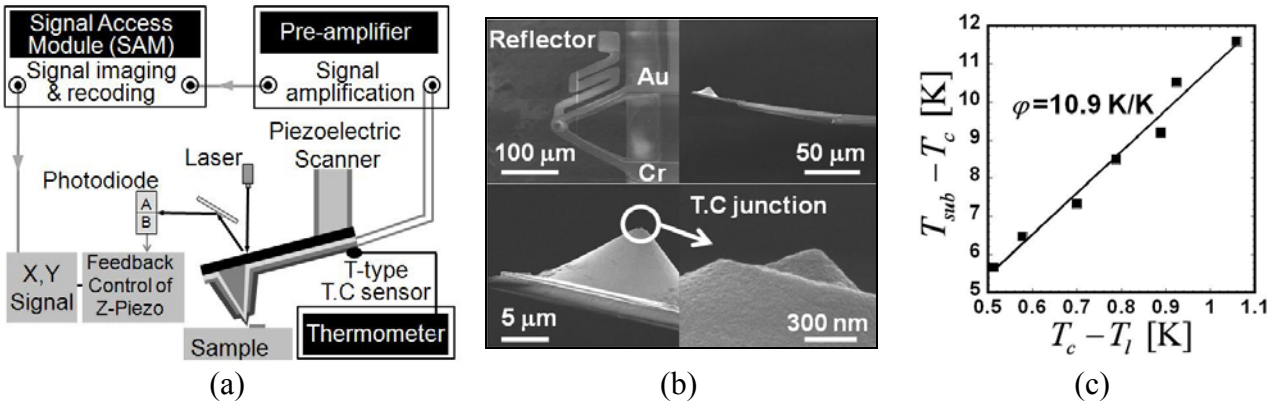
$$\frac{1}{k} = \frac{4a}{C}\left[\frac{V_c + (T_b - T_\infty)S}{V_l - V_c} - \frac{C}{G_{ts}}\right] \tag{14}$$

where S is the thermopower of the thermocouple junction of the SThM probe. Hence, by measuring V_l and V_c, we can obtain the local thermal conductivity of the sample.

EXPERIMENTAL RESULTS

Quantitative temperature profiling

The experimental setup for quantitative temperature profiling is depicted in Figure 3 (a), and consists of a preamplifier, a signal access module (SAM), a SThM probe, and a scanning probe microscope (SPM). Scanning electron microscope (SEM) pictures of the SThM probe used in this experiment are shown in Figure 1 (b). To reduce the heat transfer through the air and the cantilever, the height of the probe tip was increased to 12 μm and the cantilever material was changed from silicon nitride to silicon oxide, whose thermal conductivity is much lower than that of silicon nitride. The design and fabrication of this probe is reported in [22]. Since the dimensionless constant φ defined as C/G_{ts} in equations (8) and (9) differs for each SThM probe, it should be measured for each probe [20]. The dimensionless constant φ for the probe used in this experiment is 10.9 K/K, as shown in Figure 3 (c).



(a) (b) (c)

(b) SEM images of full SiO2 SThM probe: top view (upper left), side view (upper right), probe tip (lower left), thermocouple junction (lower right). (c) The difference between the temperature of the sample and that measured in contact mode as a function of temperature jump during tip-sample contact.

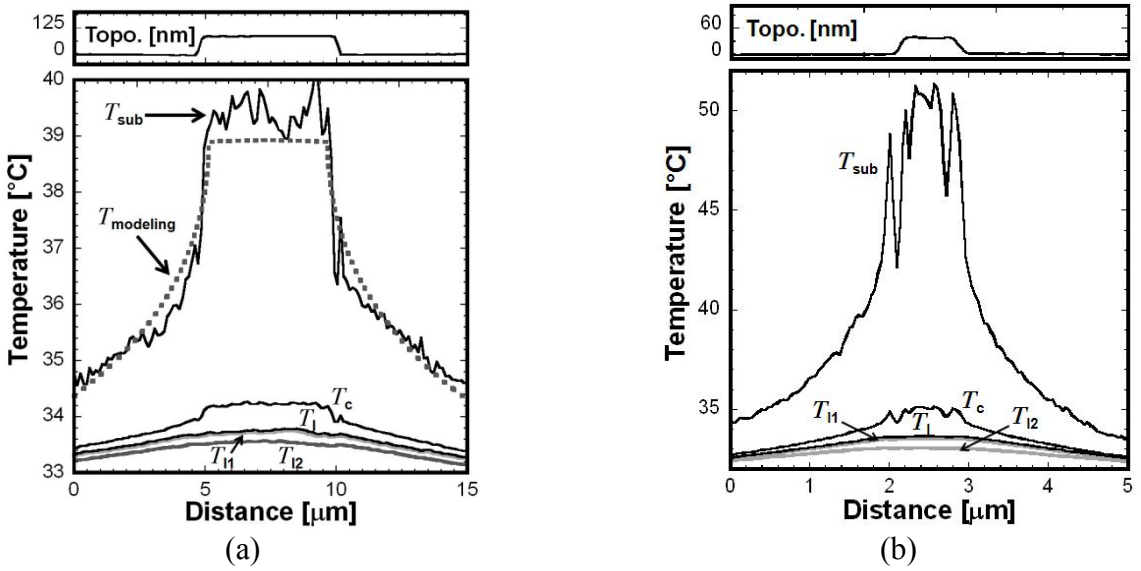


Figure 4. The temperature profile around an electrically heated aluminum line measured in contact mode T_c, the profiles obtained at lift heights of l_1 and l_2 T_{l1} and T_{l2}, the profile obtained by equation (10) T_l, and the temperature profile of the substrate obtained by equation (9) T_{sub} (a) for 5 μm wide line (b) for 500 nm wide line.

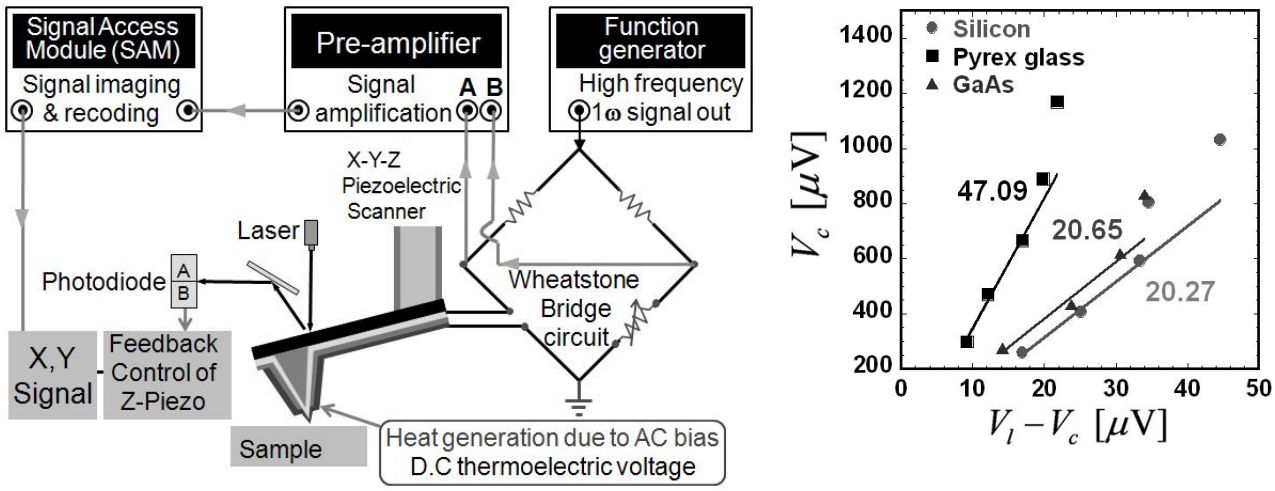
The temperature profile around an electrically heated aluminum line measured in contact mode T_c, the profiles obtained at lift heights of l_1 and l_2 T_{l1} and T_{l2}, the profile obtained by equation (10) T_l, and the temperature profile of the substrate obtained by equation (9) T_{sub} are compared in Figure 4. To confirm that the temperature profile is quantitatively correct, the temperature profile by modeling T_{model} was also compared for 5 μm wide aluminum line in Figure 4 (a). The amount of heat generation in the heater required in the modeling was obtained from the current and voltage applied to the aluminum line heater.

The temperature profile obtained using equation (9) is much closer to the modeling result than the profile obtained by direct contact mode measurement. Therefore, this technique has an advantage in quantitative temperature profiling using SThM by significantly reducing the influence of heat transfer through the air.

Quantitative thermal conductivity profiling

The experimental setup for quantitative thermal conductivity profiling is depicted in Figure 5 (a), which consists of a function generator, a preamplifier, a signal access module (SAM), a Wheatstone bridge circuit, a SThM probe, and a scanning probe microscope (SPM). The function generator was used to apply a high frequency ac bias to heat the thermocouple of the SThM probe. The Wheatstone bridge was used to remove the dominant ac voltage, and thereby improve the measurement sensitivity of the dc thermoelectric voltage generated from the thermocouple junction of the SThM probe. The dc thermoelectric voltage from the thermocouple junction was fed into the SAM and became simultaneously available with the topography signal of the SPM.

The heating of the thermocouple junction of the SThM probe is not exactly point-heating, because the junction of the probe is heated by the Joule effect. However, the current density increased approaching the junction and eventually maximized at the junction, whose diameter is about 350 nm for the particular probe used. Since the temperature peaked sharply at the junction (where the thermoelectric signal is measured), this technique is very close to a point-heating and point-sensing scheme.



(a) (b)

Figure 5. (a) Schematic diagram of experimental setup for thermal conductivity profiling. (b) Thermoelectric voltage generated from the thermocouple junction of the probe in contact with sample V_c as a function of the difference between the one in lift mode and the one in contact V_l - V_c.

In order to obtain local thermal conductivity quantitatively from equation (14), we determined C/a and a dimensionless constant C/G_{ts}. To do so, we rewrote equation (14) as

$$V_c = \left(\frac{C}{4ak} + \frac{C}{G_{ts}} \right) (V_l - V_c) - (T_b - T_\infty) S \tag{15}$$

and determined these two constants experimentally from the proportionality of V_c with respect to V_l - V_c. Silicon and Pyrex glass were used as the samples because their thermal properties are well known. The experimentally-obtained relation between V_c and V_l - V_c is shown in Figure 5 (b). From Figure 5(b), C/a and C/G_{ts} were determined to be 151 W/m-K and 20.0 K/K, respectively, for this particular probe. To ensure that these constants are valid, the same experiments were carried out for a GaAs sample whose thermal properties are also well known. The experimentally-obtained slope and the slope obtained from equation (15) match quite closely.

To estimate the spatial resolution of our technique, the thermal conductivity distributions across the samples, within which a thin silicon oxide layer was sandwiched between single crystal silicon layers, are profiled as shown in Figure 6. From the C/a and C/G_{ts} values measured above for this particular probe, and V_l and V_c, the thermal conductivity profiles were obtained using equation (14).

For the sample of 1.4 μm silicon oxide layer with tip-sample contact made only on the silicon oxide layer, thermal conductivity was measured to be around 1.4 W/m-K, which is known to be that of silicon oxide, as shown in Figure 6 (a). Hence, we show that this technique is quantitative. However, we also note that near the interface of silicon and silicon oxide, the measured thermal conductivity changes rather smoothly. This appears to be because, while the tip is positioned near the interface, both the silicon and silicon oxide regions are within the tip-sample contact and influence the heat flux from the tip to sample, as shown in Figure 6.

To estimate the spatial resolution of this technique more accurately, the thermal conductivity distributions across the samples with 200 nm-thick and 100 nm-thick silicon oxide layers were also obtained, and are shown in Figure 6(b) and (c) respectively. For the 200 nm-thick sample, the thermal conductivity of silicon oxide could be measured quantitatively near the center of the silicon oxide layer. However, for the 100 nm-thick sample, the measured thermal conductivity was not quantitatively correct, although the SThM probe could detect a region of lower thermal conductivity. From these results, the spatial resolution of this particular probe for quantitative measurement seems to be about 150 nm.

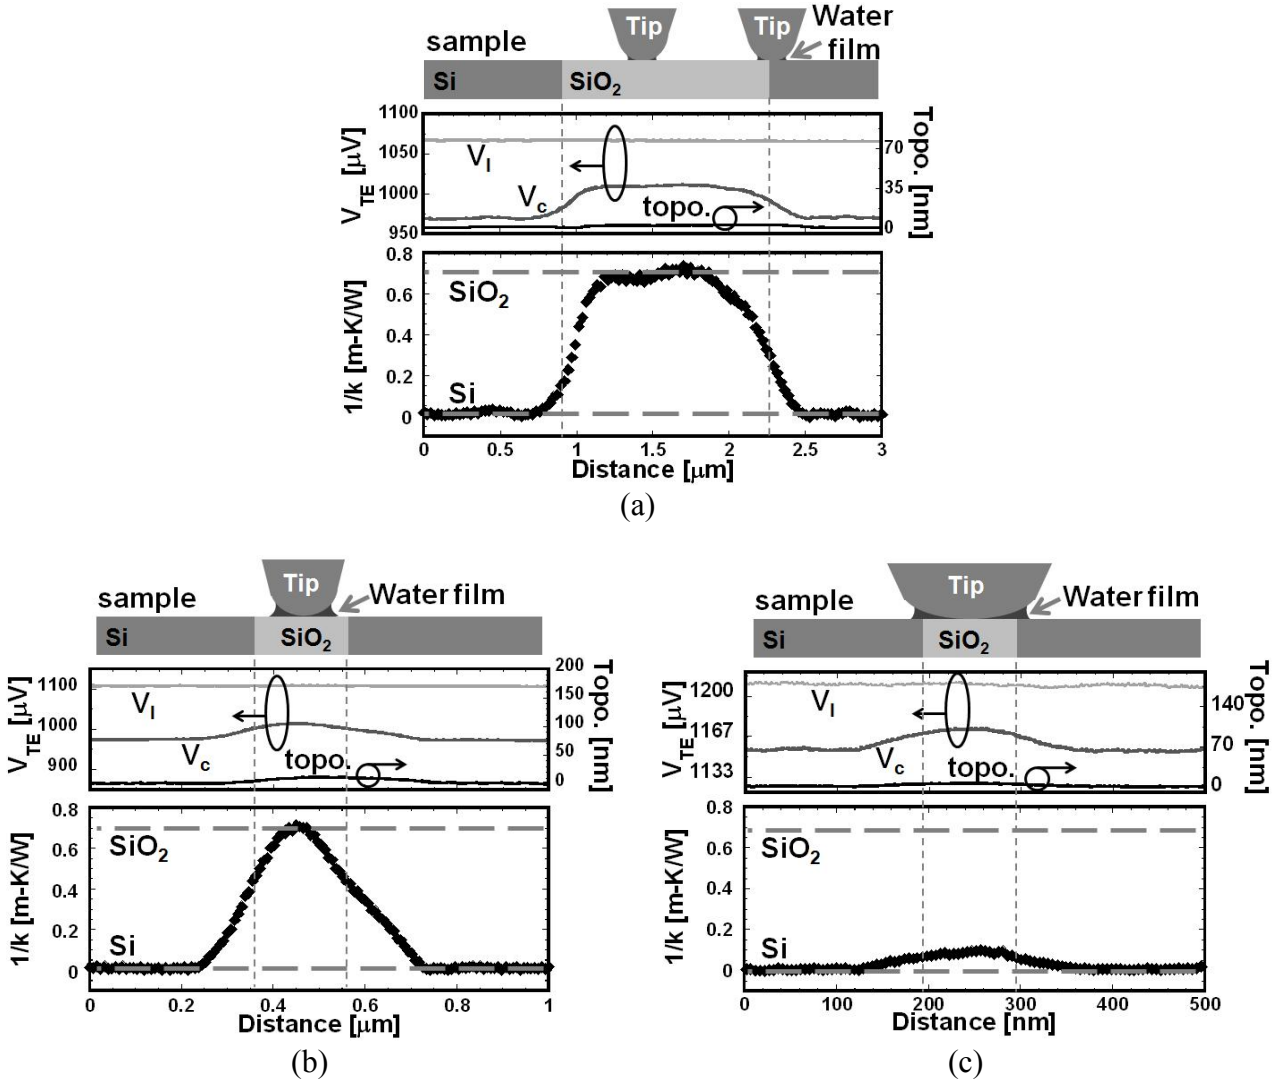


Figure 6. Thermoelectric voltage profile generated from the thermocouple junction of the SThM probe in lift mode V_l, the profile in contact mode V_c, the topography of the sample (upper), the thermal conductivity profile converted from V_c and V_l using equation (14) (lower) for (a) 1.4 μm-thick silicon oxide sample. (b) 200 nm-thick silicon oxide sample. (c) 100 nm-thick silicon oxide sample

CONCLUSIONS

In this study, we developed a quantitative temperature and thermal conductivity profiling technique which eliminates the influence of heat transfer through the air, and measures the temperature and thermal conductivity of a sample from the tip-sample heat transfer only, operating thermocouple SThM probe in both passive and active modes. The principle of our technique was explained through a rigorous analysis of the heat transfer phenomena occurring during measurement. We experimentally determined two characteristic constants of the particular SThM probe used. The spatial resolution of this technique was demonstrated by obtaining the thermal conductivity profiles of samples in which a thin silicon oxide layer was sandwiched between single crystal silicon layers. For samples with a 1.4 μm-thick silicon oxide layer and a 200 nm-thick oxide layer, the thermal conductivity distributions were quantitatively profiled. However, for a sample with a 100 nm-thick silicon oxide layer, the obtained profile was not quantitative. From the experimental results obtained thus far, the quantitative spatial resolution of this technique is estimated to be around 150 nm. In order to further improve spatial resolution, the tip radius of the completed thermocouple SThM probe should be decreased.

HEAT TRANSFER IN PATIENTS UNDER HYPOTHERMIC CONDITIONS

F.E.M. Janssen, G.M.J. Van Leeuwen and A.A. van Steenhoven *
Department of Mechanical Engineering
Eindhoven University of Technology, the Netherlands

ABSTRACT. Most bio-heat transfer models for patients under hypothermic conditions contain three sub-models: a passive heat transfer model, an active coupling between local blood flow and temperature, and a pharmacological model to incorporate the effects of drugs. In this paper an illustrative example will be given focussed on scalp cooling to prevent chemotherapy induced hair loss. Scalp cooling can reduce hair loss. Unfortunately, the efficacy of scalp cooling varies strongly. A systematic evaluation of the current hypothesis for the hair preservative effect of scalp cooling is necessary for a better understanding of the various important parameters of scalp cooling. To quantify the contribution of the putative mechanisms of scalp cooling, a computational model was developed, partly based on experimental data. With the complete model, we evaluated the effect of several scalp cooling protocol parameters.

Keywords: *Bio-heat transfer, Scalp cooling, Pharmacokinetic model*

INTRODUCTION

Chemotherapy induced hair loss is a feared side effect of cancer treatment [1]. Scalp cooling during the administration of cytotoxic drugs can reduce this hair loss [2]. Cooling can be achieved by means of a cap, that is pre–cooled in a freezer or that exchanges coolant with a reservoir. The current hypothesis for the hair preservative effect of scalp cooling is that cooling of the scalp skin reduces blood flow (perfusion) and chemical reaction rates [3]. Reduced perfusion leads to less cytotoxic drugs available for uptake, while the reduced temperature decreases uptake of and damage by chemotherapy. Altogether, less damage is done to the hair cells, and the hair is preserved.

To support this hypothesis, we conducted a series of in vitro biological cell experiments in an earlier study [4], in which local tissue concentrations were related to cell damage at different temperatures. A typical result is given in figure 1. Cell survival significantly increased with decreasing doxorubicin concentrations. When compared to an exposure temperature of 37°C, a decrease in temperature also has a significant increasing effect on cell survival. No significant differences were found between exposure temperatures of 22°C and 10ºC. At a concentration of 0.5 µg ml^{-1}, cell survival increased from 41% (37°C) to 85% and 89% by reducing temperature to 22°C and 10°C, respectively.

However, the effect of scalp cooling in clinical practice varies strongly [5]. A systematic evaluation of the current hypothesis is necessary for a better understanding of the various important parameters of scalp cooling.

In the present study, we want to quantify the contribution of the putative mechanisms by which scalp cooling prevents hair loss. To that end, a computational model has been developed based on the current hypothesis of the mechanisms of scalp cooling. The full computational model consists of sub–models that describe heat transfer in the human head, perfusion through the scalp skin as function of temperature and transport of doxorubicin (a specific chemotherapy agent) in the human body. Experiments have validated and improved the different computational models. As the heat transfer model and the skin perfusion relation is already published elsewhere [6, 7], we will here mainly focus on the pharmacokinetic model.

METHODS

Heat transfer model

Although more complicated models can be used to analyze heat transfer in perfused tissues [8], in this study a one dimensional heat transfer model was used, that uses the Pennes' equation to describe heat transfer in the human head during scalp cooling. The model consists of several tissue layers, representing the brain, skull, fat, skin, hair and cold cap. Model properties are shown in table 1, in which q_m represents the metabolic heat production and w_b the perfusion. For a more detailed description of the heat transfer model of the head, the reader is referred to [6]. Parameter studies with the heat transfer model showed that key parameters that determine the actual skin temperature during scalp cooling are the size of both the sub–cutaneous fat–layer and the hair–layer.

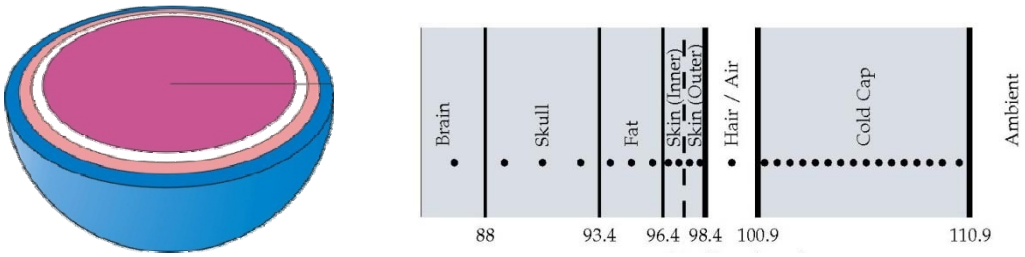

Figure 2. Schematic representation of the outer part of the heat transfer model

Table 1
Thermophysical Tissue Parameters used in the Heat Transfer Model (from [6])

	d (mm)	k (W/m·K)	c (J/ kg·K)	ρ (kg/m^3)	q_m (W/m^3)	w_b (kg/m^3·s)
Brain	88.0	0.5	3800	1000	8800	8.5
Skull	5.4	1.0	1700	1500	130	0.150
Fat	3.0	0.2	2390	1050	130	0.2
Inner skin	1.0	0.384	3570	1130	500	1.5
Outer skin	1.0	0.384	3570	1130	0	0.0
Hair	2.5	0.04	1000	1	0	0.0
Cold Cap	10.0	0.500	4300	1000	0	119.0

Relationship between temperature and blood flow

As an input in the heat transfer and pharmacokinetic models a relation is needed between local skin temperature and local skin perfusion. In an earlier study [7], we established such a relationship using laser Doppler flowmetry and thermocouple measurements and the result is given in figure 3.

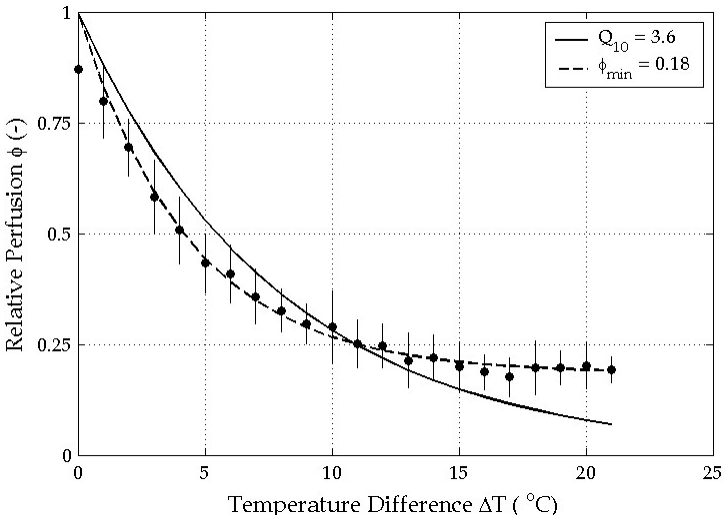

Figure 3. Average temperature difference and perfusion and best fits for minimum perfusion, Φ_{min}(—) and Q_{10} (--). Adapted from [8].

Relative perfusion as a function of the temperature difference appeared to be well described by:

$$\emptyset_w = \frac{w_b}{w_{b,0}} = \emptyset_{min} + (1 - \emptyset_{min}) e^{\left(-\frac{T_0 - T}{\Theta}\right)} \quad (1)$$

in which $w_{b,0}$ and T_0 are the perfusion and temperature in neutral state. The limit in perfusion, Φ_{min}, was found to be equal to 18%, and the rate of change, Θ, was found to be equal to 4.3ºC, indicating that 95% of the drop in perfusion is reached for a temperature difference of approximately 13ºC.

Pharmacokinetic model

An eight–compartment physiologically based pharmaco-kinetic (PBPK-) model for doxorubicin was developed. It is largely based on a previous model for doxorubicin [9], with some modifications. A schematic of this model is shown in figure 4.

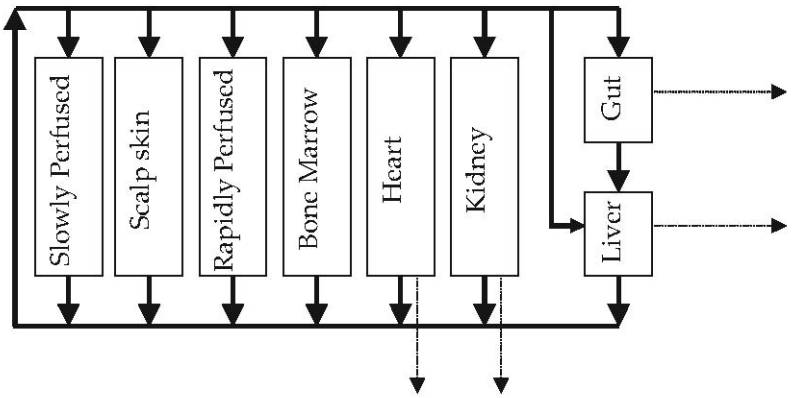

Figure 4. Schematic representation of the PBPK model for doxorubicin.
Solid lines represent the blood circulation, dashed lines represent the metabolic and excretory pathways that eliminate doxorubicin from the body. Adapted from [9].

The standard model represents a female with a body mass of 70 kg and a body height of 1.67 m, which is in agreement with the mean of the Dutch female population in 2002. For each compartment, a generic tissue mass balance for doxorubicin is formulated:

$$\frac{dA_T}{dt} = W_B (C_A - C_V) - M \tag{2}$$

in which A_T (mol) is the amount of doxorubicin in the tissue, W_B (m^3 s^{-1}) is the volumetric blood flow rate through the tissue, C_A and C_V (mol m^{-3}) are the arterial concentration entering the tissue and the venous concentration leaving the tissue, respectively, and M (mol s^{-1}) is the rate of metabolism and/or excretion of doxorubicin in the tissue. Values for blood flow and tissue volume used in the standard model are shown in table 2.

Table 2
Tissue Properties used in the Pharmacokinetic Model.

	W_B (1/min)	V_T (l)	T_{DNA} (μM)	T_{CAL} (μM)
Liver	0.35 ± 0.05	1.82 ± 0.28	23.7 ± 2.3	44.6
Heart	0.26 ± 0.04	0.35 ± 0.04	8.3 ± 4.0	43.8
Kidney	1.05 ± 0.08	0.28 ± 0.03	16.2 ± 2.2	52.3
Bone Marrow	0.29 ± 0.02	1.47 ± 0.14	19.1 ± 13.7	25
Gut	1.17 ± 0.11	1.19 ± 0.13	25.2 ± 2.3	25
Slowly Perfused	1.57 ± 0.15	51.2 ± 5	4.5	15
Scalp Skin	0.29 ± 0.03	2.89 ± 0.28	4.5 1	5
Blood	5.84	5.53	-	-

Values for perfusion and volume are obtained from [10], values for binding capacity are taken from [9]. Values are shown as mean ± standard deviation.

To account for saturable chemical-specific binding, a partitioning coefficient K_p was introduced [9], which relates the venous concentration to the tissue concentration:

$$C_V = \frac{1}{K_p} C_T \tag{3}$$

Here the partitioning coefficient is mathematically represented by [11]:

$$K_p = \left(1 + \frac{T_{DNA}}{K_{DNA} + C_T} + \frac{T_{CAL}}{K_{CAL} + C_T}\right) \tag{4}$$

with T_{DNA} and T_{CAL} the DNA and cardiolipin binding capacity available and K_{DNA} and K_{CAL} the binding affinities of doxorubicin to DNA and cardiolipin, respectively (see table 2), and C_T the doxorubicin tissue concentration $C_T = A_T/V_T$. The affinity constants for DNA and cardiolipin are set to K_{DNA} = 200 nM and K_{DNA} = 400 nM, respectively (see table 3).

Table 3
Body Properties used in the Pharmacokinetic Model.

Parameter	Symbol	Standard model
Body Mass [1]	m_b	70 kg
Height [1]	h_b	1.69 ± 0.2 m
BMI [1]	-	24.5 ± 1.7 kg m^{-2}
Surface Area	-	1.8 m2
Cardiac Output [2]	W_{CO}	5.8 l min^{-1}
Dox fraction bound to blood [3]	F_B	0.7
Affinity constant for DNA [3]	K_{DNA}	200 nM
Affinity constant for cardiolipin [3]	K_{CAL}	400 nM
Fraction renal blood flow cleared [3]	F_f	0.1

[1] Based on data obtained from Statistics Netherlands (CBS)
[2] Value obtained from [10] and [3] based on data from [9].

Binding to proteins in the blood is also accounted for. It is assumed that only unbound drug concentration in the blood C_A is available for uptake in the tissue – except for the liver, where total drugs C_{BL} is available for uptake. The fraction of doxorubicin that is bound to plasma proteins is equal to F_B =0.7 [9]. The blood compartment mass balance may now be specified as:

$$\frac{dA_B}{dt} = \sum_i W_{B,i} C_{V,i} - C_A W_{CO} - W_{B,L}(C_{BL} - C_A) \tag{5}$$

where $W_{CO} = \Sigma W_{B,i}$ is the total cardiac output. With A_B (mol) the amount of doxorubicin in the blood, the total arterial concentration C_{BL} and unbound arterial concentration C_A are defined as:

$$C_{BL} = \frac{A_B}{V_B}$$
$$C_A = C_{BL}(1 - F_B) \tag{6}$$

In some tissues doxorubicin is metabolized to non–harmful products. In the liver, kidney and the heart, doxorubicin is metabolized to doxorubicin aglycone (AG), which can be described by a linear process:

$$M_{AG} = K_{AG} C_T V_T \tag{7}$$

Other metabolic processes include the metabolism by aldo–keto reductase (AKR) to doxorubicinol in the liver and the kidney, and excretion in the faeces by P–glycoprotein (PGP) in the liver and the gut. Michaelis–Menten kinetics may be used to describe these processes:

$$M_{AKR,PGP} = \frac{V_{max-AKR,PGP} C_T}{K_{M-AKR,PGP} + C_T} \tag{8}$$

Finally, excretion of doxorubicin by filtration in the urine in the kidney compartment is modelled by:

$$M_f = P_f W_B C_A \tag{9}$$

Values for metabolic activity that are used in the pharmacokinetic model under standard conditions are shown in table 4. For each tissue compartment, see equations 2 and 5, a single ordinary differential equation (ODE) is obtained. The complete set of ODEs is solved using MATLAB.

Table 4
Doxorubicin Specific Metabolic and Excretory Parameters used in the pharmacokinetic model.

	AG[1]	AKR[2]		PGP[2]	
	K_m	K_m	V_m	K_m	V_m
Liver	12104	275	1804	10	300
Kidney	484	539	3161	10	100
Heart	760	-	-	-	-
Gut	-	-	-	0.2	80

[1] The first order rate constant K_m for metabolism to aglycone (AG) is expressed in (h^{-1} kg tissue^{-1}).
[2] The activities for aldo–keto reductase (AKR) and P–glycoprotein (PGP) are expressed as K_m (μM) and V_m (μmol h^{-1} kg tissue^{-1}).

RESULTS

Validation

Unfortunately, there is hardly any data available describing the doxorubicin concentration in time for individual organs in humans. Currently, only blood serum levels in time are available in literature. This means that the results of the model can only be compared to these blood serum levels, and that the model cannot be validated on the scale of individual organs. However, the concentration in the blood serum is a direct result of the distribution, metabolism and excretion of doxorubicin in individual organs. When the model accurately predicts blood serum levels, it is very likely that the concentration levels in each individual organ are of the correct order. Therefore, we compared blood serum levels from the study of Andersen [12] with results from our model. Figure 5 shows the blood plasma concentration (mean ± SD) of 24 patients receiving a dose of 50 mg m^{-2} as a 10 minute infusion. The results of our model describe the measured data well; peak concentration, first half–life time and final half–life time are predicted within the range of intra–individual variation.

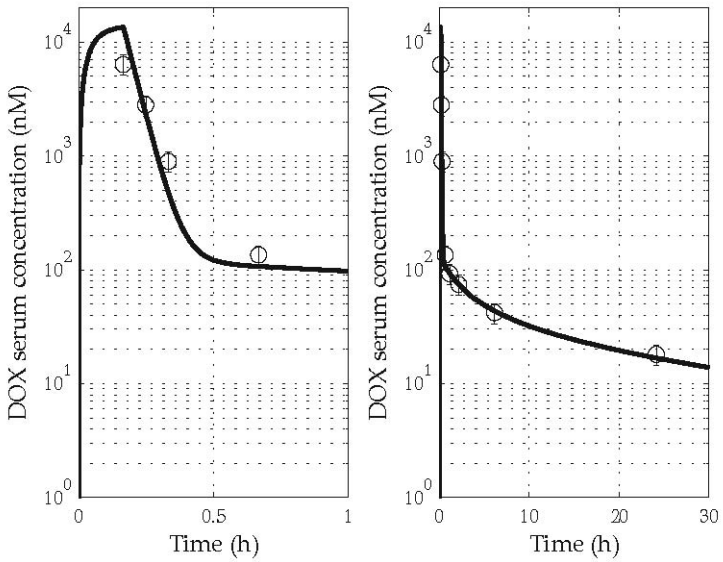

Figure 5: Blood plasma concentrations obtained by the pharmacokinetic model (–) compared to the average blood plasma concentration (○, mean ± SD) of 24 patients receiving a dose of 50 mg m^{-2} [12]. The left figure shows a time range of 30 hours, the right figure shows the first hour only.

Scalp cooling under standard conditions

The model was used for a first investigation of the effects of scalp cooling on local scalp skin concentrations. A standard chemotherapy procedure was modelled, in which the patient receives a total dose of 75 mg m^{-2} doxorubicin, intra–venously administered in a period of 2 hours. The effect of scalp cooling was compared to no cooling. In the scalp cooling case, perfusion to the scalp skin was reduced to 20% during administration of chemotherapy and the subsequent 2 hours, for a total period of 4 hours. The results of these simulations are shown in figure 6.

Blood serum levels are continuously high during the 2 hours of administration, after which they show a rapid fall. The concentration in the scalp skin is a little higher than the blood serum concentration and it stays relatively high for the complete simulation period. Doxorubicin concentration in the scalp is significantly lower when scalp cooling is applied, compared to no scalp cooling. After a certain period, no distinction in scalp skin concentration can be made between the two cases. When no cooling is applied, the maximum concentration in the scalp is equal to 1.66 μg ml^{-1} and the average concentration during the first 24 hours is 0.61 μg ml^{-1}. With scalp cooling, the maximum concentration is 0.48 μg ml^{-1} and the average concentration equals 0.38 μg ml^{-1} . Thus, reducing the perfusion by a factor of 5, see figure 3, reduces the maximum concentration by a factor of 3.5 and the average concentration by a factor of 1.6. As seen from figure 1, such a reduction can have a notable effect on cell survival.

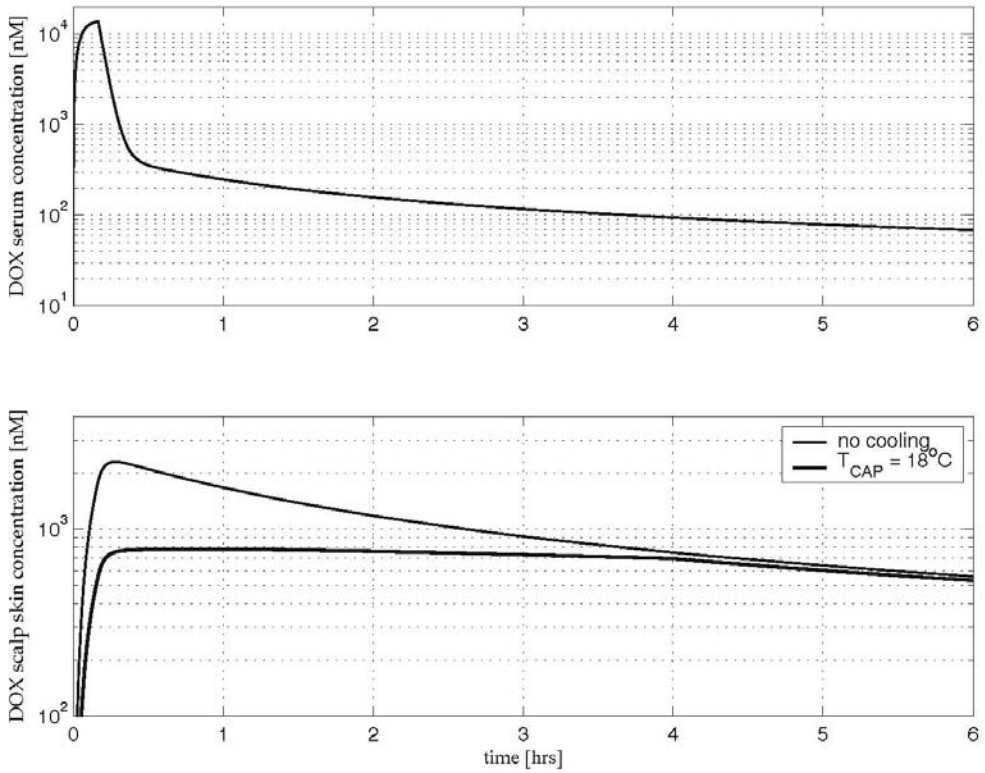

Figure 6: Model prediction of doxorubicin serum levels C_{serum} (top) and scalp skin concentration C_{scalp} (bottom) after a 2 hour intra– venous administration of a total dose of 75 mg m^{-2} doxorubicin. The bottom figure shows the effect of cooling the scalp to 19.2°C for 4 hours during administration on scalp skin concentration, compared to no cooling at all.

Parameter study

In a parameter study we investigated some important parameters in the physiologically based pharmacokinetic model for doxorubicin, see also [13]. The effect of these parameters on maximum and average scalp skin concentration during scalp cooling was evaluated. In the simulations, we used a skin temperature of T = 19.2ºC and a minimum perfusion value of Φ_{min} = 0.20. As an example, values used and results for tissue perfusion are shown in table 5. Changes in these perfusion rates are compensated by changing perfusion or volume of the rapidly perfused compartment, such that cardiac output and total body volume of the model remain the same. When the standard deviation was unknown, we used the mean value and a variation of 20% to define the lower and upper limit.

The parameter study [13] shows that the most important parameters influencing maximum doxorubicin concentration in the scalp skin during scalp cooling are the perfusion of both the scalp skin and the liver, the body mass, the body height and the fraction of doxorubicin bound to the blood. Maximum modelled doxorubicin concentration is 0.56 μg ml-1, for an increase in scalp skin perfusion from 0.23 to 0.35 l min^{-1}. A decrease in perfusion to 0.23 l min^{-1} results in a concentration of 0.42 g ml^{-1}, which is the lowest peak concentration in the parameter study. This influence of perfusion was as expected, since the concentration is flow limited. The influence on average doxorubicin concentration in the scalp skin is a bit lower, however, seeing that results range from 0.35 to 0.40 μg ml^{-1}.

Table 5
Effect of Changes in Tissue Perfusion (W_B) on Maximum Scalp Skin Concentration (C_{max}) and Average Scalp Skin Concentration C_{avg} during Cooling (T = 19.2°C, Φ_w =0.27).

	W_B (l min^{-1})		C_{max} (μg ml^{-1})		C_{avg} (μg ml^{-1})	
	down	up	down	up	down	up
Liver	0.25	0.45	0.52	0.45	0.40	0.35
Heart	0.18	0.34	0.49	0.47	0.38	0.37
Kidney	0.89	1.21	0.50	0.47	0.39	0.36
Bone marrow	0.25	0.33	0.48	0.48	0.38	0.38
Gut	0.95	1.37	0.51	0.46	0.39	0.36
Slowly perfused	1.27	1.87	0.50	0.47	0.37	0.38
Scalp skin	0.23	0.35	0.42	0.56	0.35	0.39

Up and down correspond to increasing or decreasing a parameter, respectively. Responses of the model under standard conditions are C_{max} = 0.48μg ml^{-1} and C_{avg} =0.38 μg ml^{-1}

CONCLUSION AND DISCUSSION

In this paper, we developed a computational model for mass transport of chemotherapy in the human body during scalp cooling. Doxorubicin is used as a chemotherapeutic agent. In the model, we used a lumped–parameter approach with the assumption that doxorubicin exhibits flow–limited characteristics. Comparisons of the pharmacological model of doxorubicin to plasma concentration data showed that the model was able to predict these concentrations well. Therefore, the model was used to investigate the effect of scalp cooling, especially the effect of reduced tissue perfusion, on local tissue concentrations.

The results of the model show that during scalp cooling, maximum tissue concentrations may be reduced by a factor of 3.5 when perfusion is reduced by a factor of 5. The average concentration was reduced by a factor of 1.6. As illustrated in figure 1, these reductions can have a dramatic influence on cell survival, especially when an additional effect of temperature on metabolism is present. The parameter study showed that important parameters in the model are the perfusion of both the scalp skin and the liver, the body mass and the body height. Other important parameters are the fraction of doxorubicin bound to the blood and the volume of the scalp skin.

One limitation of the pharmacological model used is that the only effect of scalp cooling that is modelled is reduced tissue perfusion. Due to cooling, mass transfer characteristics may change. In a study on the temperature dependent dermal absorption of chloroform, a large decrease in skin permeability with decreasing temperature was found [14]. In our model, the effect of reduced temperature might be modelled using a temperature dependent partition coefficient K_p (see equation 4). For this, however, knowledge of the temperature dependency of these coefficients for doxorubicin is needed. Currently, this data is unavailable. Therefore, any reduced uptake of doxorubicin due to reduced temperature is unaccounted for in the current model. This means that predicted tissue concentrations by the model might be higher than in reality.

In parallel studies, we are now extending the developed model to complete cooling of patients undergoing cardiac surgery with the emphasis on influence of anaesthesia [15,16] and individualised human thermoregulation [17].

MOLECULAR TRANSPORT PHENOMENA AND THE KINETIC BOUNDARY CONDITION AT THE VAPOR-LIQUID INTERFACE

S. Fujikawa*
Division of Mechanical and Space Engineering, Hokkaido University, Sapporo, Japan

ABSTRACT. The kinetic boundary condition at the interface of a vapor and its condensed phase for the Boltzmann equation, and evaporation and condensation coefficient are discussed in detail on the basis of the author's recent studies. By molecular dynamics simulations, the kinetic boundary condition is found to be the product of three one-dimensional Maxwellian distributions for the three velocity components of vapor molecules and a factor including a well-defined condensation coefficient. The condensation coefficient of water is successfully determined by fusing experimental data acquired by the shock tube into numerical simulations of the Gaussian-BGK Boltzmann equation. It is found that, in conditions of weak condensation near the equilibrium state, the condensation coefficient of water is equal to the evaporation coefficient (=unity) evaluated by molecular dynamics simulations at the equilibrium state and it decreases as the vapour-liquid system deviates from the equilibrium state. The boundary conditions for the Navier-Stokes-type set of equations are also derived by the perturbation analysis.

Keywords: *evaporation, condensation, kinetic boundary condition, molecular dynamics, molecular gas dynamics*

INTRODUCTION

In fluid dynamics and molecular gas dynamics, boundary conditions are of paramount importance because they have relevance to the drag and lift exerted on bodies and heat and mass transfer across boundaries. Especially, in cases where the boundary condition is for the interface of a vapor and its liquid phase, it involves some difficult problems, which have been discussed for more than one century and are not yet made clear [1-3]. This is because the derivation of the boundary condition requires detailed information of molecular phenomena at the interface, whilst the governing equations (the Navier-Stokes equations in fluid dynamics and the Boltzmann equation in molecular gas dynamics) can be derived from macroscopic or microscopic conservation laws.

As shown in Fig. 1, the regions of both sides of the interface of a vapor and its liquid phase consist of three regions, i.e., (i) a transition region where the density varies continuously from the liquid phase to the vapor one, (ii) a nonequilibrium vapor region with a temporal scale of mean free time and a spatial one of mean free path, and (iii) a local equilibrium vapor region **(**continuum region**)**. The interface of the vapor and its liquid phase is defined as that between the transition region and the nonequilibrium region, and it is in a nonequilibrium state [4].

Physical phenomena in these regions obey different governing equations, e.g., molecular dynamics (MD) in the transition region, molecular gas dynamics in the nonequilibrium region, and fluid dynamics in

Physical phenomena in these regions obey different governing equations, molecular dynamics in the transition region, molecular gas dynamics in the nonequilibrium region, and fluid dynamics in the equilibrium region.

the equilibrium region. Gas flows accompanied with mass, momentum, and energy transport at the interface are accurately described by molecular gas dynamics based on the Boltzmann equation. Then, the Boltzmann equation requires the boundary condition called the kinetic boundary condition (KBC). The KBC has two problems unresolved [4]. One is whether or not the KBC available and believed reliable is physically correct. The other is that the KBC contains two unknown parameters called evaporation and condensation coefficient [3, 4]. These coefficients have been investigated for more than one century, and they have not been determined accurately [3,5,6].

Fujikawa and his group have long engaged in accurate determination of evaporation and condensation coefficient by their original method based on molecular dynamics and molecular gas dynamics where simulation data of the latter are fused with experimental ones acquired by a shock tube [7-11]. The present paper is concerned with the author's state-of-the-art studies of the boundary condition for the Boltzmann equation, the boundary condition for the Navier-Stokes-type set of equations, and the evaporation and condensation coefficient of water.

MOLECULAR DYNAMICS

Formulation of the kinetic boundary condition

In this section, using MD simulations, we present a new KBC for the Boltzmann equation at the stationary interface of argon vapor and its condensed phase. The conventional KBC available and believed reliable, an only model, is [3, 12]:

$$f^{\text{out}} = [\alpha\rho^* + (1-\alpha)\sigma]\hat{f}^*(T_\ell) \qquad (\xi_z > 0), \tag{1}$$

$$\sigma = -\sqrt{\frac{2\pi}{RT_\ell}}\int_{\xi_z<0}\xi_z f^{\text{coll}} d\xi, \tag{2}$$

where f^{out} is the velocity distribution function of molecules leaving the interface, $\rho^*\hat{f}^*(T_\ell) = \rho^*\exp[-(\xi_x^2+\xi_y^2+\xi_z^2)/(2RT_\ell)]/[(2\pi RT_\ell)^{3/2}]$ is the equilibrium distribution function with the saturated vapor density ρ^* at the temperature of the condensed phase T_ℓ, f^{coll} is the distribution function of molecules incident on the interface, ξ_x and ξ_y are the molecular velocity components tangential to the interface, ξ_z is the normal component, R is the gas constant per unit

mass, and α is a parameter between zero and unity. The simpleness of equation (1) with (2) is suitable for analytical studies and a number of problems have been solved with this KBC [3, 12, 13].

However, equation (1) assumes, without being verified, that f^{out} is in proportion to $\hat{f}^*(T_\ell)$. On this assumption, the lack of necessary information of phenomena at the interface is augmented by the introduction of a parameter α ; the mass flux across the interface is then given as $\alpha(\rho^* - \sigma)\sqrt{RT_\ell/(2\pi)}$. Historically, α has been called the condensation coefficient and its value, e.g., for water, has excited much controversy [6]. Unless the validity of equation (1) is proven, however, such controversy may be unfruitful. Although some authors recently addressed the KBC at the interface with MD methods [14, 15], they could not reach the physically correct KBC owing to their ambiguous definitions of the evaporation and reflection of molecules [16, 17].

In the kinetic theory, the velocity distribution function f^{out} should be a function of the temperature T_ℓ at the interface and the velocity distribution function f^{coll} of molecules incident on it, in addition to the molecular velocity $\boldsymbol{\xi}$, i.e., $f^{\text{out}} = f^{\text{out}}(\boldsymbol{\xi}, T_\ell, f^{\text{coll}})$. We therefore investigate $f^{\text{out}}(\boldsymbol{\xi}, T_\ell, f^{\text{coll}})$ for various f^{coll} and a specified $T_\ell = 85$ K (near the triplepoint of argon) in nonequilibrium steady MD simulations for the argon vapor-liquid two-phase system, thereby constructing the physically correct form of KBC at the interface for argon.

The distribution function f^{out} has turned out to be expressed by

$$f^{\text{out}} = \frac{\rho_{\text{out}}}{(2\pi \text{R})^{3/2} T_\ell \sqrt{T_\ell}} \exp\left(-\frac{\xi_x^2 + \xi_y^2}{2RT_t} - \frac{\xi_z^2}{2RT_\ell} \right), \tag{3}$$

for $\xi_z > 0$, where $\rho_{\text{out}} = 2\int_{\xi_z>0} f^{\text{out}} d\boldsymbol{\xi}$ and $T_t = (1/R)\int_{\xi_z>0} \xi_x^2 \hat{f}^{\text{out}} d\boldsymbol{\xi}$ is calculated in the MD simulation ($\hat{f}^{\text{out}} = f^{\text{out}} / (\int_{\xi_z>0} f^{\text{out}} d\boldsymbol{\xi})$) . The reduced temperature $\hat{T}_t = T_t / T_\ell$ as a function of the energy flux of incoming molecules across the interface is shown in Fig. 2. We split f^{out} into two parts, i.e., $f^{\text{out}}\left(T_\ell, f^{\text{coll}}\right) = f^{\text{out}}\left(T_\ell, 0\right) + \left[f^{\text{out}}\left(T_\ell, f^{\text{coll}}\right) - f^{\text{out}}\left(T_\ell, 0\right) \right]$. The first term is independent of f^{coll} and is called the spontaneous evaporation [16]. All the effects of f^{coll} are confined into the second term, and hence it may be called the reflection. This is the only splitting that distinguishes the evaporation from the reflection without ambiguity. According to this splitting, the outgoing mass flux $\langle J_{\text{out}} \rangle = \int_{\xi_z>0} \xi_z f^{\text{out}} d\boldsymbol{\xi}$ can also be split into $\langle J_{\text{out}} \rangle = \langle J_{\text{evap}} \rangle + \langle J_{\text{ref}} \rangle$, where $\langle J_{\text{evap}} \rangle = \int_{\xi_z>0} \xi_z f^{\text{out}}(T_\ell, 0) d\boldsymbol{\xi}$ and $\langle J_{\text{ref}} \rangle = \int_{\xi_z>0} \xi_z [f^{\text{out}}(T_\ell, f^{\text{coll}}) - f^{\text{out}}(T_\ell, 0)] d\boldsymbol{\xi}$. From the balance of the mass fluxes across the interface, the difference between the incoming mass flux $\langle J_{\text{coll}} \rangle$ and the reflection mass flux $\langle J_{\text{ref}} \rangle$ should condense onto the interface. We can therefore define the condensation mass flux as $\langle J_{\text{cnds}} \rangle = \langle J_{\text{coll}} \rangle - \langle J_{\text{ref}} \rangle$. These relations enable us to rewrite $\langle J_{\text{out}} \rangle$ into $\langle J_{\text{out}} \rangle = \langle J_{\text{evap}} \rangle + \langle J_{\text{coll}} \rangle \left(1 - \langle J_{\text{cnds}} \rangle / \langle J_{\text{coll}} \rangle\right)$. Furthermore, since equation (3) yields $\langle J_{\text{out}} \rangle = \rho_{\text{out}} \sqrt{RT_\ell/(2\pi)}$, we can eliminate $\langle J_{\text{out}} \rangle$ to give

$$\rho_{\text{out}} = \frac{\langle J_{\text{evap}} \rangle}{\sqrt{RT_\ell/(2\pi)}} + \left(1 - \frac{\langle J_{\text{cnds}} \rangle}{\langle J_{\text{coll}} \rangle}\right) \frac{\langle J_{\text{coll}} \rangle}{\sqrt{RT_\ell/(2\pi)}}. \tag{4}$$

This naturally leads to the introduction of the evaporation coefficient α_e and the condensation coefficient α_c defined as [16]

$$\alpha_e = \frac{\langle J_{\rm evap} \rangle}{\rho^* \sqrt{RT_\ell/(2\pi)}}, \qquad \alpha_c = \frac{\langle J_{\rm cnds} \rangle}{\langle J_{\rm coll} \rangle}, \tag{5}$$

and by using equation (2), we obtain $\rho_{\rm out} = \alpha_e \rho^* + (1-\alpha_c)\sigma$. In Ref. [16], we have studied $\langle J_{\rm evap} \rangle$ and α_e by the vacuum evaporation simulation for argon, and demonstrated that α_e is a function of the temperature in the condensed phase alone.

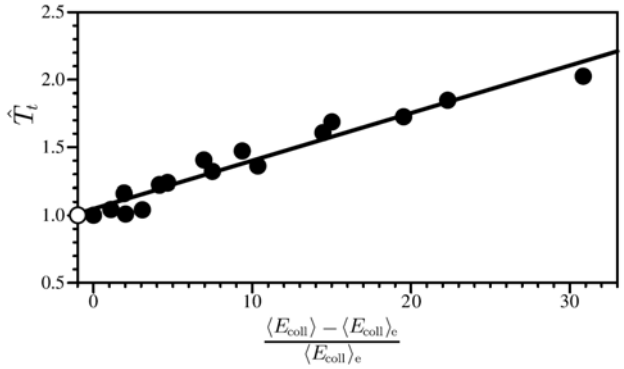

Figure 2. The reduced temperature $\hat{T}_t = T_t / T_\ell$ as a function of the energy flux of incoming molecules across the interface [4]. The open circle denotes the result of vacuum simulation [16].

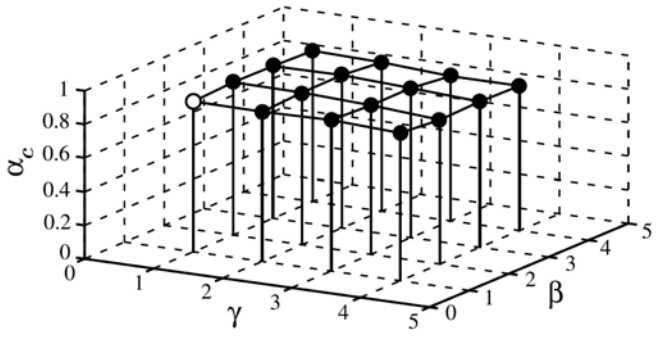

Figure 3. The condensation coefficient α_c versus β and σ which are parameters representing the deviation from the equilibrium state [4]. The open circle denotes the equilibrium state where α_c is equal to the evaporation coefficient α_e from their definitions.

The condensation coefficient α_c evaluated with the use of $\langle J_{\rm cnds} \rangle = \langle J_{\rm coll} \rangle - \left(\langle J_{\rm out} \rangle - \langle J_{\rm evap} \rangle \right)$ is plotted in Fig. 3, which clearly shows that α_c is almost equal to $\alpha_e = 0.868$ at $T_\ell = 85$K [16]. We emphasize that if α_c is a constant, it must be equal to α_e. Consequently, from equations (3)-(5), the physically correct KBC at the interface is determined as

$$f^{\text{out}} = \frac{[\alpha\rho^* + (1-\alpha)\sigma]}{(2\pi R)^{3/2} T_t \sqrt{T_\ell}} \exp\left(-\frac{\xi_x^2 + \xi_y^2}{2RT_t} - \frac{\xi_z^2}{2RT_\ell} \right), \tag{6}$$

for $\xi_z > 0$, where we have used the result in Fig. 3, i.e., $\alpha = \alpha_e = \alpha_c$. It is obvious that conventional model (1) with (2) is recovered in the limit of the equilibrium state, i.e., $T_t = T_\ell$.

In summary, using steady nonequilibrium MD simulations of the vapor-liquid two-phase system of argon, we construct the physically correct KBC at the interface in the form of equation (6). The new KBC is similar to the conventional one in the sense that f^{out} is the product of one-dimensional Maxwellian distributions. However, it does not contain any arbitrary parameters: α should be the evaporation coefficient defined in equation (5), and T_t is the linear function of $\langle E_{\text{coll}} \rangle$ as verified in Fig. 2. In particular, Fig. 3 brings the long lasting controversy over α to an end.

CONDENSATION IN SHOCK TUBE AND MOLECULAR GAS DYNAMICS

Condensation in shock tube

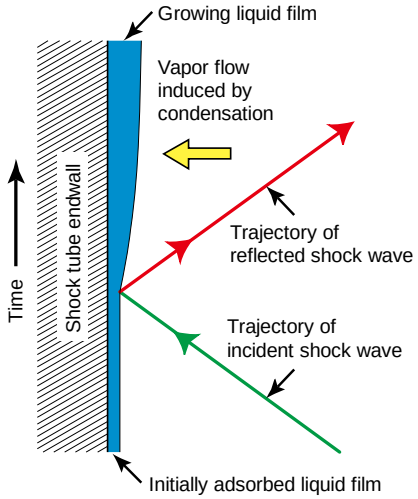

Figure 4. The growth of the liquid film on the shock tube end wall behind the reflected shock wave.

A shock tube is a suitable device to realize a nonequilibrium state at the interface between the vapor and its condensed phase [7-11]. Figure 4 shows the propagation process of shock waves in the vapor advancing toward and reflecting from the endwall of the shock tube. Just at the instant when the shock wave is reflected at the endwall on which an adsorbed liquid film with a thickness of a molecular scale exists initially, the pressure, temperature and density of the vapor far from the endwall increase rapidly and these are held at higher values compared with the initial ones. However, the vapor temperature adjacent to the endwall changes little because the endwall made of a thick glass has a large heat capacity compared with that of the vapor, whereas the vapor pressure increases almost to the pressure in the main stream. Thus, the vapor becomes supersaturated at the surface of the adsorbed liquid film, and it begins to condense in the form of a liquid film on the adsorbed film. The liquid film grows with the lapse of time to a macroscopic scale.

Shock tube

Figure 5 shows a horizontal type of shock tube used in the experiment, in which the optical interferometer is incorporated for the measurement of liquid film thickness [11]. The length of the low pressure section (test section, attained vacuum level =1.0×10^{-2} Pa) is 2830 mm, and the length of the high pressure section is 2600 mm. Two sections are connected coaxially, and a thin aluminum diaphragm is sandwiched between them. The cross section of the shock tube is the circle

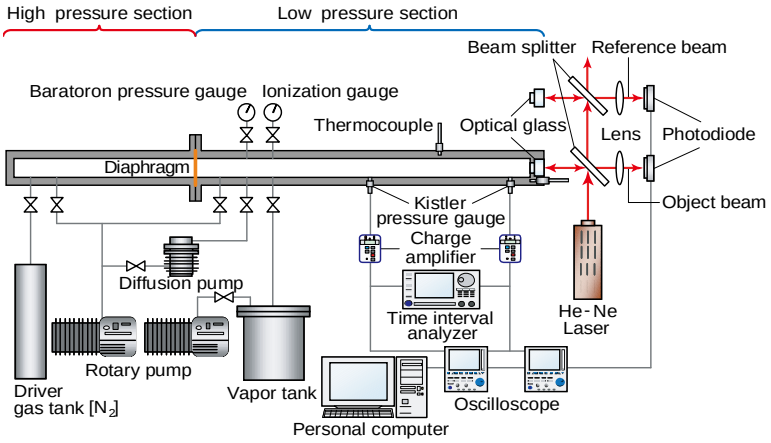

Figure 5. The shock tube and optical interferometer.

of 74.3 mm in diameter. The endwall of the test section consists of a quartz glass with the thickness of 15 mm, and its surface is polished at the flatness level of $\lambda/20$ (λ=632.8 nm) to prevent the diffused reflection of a laser beam for optical measurement and to make the laser-shed region of a liquid film on the surface as uniform as possible. The Mach number of the incident shock wave is estimated from the distance (=1000 mm) between two pressure gauges (type 701A Kistler Instrument AG, Winterthur, Switzerland) and the passage time of the shock wave between them.

The variation in time of a liquid film thickness is obtained by the measurement of light reflectance from the optically transparent film system, because the growing film, together with the glass endwall, forms a kind of interferometer. In the measurement of light reflectance, the following special device is made to eliminate systematic noises from the light reflectance. A light beam from the light source is divided into two beams; one is the physical beam containing information of the liquid film thickness and the other is the reference one which is subtracted from the light reflectance of the physical beam in order to eliminate the noises. The physical and reference beams are detected by two photodiodes, respectively.

Molecular gas dynamics analysis

As shown in Fig. 6, a steady shock wave with plane front in the vapor is formed far from the endwall and propagates toward it. In front of this incident shock wave with Mach number M, the molecular distribution function is a stationary Maxwellian with the temperature T_0 and the density ρ_0. Behind the shock wave, the distribution function is also Maxwellian with the temperature T_b, the density ρ_b and the velocity v_b. These quantities both in front of and behind the shock wave can

be connected by Rankine-Hugoniot relations. An adsorbed liquid film is supposed to exist initially on the endwall, as it does actually.

After the shock wave is reflected at the endwall, condensation takes place in the form of a liquid film on the surface of the initially adsorbed liquid film, and the liquid film grows with the lapse of time. The temperatures of the liquid film and endwall change due to the release of latent heat of condensation. Therefore, we need to solve the Boltzmann equation for the vapor together with the heat conduction equations for the liquid film and endwall. We assume that this phenomenon is a one-dimensional problem. The coordinate X stems from the interface moving due to condensation. The Gaussian BGK-Boltzmann equation is adopted as the governing equation for the water vapour

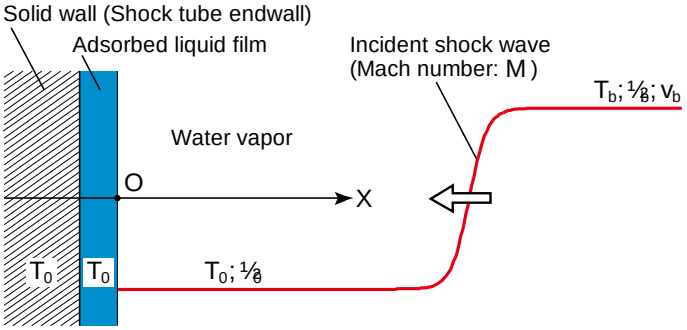

Figure 6. The schematic diagram of numerical model of film condensation on the shock tube endwall behind the reflected shock wave.

and given by [18]

$$\frac{\partial f}{\partial t}+(\xi_x-v_\ell)\frac{\partial f}{\partial X}=\frac{p}{\mu(1-v+\theta v)}(G(f)-f), \tag{7}$$

where $f(X,t,\boldsymbol{\xi},\eta)$ is the molecular distribution function, t is the time, $\boldsymbol{\xi}=(\xi_x,\xi_y,\xi_z)$ is the molecular velocity in which ξ_x,ξ_y,ξ_z are the x-, y-, z-components, η is the internal energy parameter, v_ℓ is the velocity of the moving interface, p is the pressure, $\mu(T)$ is the viscosity coefficient which is a function of the temperature T, and v and θ are constants. The function $G(f)$ in the right hand side of equation (7) is given by

$$G(f)=\rho f_{\mathrm{tr}}^{G} f_{\mathrm{int}}^{G}, \tag{8}$$

$$f_{\mathrm{tr}}^{G}=\frac{1}{\sqrt{\det(2\pi\tau_{ij})}}\exp\left(-\frac{1}{2}(\xi_i-v_i)\tau_{ij}^{-1}(\xi_j-v_j)\right), \tag{9}$$

$$f_{\mathrm{int}}^{G}=\frac{1}{\Gamma\left(\frac{n}{2}+1\right)(RT_{\mathrm{rel}})^{n/2}}\exp\left(-\frac{\eta^{2/n}}{RT_{\mathrm{rel}}}\right), \tag{10}$$

where ρ is the density, f_{tr}^{G} is the translational distribution function of polyatomic molecules, f_{int}^{G} is the distribution function of internal motions, det is the determinant, Γ is the gamma function, R is the gas constant per unit mass and n is the internal degrees of freedom of molecules which are taken to be 3 for water so that the theoretical specific heat ratio $(\gamma = 8/6)$ can coincide with the experimental one. The other quantities are defined by

$$\rho = \iint f \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,,\ \rho v_x = \iint \xi_x f \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,,\ \frac{3}{2}RT_{\mathrm{tr}} = \frac{1}{\rho}\iint \frac{1}{2}(\xi_i - v_i)^2 f \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,,$$

$$\frac{n}{2}RT_{\mathrm{int}} = \frac{1}{\rho}\iint \eta^{2/n} f \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,,\ T = \frac{3}{n+3}T_{\mathrm{tr}} + \frac{n}{n+3}T_{\mathrm{int}}\,,\ p = \rho RT\,,$$

$$T_{\mathrm{rel}} = \theta T + (1-\theta)T_{\mathrm{int}}\,,\ \rho\Theta_{ij} = \iint (\xi_i - v_i)(\xi_j - v_j) f \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,,$$

$$\tau_{ij} = (1-\theta)[(1-\nu)RT_{\mathrm{tr}}\delta_{ij} + \nu\Theta_{ij}] + \theta RT\delta_{ij}\,,$$

where v_x is the velocity component in the x direction, T_{tr} is the translational temperature, T_{int} is the internal temperature, T_{rel} is the relaxation temperature, $\rho\Theta_{ij}$ is the stress tensor, τ_{ij} is the corrected tensor and δ_{ij} is the Kronecker's delta. The integration with respect to $\boldsymbol{\xi}$ is carried out over the whole space of $\boldsymbol{\xi}$ unless otherwise stated, and the integration with respect to η is carried out in the domain of $[0,\infty)$.

The Gaussian-BGK Boltzmann equation is solved with the following kinetic boundary condition for molecules going out from the interface into the vapour phase [6]:

$$f^{\mathrm{out}} = [\alpha_{\mathrm{e}}\rho^{*} + (1-\alpha_{\mathrm{c}})\sigma] f_{\mathrm{tr}}^{\mathrm{eq}} f_{\mathrm{int}}^{\mathrm{eq}} \quad (\xi_x > v_\ell), \tag{11}$$

$$f_{\mathrm{tr}}^{G} = \frac{1}{(2\pi RT)^{3/2}} \exp\left(-\frac{(\xi_x - v_\ell)^2}{2RT_\ell} - \frac{\xi_y^{\,2} + \xi_z^{\,2}}{2RT_\ell} \right), \tag{12}$$

$$f_{\mathrm{int}}^{G} = \frac{1}{\Gamma\left(\frac{n}{2}+1\right)(RT_\ell)^{n/2}} \exp\left(-\frac{\eta^{2/n}}{RT_\ell} \right), \tag{13}$$

where α_{e} is the evaporation coefficient, α_{c} is the condensation coefficient, $\rho^{*} = p^{*}/RT_\ell$ is the saturated vapor density at the temperature T_ℓ of the liquid film surface, p^{*} is the saturated vapor pressure evaluated from Antoine's formula, and

$$\sigma = -\sqrt{\frac{2\pi}{RT_\ell}} \int_{\xi_x < v_\ell} (\xi_x - v_\ell) f^{\mathrm{coll}} \mathrm{d}\boldsymbol{\xi}\mathrm{d}\eta\,, \tag{14}$$

where f^{coll} is the molecular distribution function incident on the interface. The condensation coefficient is determined from the net condensation mass flux at the interface. The flux $\rho_\ell v_\ell$ can be given by the mass conservation equation at the interface:

$$\rho_\ell v_\ell = (\alpha_{\mathrm{c}}\sigma - \alpha_{\mathrm{e}}\rho^*)\sqrt{\frac{RT_\ell}{2\pi}}, \tag{15}$$

where ρ_ℓ is the density of the liquid film. When the vapor-liquid system is in the equilibrium state, $\rho^* = \sigma$ and $\rho_\ell v_\ell = 0$ and hence $\alpha_{\mathrm{e}} = \alpha_{\mathrm{c}}$. Making use of equation (15) allows us to eliminate the evaporation coefficient α_{e} and the condensation coefficient α_{c} from equation (11) and leads to

$$f^{\mathrm{out}} = \left(\sigma - \rho_\ell v_\ell \sqrt{\frac{2\pi}{RT_\ell}}\right) f_{\mathrm{tr}}^{\mathrm{eq}} f_{\mathrm{int}}^{\mathrm{eq}} \qquad (\xi_x > v_\ell). \tag{16}$$

Therefore, once v_ℓ is experimentally given as a function of time, the Boltzmann equation can be uniquely solved with the distribution function f^{out} given by equation (16). In consequence, $\rho_\ell v_\ell$, T_ℓ, ρ^* and σ in equation (15) become known, and the unknowns in equation (15) are only α_{e} and α_{c}. Note that α_{e} is a function of T_ℓ alone from its definition. Therefore α_{c} can be evaluated from equation (15) by using the value of α_{e} which has been estimated by the recent molecular dynamics simulations for water [17]. The use of this value of α_e will be justified by the experiment.

Results

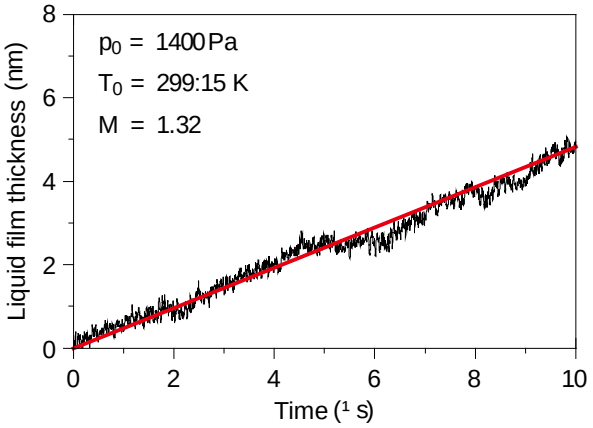

Figure 7. The time evolution of the liquid film thickness.

Figure 7 shows the variation in time of the liquid film thickness. Note that the origin of the time is reset at the condensation onset. The red solid line is an approximated curve for the converted experimental data. The slope of the curve means the moving velocity of the surface of liquid film v_ℓ. It is found that the curve can be approximated well by a straight line, i.e., v_ℓ is constant for a short time. By using the velocity v_ℓ for the boundary condition given by equation (16), the numerical simulation is conducted and the value of the condensation coefficient can be uniquely deduced.

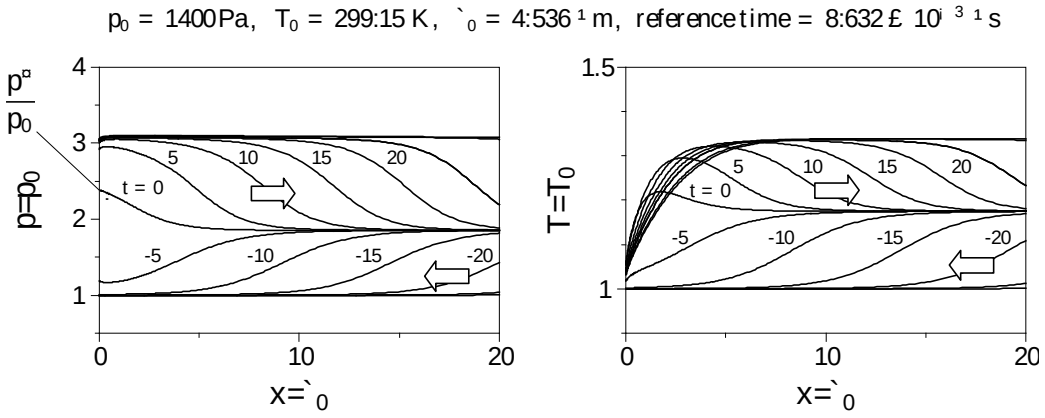

Figure 8. The propagation process of the shock waves advancing toward and reflecting from the shock tube endwall: (a) pressure profiles; (b) temperature profiles. The time is normalized by the reference time. The condition is the same as that in Fig. 7.

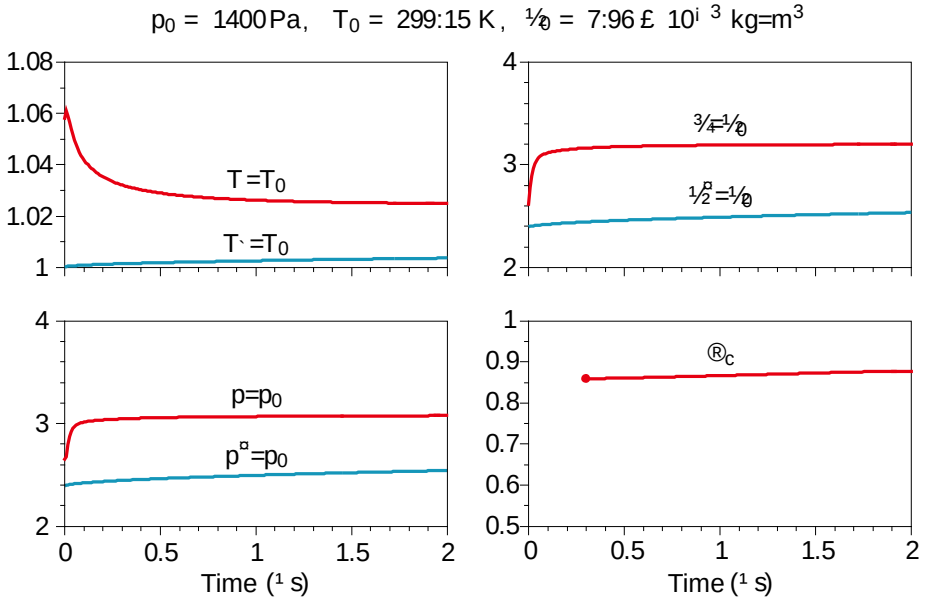

Figure 9. The variation in time of macroscopic quantities at the interface and the determined condensation coefficient α_c. The red circle at the left end on the α_c - line is the starting time of the acquisition of α_c. The condition is the same as that in Fig. 7.

Figure 8 shows the propagation process of the shock waves advancing toward and reflecting from the boundary: (a) pressure profiles, (b) temperature profiles. The abscissas of (a) and (b) are both the distance from the liquid film surface in the vapor. The time indicated for each profile in (a) and (b) is normalised by the reference time. The pressure at the interface rises gradually during the incidence and reflection process of the shock waves and it approaches a constant. On the other hand, the temperature profiles show that the thermal boundary layer including the Knudsen layer, which is the nonequilibrium region of vapor near the interface, is formed behind the reflected shock wave.

Figure 9 shows the variation in time of macroscopic quantities at the interface. After the onset time of condensation, the temperature T, the pressure p, and σ set in an almost steady state immediately.

Then, from Fig. 9(a), we can see that the variation in the liquid film temperature T_ℓ is about 0.5 % for 2 μs. Therefore, those of the saturated vapor pressure p^* and the saturated vapor density ρ^* are about 8 %. As a result, from equation (15), the condensation coefficient α_c may be regarded as a constant value for 2 μs after the condensation onset.

Figure 10 shows the relationship between the condensation coefficient and σ/ρ^*. The σ/ρ^* of the abscissa denotes the ratio of the collision mass flux $\sigma\sqrt{RT_\ell/(2\pi)}$ onto the interface to the mass flux $\rho^*\sqrt{RT_\ell/(2\pi)}$ at the equilibrium state. We can see that the condensation coefficient of water approaches unity as σ/ρ^* does unity, i.e., the equilibrium state. The red circle at $\sigma/\rho^*=1$ is the value (1.00 at 300K) of α_e, estimated by the MD simulation [17]. The red solid line is drawn by the method of least-squares so as that it coincides with the above value of α_e at the equilibrium state. This asymptotic behaviour of α_c approaching α_e, as σ/ρ^* does unity, may justify the use of α_e evaluated by the MD simulation. The condensation coefficient of water can be expressed by the following equation:

$$\alpha_c = \frac{\rho^*}{\sigma}(\alpha_e - A) + A, \tag{17}$$

where α_e=1.00 and A = 0.47. Consequently, we can estimate the condensation coefficient of water by using equation (17) in weak condensation states at the room temperature. For comparison, the condensation coefficient of methanol is shown by blue circles and the blue line ($\alpha_e = 0.86$ at $\rho^*/\sigma = 1.0$). We can notice that there is a significant difference between water and methanol.

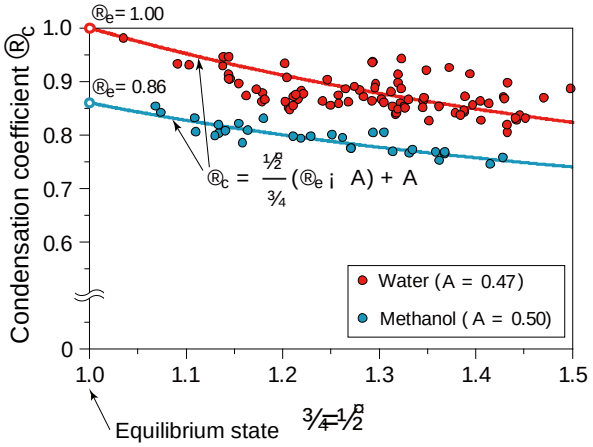

Figure 10. The condensation coefficient versus σ/ρ^* for water (red circles). For comparison, the condensation coefficient of methanol is shown (blue circles) [20]. The σ is calculated from equation (14).

MOLECULAR GAS DYNAMICS AND BOUNDARY CONDITION FOR FLUID-DYNAMICS-TYPE SET OF EQUATIONS

Asymptotic analysis

We will deal with a time-independent problem for weak evaporation or condensation where the half-infinite extent of a vapor with the pressure p_∞, the temperature T_∞ and the density ρ_∞ is in contact with its half-infinite liquid phase with the constant temperature T_ℓ [21]. Evaporation or condensation takes place at the interface between the vapor and the liquid, depending on whether or

not the pressure at the interface is lower than the saturated vapor pressure $\rho^*(T_\ell)$ at the temperature T_ℓ. We will adopt the Gaussian-BGK Boltzmann equation applicable to a polyatomic gas [18] and derive the boundary condition at the boundary for fluid-dynamic-type, i.e., Navier-Stokes-type, set of equations.

The following assumptions are made: (i) the interface is planar and at rest, and hence the phenomenon in question is spatially one-dimensional, dependent on the X axis normal to the interface. (ii)the vapor is the ideal gas. (iii) the boundary condition is Eq.(11) for the case of $\alpha_e = \alpha_c = \alpha$ and $v_\ell = 0$.

The Gaussian-BGK Boltzmann equation is equation (7). We will study the time-independent solution for weak evaporation or condensation on the basis of the asymptotic theory for small Knudsen numbers. According to Sone's book [12], we will seek a moderately varying solution of the Gaussian-BGK Boltzmann equation in a power series (S expansion) as

$$\phi = k\phi_{S1} + k^2\phi_{S2} + \cdots, \quad k = \frac{\sqrt{\pi}}{2}\frac{\lambda_0}{L} = 1, \tag{18}$$

where $\phi = (f - f_0)/f_0$ is the nondimensional distribution function$\left[\phi = O(k)\right]$, f_0 the equilibrium distribution function in the reference equilibrium state (the subscript 0 represents the reference equilibrium state), ℓ_0 the mean free path in the reference state, and L the characteristic length of the system. The mean free path is given by

$$\ell_0 = (1 - \nu + \theta\nu)\frac{\mu_0}{p_0}\frac{2}{\sqrt{\pi}}\sqrt{2RT_0}. \tag{19}$$

Corresponding to the expansion (18), the macroscopic variables are also expanded in k.

The resulting fluid-dynamic-type set of equations are

$$\frac{\partial P_{S1}}{\partial x_i} = 0, \tag{20}$$

$$\frac{\partial u_{iS1}}{\partial x_i} = 0, \tag{21}$$

$$u_{jS1}\frac{\partial u_{iS1}}{\partial x_j} = -\frac{1}{2}\frac{\partial P_{S2}}{\partial x_i} + \frac{\mathrm{Pr}}{2}\frac{\partial^2 u_{iS1}}{\partial x_j^2}, \tag{22}$$

$$u_{iS1}\frac{\partial \tau_{S1}}{\partial x_i} = \frac{1}{2}\frac{\partial^2 \tau_{S1}}{\partial x_i^2}, \tag{23}$$

$$\frac{\partial u_{iS2}}{\partial x_i} + u_{iS1}\frac{\partial \omega_{S1}}{\partial x_i} = 0, \tag{24}$$

$$u_{jS1}\frac{\partial u_{iS2}}{\partial x_j}+(u_{jS2}+\omega_{S1}u_{jS1})\frac{\partial u_{iS1}}{\partial x_j} = -\frac{1}{2}\frac{\partial}{\partial x_i}\left(P_{S3}\frac{\mathrm{Pr}}{2}\frac{\partial^2\tau_{S1}}{\partial x_j^2}\right)+\frac{\mathrm{Pr}}{2}\frac{\partial^2 u_{iS2}}{\partial x_j^2}+\frac{\mathrm{Pr}}{2}\frac{\partial}{\partial x_i}\left[\beta\tau_{S1}\left(\frac{\partial u_{iS1}}{\partial x_j}+\frac{\partial u_{jS1}}{\partial x_i}\right)\right], \tag{25}$$

$$u_{jS1}\frac{\partial \tau_{S2}}{\partial x_i}+(u_{jS2}+\omega_{S1}u_{jS1})\frac{\partial \tau_{S1}}{\partial x_j}-\frac{2}{5+n}u_{jS1}\frac{\partial P_{S2}}{\partial x_j} = \frac{\mathrm{Pr}}{5+n}\left(\frac{\partial u_{iS1}}{\partial x_j}+\frac{\partial u_{jS1}}{\partial x_i}\right)^2+\frac{1}{2}\frac{\partial^2}{\partial x_i^2}\left(\tau_{S2}+\frac{\beta}{2}\tau_{S1}^2\right), \tag{26}$$

where $x = X/L$ and $\omega_{Sm}, \tau_{Sm}, P_{Sm}$ and $u_{iSm}(m=1,2)$ are expansion coefficients of the nondimensional density $\omega=(\rho-\rho_0)/\rho_0$, the temperature $\tau=(T-T_0)/T_0$, the pressure $P=(1+\omega)(1+\tau)-1$, and the velocity $u_i = v_i/\sqrt{2RT_0}$, respectively. The viscosity is assumed as $\mu=\mu_0(1+\tau)^\beta$. We should remark that (i) equations (20)-(26) are the same as those for the BKW model [19], if we set $n=0$ (monatomic gas), $\mathrm{Pr}=1$ and $\beta=1$; (ii) the temperature associated with translational motion T_{tr} and that with internal motion T_{int} are equal to T up to the order shown above.

Knudsen layer

The Knudsen layer analysis can also be carried out in the same way as that given in Sone's book [12], and thereby the Knudsen layer corrections and the boundary condition for the fluid-dynamic-type equations can be obtained. The result in the leading order of approximation is

$$(u_{iS1}-u_{wi1})t_i = 0, \tag{27}$$

$$u_{iK1} = 0, \tag{28}$$

$$\begin{pmatrix} P_{S1}-P_{w1} \\ \tau_{S1}-\tau_{w1} \\ \omega_{K1} \\ \tau_{\mathrm{tr}K1} \\ \tau_{\mathrm{int}K1} \end{pmatrix} = u_{iS1}n_i \begin{pmatrix} C_4^*-2\sqrt{\pi}\dfrac{1-\alpha}{\alpha} \\ d_4^* \\ \Omega_4^* \\ \Theta_{4\mathrm{tr}}^*(y) \\ \Theta_{4\mathrm{int}}(y) \end{pmatrix}. \tag{29}$$

Here, (i) $u_{iS1,}$ T_{S1} and P_{S1} are evaluated at the interface; (ii) u_{wi1}, T_{w1} and P_{w1} are, respectively, the first expansion coefficients of the nondimensional velocity and temperature of interface, and the saturated vapor pressure at the temperature, e.g., $v_\ell/\sqrt{2RT_0} = ku_{wi1}+\cdots$ and so on; (iii) u_{iK1}, ω_{K1}, $\tau_{\mathrm{tr}K1}$ and $T_{\mathrm{int}K1}$ are, respectively, the Knudsen layer corrections for the velocity, density and temperature associated with translational and internal motions; (iv) n_i and t_i are unit vectors normal and tangential to the interface, respectively; (v) y is the coordinate stretched in the n_i

direction, $x_i n_i = ky$. The values of slip coefficients C_4^* and d_4^* and the functional forms of Knudsen layer functions $\Omega_4(y), \Theta_{4\mathrm{tr}}^*(y)$ and $\Theta_{4\mathrm{int}}^*(y)$ are dependent on the parameters θ and ν and the internal degrees of freedom n.

We set $\theta = 0.6471, \nu = -0.5$ and $n = 6$ corresponding to methanol vapor at room temperature, $\mathrm{Pr} = 0.86$ and the radio of specific heats 1.22. In that case, we obtain

$$C_4^* = -2.0723, \qquad d_4^* = -0.2185, \tag{30}$$

and

$$\Omega_4^*(0) = 0.475, \quad \Theta_{4\mathrm{tr}}^*(0) = -0.083, \quad \Theta_{4\mathrm{int}}^*(0) = 0.145. \tag{31}$$

The slip coefficients and the Knudsen layer functions for the BKW model and for the usual Boltzmann equation for hard-sphere gas are precisely determined and tabulated in Sone's book [12]:

$$\begin{aligned} &C_4^* = -2.1412, \quad d_4^* = -0.4557, \quad \Omega_4^*(0) = 0.37815, \quad \Theta_4^*(0) = 0.05206, \quad (\text{hard}-\text{sphere}), \\ &C_4^* = -2.13204, \quad d_4^* = -0.44675, \quad \Omega_4^*(0) = 0.36303, \quad \Theta_4^*(0) = 0.03717, \quad (\text{BKW}). \end{aligned} \tag{32}$$

As seen from equations (30)-(32), C_4^* for the Gaussian-BGK model for the polyatomic gas (methanal) is rather close to those for the monatomic gas. The coefficient d_4^* for the polyatomic gas is, however, about half of that for the monatomic gas. Derivation of the coefficients for water vapor is now under progress.

One-dimensional steady and weak evaporation or condensation

The one-dimensional steady solution for weak evaporation or condensation is clearly explained based on the S expansion, and the result is directly applied to the present case. For the given conditions at infinity, (p_∞, T_∞), and the liquid temperature at the interface T_ℓ, the solution in the vapor phase can be written as

$$\frac{p - p_\infty}{p^*} = \frac{p_\infty - p^*}{p^*} \left[\frac{\Omega_4^*(y) + \dfrac{3}{3+n}\Theta_{4\mathrm{tr}}^*(y) + \dfrac{3}{3+n}\Theta_{4\mathrm{int}}^*(y)}{C_4^* - 2\sqrt{\pi}\dfrac{1-\alpha}{\alpha}} \right], \tag{33}$$

$$\begin{aligned} \frac{T - T_\infty}{T_\ell} = &\left(\frac{p_\infty - p^*}{p^*} \frac{d_4^*}{C_4^* - 2\sqrt{\pi}\dfrac{1-\alpha}{\alpha}} - \frac{T_\infty - T_\ell}{T_\ell} \right) \exp\left(\frac{p_\infty - p^*}{p^*} \frac{1}{C_4^* - 2\sqrt{\pi}\dfrac{1-\alpha}{\alpha}} \frac{4X}{\sqrt{\pi}\ell_0} \right) \\ &+ \frac{p_\infty - p^*}{p^*} \frac{1}{C_4^* - 2\sqrt{\pi}\dfrac{1-\alpha}{\alpha}} \left[\frac{3}{3+n}\Theta_{4\mathrm{tr}}^*(y) + \frac{n}{3+n}\Theta_{4\mathrm{int}}^*(y) \right], \end{aligned} \tag{34}$$

$$\frac{v}{\sqrt{2RT_\ell}} = \frac{p_\infty - p^*}{p^*} \frac{1}{C_4^* - 2\sqrt{\pi}\dfrac{1-\alpha}{\alpha}}, \tag{35}$$

where $y = 2X/(\sqrt{\pi}\ell_0)$ is the mean free path of the saturated vapor at the temperature T_ℓ and, hereafter, v denotes the velocity component normal to the interface. Thus, p, T and v everywhere in the vapor phase are determined by p_∞, T_∞ and T_ℓ, the slip coefficients and C_4^* and d_4^*, the Knudsen layer functions, and the condensation coefficient (= the evaporation coefficient) α.

CONCLUSIONS

The state-of-the-art studies of evaporation and condensation based on molecular dynamics (MD), molecular gas dynamics and the shock-tube experiment have been presented by focusing on the kinetic boundary condition (KBC) at the interface of the vapor and its condensed phase, and the evaporation and condensation coefficient. The principal results can be summarized as follows.

(1) The physically correct kinetic boundary condition (KBC) is formulated by MD simulations. This KBC is similar to the conventional model, but not contain any arbitrary parameters.
(2) Molecular gas dynamics simulations and experiments by shock tube make it possible to obtain the correct values of evaporation and condensation coefficient of water; the evaporation coefficient is just unity, and the condensation coefficient is equal to the evaporation coefficient at the equilibrium state and it decreases with increasing in the nonequilibriun degree.
(3) One-dimensional steady and weak evaporation or condensation has been analyzed and the boundary condition for the Navier-Stokes-type set of equations has been obtained by the perturbation analysis.

Precise analysis of evaporation and condensation very near the equilibrium state is in progress based on molecular gas dynamics [22], and the corresponding experiment using sound resonance is also in progress. [23]. These studies are expected to clarify the more exact value of the evaporation coefficient very near the equilibrium state. The evaporation coefficient, surface tension coefficient and saturated vapour pressure of a nanodroplet are investigated in detail by molecular dynamics simulations [24].

ACKNOULEDGEMENTS

This work has been done with the author's former colleagues, Dr. Takeru Yano (Professor of Osaka University), Dr. Tatsuya Ishiyama (Assistant Professor of Tohoku University) and Dr. Kazumichi Kobayashi (Assistant Professor of Osaka Prefecture University). It is also indebted to Dr. Masao Watanabe (Associate Professor of Hokkaido University) and to the author's many graduate students, especially Messrs. Hisao Yaguchi, Shigeto Nakamura, Masashi Inaba and Daigo Yamano. It was financially supported by the Grant in Aid for Scientific Research of the Japan Society for the Promotion of Science (JSPS) from 2005 to 2008 (Grant No.17360074). The author would like to express his deepest gratitude to his former and present colleagues, graduate students and JSPS.

BOILING AND TWO-PHASE FLOW IN NARROW GAPS – WITH APPLICATION TO THERMAL PACKAGING OF CHIP STACKS

A. Bar-Cohen[1*], K.J.L. Geisler[2], E. Rahim[1]
[1]University of Maryland, College Park, MN, USA
[2]General Dynamics Advanced Information Systems, Bloomington, MN, USA

ABSTRACT. Application of the available theories, correlations, and experimental data for pool and flow boiling as well as convective transport in narrow gaps, to a notional 3D chip stack configuration, reveals that single phase natural convection cooled die stacks can be expected to dissipate in the range of 25 MW/m^3 when immersed in candidate Fluorinert™ electronics cooling liquids, while optimum pool boiling configurations are shown to dissipate 200 to 400 MW/m^3 over a wide range of system pressures. Alternatively, chip stacks optimized for single phase forced convection are predicted to yield volumetric heat transfer rates from 100 to 300 MW/m^3, and flow boiling configurations are demonstrated to exceed 1 GW/m^3. Optimum die spacings for both single and two phase cooling are found to be in the range of 0.2 mm to 0.6 mm for typical microelectronics geometries. Heat transfer performance maps summarizing the upper limits for each of these immersion cooling approaches are presented.

Keywords: *chip stack, liquid cooling, electronics, boiling, heat transfer*

INTRODUCTION

While homogeneous and heterogeneous chip stacks are a crucial building block in advanced microsystem architectures, effective thermal management of stacked chips remains a most difficult challenge. In addition to providing increased packaging density, 3D die stacking, as illustrated in Figure 1, accommodates shorter interconnect distances between devices, reduced power dissipation and improved electrical performance. A first-order approach for cooling these devices is to rely on conduction through the various layers up to the top of the package and/or down to the underlying PCB. More advanced thermal packaging approaches might include between-die solid conductors to improve lateral heat spreading to the package periphery [1], but the relatively low thermal conductivity of the electrical insulators typically considered for this role would be expected to yield large temperature gradients. On the other hand, immersion cooling techniques, which provide fluid flow in the narrow channels formed between stacked dies and high heat transfer coefficients directly on the die surfaces, could be very efficient in dissipating high volumetric heat generation rates, isothermalizing the silicon layers, and accommodating Joule heating in high current-density interconnects.

Single phase natural convection in dielectric liquids provides a quantitative baseline for direct liquid cooling of 3D chip stacks. Nucleate pool boiling also includes the advantages of passive, buoyancy-driven flow, but with significantly increased heat transfer rates above natural convection. Further enhancement in the dissipated heat flux and volumetric heat transfer rates can be achieved by the introduction of forced flow through the narrow channels in the chip stack, both single phase forced convection and, even more, flow boiling. Using available heat transfer coefficient correlations, the

Sample results for representative 3D chip stacks immersed in saturated FC-72 are generated, and performance maps summarizing the upper limits for each of these cooling approaches are presented and discussed.

PASSIVE IMMERSION COOLING

Passive techniques, which require no input power, are often desired for improved reliability and ease of implementation when compared to active, forced flow approaches. While heat transfer performance may be relatively limited, capabilities may be sufficient for certain application classes, in particular portable and/or consumer electronic products.

Single phase natural convection

Single phase natural convection is the easiest form of direct liquid cooling to implement and provides a lower bound for pool boiling and a benchmark solution for other advanced cooling approaches. An illustration of the basic geometry of a vertically-oriented die stack appears in Figure 2. The gravity vector is taken to be parallel to the die length, L, and perpendicular to the stack height, H.

Following the composite Nusselt number correlation derivations of Bar-Cohen and Rohsenow [2] and including the Prandtl number correction of Bar-Cohen and Schweitzer [3], Geisler [4] derived and validated a composite Nusselt number correlation for symmetrically-heated, vertical microchannels immersed in saturated FC-72 at atmospheric pressure, based on the use of the fully-developed and isolated plate asymptotes, as

$$\mathrm{Nu}_\delta \equiv \frac{h\delta}{k} = \left[\left(\frac{24}{\mathrm{El}} \right)^2 + \frac{0.705^{-2}}{\sqrt{\mathrm{El}}} \right]^{-1/2} \tag{1}$$

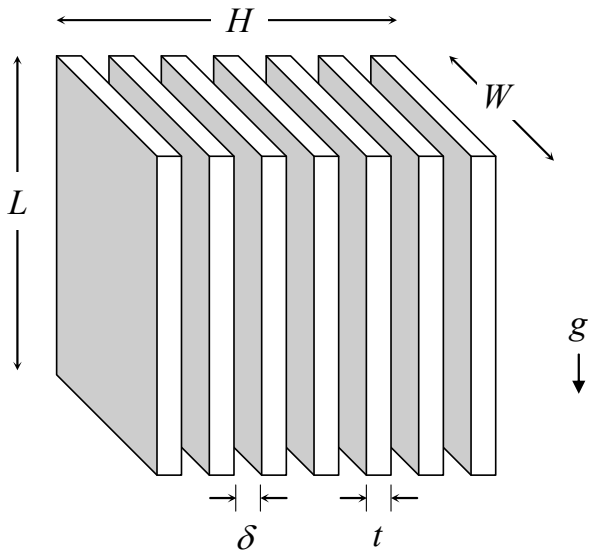

Figure 2. Die stack geometry and nomenclature

where the Elenbass number, El, is defined as,

$$\mathrm{El} \equiv \mathrm{Ra}_L \frac{\delta^4}{L^4} = \frac{c_p \rho^2 g \beta (T_{\mathrm{die}} - T_{\mathrm{amb}}) \delta^4}{\mu k L} \tag{2}$$

Following Elenbaas [5], the heat transfer coefficient defined by equation (1) includes the fluid temperature rise in the channel and is, therefore, based on the temperature difference between the channel wall and the fluid at the channel inlet. Figure 3 contains a graph of the composite Nusselt number relation, equation (1), along with the associated fully developed and isolated plate limits. The transition region from fully developed to isolated plate behavior is shown to occur in the range of Elenbaas numbers from 10 to 200.

Using the definitions of the Nusselt number and heat transfer coefficient, the total heat transfer rate from an array of vertical dies can be written as

$$q = 2LWHk\Delta T\left(\frac{\mathrm{Nu}_\delta}{\delta(\delta + t)}\right) \tag{3}$$

where the dies are $L \times W$ in size with thickness t, and H is the height of the entire stack—as illustrated in Figure 2. Optimum die spacings, which maximize the volumetric cooling rate from a chip stack may be found by substituting the channel Nusselt number expression, equation (1), into equation (3), taking the derivative of the resulting expression with respect to δ, and setting the result equal to zero. This process yields the following transcendental equation.

$$\left(2\delta + 3t - a^{-2}\mathrm{El}^{3/2}\delta\right)_{\mathrm{opt}} = 0 \tag{4}$$

where

$$a = 24 \cdot 0.705 = 16.92 \tag{5}$$

The optimum Elenbaas number in the thin die limit, equation (4) with $t = 0$, is marked in Figure 3. This optimum point (El = 69.0, Nu = 1.66) is clearly shown to occur in the transition region between the fully developed channel and isolated plate limits. The subtle effect of die thickness on optimum spacing is shown in Figure 4. As die thickness increases, fewer dies can be accommodated in a fixed stack height or volume, and larger gaps—with their associated higher heat transfer coefficients—are needed to maximize the stack volumetric heat transfer rate. It should be noted, however, that since both the die thickness and the larger gap lead to a smaller number of chips per unit volume, and since the heat transfer coefficient increase is modest, the total chip stack heat transfer rate—even at the optimum spacing—decreases as the die thickness increases.

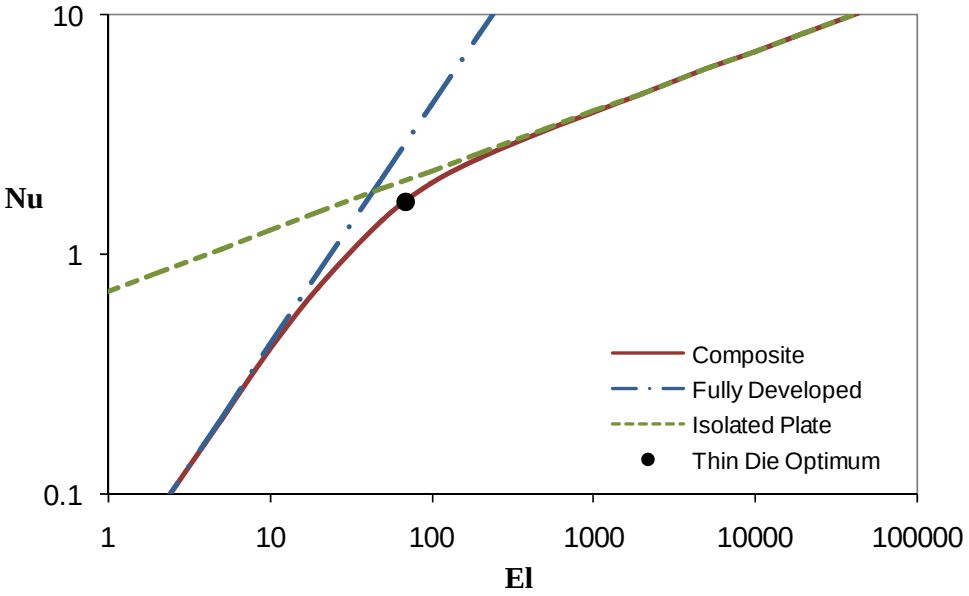

Figure 3. Isothermal Nusselt number correlations for symmetrically heated channels immersed in saturated FC-72 at atmospheric pressure

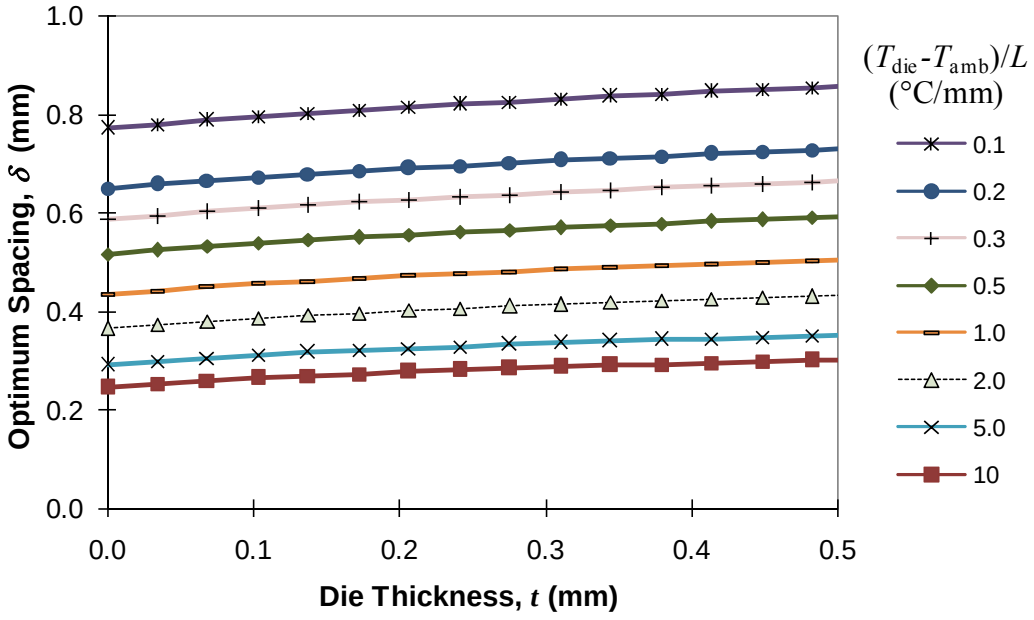

Figure 4. Optimum spacing as a function of die thickness for natural convection in saturated FC-72 at atmospheric pressure

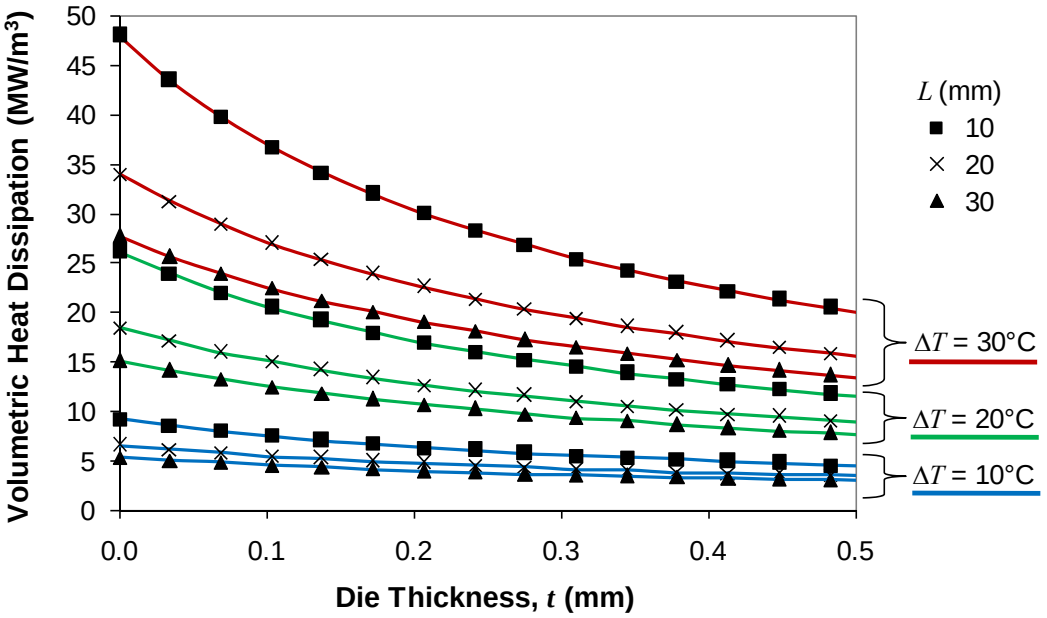

Figure 5. Natural convection volumetric heat dissipation rates for optimum die stacks in saturated FC-72 at atmospheric pressure

Figure 5 shows the volumetric heat dissipation rates, as a function of die thickness for optimally-spaced die stacks, obtained with equation (4). Over the geometric parameter ranges of interest ($t < 0.5$ mm, $L = 10$–30 mm, and $\Delta T = 10$–30°C), optimum die spacings are found to range from 0.25 mm to 0.85 mm, while volumetric heat dissipation rates reach several tens of MW/m^3. While volumetric heat transfer rates for vanishingly thin die immersed in FC-72 can be expected to reach as high as 50 MW/m^3, for more typical configurations where die thickness is approximately equal to these optimum spacings, volumetric dissipation rates are reduced to approximately half of the thin die values, *i.e.* falling in the vicinity of 25 MW/m^3.

Pool Boiling

Unfortunately, the desirable chemical inertness and electrically insulating characteristics of candidate immersion fluids also tend to be accompanied by relatively poor thermal properties. As a consequence, even the optimum natural convection heat transfer coefficients result in cooling rates that are insufficient to meet the demanding requirements of high performance microprocessors. Fortunately, nucleate boiling, which provides significant increases in heat flux with very modest increases in surface temperature, may be employed to significantly enhance heat transfer rates from microelectronics immersed in dielectric liquids.

The upper limit of nucleate boiling is the Critical Heat Flux (CHF), representing the point where the large volume of generated vapor prevents fresh liquid from replenishing the supply at the surface. As a result, the surface becomes blanketed by a thin layer of vapor and increases greatly in temperature. As this temperature excursion can be on the order of 100°C or more, electronics cooling applications are most often restricted to the single phase and nucleate boiling regimes, with CHF as an absolute upper limit. The well known Kutateladze-Zuber CHF relation [6] was developed for saturated pool boiling on large, thick, upward-facing horizontal plates.

$$q''_{\text{K-Z}} = \frac{\pi}{24} C_{\text{lg}} \sqrt{\rho_{\text{g}}} [\sigma_{\text{l}} g(\rho_{\text{l}} - \rho_{\text{g}})]^{1/4} \tag{6}$$

The Zuber analytical treatment considered the Taylor instability criterion for coalesced bubble vapor columns and defined CHF as occurring when the liquid-bubble interface becomes unstable. More recent research has suggested that, for horizontal heaters, lateral bubble coalescence creates dry patches on the surface that eventually reach the Leidenfrost temperature and cause CHF [7]. Mudawar *et al*. [8] derived an interfacial lift-off model for CHF on vertical surfaces based on an analysis of Kelvin-Helmholtz waves. Their resulting equation is identical in form to equation (6), despite being based on a different mechanism. Regardless of its derivation, equation (6) remains relatively accurate and, in particular, captures the effect of pressure on CHF.

In confined die stack geometries, boiling activity can be expected to produce axial quality and vapor fraction gradients, leading to distinct two phase flow regimes. The presence of this vapor will increase fluid buoyancy in the channel. But as boiling activity increases, the growing vapor fraction may eventually lead to dry out (premature CHF) at the heated surfaces, beginning at or near the channel exit, and causing severe heat transfer degradation. Based on earlier work by Monde *et al*. [9] and Bonjour and Lallemand [10], Geisler and Bar-Cohen [11] correlated CHF for symmetrically heated channels as

$$q''_{\text{chan}} = q''_{\text{K-Z}}\left[1+\gamma\left(\frac{L}{\delta}\right)^{1.517}\right]^{-1} \tag{7}$$

where

$$\gamma = 1.08\times10^{-4}\left(\rho_{\text{l}}/\rho_{\text{g}}\right)^{1.343(p/p_c)^{0.252}} \tag{8}$$

The volumetric cooling rate attained at critical heat flux (CHF) may be expressed as

$$\left(\frac{q}{V}\right)_{\text{CHF}} = \frac{Aq''_{\text{CHF}}}{V} = \frac{2nLWq''_{\text{CHF}}}{nLW(\delta+t)} = q''_{\text{CHF}}\frac{2}{(\delta+t)} \tag{9}$$

where n is the number of dies, $H/(\delta+t)$, and q"$_{\text{CHF}}$ is the pool boiling critical heat flux.

Geisler and Bar-Cohen [12] combined equations (6) and (7) with a factor from the literature based on heated surface properties that captures the reduction in CHF expected with decreasing die thickness [7], yielding

$$\left(\frac{q}{V}\right)_{\text{CHF}} = \frac{\pi}{24}\frac{C_{\text{lg}}\sqrt{\rho_{\text{g}}}[\sigma_{\text{l}}g(\rho_{\text{l}}-\rho_{\text{g}})]^{1/4}}{1+\gamma(L/\delta)^{1.517}}\left(\frac{t\sqrt{(\rho c_p k)_{\text{h}}}}{t\sqrt{(\rho c_{\text{p}}k)_{\text{s}}}+0.1}\right)\left(\frac{2}{\delta+t}\right) \tag{10}$$

Figure 6 shows volumetric heat dissipation results for 20 mm long dies immersed in saturated FC-72 at atmospheric pressure as predicted by equation (10). At vanishingly small channel spacings, CHF goes to zero, while the array volume asymptotes to a constant $V=nLWt$. At large spacings, corresponding to $L/\delta < 10$, boiling channels achieve their large spacing CHF limit, and additional spacing increases provide no improvement in overall heat transfer but continue to increase the array volume. Thus, an optimum channel spacing exists in the range $0 < \delta < L/10$ where volumetric heat dissipation is maximized. Peak heat dissipation rates range from 200 to 300 MW/m^3—an order of magnitude higher than can be achieved in single phase natural convection.

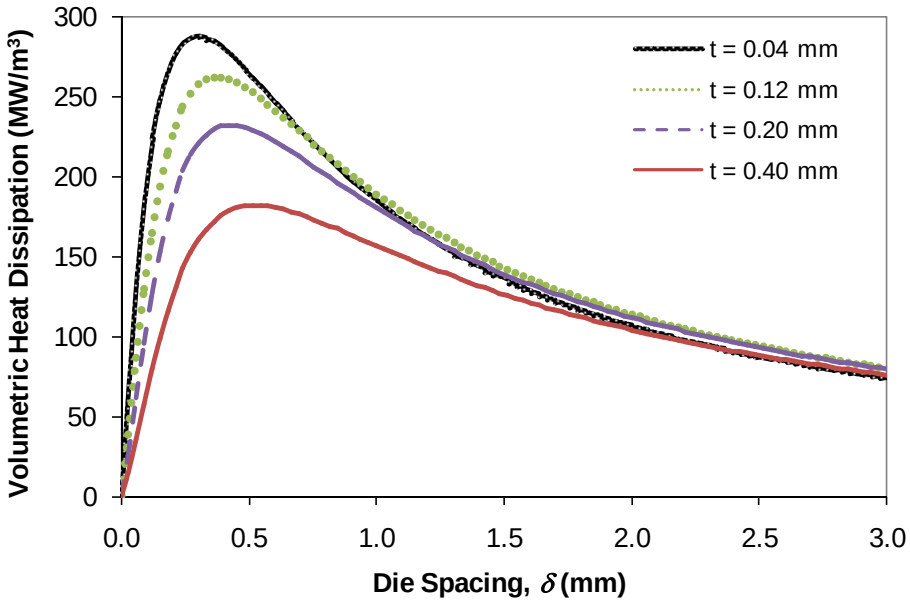

Figure 6. Volumetric heat dissipation at CHF for 20 mm long stacked silicon dies immersed in saturated FC-72 at atmospheric pressure

Optimum die spacings that maximize volumetric heat dissipation may be found by taking the derivative of equation (10) with respect to channel spacing and setting it equal to zero. Algebraic manipulation yields

$$\left(\frac{L}{\delta_{\text{opt}}}\right)=\left[1.517\gamma\left(1+\frac{t}{\delta_{\text{opt}}}\right)-\gamma\right]^{-1/1.517} \tag{11}$$

Figure 7 shows optimum spacing results, calculated using equation (11) over a range of die length and thickness for saturated FC-72 at atmospheric pressure ($\gamma = 0.002412$). As in the case of single phase optimization, as die thickness increases, the number of dies and, hence, gaps per unit volume decreases, thus decreasing the volumetric penalty of larger spacings, while providing modestly higher heat transfer coefficients. It is interesting to note that optimum die spacings are, thus, approximately half a millimeter for both single phase natural convection and pool boiling.

The optimum spacing found with equation (11) can then be used in equation (10) to find the maximum volumetric heat dissipation for a given die length and thickness. Figure 8 shows loci of maxima found in this manner for silicon dies immersed in saturated FC-72 at atmospheric pressure over an unrealistically wide die thickness range of 0.004–4 mm (for illustrative purposes). Optimum volumetric heat dissipation rates are clearly on the order of several hundred MW/m^3. The 280MW/m^3 peak in the $L = 20$ mm curve of Figure 8 occurs at approximately $\delta = 0.3$ mm and $t = 0.04$ mm. For die lengths of 10 and 30 mm, volumetric heat dissipation is a maximum for $t \approx 0.03$ and 0.05 mm, respectively. Fortunately, it can be shown that, in terms of die thickness, the peak volumetric cooling rates are relatively broad and that the effusivity effect on CHF does not significantly counteract the volumetric benefits of decreasing die thickness until $t < 10$ μm [4].

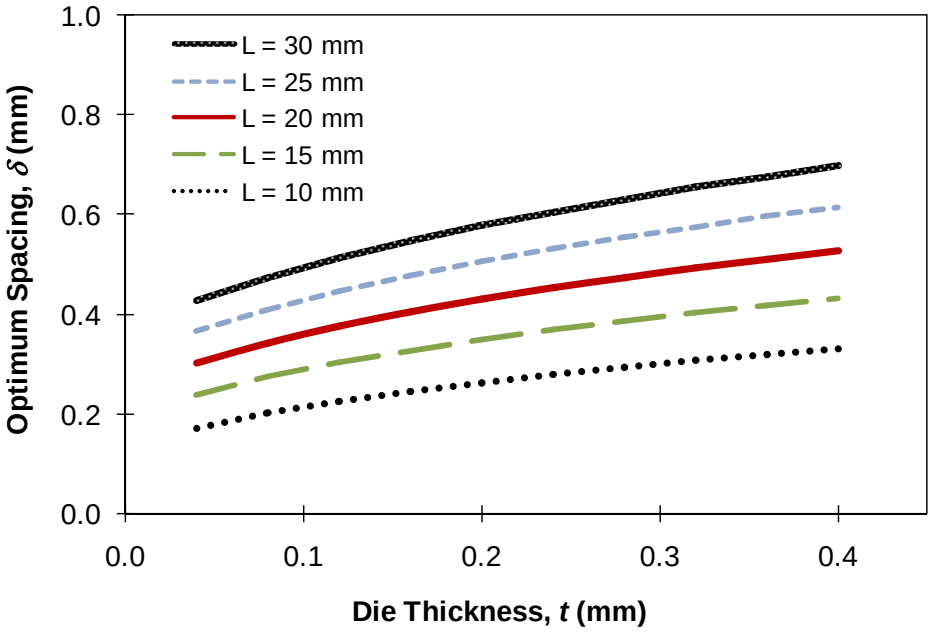

Figure 7. Optimum die spacing calculated using equation (11) for saturated FC-72 at atmospheric pressure

SINGLE PHASE MICROCHANNEL COOLERS

Introduction

Attention now shifts to direct liquid cooling approaches which require active pumping of the working fluid, starting with single phase forced convection. Microfabrication techniques have been used to create microchannel heat sinks and coldplates since the early 1980's [13]. Such liquid cooled microchannel coolers are characterized by sub-millimeter gaps and large channel aspect ratios. Flow in such channels results in very thin boundary layers and convective heat transfer coefficients that easily exceed the natural convection values cited above and may rival the highest heat transfer rates achievable in pool boiling. Applying this technique to 3D chip stacks, the entire stack may be seen to be analogous to a microchannel cooler, with dielectric liquid forced between the tightly-spaced chips.

Governing equations

The thermal behavior of single phase flow in high aspect ratio microchannels formed between parallel plates or within a chip stack may be predicted with the Kakac *et al*. [14] isoflux equations for the heat transfer coefficients attained in developing laminar flow. The average Nusselt number, based on the hydraulic diameter and divided into three flow length segments, is given by:

$$\mathrm{Nu}_{D_\mathrm{h}} = 2.236x^* - 0.333 \ \text{ for } \ x^* < 0.001 \tag{12}$$

$$\mathrm{Nu}_{D_\mathrm{h}} = 2.236x^* - 0.333 + 0.9 \ \text{ for } \ 0.001 < x^* < 0.01 \tag{13}$$

$$\mathrm{Nu}_{D_\mathrm{h}} = 8.235 + 0.0364/x^* \ \text{ for } \ x^* > 0.01 \tag{14}$$

where

$$\mathrm{Nu}_{D_\mathrm{h}} \equiv \frac{hD_\mathrm{h}}{k} \tag{15}$$

$$x^* = \frac{L/D_\mathrm{h}}{\mathrm{RePr}} \tag{16}$$

and

$$D_\mathrm{h} = 2\delta \ \text{ (for } \delta << W\text{)} \tag{17}$$

As the reader might anticipate from the analyses shown in the previous sections, to a good first approximation flow in volumetrically-optimized microgaps within a chip stack approach fully developed conditions at the channel exit. Consequently, in determining average heat transfer coefficients for optimized configurations, only the $x^* > 0.01$ segment, equation (14), is required.

The Reynolds number, which is based on hydraulic diameter, may be expressed in terms of mass flux, G (kg/m^{2}s), as

$$\mathrm{Re} = \frac{G2\delta}{\mu} \tag{18}$$

With the Nusselt number correlations provided above, the wall heat transfer coefficient is based on the average temperature of fluid in the channel, $(T_{out}+T_{in})/2$, where

$$\left(T_{\text{out}} - T_{\text{in}}\right) = \frac{q}{c_p G \delta W} \tag{19}$$

Combining this equation with the definition of the heat transfer coefficient yields:

$$q = \left(T_{\text{die}} - T_{\text{in}}\right) W \left(\frac{1}{2Lh} + \frac{1}{2c_p G \delta} \right)^{-1} \tag{20}$$

Considering that the volume of a single channel is $LW(\delta+t)$, volumetric heat dissipation may be expressed as

$$\frac{q}{V} = \frac{\left(T_{\text{die}} - T_{\text{in}}\right)}{L\left(\delta + t\right)} \left(\frac{1}{2Lh} + \frac{1}{2c_p G \delta} \right)^{-1} \tag{21}$$

where

$$h = \frac{\text{Nu}k}{D_{\text{h}}} = \frac{8.235k}{2\delta} + 0.0364 \frac{2G\delta c_p}{L} \tag{22}$$

Heat transfer rates

Sample results for the dependence of volumetric heat dissipation on die spacing are shown in Figure 9 for saturated FC-72 at atmospheric pressure, assuming a die length of 20 mm and thickness of 0.3 mm, with an average die temperature 30°C above the inlet, and for various channels mass fluxes. These data demonstrate than when mass flux, G, (and, therefore, average channel velocity) is fixed, there exists an optimum spacing which maximizes the volumetric heat transfer. For the examples shown in Figure 9, the optimum spacings are near 0.1 mm, and volumetric heat dissipation rates approach 250 MW/m^3.

In order to find these optima explicitly, one can take the derivative of equation (21) with respect to channel spacing and set it equal to zero. This process yields the following fourth order polynomial in δ.

$$\frac{8 \cdot 0.0364^2 + 4 \cdot 0.0364}{8.235} \Gamma \delta^4 - \frac{2}{t} \delta^3 + \left(4 \cdot 0.0364 - 1\right) \delta^2 + \frac{8.235}{2\Gamma} = 0 \tag{23}$$

where

$$\Gamma = \frac{G c_p}{kL} \tag{24}$$

Detailed expressions for the coefficients in equation (23) are shown to demonstrate their lineage back to the Nusselt number correlation, equation (14). Unfortunately, analytical solutions to the roots of equation (23) are prohibitively complex. Numerical solution of equation (23) must be pursued carefully, not only to select the proper root, but also to ensure convergence, as the values of

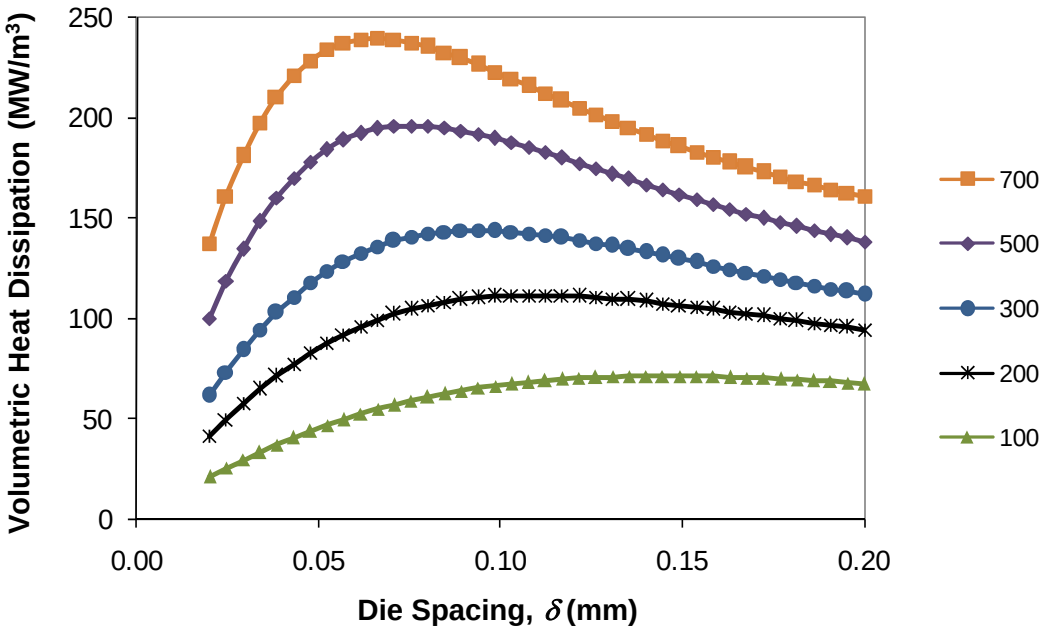

Figure 9. Volumetric heat dissipation results for single phase forced convection cooled die stacks with $L = 20$ mm, $t = 0.3$ mm, and $\Delta T = 30°C$

the polynomial coefficients may differ by fifteen to twenty orders of magnitude. It is interesting to note that the optimum spacing is only dependent on temperature through the temperature dependence of the fluid thermal conductivity and specific heat. Further, the relationship between die thickness and optimum spacing depends only on Γ. Figure 10 shows the results of numerical solution of equation (23) and demonstrates that over a wide parametric range, optimum spacings fall between 0.02 mm and 0.2 mm.

Figure 11 shows volumetric heat dissipation rates as a function of die thickness for optimally-spaced stacks of 20 mm long dies in saturated FC-72 at atmospheric pressure, with an average die to inlet temperature rise of 30°C. Over a range of mass flux from 100 to 700 kg/m^{2}s and die thicknesses between 0.1 and 0.5 mm, heat transfer rates are shown to range from 100 to 500 MW/m^3—comparable to the results shown in the previous section for die stacks optimized for pool boiling. For a given set of conditions, the single phase forced convection provides less heat transfer per die than pool boiling, but the optimum spacing is smaller so the net result is comparable volumetric heat transfer. Over a wider parametric range ($L = 10$–30 mm, and $\Delta T = 10$–$30°C$), optimum die spacings range from 40 to 190 μm, while volumetric heat dissipation rates span 13 to 850 MW/m^3. Corresponding Nusselt numbers are in a very narrow range, 8.6 ± 0.3, signifying near fully developed channel flow ($x^* = 0.06$–0.2). Reynolds numbers are deep into the laminar regime, less than 300, validating the appropriateness of the various correlations employed.

FLOW BOILING

Introduction

The relatively high heat transfer rates attainable with nucleate pool boiling and forced convection of dielectric liquids flowing through miniature channels, respectively, makes the forced evaporative flow of such liquids in a heated microgap channel between chips a most promising candidate for the thermal management of advanced semiconductor devices. Interestingly, gas-driven flow of a dielectric liquid through miniaturized channels, formed by the microgaps between gallium arsenide chips and adjacent circuit boards, was used to provide thermal management for a compact, three-dimensional, high performance module in the Cray-3 computer developed in the 1990's [15]. Regrettably, few validated correlations exist for flow boiling in miniature channels, but understanding and identification of the prevailing flow regimes can facilitate a regime-informed extrapolation of available data and traditional flow boiling correlations to the prediction of heat transfer rates in the gaps formed between chips in a 3D stack.

Flow regimes

The inherent complexity of two-phase thermal transport and its parametric sensitivities in miniature channel flow can be expected to lead to substantial variations in the heat transfer coefficient as the vapor quality increases from near-zero (saturated liquid) to near-unity (saturated vapor) conditions. The physics-based models used in the Taitel and Dukler flow regime maps appear to offer the best basis for determining the prevailing flow regimes in evaporating refrigerant and dielectric liquid flow within miniaturized channels [16].

As an example, Kim *et al*. [17] performed an exploratory experimental study of the thermofluid characteristics of flow boiling in a 10 mm wide by 37 mm long (in the flow direction) microgap channel. The asymmetrically heated channel, formed between a heated copper surface and an acrylic visualization window, was tested in a horizontal orientation. Channel spacings of 110, 210, and 550 μm were investigated. The inlet temperature of the coolant was maintained at 25 ± 0.2°C, with mass flux varying from 56 kg/m^{2}s to 1270 kg/m^{2}s. Figure 12 provides a Taitel-Dukler flow regime map for FC-72 flowing at 133 kg/m2s through the 110 μm microgap channel studied by Kim *et al*. [17]. While the four primary flow regimes—*i.e*. Stratified, Intermittent, Bubble, Annular—are identified on the map, for the 210 and 500 μm channels and for liquid volumetric flow rates from 0.17 ml/s to 0.83 ml/s, the liquid and vapor superficial velocities lead to microchannel operation exclusively in the Intermittent and Annular flow regimes.

Heat transfer limits

Building on the foregoing success in validating a flow-regime-informed approach to the analysis and evaluation of the two-phase heat transfer coefficients in miniature channels, Bar-Cohen and Rahim [16], examined the predictive accuracy of five classical two-phase heat transfer correlations, namely those due to Chen [18], Kandlikar [19], Gungor-Winterton [20], Gungor-Winterton Revised [21], and Shah [22].

The comparison of the correlations to the available miniature channel data for refrigerants and dielectric liquids was conducted by dividing the available data into three categories: Intermittent Flow, Annular Flow-low quality, and Annular Flow–moderate quality. The peak heat transfer coefficient reported for each set of conditions was used as the criteria for separating the "low quality" and "moderate quality" sub-regimes of annular flow. When the data are aggregated in this "regime-sorted" manner, Bar-Cohen and Rahim [16] showed that selecting the best fitting of the classical correlations for each of the flow regime categories, yields predictive agreement with regime-sorted heat transfer coefficients that does not depart significantly from the agreement found in large pipes and channels. In particular, the dominant, low quality Annular data was found to be

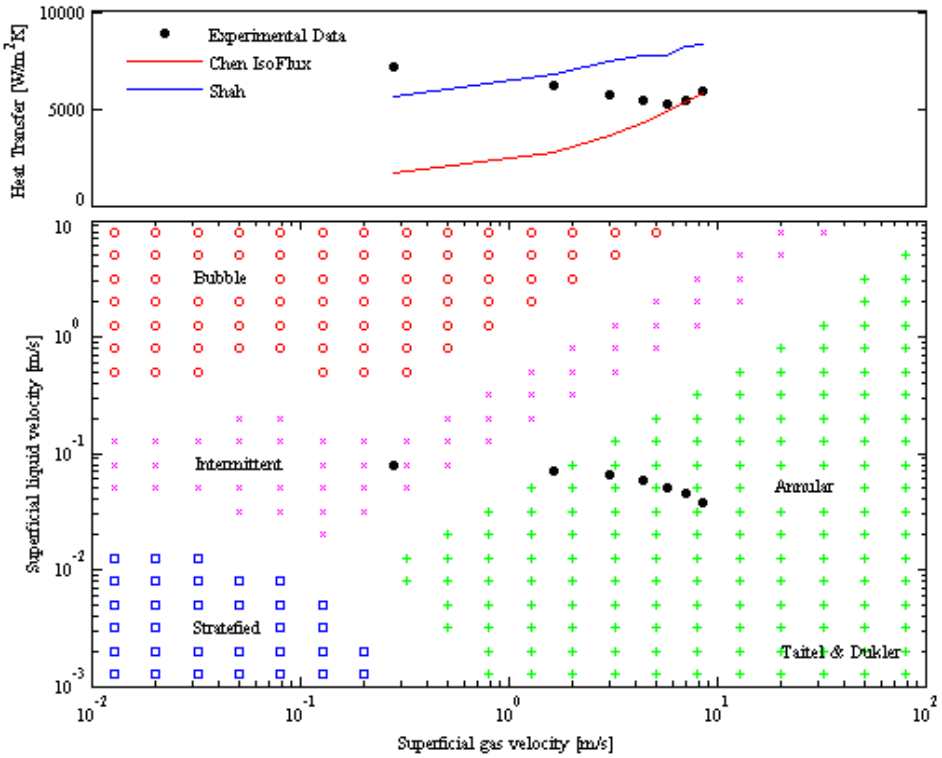

Figure 12. Heat transfer coefficient comparison and Taitel-Dukler flow regime map for 110 μm channel, with data representing a mass flux of 133.3 kg/m^{2}s and heat flux of 16.8 kW/m^2

correlated by the Chen correlation to within an average discrepancy of just 24% and standard deviation of 31%, while the Shah correlation provides agreement to within an average discrepancy of 32% and standard deviation of 40% for data in the Intermittent regime.

The measured values of the area-averaged experimental heat transfer coefficients from Kim *et al.* [17], spanning a range of 5 kW/m^{2}K to 7.5 kW/m^{2}K as a function of superficial vapor velocity (or quality), are shown in Figure 12 above the flow regime map, along with predictions based on the Shah [22] and Chen [18] correlations. In agreement with expectations, all but one of these heat transfer coefficient values are seen to be bounded by these two correlations.

Performance limits and optimum spacings

Based on the foregoing, it would appear that the highest heat transfer rates in two-phase flow through miniature channels will be attained in the annular regime, relying on the evaporation of vanishingly thin liquid films. Previous work has shown that the venerable Chen correlation can predict the heat transfer coefficients in this regime, prior to local dryout, with a standard deviation of 31%. The Chen correlation finds the two phase heat transfer coefficient as the sum of the nucleate boiling contribution (microscopic contribution, or h_{mic}) and the convective boiling contribution (macroscopic contribution, or h_{mac}).

$$h_{\mathrm{TP}} = h_{\mathrm{mic}} + h_{\mathrm{mac}} \tag{25}$$

The microscopic contribution was found as

$$h_{\mathrm{mic}} = 0.00122\left[\frac{k_{\mathrm{l}}^{0.79} c_{p,\mathrm{l}}^{0.45} \rho_{\mathrm{l}}^{0.49}}{\sigma^{0.5} \mu_{\mathrm{l}}^{0.29} h_{\mathrm{lg}}^{0.24} \rho_{\mathrm{g}}^{0.24}}\right]\left[T_{\mathrm{w}} - T_{\mathrm{sat}}(P_{\mathrm{l}})\right]^{0.24}\left[P_{\mathrm{sat}}(T_{\mathrm{w}}) - P_{\mathrm{l}}\right]^{0.75} S \tag{26}$$

where S is the suppression factor which was originally presented by Chen in a graphical format. The empirical fit of the suppression factor as introduced by Collier was used in this study as

$$S\left(\mathrm{Re}_{\mathrm{tp}}\right)=\left(1.25+2.56\times10^{-6}\,\mathrm{Re}_{\mathrm{tp}}^{1.17}\right)^{-1} \tag{27}$$

The macroscopic contribution was found using the Dengler-Addoms correlation with a Prandtl number correction factor to generalize the correlation beyond water as a working fluid.

$$h_{\mathrm{mac}}=h_{\mathrm{l}}F\left(X_{tt}\right)\mathrm{Pr}_{\mathrm{l}}^{0.296} \tag{28}$$

where the empirical fit of the enhancement factor, F, as a function of the Martinelli parameter, X_{tt}, provided by Collier was used in this study as

$$F\left(X_{tt}\right)=1 \text{ for } X_{tt}^{-1}\le 0.1 \tag{29}$$

$$F\left(X_{tt}\right)=2.35\left(0.213+\frac{1}{X_{tt}}\right)^{0.736} \text{ for } X_{tt}^{-1}>0.1 \tag{30}$$

The macroscopic contribution was found to be dominating in the micro channel flow boiling as the nucleate boiling is suppressed because of the very thin liquid film and the insufficient super heat at the channel (die) wall.

Volumetric heat transfer rates, obtained via the Chen correlation, for microgap channels of 50 μm to 1.3 mm, operating with mass fluxes of 100 to 1000 kg/m^{2}s are shown in Figure 13. These values are based on the maximum heat transfer coefficient for values of mass flux and channel gap in such a way not to exceed a wall temperature of 85$^{\mathrm{o}}$C, for a single channel between two dies of 20 mm by 20 mm each.

As can be seen in Figure 13, to the accuracy of the Chen correlation used, an optimum gap of approximately 0.150 to 0.200 mm appears to exist for the two-phase cooling of such a chip stack and to be nearly insensitive to mass flux. A maximum volumetric heat dissipation of 2.1 GW/m^3 is achievable with a mass flux of 1000 kg/m^{2}s of FC-72 in a 0.150 mm single gap channel. This volumetric cooling rates drops quickly as the mass flux decreases and the gap size increases. Thus, at a mass flux of 100 kg/m^{2}s the optimum gap yields a volumetric cooling rate of 200 MW/m^3 and for gaps of approximately 1 mm, even the highest mass flux of 1000 kg/m^{2}s yields cooling rates below 200 MW/m^3.

PERFORMANCE MAPPING

In addition to the range of possible volumetric cooling rates discussed in the individual sections above, it is instructive to make a direct comparison of the heat densities associated with the four considered heat transfer modes through the use of performance maps. Since it is often not possible to capture the full value or cost associated with a particular cooling technique with just one pair of metrics, several performance maps will be discussed. For purposes of this comparison, it will be assumed that saturated FC-72 at 1 atm is the working fluid and that the chips are 20 mm square and 0.3 mm thick with an allowed maximum chip surface temperature of 85°C. Fluid flow rates and velocities for natural convection and pool boiling are determined by the physics of these buoyancy-driven flows, while for the forced flow approaches, flow rate or inlet velocity must be specified.

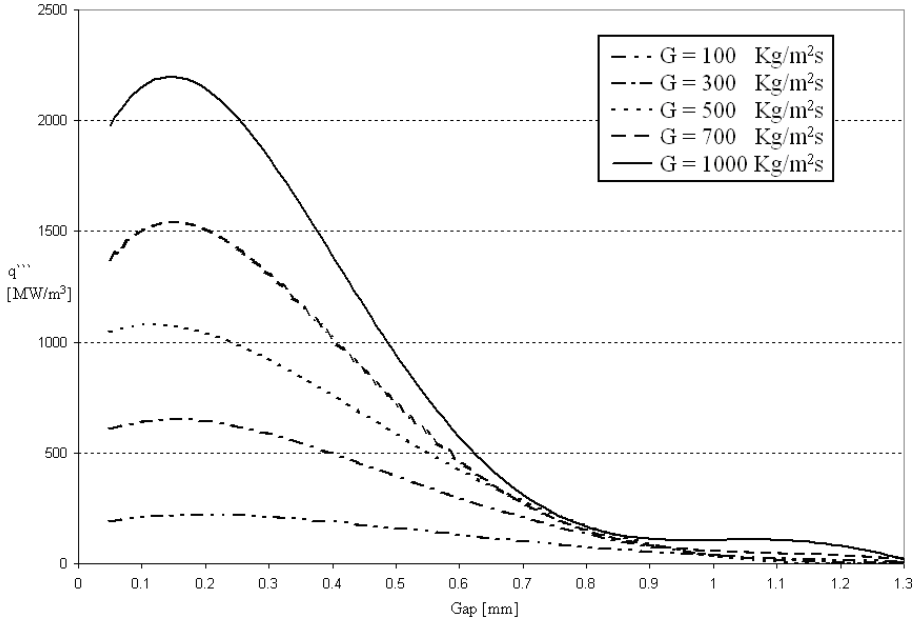

Figure 13. Volumetric heat dissipation in two-phase flow of FC-72 in a single channel mini gap

Figure 14 shows a 3D chip stack immersion cooling performance map, expressed in terms of volumetric heat dissipation versus gap dimension. In Figure 15, the data behind Figure 14 is displayed in terms of chip surface heat flux. Since in a given application the total (volumetric) flow rate available to a stack can be expected to be determined by system-level capabilities and considerations, the forced flow curves in Figure 14 are based on a condition of fixed volumetric flow rate per gap. For the case of fixed volumetric flow rate, V, the Reynolds number, equation (18), can be shown to be independent of chip spacing:

$$\mathrm{Re} = G\left(\frac{2\delta}{\mu}\right) = \left(\frac{\rho V}{\delta W}\right)\left(\frac{2\delta}{\mu}\right) = \frac{2\rho V}{\mu W} \tag{31}$$

For single phase forced convection, the transition to turbulence is expected to begin at a Reynolds number of 2300. Beyond this point, the McAdams equation for turbulent single phase forced convection is employed

$$\mathrm{Nu}_{D_h} = 0.023\,\mathrm{Re}_{D_h}^{0.8}\,\mathrm{Pr}^{0.333} \tag{32}$$

For the conditions and geometry on which the curves of Figure 14 are based, the transition to turbulence occurs between 6 and 7 mL/s.

Clearly, as expected, in Figures 14 and 15 the highest volumetric heat dissipations and highest chip surface heat fluxes are achieved with flow boiling. Likewise, single phase natural convection provides the lowest heat transfer capability of the four modes shown. For gap spacings in the 0.2 to 0.3 mm range, single phase forced convection and pool boiling provide roughly equivalent performance, with pool boiling improving at larger spacings and forced convection improving with reductions in gap size. As discussed in earlier sections, volumetric heat dissipation for the two passive cooling modes peaks at gap spacings near 0.5 mm, with sharply reduced performance below 0.2 mm for natural convection and 0.1 mm for pool boiling. On the other hand, for the active cooling modes (forced convection and flow boiling), both chip stack volumetric heat dissipation and chip surface heat flux are maximized at small gap spacings and decrease with increasing gap size.

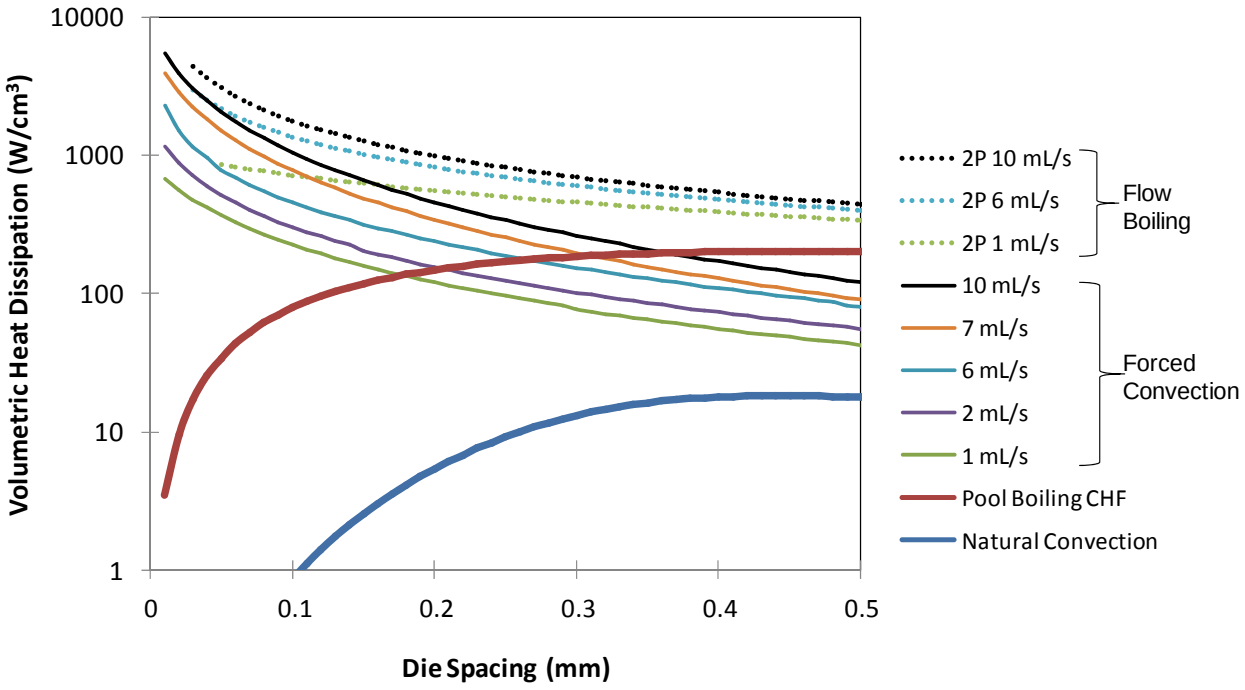

Figure 14. Volumetric heat dissipation performance map, fixed volumetric flow rate

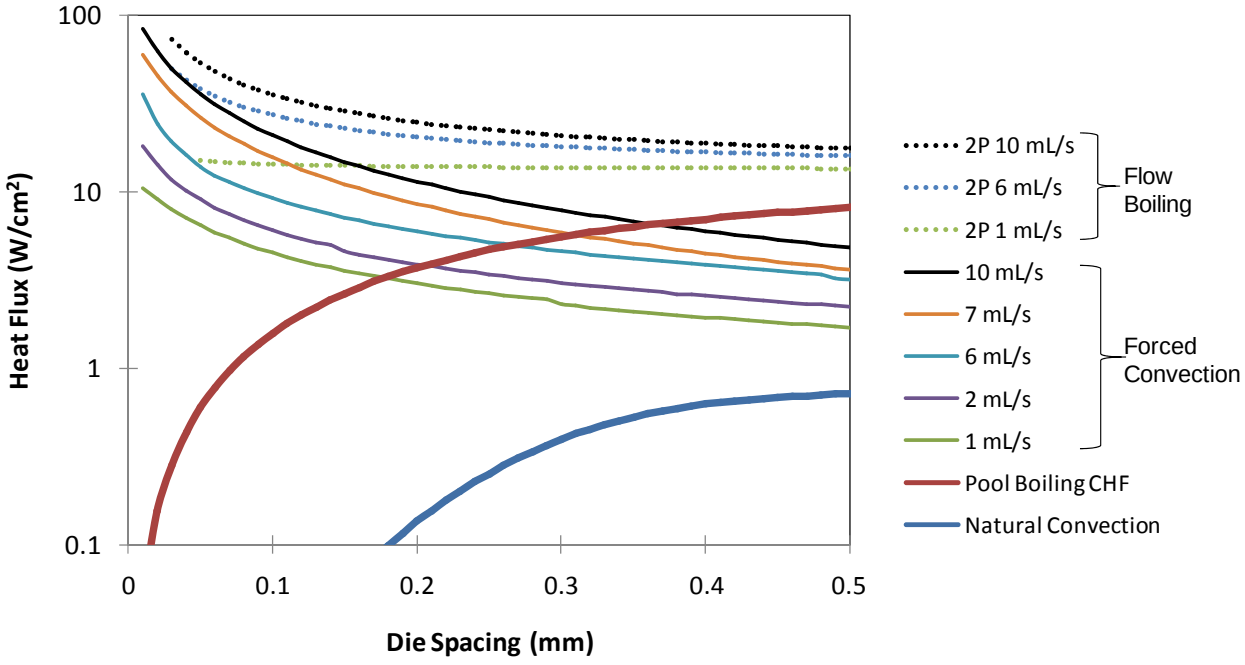

Figure 15. Heat flux performance map, fixed volumetric flow rate

Passive techniques (natural convection and pool boiling) require no input power and may be easier to implement but provide somewhat limited heat transfer capability. It should be noted that proven immersion cooling enhancement techniques (*e.g.* liquid subcooling, liquid mixtures, surface modifications, *etc.*) could be employed to push these limits significantly higher. While the greatest heat transfer performance is achieved with forced flow approaches with very small spacings, channel pressure drop and, therefore, pumping power requirements can be expected to increase drastically with increasing flow rates and decreasing gap sizes. As the curves of Figures 14 and 15 are based on a fixed volumetric flow rate condition, reducing the gap size by a given factor increases the liquid velocity at the channel inlet by that same factor.

Figure 16 shows a performance map for volumetric heat dissipation like Figure 14 but, in this case, based on a condition of fixed gap inlet velocity. The natural convection and pool boiling curves are unchanged, but the forced flow curves display different features. The single phase forced convection curves are the most changed. With inlet velocity fixed, heat transfer capability drops dramatically at the smallest die spacings as the sensible heat rise in the fluid limits performance. In terms of both volumetric heat dissipation and chip surface heat flux, local maxima are observed at die spacings ranging from 0.02 to 0.05 mm. A reduction and subsequent increase and second local maxima is later observed at higher die spacings. Since velocity is constant for these calculations, Reynolds number increases with increasing spacing, and this second peak represents the transition to turbulence. While turbulent flow provides greatly increased heat transfer performance, its associated increased pressure drop characteristics may render it impractical for some applications.

In all of the performance maps, Figures 14-16, and regardless of the flow condition imposed, flow boiling curves are terminated on the low end as flow exit quality is necessarily limited to values less than 1. The main result of holding inlet velocity constant in Figure 16 for flow boiling is that the curves are flatter and display a subtle maximum in the vicinity of this limit.

CONCLUSIONS

The foregoing has explored the thermal management potential of direct liquid cooling of 3D chip stacks, a crucial building block in advanced microsystem architectures of the future. The introduction of miniature liquid passages between adjacent chips, providing convective and/or ebullient heat transfer, along with buoyant fluid flow in these narrow gaps, was shown to offer a most promising alternative to conduction cooling of three-dimensional chip stacks. It was shown that cooling densities ranging from 25 MW/m^3 (or $25W/cm^3$) for natural convection, to 200 to 400 MW/m^3 for pool boiling, to 100 to 300 MW/m^3; for forced convection, and in excess of 2 GW/m^3 for flow boiling could be achieved using FC72 as the dielectric coolant. Optimum die spacings for both single and two phase cooling were found to be in the range of 0.2 mm to 0.6 mm for typical microelectronics geometries.

It may, thus, be surmised that passive immersion cooling—relying on natural convection and/or pool boiling—could provide the requisite thermal management capability for 3D chip stacks anticipated for use in much of the portable equipment category. Alternatively, pumped flow of dielectric liquids through the microgaps in 3D stacks, providing single phase and/or flow boiling heat absorption, could meet many of the most extreme thermal management requirements for high-performance 3D microsystems.

However, due to the thermofluid complexity of ebullient phenomena and the paucity of data for pool and flow boiling of dielectric liquids in microgaps, much more fundamental research is needed to solidify the physical understanding of these phenomena and to underpin the basic relations needed for the design and optimization of 3D immersion cooled microsystems.

THE INFLUENCE OF BOUNDARY CONDITIONS ON TURBULENT JETS

Andrew Pollard[1]
Department of Mechanical and Materials Engineering
Queen's University at Kingston, ON, CANADA K7L-3N6

ABSTRACT In this paper free round turbulent jets and the influence of boundary conditions are considered. The boundary conditions include altering the exit conditions of the mean and turbulence quantities, altering the vorticity generation at the exit through the introduction of tabs and altering the entrainment by the introduction of walls. The notion of a mixing transition is reviewed using new experimental data obtained using a novel flying hot wire experiment. Various structure eduction schemes are applied to the near field of a jet to assist in the identification of important features in the flow.

Keywords *Round jets, boundary conditions, hot wire anemometry, wall jets, jets with tabs, structure eduction*

INTRODUCTION

The round turbulent jet is basic to our understanding of turbulence, and the addition of physico-chemical phenomena such as mixing and combustion greatly complicate this canonical flow, see Pollard and Candel [1]. A free jet can be created rather straightforwardly: blow a fluid through a "nozzle" and it happily reacts with its surroundings by entraining the ambient fluid. What this paper attempts to review are: what are the influences of the initial conditions of the jet itself (mean and turbulence velocity distributions across the jet at the exit of the nozzle); what are the influences brought to the jet by altering the external ambient fluid or boundary conditions; what structural changes occur to the turbulence in each of these cases and what are the effects of Reynolds number on the preceding as well as on turbulence length scales.

The self-similar far field and propagation of inlet effects

Traditional similarity solution for the far field of a round jet has been shown by George [2] to be flawed. He postulated another approach that may be taken to achieve a self-similar solution: the "traditional" approach, which assumes a point source of momentum that is independent of source conditions, does not account for the "considerable evidence that the growth rates in jets arising from different source conditions are (also) different". The inclusion of initial conditions and no *a-priori* assumptions about the functional dependence of U_S, R_S and δ is required. To achieve solutions that result in self-similarity the solution must account for a dynamic relative balance at any given axial and radial location and must include *source conditions*, George [2] derived the following:

$-f^2 + (f'/\eta)\int_0^\eta f\eta\, d\eta = \left\{R_S / (U_S^2 d\delta/dx)\right\}(\eta g_{12})'/\eta$ which all jets must obey if they are self-similar, with the differences being only an amplitude factor due to the {.} term. That is, all mean and Reynolds stress profiles arising from different experiments will be the same profile *shape* and the same Reynolds stress profile shape, but the amplitudes will vary due to the {.} factor. The overarching conclusion reached by George and his group was "the Reynolds stress which when plotted as $\overline{uv}/U_C^2$ will vary from experiment to experiment (*sic)* because its own scale represented in these variables is $U_S^2 \frac{d\delta}{dx}$".

Reynolds number effects

A jet becomes fully turbulent when the Reynolds number exceeds ~10^4, Ricou and Spalding [3]. It is approximately at and beyod this Re that the entrainment of ambient, quiescent fluid saturates so that the mass flow rate across any cross-section becomes constant. Below this Re, the mass flux increases with decreasing Re. What has not been addressed completely in the literature is why Re> ~10^4 is needed to achieve fully turbulent flow.

There is a large corpus of literature that explore experimentally the turbulent round jet over a variety of axial extents and Reynolds numbers, see Ball and Pollard [4]; however, most of these studies consider a variety of axial locations at which some basic quantities are assembled and presented, such as mean velocity decay rates, turbulence stress distributions etc and correlations. The invention of PIV and 3-D versions of it have provided increased opportunity to explore vorticity and other multi-dimensional features, see for example, Weisgraber and Liepmann [5] and most recently Ganapathisubramani *et al.* [6].

If inlet conditions are important, as argued by George [2], then the effects of Re can only be compared using data from experimental rigs that are either the same or enough details are known that all other effects may be eliminated. Panchapakesan and Lumley [7] and Hussein *et al.* [8] considered two different Reynolds numbers (1.1×10^4 and 9.55×10^4, respectively); Hussein *et al*. briefly discuss the effects of Reynolds number as the reason for the differences between their results and Panchapakesan and Lumley [7]. Dimotakis [9] has argued that most shear flows undergo a "mixing transition" to achieve a universal behaviour for the turbulence, and the Reynolds number ($U\delta/\nu$) for this to occur must be greater than $1\text{-}2\times10^4$, which is in accord with Ricou and Spalding [3].

A Brief History of the Near to Intermediate Field of a Turbulent Round Jet

The near to intermediate field of a round jet has been the subject of many investigations. It is convenient to classify these into three main categories (a) characterisation, (b) phase averaged properties and (c) coherent structure identification using minimal spatial and temporal averaging.

(a) Characterisation

Perhaps the most influential paper that characterised a round jet was that of Wygnanski and Fiedler [10]. This paper provided extensive time-averaged distributions of turbulent stresses, skewness and flatness factors, spatial- and auto-correlations, various spatial scale lengths, spectra and estimates of convection velocities. While those data obtained were carefully obtained, they were inconsistent when

subjected to closure of the mean momentum equation for a jet that issued into an infinite environment, George et al. [11] (see George [2]) and this is because the jet used by Wygnanski and Fiedler did not issue into an infinite environment. That is, the data reliably characterise the flow used, but not that of a "free" jet. The latest paper that attempts to examine Reynolds numbers effects on round jets is Malmstrom *et al.* [12]; however, they did not address the question "why Re~$2x10^4$?"

(b) Conditional sampling and phase-averaged properties

The recognition that turbulence contains "structure" was firmly established with the flow visualisation of a supersonic mixing layer, Brown and Roshko [13]. This discovery, and the advent of computer controlled data acquisition set the stage for a new era in turbulence research. Yule [14] investigated the near field of a round jet using conditional sampling hot wire methods. Phased-averaged details for a round jet emerged from Hussain's laboratory, see *e.g.* Hussain and Zaman [15,16]. Conditional averaging use ensemble averages based on the use of a trigger-event; and, as will be returned to later, this introduces some considerable subjectivity since to educe a structure the trigger-event should be associated with that structure. Or, in other words, the structure educed will depend on the scheme used. Phase-averaging decomposes the instantaneous velocity signal $\mathbf{u}(\mathbf{t})$=(U+u', V+v', W+w') into global time-mean, a periodic "coherent" or ensemble average part, and the background "random" part. Note that because of this procedure, only the total signal can close the Navier-Stokes equations.

Hussain and Zaman [15,16] considered jets with mean Re_D ~ 25,000 and a variety of exit boundary layer thicknesses at the nozzle exit (momentum thickness $0.0203 < \Theta < 0.0511$). The jet was "forced" at the preferred mode. The preferred mode refers to the Strouhal number $St_D=fD/U_O$, where f is the excitation (forcing) frequency; the preferred mode St_D~0.3. The mean flow profile instability leads to the formation of coherent structures, which are characteristically transient, and which metamorphose into other "structures" as they evolve with distance downstream. A good example is the work of Yule [14] wherein "cartoons" attempt to point out the basic vortex structures and their interaction in the near-field before the establishment of "full" turbulence beyond the potential core. These structures evolve from the basic instability within the shear layer of the jet. Jet instability can be either convective or absolute; that is, convective is rather more parabolic in nature while absolute is equivalent to elliptic where a perturbation can travel both up and down-stream. In the near field of a jet, >25% of the energy in the flow is contained in the coherent part of the flow, Fiedler [17]. Thus, turbulence energy is distributed through mean, coherent and incoherent components. For future reference, since coherent energy is prominent in the near field, this provides the opportunity for passive and active control. However, phase-averaged structures are educed from data that give no or very little insight into the time domain. A Large Eddy Simulation of a round jet provides opportunities to explore the rich landscape of features as illustrated in figure 1.

(c) Turbulence structure and structure eduction methods

Irrespective of the method used, whether it is theory, experiment or computation, the Navier-Stokes must be satisfied (*often a failure by experimentalists*). And, if the solutions to the Navier-Stokes equations are at hand, say from a direct numerical simulation, the energy contained in the variety of spatial and temporal scales are fully available for interrogation.

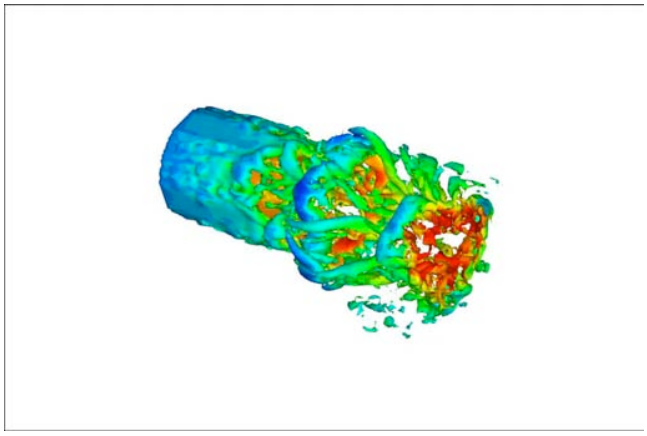

Figure 1: Instantaneous isosurfaces of vorticity magnitude, Large Eddy Simulation of round jet at Re_D = 68,000 using reprocessed data from McIlwain and Pollard [18].

The distribution of energy, however, is complexly intertwined throughout the terms and the spectrum of length scales in for example the transport equation for turbulence energy. Various methods have been used to identify these length scales and the energy budgets have been established for various points in a turbulent jet (but not for a wide range of Re). The most insight into the dynamics of a turbulent jet has been through the application of structure eduction methods using simulation data and the application of say, the proper orthogonal decomposition, to analyse time varying data obtained using rakes of 138 hot wires, Citriniti and George [19].

Coherent structures are related to the vorticity and strain in the flow field. The eigenvalue equation corresponding to the velocity gradient tensor $\nabla u_{ij} = \partial u_i / \partial x_j$ is $\lambda^3 - I_3\lambda^2 + I_2\lambda - I_1 = 0$ where the coefficients I_i represent the three invariants of the tensor. Specifically,

$$I_1 = R = \det(\partial u_i / \partial x) = (\lambda_1\lambda_2\lambda_3) = \frac{1}{3}(\lambda_1^3 + \lambda_2^3 + \lambda_3^3) \quad ,$$

$$I_2 = Q = \frac{1}{2}\left\{(\frac{\partial u_i}{\partial x_j})^2 - \frac{\partial u_i}{\partial x_j}\frac{\partial u_j}{\partial x_i}\right\} = \lambda_1\lambda_2 + \lambda_2\lambda_3 + \lambda_3\lambda_1 = -\frac{1}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2) = \frac{1}{2}P^2 - \frac{1}{2}\left\{\frac{\partial u_i}{\partial x_j}\frac{\partial u_j}{\partial x_i}\right\}$$

$$I_3 = P = \frac{\partial u_i}{\partial x_j} = \lambda_1 + \lambda_2 + \lambda_3 \,,$$

where R, Q and P are alternate symbols often used in the literature. Note that large positive values of Q (see for example Hunt *et al.* [20]) suggest significant enstrophy, see below, (Davidson [21]). Note that $\partial u_i / \partial x_j = S_{ij} + \Omega_{ij}$ represents the sum of the rate of strain and rotation tensors. The negative second eigen-value method $-\lambda_2$ of Jeong and Hussein [22] requires that the second eigenvalue of $S_{ij}^2 + \Omega_{ij}^2$ be negative.

There are other fields that can help to draw out some of the structural dynamics in turbulence. These include vorticity magnitude, helicity, palinstrophy, enstrophy, the Lamb vector, the dissipation of enstrophy all of which (including the eigenvalue-based methods mentioned earlier) require the specification of a threshold level for the eduction to be “useful”. These vorticity-based techniques are defined as:

Vorticity: $\vec{\omega} = \vec{\nabla} x \vec{v}$

Vorticity magnitude: $$\left|\vec{\omega}\right| = \left\{ (\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z})^2 + (\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x})^2 + (\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y})^2 \right\}^{1/2}$$

Helicity: $$\xi = \vec{v} \bullet \vec{\omega} = u\omega_x + v\omega_y + w\omega_z$$

Palinstrophy: $$\Pi = \frac{1}{2}\left|\vec{\nabla} \times \vec{\omega}\right|^2$$

Enstrophy: $$E = \left\{ \frac{1}{4}(\omega_X^4 + \omega_Y^4 + \omega_Z^4) + \omega_X^2\omega_Y^2 + \omega_Y^2\omega_Z^2 + \omega_X^2\omega_Z^2 \right\}^{1/2}$$

Lamb vector: $$\vec{\Lambda} = \vec{v} \times \vec{\omega}$$

Dissipation of enstrophy: $$\Delta = \left\{ \frac{\partial \omega_Z}{\partial y} - \frac{\partial \omega_y}{\partial z} \right\}^2 + \left\{ \frac{\partial \omega_x}{\partial z} - \frac{\partial \omega_z}{\partial x} \right\}^2 + \left\{ \frac{\partial \omega_y}{\partial x} - \frac{\partial \omega_x}{\partial y} \right\}^2$$

A new method has been proposed by Larcheveque and Larcheveque [23] that purports to not require the setting of a threshold. The basis for the method involves expressing the surface of constant vorticity in the basis of eigenvectors of the Hessian matrix $H_{ij}(\omega) = \frac{\partial^2 \omega}{\partial x_i \partial x_j}$. An isosurface is where the difference between the vorticity magnitude at any two points, say M and M_O equals zero. This can be expanded in terms of a vector connecting any two points on the surface $\overrightarrow{MM_O}$ as follows: $\omega_M - \omega_{M_O} = \overrightarrow{MM_O} \bullet \vec{\nabla}(\omega_{M_O}) + \frac{1}{2}\overrightarrow{MM_O}^T H(\omega)_{M_O} \overrightarrow{MM_O}$. A useful property of this equation is that when it is written as the basis of eigenvalues of the Hessian the following quadratic is obtained: $\lambda_1(X + \frac{a}{\lambda_1})^2 + \lambda_2(Y + \frac{b}{\lambda_2})^2 + \lambda_3(X + \frac{c}{\lambda_3})^2 = \frac{a^2}{\lambda_1} + \frac{b^2}{\lambda_2} + \frac{c^2}{\lambda_3}$. The invariants determine the shape of the structures, which are highlighted in the following table.

	I_1	I_2	I_3
Pancake vortices	<0	>0	<0
Tubular vortices	<0	>0	≥0
Rotational sheets	<0	≤0	≥0
Planar sheets	<0	≤0	≥0

Table 1: Invariants for different vortex structures, after Larcheveque and Larcheveque (2007) [23].

The Navier-Stokes may be recast into $\frac{\partial \vec{u}}{\partial t} - \vec{\Lambda} = -\nabla h - \nu(\nabla \times \nabla \times \vec{u})$, Mallinson [24] and the viscous dissipation term is twice the square root of the palinstrophy, which itself appears in the transport equation for enstrophy, see Davidson [21].

NUMERICAL SIMULATIONS

There have been numerous investigations of round jets that rely on Reynolds averaged Navier-Stokes modelling of turbulence. I have chosen not to include them here.

Large eddy and direct numerical simulations (LES/DNS) of free jets continue to emerge in the literature. For LES, these include Olsson and Fuchs [25], McIlwain and Pollard [18], Bogey and Bailly [26], Uddin and Pollard [27-29] and Kim and Choi [30]. These simulations cover a wide range of initial conditions and Reynolds numbers, but save for Uddin and Pollard [27-29] all focus on the near field (typically x/D<15). For DNS, the Reynolds number and the integration domain are small, typically Re<2500 and x/D<40. The reason for the low Re, is due purely to spatial and temporal resolution requirements of DNS. That is, it can be demonstrated (see Reynolds [31]) that the number of CV's required scales with $L / \lambda_k \approx Re^{3/4}$, where L is the domain size length scale and λ_k is the Kolmogorov length scale, and the time step scales with $Re^{1/2}$, so that memory scales with $Re^{9/4}$ and CPU time scales with $Re^{11/4}$. To place this into perspective, to perform one DNS of the flow over a commercial airliner at cruise conditions would take about a 10^9 years using existing computer technology.

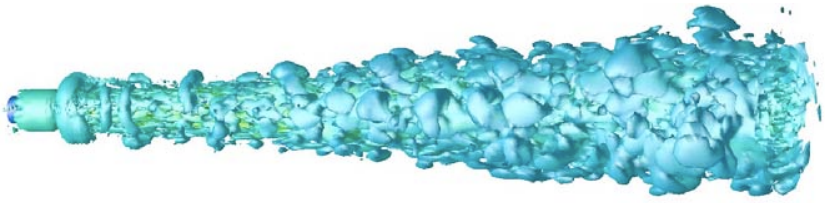

Figure 2: LES of a round jet, Re_D~7000, {unpublished work by Golanski and Pollard}.

A sample LES of a free round jet is illustrated in figure 2. This jet covered 0<x/D<35, using 256x120x64 control volumes in x-r-θ coordinate directions. The MPI parallel code uses second order differencing with a three-step fractional step method. Structure is educed using the Laplacian of the pressure (see Dubief and Delcayre [33]), normalized by the square of the mean exit velocity. The magnitude of the Laplacian (in this case 0.05) varies and is "coloured" by the magnitude of the streamwise velocity and this provides different levels of "colour" to the isosurfaces.

The data from McIlwain and Pollard [18] have been interrogated using the above noted schema; these are displayed in figure 3. Figure 3(a-h) use the same database to educe "structure". In Figure 3(a-e), the Q value, enstrophy, negative second eigenvalue, palinstrophy and helicity are displayed. These figures have employed different threshold magnitudes, while in figure 3(a) Q was coloured by the velocity magnitude. Clearly Q, $-\lambda_2$ and E all provide very similar "pictures" of the structure. The palinstrophy, which mimics the viscous dissipation of enstrophy (and similarly in the transformed Navier-Stokes equation that contains the Lamb vector) possess a finer scale; however, as this is LES, this is misleading as dissipation is not resolved. The complex vortex structure is evident, as well as the "flotsam" that indicates regions of fluid rotation vs. fluid stretching/compression. The Q-value reinforce the braid-like structures near x/D~4, which are opposite in sign to helicity. The palinstrophy

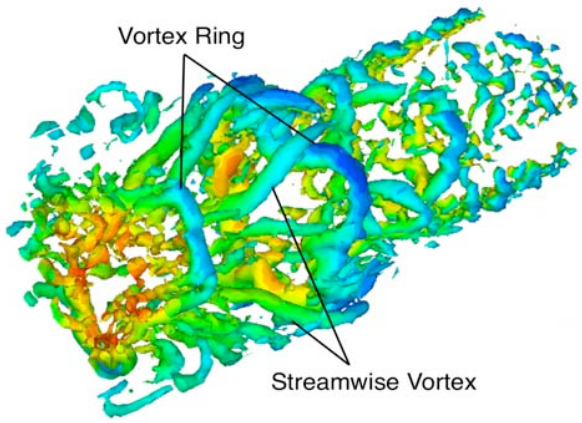

Figure 3a: Q-value

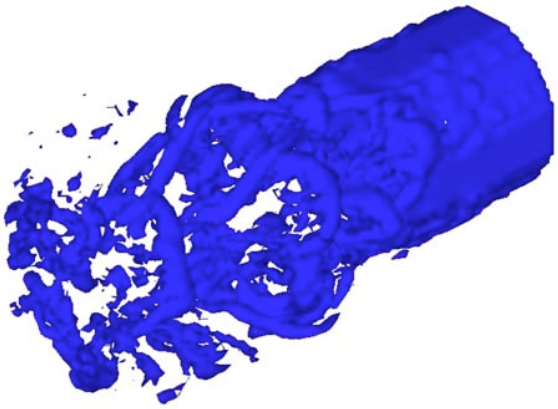

Figure 3b: Enstrophy

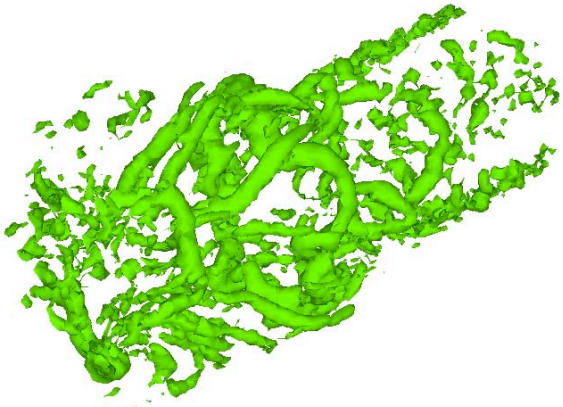

Figure 3c: Negative second eigenvalue

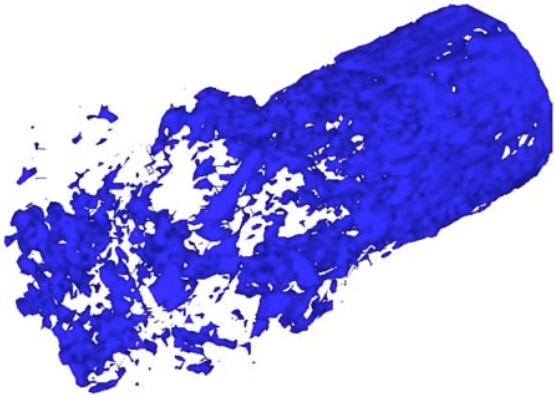

Figure 3d: Palinstrophy

Figure 3e: Helicity

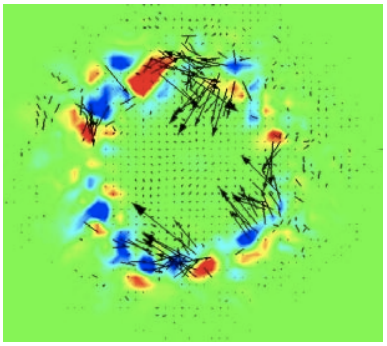

Figure 3f: Helicity and Lamb vector, x/D=1.6

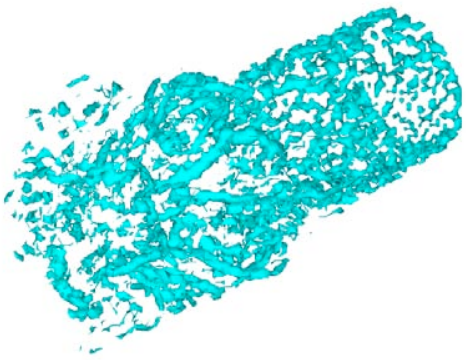

Figure 3g: Larcheveque and Larcheveque method, pancake vortices

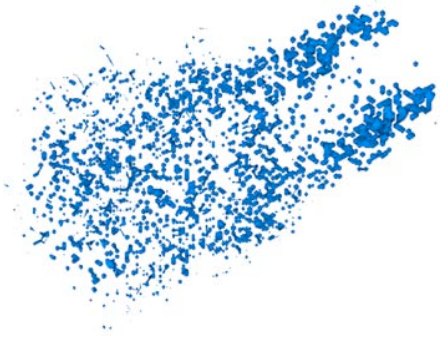

Figure 3h: Larcheveque and Larcheveque method, planar sheet vortices

field provides a richer background link to the Lamb vector. Interestingly, Davidson [21] states (pg 210) "(*sic*) regions of high helicity tend to correspond to regions of low (*sic)* Lamb vector (for a given energy and enstrophy). However, (*sic*) the Lamb vector corresponds to the non-linear term in the Navier-Stokes equations which, in turn, drives the energy cascade. So perhaps regions of high helicity tend to exhibit a somewhat depleted energy cascade, with a relatively low value of ε (dissipation)".

In figure 3(f), the jet cross-sectional plane at about x/D=3 is displayed using the helicity concomitantly with the Lamb vector. The helicity magnitude indicates the alignment between the velocity and vorticity vectors so the blue and the red colours indicate ±180 phase. The Lamb vector (arrows in fig. 3f) is the cross product of the velocity and vorticity vectors and thus the arrows indicate translation magnitude for a given vorticity; that is, the arrows suggest flow into the centre of the jet, which is clearly non-axisymmetric.

Figure 3(g, h) displays the application of the Larcheveque and Larcheveque method for the pancake and planar vortex sheet vortices. While the pancake vortices clearly indicate recognisable structure, the planar sheets do not.

Effects of mean and turbulence inlet distributions on free turbulent round jet.

Recently, Uddin and Pollard [27, 28, 29] performed LES of a round jet within a mild co-flow. The work considered the effects of initial conditions on the evolution of the mean and Reynolds shear stresses in the near to far field. The Reynolds number was ~7,200, and utilized 1024x144x72 CV's and over 125,000 CPU hours on 16 CPU HPC facility were required to run all four cases.

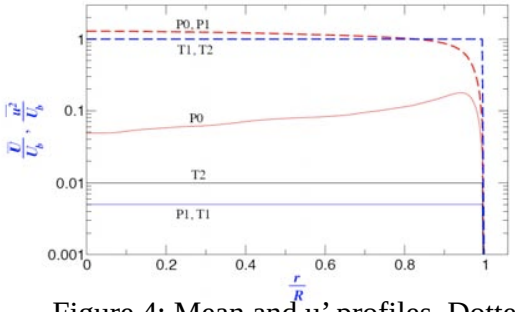

Figure 4: Mean and u' profiles. Dotted and solid lines represent mean and RMS quantities respectively.

The inlet conditions are provided in Figure 4. T1 represents a

synthesised top hat mean velocity with a time averaged streamwise intensity of 0.05%, which corresponds to the experimental conditions of Nickels and Perry [34]; T2 is T1, but with a turbulence intensity of 1%; P0 is fully developed pipe flow obtained from separate LES and P1 is same as P0 with an average streamwise turbulence intensity of 1%.

Data are scaled using Townsend's approach $\Delta^2 = \int_0^\infty \{U(r) - U_1\} r^2 \, dr \,/ \int_0^\infty \{U(r) - U_1\} \, dr$, where U, U_1 are the mean velocity of the jet and co-flow respectively (U/U_1=11). The mean axial velocity and the Reynolds shear stress distributions (f(r)) are not at all influenced by altering the inlet conditions; however, as can be observed in the plots of Reynolds normal stresses, there are significant effects, see figure 5. These are not just scaling issues, as noted by George [2]. It may be that the Reynolds number is too low (does not exceed the "mixing transition" $Re>10^4$), or that the simulations are influenced by the external co-flow, which will result in the far field "jet" to become a wake-like.

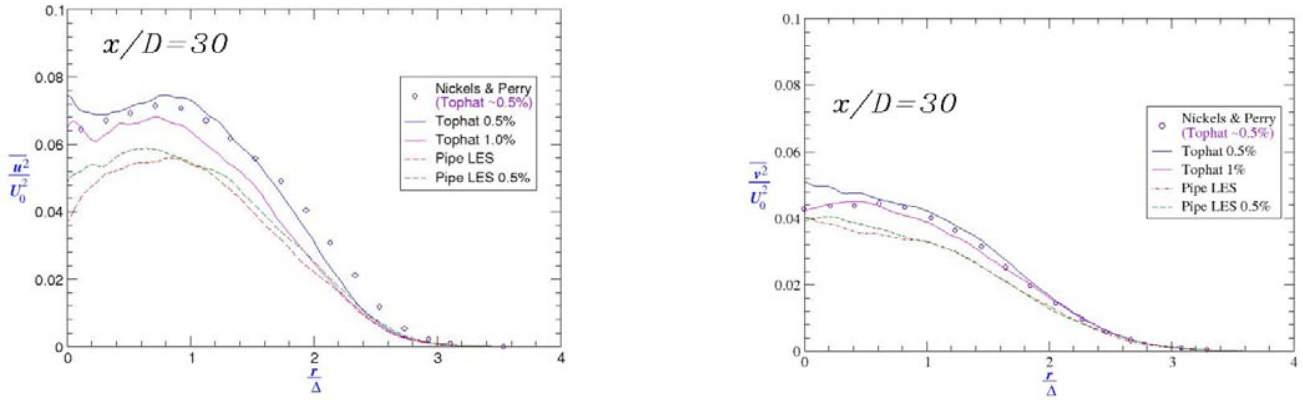

Figure 5: Axial (u') and transverse (v') turbulence intensities for LES of round jet, Uddin and Pollard [27]

Figure 6: LES of round jet; note the fading of structure as the jet fluid evolves downstream

Malmstrom *et al.* [12] concluded, without reference to George *et al.*, that "outlet turbulence could have such an influence (mean axial velocity decay rate coefficient decrease for Re<~20,000).

There remains some considerable opportunity to explore the intermediate field of a round jet (say at x/D<40) to determine how the various structures that have been identified in the simulations evolve and especially as a function of Reynolds number, Ball and Pollard [4]. Given that structures identified

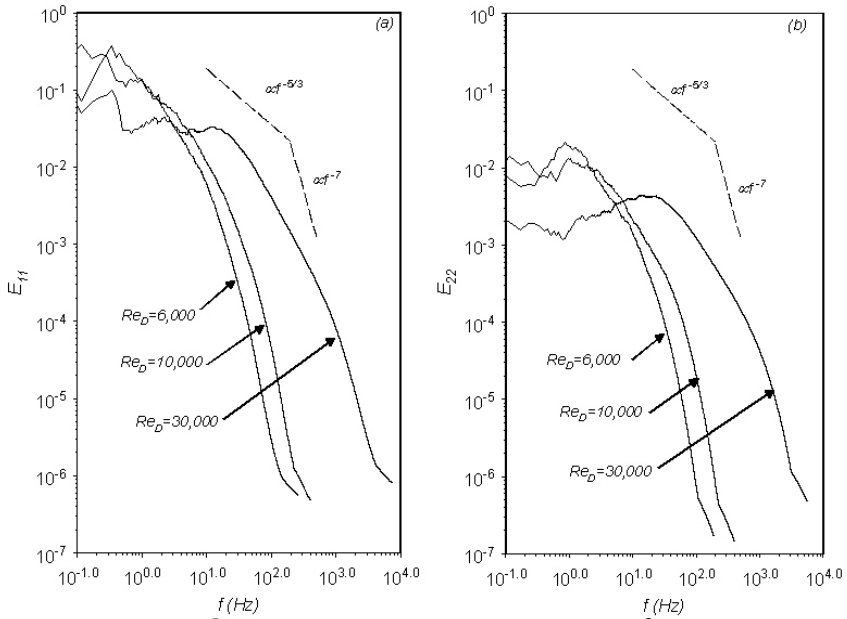

Figure 7: Velocity spectra at *r/D=0* at *x/D=10* for *Re*$_D$*=6,000, 10,000* and *30,000*. (a) *u*-spectra, (b) *v*-spectra.

alter their magnitudes as they are advected downstream, it is very difficult to "track" them, see figure 6.

Dimotakis [9] has proposed that the finding of Ricou and Spalding may be traced not to the large scale structure in the flow, which are peculiar to the geometry considered, rather to the physical significance of the various scales of the turbulence and their Reynolds number scaling. That is, there is a decoupling between the large scales and those free from the effects of viscosity. Starting with the theory presented in Kolmogorov [35], Dimotakis linked the outer scale, δ, to a variety of other length scales; *i.e.* , and using some additional scaling arguments, arrived at:

$$\mathrm{Re}^{-3/4} < \frac{\lambda_k}{\delta} \approx 50\,\mathrm{Re}^{-3/4} < \frac{\lambda}{\delta} < \frac{\lambda_L}{\delta} \approx 5.0\,\mathrm{Re}^{-1/2} < 1$$

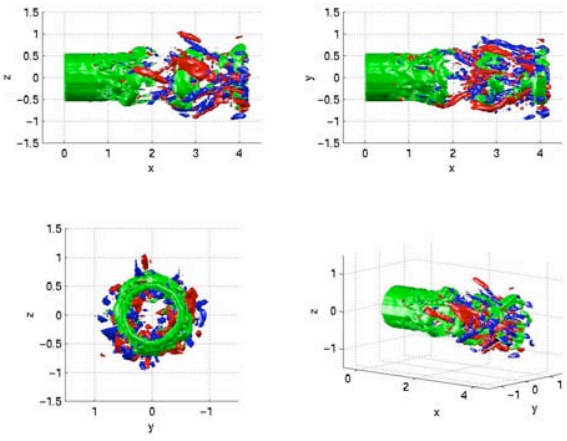

Figure 8: Round jet streamwise (Red{+}, blue{-}) and azimuthal (green) vorticity magnitude in LES of round jet 0<x/D<5. McIlwain *et al.* [38]

where $\mathrm{Re} = \frac{U\delta}{\nu}$, and λ_k, λ_V and λ_L are the Kolmogorov, viscous and the Leipmann-Taylor microscale and λ is a range of scales that are unaffected by the outer scale. Dimotakis suggests that $\lambda_L / \lambda_V > 0.1\mathrm{Re}^{1/4}$ or that $\mathrm{Re}>10^4$, or the number of viscous scales within a Taylor microscale and then argues that "viscous decoupling of the outer and inner scales of turbulence as responsible for the transition criterion" or mixing transition. To test Dimotakis' hypothesis, Fellouah and Pollard [36, 37] considered the round jet using a novel flying hot wire experimental facility. This work considered 6,000 < Re_D <100,000, using the same set-up, data acquisition systems etc. over 0.04 < x/D < 25. Data were obtained using single and cross hot wires. They have

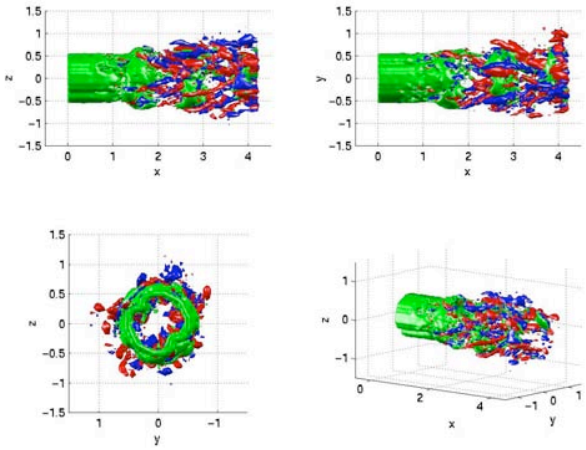

Figure 9: Round jet with two tabs. Streamwise (Red{+}, blue{-}) and azimuthal (green) vorticity magnitude in LES of round jet 0<x/D<5 with 2 tabs at 135^o and 315^o. Note increased appearance of streamwise vorticity (same contour levels) as compared to free round jet in Fig. 8.

demonstrated that the mixing transition is non-local and that it appears to occur at the appearance of the -5/3 inertial subrange rather than at the transition between the inertial and dissipation (k^{-7}) ranges. Figure 7 provides the velocity spectra on the jet centreline *x/D=10*, and for the three Reynolds numbers considered. It is clear the mixing transition, which demarcates *Re=10,000* and *Re=30,000*, display very different velocity spectral energy content, most noticeably at *x/D=10*. The inertial sub-range is certainly evident at *Re=30,000* than at the lower Reynolds numbers, while the dissipation range is in greater evidence for the lower, sub-mixing transition Reynolds numbers. Dimotakis argues that the mixing transition should occur when there is a separation between the large and viscous scales and free from viscous effects; that is between the inertial sub-range and the dissipation range. Based on those data presented here, it is the appearance on the inertial sub-range itself that may indicate the mixing transition, Fellouah and Pollard [36].

Effects of passive interaction with the exit flow of a round jet

McIlwain, Holme, Waterman and Pollard [38] introduced delta tabs to better understand the physics of inlet conditions on the formation and evolution of structure in a jet. The jet was forced at a Strouhal frequency of 0.35 and the jet was populated with either 1, 2, 3 or 4 tabs located at 45^o, 135^o 225^o and 315^o, respectively. Reynolds numbers for all jet simulations was kept at 68,000. Through direct comparison with simulation data, and using exactly the same structure eduction scheme and threshold levels, McIlwain *et al.* determined that when tabs are used the zeroth mode (the ring vortex) in the near field is significantly distorted in the azimuthal direction and this gives rise to increased appearance of streamwise "braids", see figures 8 and 9. McIlwain *et al.* calculated the entrainment for each case considered and determined that the rate of entrainment increased as the number of tabs was increased, relative to the free-jet, no-tab case. There is little difference in the rate of entrainment between the round jet without tabs and the round jet with one tab. However, the mass flow rate of the round jet with four tabs is 10% greater than either of the other two flows at *x/D* = 3.0 and 12% greater at *x/D* = 4.2. Between 0.0 < x/D < 2.5, the flow rate of all three jets is similar.

The round jet with four tabs entrains approximately 6% more fluid compared to the other two flows. All flows with tabs indicate an increase in the rate of entrainment as the rings are torn apart particularly at *x/D* = 2.5 for the jet with four tabs, and at *x/D* = 3.0 for the single and two-tab flows. This location also corresponds to the point where the braid-shaped structures begin to dominate the flow field. In the jet with four tabs, the braid-shaped structures that form at the bulges in the shear layer cause the rings to break apart faster, and appear to be responsible for the increased entrainment. This result supports

previous findings that the streamwise braid-shaped structures have greater effect on flow entrainment than the azimuthal ring-shaped structures.

Effects of walls on the evolution of a "free" jet

Ewing and Pollard [39] postulated a model for the anisotropic spread rate based on the structural features uncovered in some experiments. This hypothesis was based on the interaction of the zero'th mode vortex (Kelvin-Helmholtz) with the wall, see figure 10.

The anisotropic spread rate, which is a well known phenomenon in 3D wall jets, see Launder and Rodi [40]. However, Ewing and Pollard [39] captured the main reason for this.

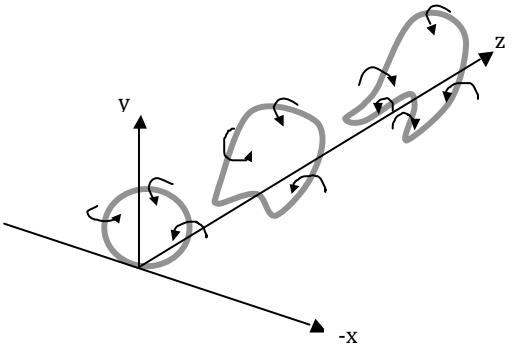

Figure 10: Breakdown of round jet in proximity to a wall, located at y=0, as hypothesised by Ewing and Pollard [39]

In my laboratory, investigations that used both experimental and computational approaches have been used to explore this feature of wall jets. In figure 11, the rather smeared views of a round wall jet (on the wall case) taken at different times on the same axial plane clearly demonstrate that the anisotropic picture suggested in earlier work is probably due to the integrated effects of measurements rather than the conditional "snap-shot" that reflects the periodic structure. Figure 11 (top) suggests anisotropy in the spreading while clearly its neighbour (bottom) doesn't. Further investigation and better time-resolved flow visualization, see figure 12, for the off-the-wall case, indicates vortex structure that reinforces the spatial and temporal anisotropic behaviour. To quantify some features of the vortex structure, Benaissa *et al.* 41] used rakes of hot wires and conditional averaging to deduce the angles and other features of the main structures in the wall jet. This time delay is associated with the angle α noted in the flow visualisation. An estimate of the angle based on this time delay of 2.4 ms is 45. This estimate is based on a convection velocity (Taylor's frozen turbulence hypothesis) of 10 m/s (velocity at $y_{1/2}$). For the spread in the span wise direction, conditional averages in the Z direction a suggest a shorter time delay in this direction estimated to be 1.4 ms., thus $\beta \sim 25^{o}$. The far-field anisotropic spread rate is, on average, $\frac{\partial y_{1/2}}{\partial x} = 0.048 \pm 0.003$ and $\frac{\partial z_{1/2}}{\partial x} = 0.26 \pm 0.02$. The experimental data suggest a complex vortex interaction

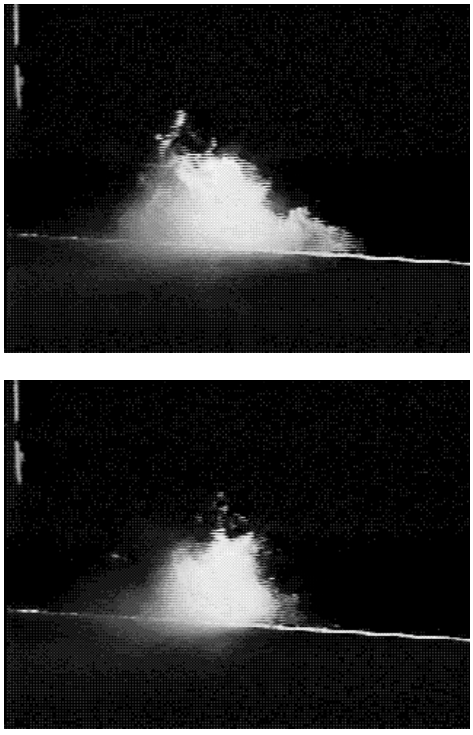

Figure 11: Smoke visualisation of round wall jet. The two images represent, at x/D=10, side lobe ejection (top) and no-side lobe ejection, (bottom).

mechanism, further details of which have explored using large eddy simulation in Pollard *et al.* [42].

Pollard *et al.* [42] considered a square wall jet, as a substitute for the round jet. Briefly, the ring vortices that emerge from the orifice begin to change into horseshoe vortices at a streamwise location of approximately z/D=7, for the "on-the-wall" case, which is the same location at which the streamwise braids begin to dominate the flow. It also appears that the vortex inclines towards the wall as it develops downstream. The top of the horseshoe vortex moves faster than the base, which is slowed down by the viscous effects near the wall. This causes the stretching of the legs of the structure and the formation of quasi-streamwise vortices.

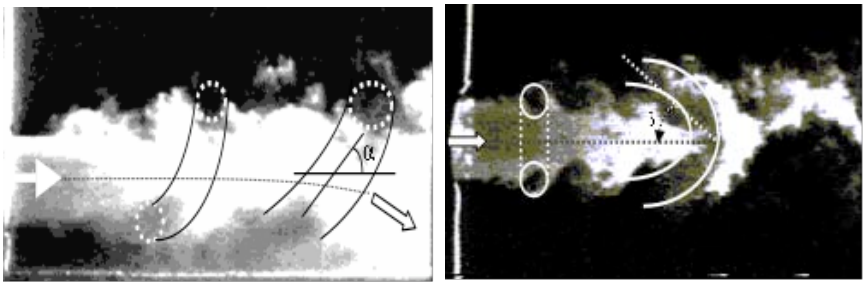

Figure 12: Elevated wall jet. Round jet located at h/D=1 (wall to jet centreline) above the wall. The cartoon superimposed on the visualisations indicate the supposed vortex structure. The angles were determined using conditional averaging of hot wire signals, see Benaissa *et al.* 2004.

The comparison between the plots of Q-value and streamwise vorticity, see figure 13, reveals that the largest lateral spread rate appears in the region where streamwise vortices are the most present in the coherent structures. Thus, the inclination of horseshoe structures and their alignment in the streamwise direction could explain the large lateral growth rate. The increase in the inclination of structures would enhance the size of lateral ejection explaining the significant increase in the lateral spread rate as the flow evolves downstream.

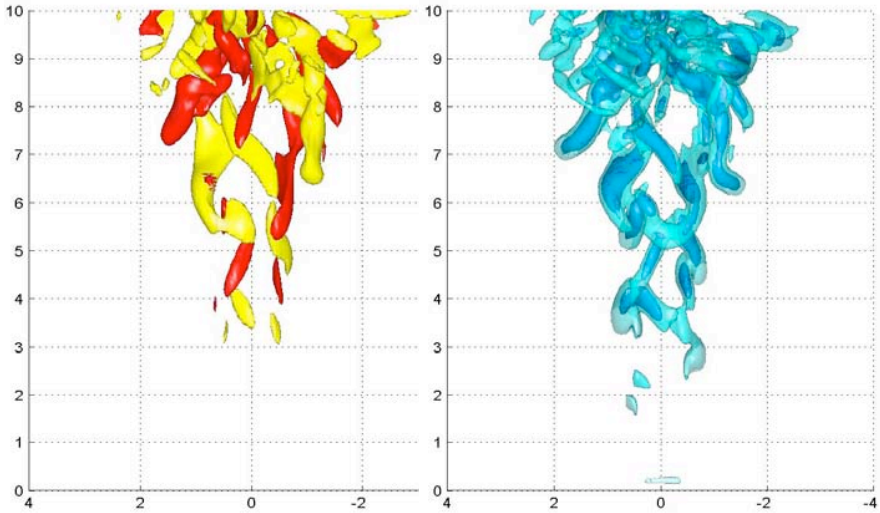

Figure 13: Plan view of streamwise vorticity (left) and Q (right) for on the wall square wall jet case. The streamwise vorticity colours indicate +/- sense of rotation.

The wall jet, when elevated from the wall more clearly demonstrates the complex vortical behaviour of the jet, and gives tantalising indications of the vortex structure found by Ewing and Pollard [39], see figure 14.

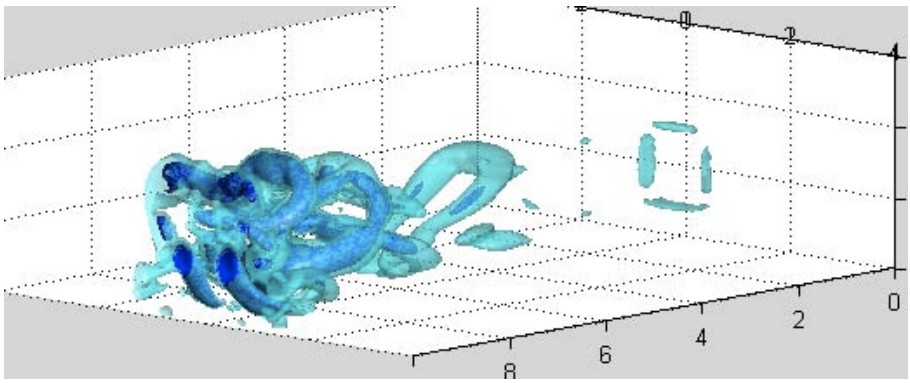

Figure 14: Off-the-wall h/D=1 case. Q-values. The two arrows indicate the tails of two legs of a horseshoe vortex, which spread laterally. This lateral spread enhances the anisotropic spread rate of the wall jet. There are hints of vortex structure suggested by Kasagi [43] for "alternate modes" in a bifurcating jet.

SUMMARY REMARKS

The round jet has been revisited. The hypothesis, which needs to be proved, is: turbulence "structure" dominates any high Re flow, and as exemplified by the influence of interference by tabs and walls, the initial structure evolves uniquely dependent upon the boundary conditions. More important, as Re increases, the turbulence structure evolves to a "state" that limits a particular flow-regime to super-saturate entrainment of irrotational fluid. This suggests that the entrainment, as governed by the circulation of individual structures evolves to a maximum and limiting entrainment-enabling state. The mixing transition ideas of Dimotakis have been further explored.

As with computers, experimental methods continue to increase in capacity. The recent paper by Ganapathisubramani *et al.* [6] considers three dimensional, **time-resolved** PIV. They considered a round jet at Re_D=5100 (Re_λ~150). They acquired all 9 components of the velocity gradient tensor at x/D~35. They educed structure using essentially the same method as McIlwain and Pollard [18] and inferred small scale vortex strength around vortex-tube-like structures or "worms" (after Jimenez *et al.* [44]). They additionally focused on the alignment (dot product) between the vorticity vector and the eigenvectors of the rate of strain tensor. The angle between the eigenvector and vorticity vector is φ they deduced that the vorticity vector aligns with strain (*i.e.* cos φ=1) and least likely (*i.e.* cos φ=0) with compressive strain and indeed the vorticity vector "is perpendicular to the principal compressive strain." They also had enough data to calculate the dissipation, which, from an experimental investigation, is a significant accomplishment. Unfortunately, the paper does not consider the role of these fine-scale structures on entrainment. However, the paper does suggest that the hypothesis put forward above has merit and indeed, my laboratory is pursuing this now.

This paper has considered a "simple" question, drawn from an observation by Ricou and Spalding. The paper has provided tantalizingly glimpses of what is posited as the rich structural landscape of this flow. Through theory, simulations and experiments we have learned that turbulence has a memory of its origins and that to alter the initial and boundary conditions the structure of the turbulence is altered.

ACKNOWLEDGEMENTS

It is with pleasure that I acknowledge the assistance of Ms. Emily Sheridan, Drs. H. Fellouah and F. Golanski and Mr. C.G. Ball who provided some of their unpublished research results. This paper was prepared while the author was on sabbatical at the University of Auckland, New Zealand, and ably hosted by Professor G.D. Mallinson. I have enjoyed continued funding from the Natural Science and Engineering Research Council of Canada. I also acknowledge the significant computational resources provided to my students and laboratory by the High Performance Computing Virtual Laboratory (www.hpcvl.org).

ON HEAT TRANSFER AND FLUID FLOW IN RIBBED DUCTS USING LIQUID CRYSTAL THERMOGRAPHY AND PIV MEASUREMENTS

B. Sundén*
Lund University, Department of Energy Sciences, Division of Heat Transfer, P.O. Box 118, Lund, SE-22100 Sweden

ABSTRACT. Enhancement of forced convection is important in many engineering applications. Surface modifications like rib-roughening are commonly used in applications such as compact heat exchangers and gas-turbines. This paper gives a brief summary of heat transfer and fluid flow in ribbed ducts using liquid crystal thermography and PIV measurements. Details of the flow pattern and the influence of rib configuration and arrangement on heat transfer are discussed. Nevertheless, our understanding of the flow physics in ribbed channels is not yet complete and further studies are needed.

Keywords: *ribbed ducts, heat transfer, flow pattern, liquid crystal thermography, PIV measurements*

INTRODUCTION

Periodic ribs are often used in the design of heat exchanger channels in order to enhance the heat transfer rate and thus to improve the overall process efficiency. Historically ribs have been introduced in the cooling passages of gas turbine blades because of the extremely high thermal loads and reduced dimensions. It has been found that the main thermal resistance to the convective heat transfer is due to the presence of viscous sub-layer on the heat-transferring surfaces. The presence of ribs makes the viscous sub-layer break down by virtue of flow separation and reattachment, which reduces the thermal resistance and considerably enhances the heat transfer. However, the use of ribs gives rise to higher friction and hence higher pumping power. Thus, many experimental studies have been carried out to determine the rib configuration and arrangement that produce optimum effects. Among the parameters affecting the heat transfer characteristics, the ratio of the rib height to channel height (e/H) [1-5] and the rib pitch to height (P/e) [1-3, 6] are important ones. In general, an increase in the rib height increases the heat transfer. It is also found that if the core flow is strongly perturbed by the presence of high ribs there appears to be a more sharp increase of the flow resistance than the enhancement of heat transfer. The optimum e/H is known to be around 0.1 [1]. There also exists an optimum pitch, since the pitch should be longer than the reattachment length formed behind the rib. The ratio of the rib pitch to height recommended is about 10 for the Reynolds range of interest [1]. Since the optimum values of the aforementioned parameters are well established through extensive experimental data, we shall give more attention to other geometric parameters.

Heat transfer in a ribbed channel is locally deteriorated immediately behind the ribs (i.e. hot spots) due to the formation of a corner eddy. The heat transfer in this region is essentially dominated by conduction since the flow is nearly stagnant relative to the mainstream flow. Attempts have been made to overcome the adverse effect by changing the geometry of the rib cross section. Han et al. [7] applied

modelling clay to fill the corners of the rectangular ribs to create two distinct geometries. It was found that the clay has a modest effect on the heat transfer coefficients, and the influence of the rib shape on the heat transfer coefficients disappears at higher Reynolds number where the flow is in the completely rough regime. Lockett and Collins [8] reported that the hot spots were alleviated when the more streamlined (or rounded) ribs were used. Moreover, they found that the heat transfer distribution depends on the Reynolds number for the rounded rib, but independent for square-rib geometry. Taslim and Korotky [9] pointed out that the rounded ribs deteriorate the heat transfer performance. Liou and Hwang [10] showed that semicircular ribs result in a lower heat transfer rate than the conventional square rib. Chandra et al. [11] studied the effect of rib profiles on the heat transfer rate. They found that square ribs produce higher heat transfer augmentation than any other rib profile. Therefore, they claimed that the greater number of sharp corners of a rib yield increasingly higher heat transfer coefficient and friction factor. Contrary to the conclusions of Chandra et al. [11], Ahn [12] argued that the triangle-ribbed shape has the highest heat transfer performance. More recently, Ahn et al. [13] performed large eddy simulation of flow and heat transfer in a channel roughened by square and semicircular ribs. They found that the two ribs produce nearly the same heat transfer, but the semicircular ones yield lower drag than the square one. As is clear from the above-mentioned results, the effects of rib cross-sectional shape on the heat transfer characteristics is still open to debate.

In addition to varying the rib cross section profile, another way to avoid hot spots is to replace the solid-type ribs by perforated ribs. Because part of the air flow passes through the perforated ribs and directly impinges on the recirculating region behind the rib, the hot spots may not arise. Hwang and Liou [14, 15], employed the holographic interferometry to measure the heat transfer characteristics in a channel with perforated ribs. The results indicated that the perforated ribs have the advantages of eliminating the hot spots and providing a superior heat transfer performance. Meanwhile, Liou and Wang [16] and Liou et al. [17] investigated the heat transfer and friction characteristics in a duct with detached ribs. It was found that the thermal performance was better for the detached-ribbed duct flows than in the attached-ribbed duct flows. Basically, the hot spots around the concave corners behind the attached ribs were absent for the detached-ribbed duct flows. Later on, Liou et al. [18] compared the thermal performance between the detached solid-rib array and the detached perforated-rib array. They concluded that the duct flow with solid-type ribs is superior compared to a duct with perforated ribs. However, Kukreja and Lau [19] pointed out in their experiments that the perforated ribs are not as good as solid ribs in enhancing heat transfer. Although perforated ribs caused lower pressure drop, they did not improve the thermal performance. Increasing the size of the holes, the number of the holes, or the total hole area did not increase the overall heat transfer. More recently, Moon and Lau [20] carried out experiments to determine the average and local heat transfer between two blockages with holes. They showed that the local heat transfer distribution is strongly dependent on the configuration of the hole array in the blockages. In general, the smaller holes cause higher heat transfer enhancement, but also significantly larger increase of pressure drop than larger holes. These seemingly controversial results call for further studies to investigate the detailed flow fields and heat transfer distribution in ducts roughened with perforated-type ribs.

Apart from the transverse pattern, ribs can also be arranged in inclined as well as V-shaped configurations. It is postulated that the secondary flow induced by the inclined and V-shaped ribs affects the heat transfer significantly. Han et al. [7] found that the highest heat transfer for a given friction power is achieved with ribs with 45° angle of attack. In a similar investigation Han et al. [21] studied the heat transfer characteristics in square channels with parallel, crossed and V-shaped angled ribs, respectively. They found that the V-shaped ribs directed opposite to the main flow provide the highest heat transfer enhancement while the V-shaped ribs pointing the flow direction generate the largest pressure drop penalty. It was conjectured that differences in the secondary flow are the explanation for the observed results. Lau et al. [22] came up with same conclusions as Han

et al. [21] in their experimental studies. They showed that the V-shaped ribs pointing upstream with 60° attack angle gave the highest heat transfer coefficients. Taslim et al. [3] performed an experimental investigation using liquid crystal thermography to determine the local heat transfer coefficients in a square duct with angled, V-shaped and discrete ribs on two opposite walls. They reported that the heat transfer is highest for V-shaped ribs pointing downstream, which is obviously contrary to the results of Han et al. [21]. Applying the same measurement technique as Taslim et al. [3], Gao and Sundén [23] found that V-shaped ribs pointing downstream are superior to the V-shaped ribs pointing upstream in enhancing the heat transfer. Recently, by performing numerical simulations, Jia et al. [24] supported the statement that the V-shaped ribs pointing downstream produce higher heat transfer coefficients. They supposed that the discrepancy is probably attributed to the insufficient number of sampling points in the Han et al. [21] measurements in which thermocouples were utilized.

With rapid development of measurement techniques, great opportunities are opened up to map the detailed temperature distribution on a surface and gain insight of the flow structures in complex flows. This will significantly enhance our understanding of the flow and heat transfer characteristics in ribbed ducts and shed light on the design optimization of the various cooling systems. In this paper, focus is on the applications of the liquid crystal thermography (LCT) and particle image velocimetry (PIV) in research concerning the heat transfer and fluid flow in ribbed ducts. Part 2 gives brief descriptions of LCT and PIV. In Part 3, recent developments are presented and discussed. The conclusions are placed in Part 4.

EXPERIMENTAL SETUP AND PROCEDURES

Liquid Crystal Thermography

Liquid crystal thermography is based on substances called thermochromic liquid crystals. Basically, liquid crystals are substances in an intermediate phase that is between the pure solid and pure liquid phases, thus sharing some of the properties of both liquids and crystals. Liquid crystals are conventionally divided into three classes, which are termed as smectic, nematic and cholesteric according to the molecular structures. The cholesteric liquid crystals are often used as temperature sensors because the molecules can selectively reflect visible light depending on the surrounding temperature. At temperatures below the critical value (event temperature), a liquid crystal is in the solid state and will appear transparent. Once the temperature is above the threshold, the liquid crystal material will reflect a unique wavelength of visible light when illuminated by white light and viewed under fixed optical conditions. As temperature rises, the reflected colour will change. Finally, when the temperature exceeds the clearing point, the material will enter the pure liquid state and will revert back to being transparent. Therefore, this character enables cholesteric liquid crystals to serve as an effective temperature-sensing medium.

LCT is an economical and affordable technique compared with the infrared thermal imaging method. A resolution of less than 0.1 ˚C is easily obtainable for narrow band liquid crystals. In addition, its short response time, in the order of 0.1 sec, means that it can respond to the temperature change very quickly. However, liquid crystals can only be used at relatively low temperatures. For example, the active bandwidths of most commercially available LCT products are limited to the temperature range from -30 ˚C to 120 ˚C. Over the development of LCT, several methods have been employed to interpret the colour of liquid crystals. Currently, the hue-temperature calibration method is most commonly used due to its high resolution in heat transfer research field. Figure 1 shows the profile of hue-temperature relation. It is found that the hue is fairly linear with temperature in the range of 30 to 130, which corresponds to the temperature range of 35 ˚C to 37 ˚C. Above 38 ˚C, the hue value is not quite sensitive to the variation of temperature.

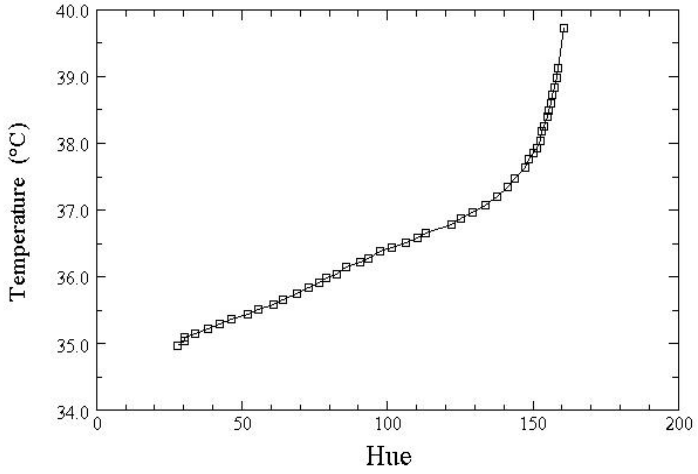

Figure 1 Hue-temperature calibration

Data Reduction

The heat transfer result is presented in terms of local Nusselt number, that is,

$$Nu = \frac{(Q_{el} - Q_{loss}) \cdot D_h}{(T_w - T_{bulk}) \cdot k_f \cdot A} \tag{1}$$

where Q_{el} is the measured input power to the heater, Q_{loss} is the dissipation rate in terms of radiative heat transfer to the surroundings and the conductive heat transfer through the back of the heated surface. In estimating the radiative heat loss, the surface and air bulk temperature are considered as constant when taking into account the fact that the air temperature rise from entrance to exit is less than 2 °C. For polished Inconel, the emissivity is approximately equal to 0.05. The conduction heat leakages are calculated from the temperature difference across the heated wall. Two thermocouples are installed at the back of the heated surface. The sum of the two terms is found to be less than 6% of Q_{el}. In Eq. (1), k_f is the air thermal conductivity and A is the area of the heating surface; T_w is the surface temperature indicated by the liquid crystal, and T_{bulk} is the local air bulk-mean temperature. All the thermal properties are evaluated at the air bulk-mean temperature. The experimental uncertainty is also analysed. Based on the normal distribution with 95% confidence, the uncertainty in local Nusselt number is estimated to be within ±6%. This value takes into account such independent variables as electric current, resistance of heater, liquid crystal thermographic reading, air bulk temperature, and dissipation rate.

Particle Image Velocimetry

PIV techniques have been developed in the last two decades and became widely used in the study of fluid mechanics. PIV is often used to measure the instantaneous velocity field in a 2D plane with relatively high spatial resolution. The velocity is computed by finding the displacement of tracer particles in a given time interval. The basic principle of PIV is presented in Figure 2. The measured flow is seeded with small tracer particles. These seeding particles are supposed to faithfully follow the motions of the fluid. A pulsed light sheet is used to illuminate the interesting area of the flow field twice to catch the flow movement. The light scattered by the tracer particles is recorded on a CCD sensor. The digital PIV recording is then divided into small interrogation windows. The calculation of the particle displacement is done by cross-correlating the two corresponding interrogation windows. Using the fast Fourier transformation (FFT), the position of the highest peak in the correlation domain indicates the mean displacement of the particles in a particular

interrogation window. Repeating the process, the displacement vectors of all interrogation windows are finally transformed into a complete instantaneous velocity map.

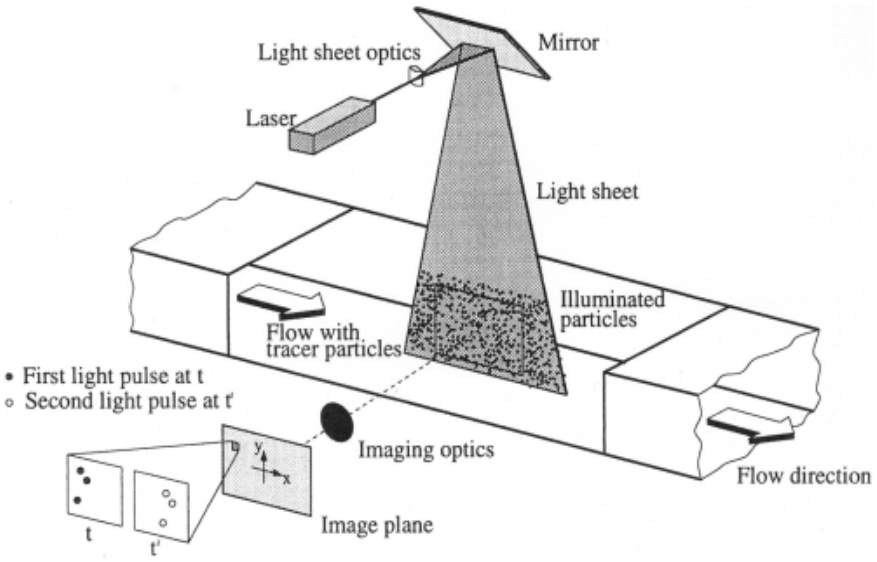

Figure 2 Basic principle of PIV

Measurement Procedure

A commercially available PIV system developed by Dantec Dynamics has been used in our recent present investigations. The system is arranged to measure the velocity fields in the vertical symmetry plane and the horizontal plane of the ribbed channel. Oil-based aerosol with mean particle diameter of 1μm is generated by a TSI 9306 six-jet atomizer. The concentration of the seeding particles is regulated by the compressed air pressure and the number of Laskin nozzles. In order to get homogeneous trace particles, the channel inlet is preceded by a plenum with two screens. A Quantel Q-switched Nd:YAG laser provides the pulsed illumination with a wavelength of 532 nm. The duration of each pulse is 10 ns and the maximum output energy is 120 mJ. The light-sheet thickness in the test section is kept at 0.8 mm. A digital camera containing a CCD chip with 1280 × 1024 pixels and a Nikon AF Micro 60f/2.8D lens with an optical filter are used to record the particle images. Typically, the magnification factors range from 50 μm/pixel to 70 μm/pixel.

The time interval between laser pulses is set such that the particles move at most 8 pixels between the pair of images. In our experiments, the time interval varies from 10 to 20 μs depending on the velocity magnitude and the desired resolution. Within each window, the number of seeding particles is greater than 5 and the particle image size projected onto the CCD sensor is approximately 3 pixels. FFT-based cross-correlation coupled with a two-dimensional Gaussian fit is applied to find the correlation peak position. Assuming that the measured particle displacement is accurate to the extent between 0.01 to 0.1 pixels, which is the commonly accepted range, the experimental uncertainty in the instantaneous velocity measurement is estimated to be less than 2%. The sample size is another error source for the mean and fluctuating velocity statistics. In the present study, 500 images are generated for each measurement plane. The uncertainties of the velocity gradient $\frac{d<u>}{dy}$ and shear stress $<-u'v'>$ are estimated to be within 5% and 10%, respectively.

RECENT WORKS

Separated Flow and Heat Transfer in a Ribbed Channel

Although the repeated ribs may be considered as a roughness elements, it may also be viewed as a problem in boundary layer separation and reattachment [25]. The heat transfer enhancement mechanism from separation and reattachment is not yet clear since the physics of the flow associated with separation is complex in nature. Usually, the flow in channels fitted with transverse periodic ribs is used as a simple model to study the effect of separation on the heat transfer. Unlike the flow over a backward-facing step, the flow over a rib is more complicated since it displays an additional separation bubble in the region upstream of the rib. According to Bradshaw and Wong [26], the flow over a rib (or fence) involves two 'strong perturbations' (two separation bubbles) and is an extremely difficult flow to understand. In general, the flow separates at the edge of the rib, forming a widening free shear layer which reattaches downstream on the floor. The separated shear layer splits into two parts at the reattachment point, where one part of the flow is deflected upstream into the recirculating region; the other part of the flow redevelops downstream to form a new boundary layer which grows in thickness. The wall shear stress is vanishing at the reattachment point. Further downstream, due to the adverse pressure gradient caused by the next rib, the flow separates once again and forms a secondary separation bubble. Figure 3 plots the overall streamlines between consecutive ribs in a ribbed channel. In this figure, the ribs obstruct the channel by 15% of its height and are arranged 12 rib heights apart. The Reynolds number, based on the bulk-mean velocity and the height of the channel, is 22,000. All the following results presented in this section are based on this rib arrangement and flow condition.

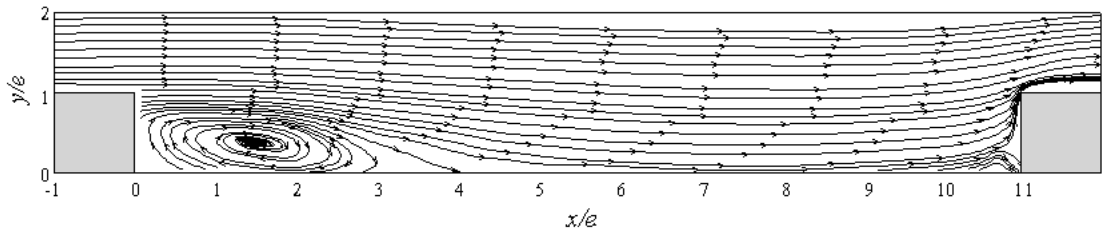

Figure 3 Global flow features between two consecutive ribs, Wang et al. [27]

Figure 4 shows the map of the heat transfer enhancement between two ribs. The spatial variations of local heat transfer clearly reveal the footprints of flow separation, reattachment and redevelopment. It clearly shows that the maximum heat transfer occurred at the reattachment region. Further downstream, the Nusselt number is decaying gradually because the new boundary layer grows in thickness. However, the Nusselt number is rising up in the vicinity of the downstream rib.

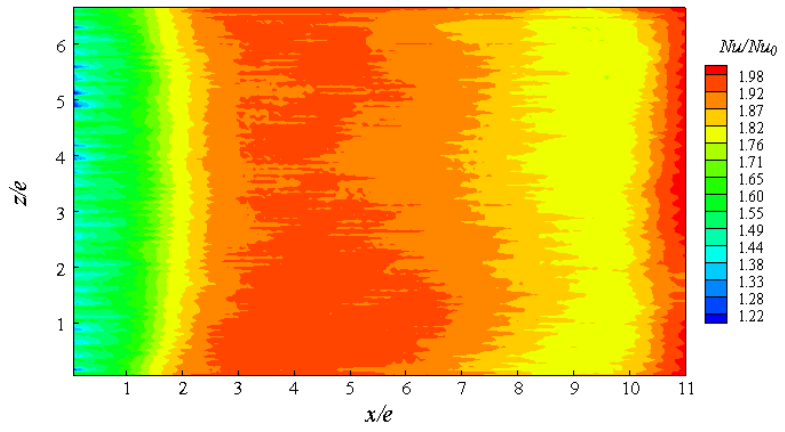

Figure 4 Nusselt number in the region between two consecutive ribs, Wang and Sundén [28]

Heat transfer is strongly dependent on the inner-wall flow features. In order to exhibit this relationship, Figure 5 displays the profiles of skin-friction coefficient and Nusselt number along the centerline between two consecutive ribs. This figure conveys the impression that the location of the maximum heat transfer coefficient is quite consistent with the reattachment point (x/e = 3.6) within the permissible measurement errors. At the reattachment point, the wall shear stress vanishes. In the post-reattachment region ($4 < x/e < 8$), the steep rise of the skin-friction factor is accompanied with the gradual decrease of heat transfer coefficient.

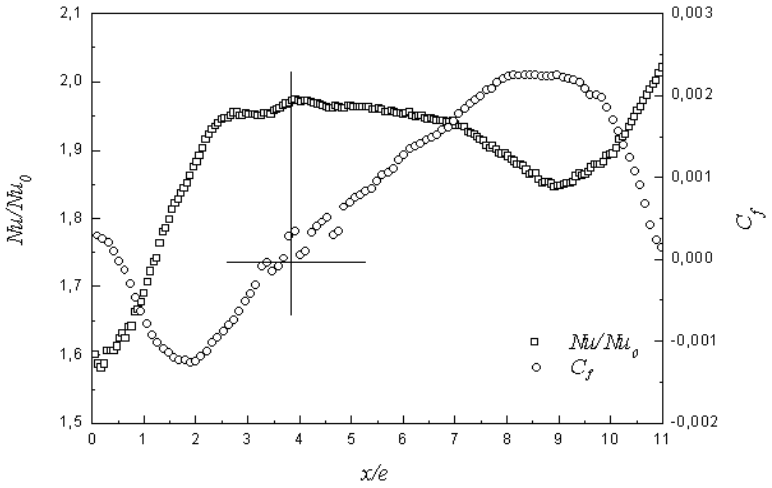

Figure 5 Comparison between the skin-friction factor and Nusselt number along the centreline, Wang [26]

Figure 6 shows the features of the maximum shear stress plotted against streamwise distance. The general level of the maximum shear stress rises gradually with increasing distance up to the reattachment point, and then decreases rapidly between x/e = 3.7 and 4.7. Following the rapid decay after reattachment, a short plateau is observed in the region $5 < x/e < 6.5$.

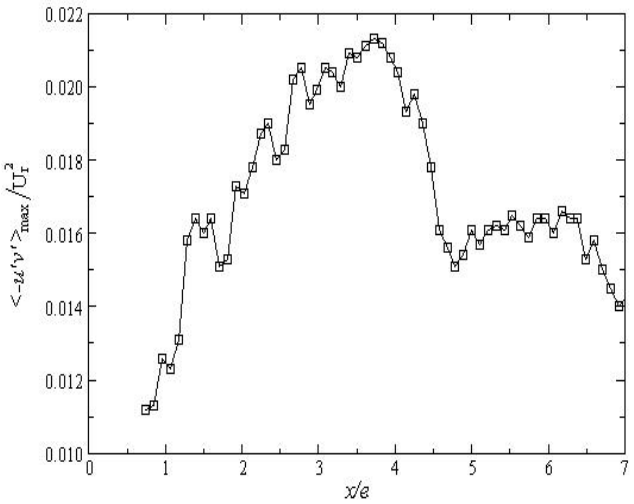

Figure 6 Maximum Reynolds shear stress distribution, Wang and Sundén [28]

For a two-dimensional flow, the turbulence kinetic energy production is approximated as

$$Q_{en} = < -u'v' > \frac{\partial U}{\partial y}$$

Figure 7 gives the turbulent kinetic energy production. It is evident that the quantities exhibit distinct peaks at *y/e* = 1 for the region upstream of the reattachment point (*x/e* = 2 and 3.6). Further inspection of the maximum turbulence production shows that the peak is approximately coincident with the inflexion point. This means that the velocity gradient $\frac{dU}{dy}$ at the inflexion point plays a dominant role in the production of turbulence as flow separation occurs.

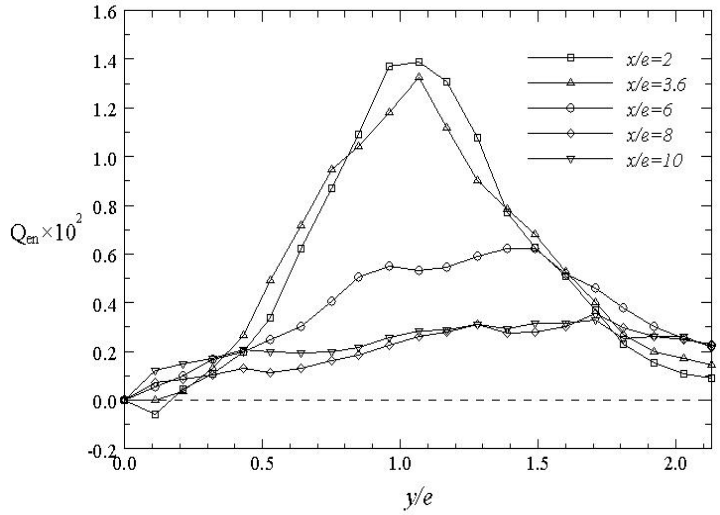

Figure 7 Turbulence kinetic energy production, Wang and Sundén [28]

Two-point correlations are instrumental in studying flow structures because they reveal how coherent the flow structure is over a certain distance. The size of the structures is roughly twice the distance between the origin and the point where the correlation coefficient levels off to zero. The two-point correlation coefficient is defined as

$$R_{u_i u_i, x_j} = \frac{< u'_i(x_{j0}) u'_i(x_j) >}{\sqrt{< u'^2_i(x_{j0}) >} \sqrt{< u'^2_i(x_j) >}}$$

where u_i' is an instantaneous velocity fluctuation, and x_{j0} is a fixed location. The distance between the two points is expressed by $r_{x_j} = x_j - x_{j0}$. Figure 8 shows the distribution of the streamwise velocity correlation $R_{uu,z}$ in the spanwise direction. Four points (*x/e*, *y/e*) in the symmetry plane are selected as origin, *i.e.*, A (0.5, 1), B (5.5, 2), C (5.5, 1) and D (8, 1), respectively. Apart from point A, which is immediately downstream separation, the other three are located in the post-reattachment zone. It is apparent that all the points at *y/e* = 1 show a similar size of the spanwise structures and the correlation virtually vanishes at 1.3*e*. For point B, however, the correlation length is approximately 1.7*e*. In addition, it is noticed that all the points demonstrate pronounced negative values down to −0.2 for large spanwise separation. This is likely caused by the streamwise eddies which are inclined in the vertical direction.

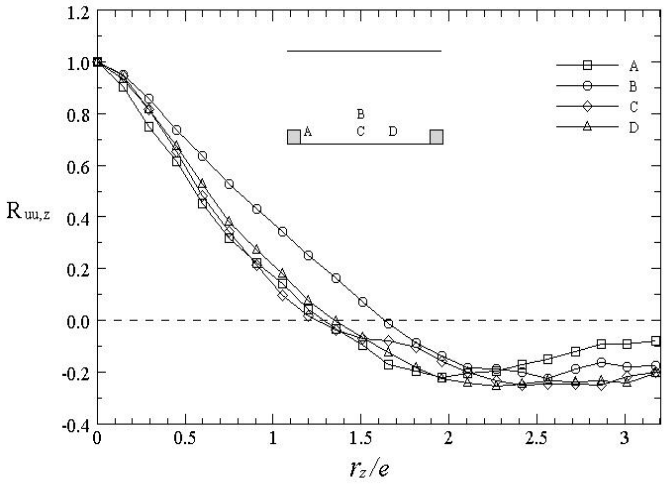

Figure 8 Spanwise *u'* correlation coefficient at different points (*x/e*, *y/e*) in the flow field, A (0.5, 1), B (5.5, 2), C (5.5, 1), D (8, 1), Wang and Sundén [28]

When the flow separates at the edge of a rib, spanwise vortices are generated in the shear layer due to the Kelvin-Helmholtz instability. To identify these vortical structures in an instantaneous velocity field, one should vary the reference frame velocity. When the reference frame velocity matches the convection velocity of an eddy, it becomes recognizable as a roughly circular pattern. This method of visualization is called Galilean decomposition. Figure 9 shows an instantaneous velocity vector field in which the reference frame moves at U_f = 5.0 m/s. The figure clearly displays two distinct vortices being shed downstream of the rib. The vortices have a size approximately one-half of a rib height and are inclined at approximately 20° with respect to the *x*-axis.

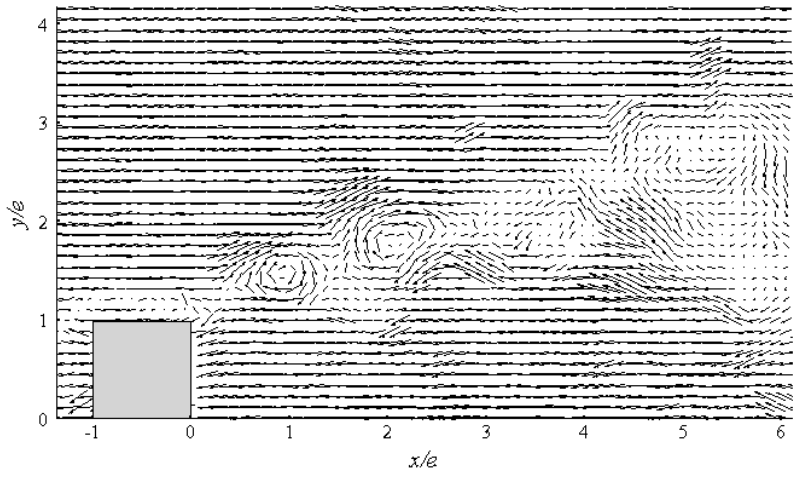

Figure 9 Galilean transformation for visualizing vortices, Wang and Sundén [28]

The Effect of Rib Cross Section Profile

Wang and Sundén [30] investigated the heat transfer characteristics in a square channel with various-shaped ribs. Four geometries were considered in their study, that is, square, triangular, trapezoidal with decreasing height in the flow direction, and the trapezoidal with increasing height in the flow direction. The results showed that the trapezoidal ribs with increasing height in the flow direction provide the highest heat transfer enhancement and are likely to be used to suppress the local hot spots occurring

immediately downstream the rib. Figure 10 shows the comparison of heat transfer among the various rib shapes.

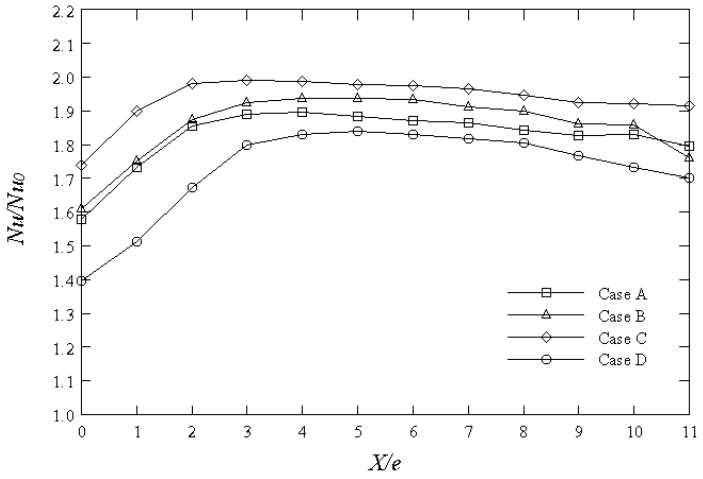

Figure 10 Local heat transfer along the centreline; Case A, square ribs; Case B, Triangular ribs; Case C, trapezoidal ribs with decreasing height in the flow direction; Case D, trapezoidal ribs with increasing height in the flow direction, Wang and Sundén [30]

Based on the experimental work of Wang and Sundén [30], Kamali and Binesh [31] performed numerical simulations to study the heat transfer and friction factor in a channel roughened with various-shaped ribs. They found good agreement between the predicted results and the measurements. Figure 11 shows the streamlines of the reprehensive cases for Re = 20000, e/H = 0.1 and P/e = 12 in their simulations. Of the four cases, the flow over the square rib appears to be the most complex; since the rib face is perpendicular to the flow direction, sizable primary and secondary recirculation regions form near the front and rear corners at the rib bottom are recognized. The size of the recirculation zone, however, is largest for the trapezoidal rib with increasing height in the flow direction and smallest for the square rib.

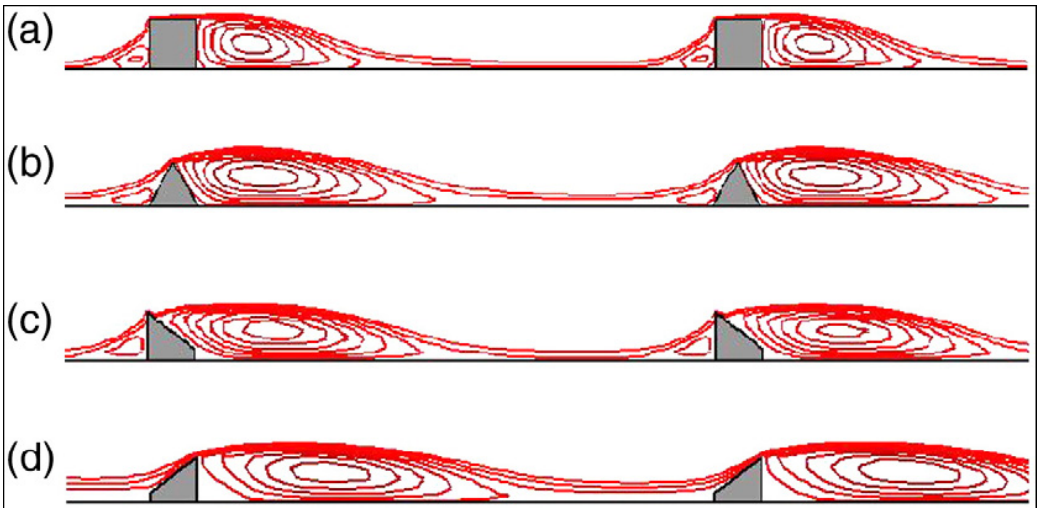

Figure 11 Streamlines for representative ribs, Kamali and Binesh [31]

Effect of Rib Arrangement

Gao and Sundén [32] carried out experiments to investigate the heat transfer in a rectangular duct roughened by V-shaped ribs. The aspect ratio of the duct is 1/8. The rib height-to-hydraulic diameter ratio is 0.06, with an attack angle of 60°. The pitch ratio is 10. Figure 12 shows the RGB images taken for the V-shaped ribs pointing upstream at *Re* = 6000. The significant spanwise variation of the heat transfer coefficients is noticeable. The V-ribs generate two double-cell counter-rotating vortices that extend over the whole cross section. Figure 4 shows the RGB images taken for the V-shaped ribs pointing downstream at *Re* = 6000. It is clear that the spanwise heat transfer coefficients are totally different from that of the V-ribs pointing upstream. For the central part where the V-ribs pointing upstream induced the highest heat transfer coefficients, the V-ribs pointing downstream produce the lowest heat transfer coefficients. For both the bottom and top side, where the V-ribs pointing upstream induced the lowest heat transfer coefficients, the V-ribs pointing downstream produce the highest heat transfer coefficients. For the V-ribs pointing downstream, two double-cell counter rotating vortices are generated but with opposite direction.

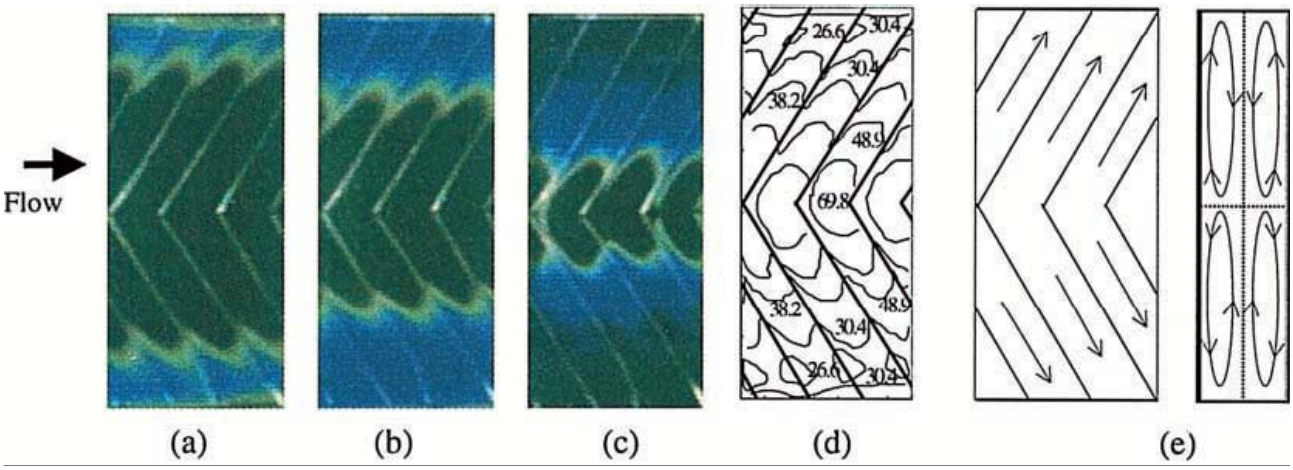

Figure 12 V-shaped ribs pointing upstream at *Re* = 6000. (a) q_w= 354 W/m^2, (b) q_w= 437 W/m^2, (a) q_w= 660 W/m^2, (d) Local Nusselt number contours, (e) Schematic pattern of secondary flow induced by V-ribs, Gao and Sundén [32]

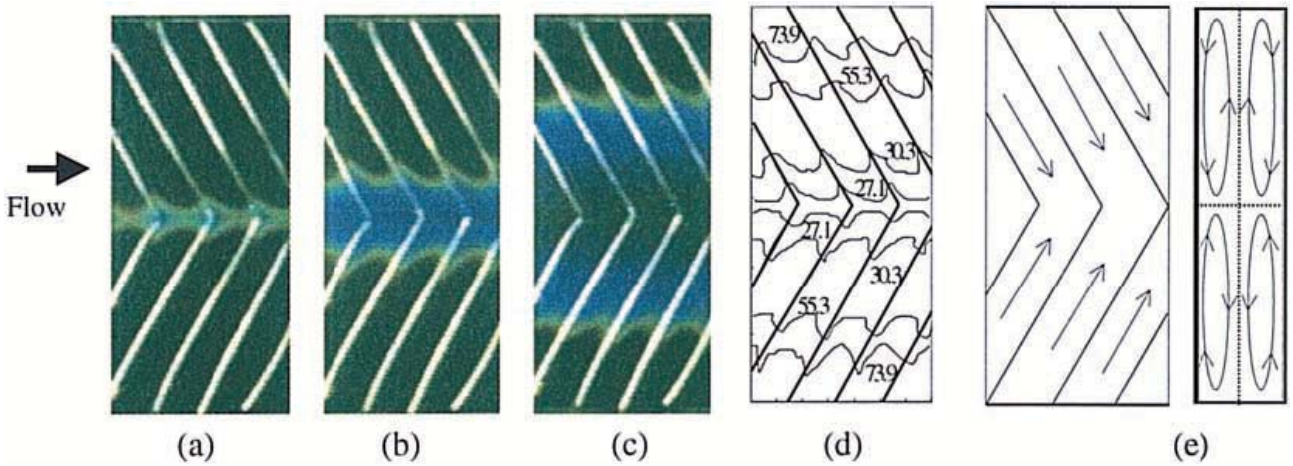

Figure 13 V-shaped ribs pointing downstream at *Re* = 6000. (a) q_w= 383 W/m^2, (b) q_w= 455 W/m^2, (a) q_w= 575 W/m^2, (d) Local Nusselt number contours, (e) Schematic pattern of secondary flow induced by V-ribs, Gao and Sundén [32]

The averaged Nusselt numbers plotted against Reynolds number are illustrated in Figure 14. Compared with the smooth channel, the heat transfer is appreciably enhanced in the channel roughened by V-shaped ribs. In the tested Reynolds number range, the enhanced heat transfer caused by the V-ribs pointing downstream is higher than those caused by the V-ribs pointing upstream.

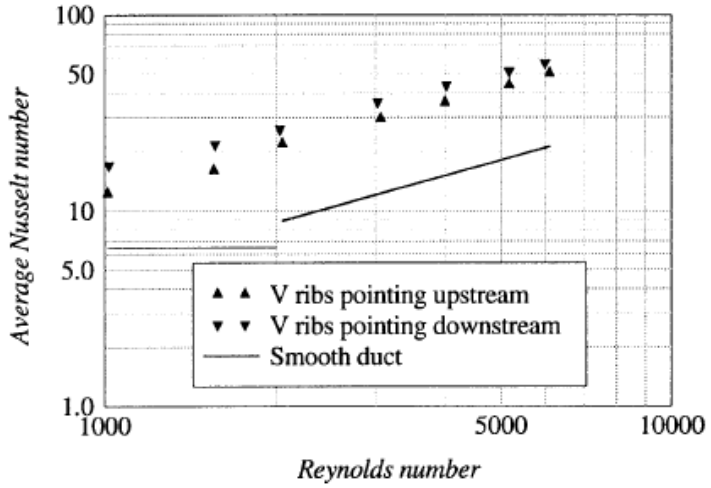

Figure 14 Average Nusselt number versus Reynolds number, Gao and Sundén [32]

CONCLUSIONS

Heat transfer and fluid flow in ribbed channels continue to be a topic of considerable practical and theoretical interest. The present paper has only briefly touched on a very few of the many areas involving the enhancement of heat transfer and separated flow in ribbed ducts. Further research and studies are needed to gain the sight into the physical process and shed light on the design optimization of the future cooling systems.

MASS TRANSPORT PHENOMENON ON FUEL CELLS AND CO_2 UNDERGROUND SEQUESTRATION

S. Hirai[1] *, S. Tsushima[1]
[1]Tokyo Institute of Technology

ABSTRACT. The global warming caused by the production of carbon dioxide (CO2) from burning fossil fuels is getting widespread international attention. A significant reduction in the volume of CO2 emissions to the atmosphere is requiring urgent solution. There are number of ways by which CO2 emissions can be reduced, improvement of energy efficiency, use of renewable energy, and carbon sequestration. In this article, we describe two realistic countermeasures, CO2 capture and sequestration (CCS) and hydrogen fuel-cell energy system to mitigate global warming. In both fields, mass transport plays a key role for improvement and prediction of the systems. We present experimental and numerical investigations on mass transport process in both CCS and polymer electrolyte membrane fuel cells (PEMFCs).

Keywords: *mass transport, CO_2 capture and sequestration, fuel cell, polymer electrolyte membrane*

INTRODUCTION

Modern civilization is being maintained by a large consumption of the fossil fuel, and it is being predicted that CO_2 concentration, now at 370-380ppm, would become several times larger in future. Therefore, it is immediately required to take global warming measures. CO_2 capture and sequestration (CCS) and hydrogen fuel-cell energy system have been gathering much attention as realistic countermeasures to mitigate global warming.

CO_2 underground sequestration is CO_2 captured from large-scaled power plants injected into aquifers. Captured CO_2 can also be utilized for enhanced oil recovery (EOR). In the aquifers, CO_2 possibly rises upward due to buoyancy effect. Therefore, more recently, residual gas trapping mechanism at the aquifers is also investigated for secure geological storage of CO_2 in the underground [1]. For long-term sequestration of CO_2, fundamental understanding on CO_2-water two-phase flow behaviors in porous rock materials is inherently needed.

Hydrogen energy systems also have been gathering much attention in term of efficient utilization of fossil fuel and energy security. Polymer electrolyte membrane fuel cells (PEMFCs) are considered power sources for vehicle and on-site power generation in the future. For implementation of PEMFCs, further improvement on energy efficiency and power density as well as robustness and durability of the system are needed. Water inside the fuel cells plays a key role for both cell performance and durability, motivating experimental and numerical studies on water transport in PEMFCs.

In the following sections, we describes our research activities in CCS and fuel cells, focusing on mass transport process with advanced in-situ diagnostics, which are applied to acquire fundamental understanding.

CO_2 UNDERGROUND SEQUESTRATION

MRI visualization of CO_2–water behaviors in a rock-core sample

We performed MRI visualization of a rock-core after CO_2 injection. Noninvasive measurement of a water distribution is one of the advantages of the MRI technique. Nuclei with non-zero spin angular momenta have an intrinsic magnetic dipole moment. In a static magnetic field, B_0, each nuclear spin precesses with frequency, $\omega_0=\gamma B_0$, where ω_0 is called the Larmor frequency and γ is the gyromagnetic ratio, characteristic of the nuclei being studied. The Larmor frequency for protons at 7.05 T, which is the strength of magnetic field used in our MRI system (Varian Unity Inova model 300/150 SWB), is about 300 MHz. By applying a radio frequency magnetic field at the Larmor frequency, the nuclear magnetic resonance signal due to precession is observed after the magnetization is rotated away from the static field. In MRI, spatial information is converted into the MR signals by applying a gradient magnetic field. Hence, the distribution of proton density can be imaged in any cross-section. In our experiments, the gradient coils provided a maximum gradient strength of 0.24 T/m.

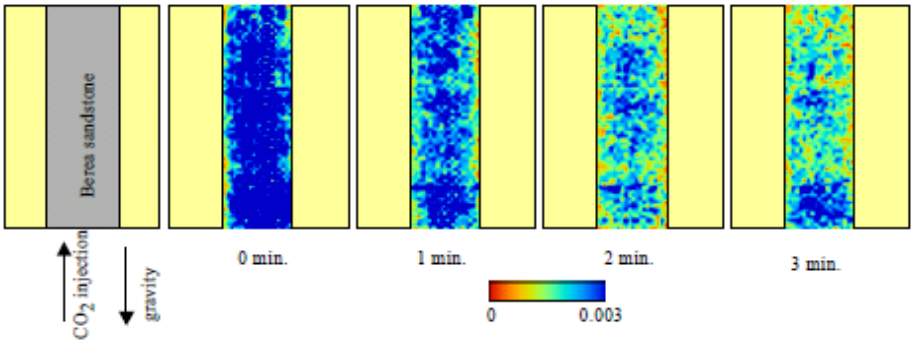

Figure.1 Distribution of water in Berea sandstone core at 9.0MPa, 42°C with CO_2 injection

In preliminary experiments, we confirmed that the MR signal intensity from any local position was proportional to the water content in the porous medium. This means that measured MR signal intensity reflects local water saturation, which is defined as the fraction of the void volume occupied by water [2], in the porous media. In the experiments with CO_2 injection, we measured the initial MR signal intensity distributions in the porous medium filled with water. Then, we started to supply CO_2 into the porous medium with time-series acquisition of MR images. As shown in Fig.1, the injected CO_2 would replace some water in the porous medium thus decreasing the MR signal intensity. The local water saturation in the porous medium can be defined as the ratio of MR signal intensity with the CO_2 gas to that without gas. MRI results were analyzed for the coreflood interpretation method to determine the local Darcy phase velocities and capillary dispersion rate for a range of water saturations. As shown in our previous study [1], we successfully estimated the properties of two-phase flow such as Darcy phase velocities and the capillary dispersion rate function on a basis of the *in-situ* saturation profiles obtained by MRI.

Super-atomization of liquid CO_2 for stable geological storage

As the caprock structures exists only few sites in areas surrounding Japan, it is necessary to develop a new geological storage technique. We proposed a technique of trapping super-atomized liquid

CO_2 in a porous structure to realize stable geological storage and boost the efficiency of storage. The atomized liquid CO_2, which is the same scale as the gap diameter in the aquifer might be trapped stably by the interface tension.

In our previous study [3], the super-atomization process and the emulsion stability have been examined experimentally. The liquid CO_2 was atomized by using a static mixer placed in a closed circulatory channel. In order to measure the size of the super-atomized liquid CO_2, dynamic light scattering was employed. Since water and liquid CO_2 are mutually immiscible, a surfactant (trisiloxane) was added to assist the atomization of liquid CO_2.

As the result, the liquid CO_2 could be atomized by getting through the static mixer, however its lifetime was about 20 seconds without surfactant. On the other hand, liquid CO_2 was super-atomized in the presence of the surfactant and long lifetime was achieved. In the presence of 2.0 mass% surfactant concentrations, the liquid CO_2 was super-atomized with an average diameter of 5 μm and lifetime of the atomized state was for 120 min. The diameter of the super-atomized liquid CO_2 was same scale as the gap diameter in the aquifer. Additionally, the lifetime is substantially long for CO_2 injection process. For these experimental results, a feasibility of stable CO_2 geological storage has been suggested.

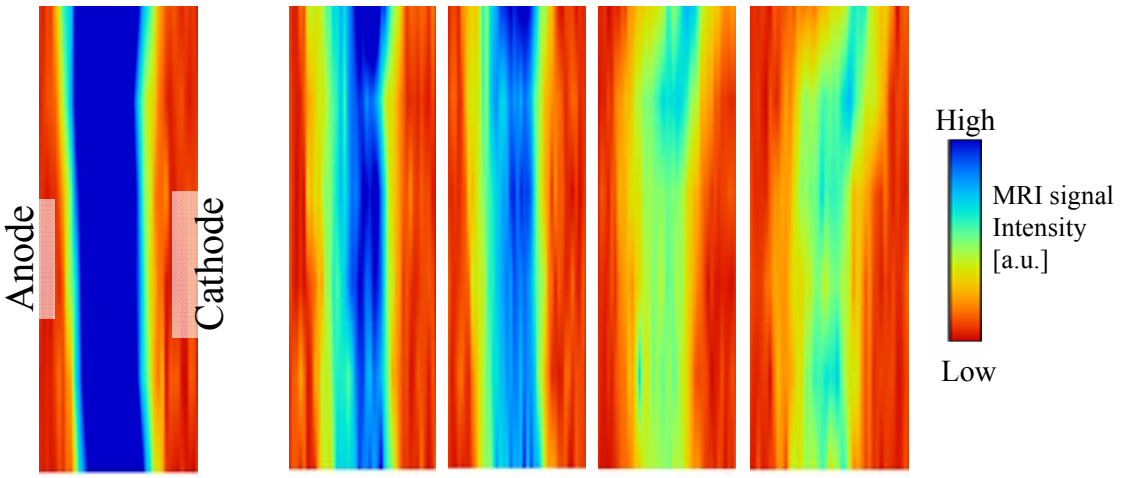
WATER TRANSPORT AND DEGRADATION ANALYSIS IN PEMFC

MRI visualization of water content in a polymer electrolyte membrane in an operational fuel cell

In PEFCs, appropriate water management to maintain polymer electrolyte membrane (PEM) hydrated is of great importance, because the ion conductivity of membrane is lower at lower water content. Consequently, it is of great interest to water content and water transport process in PEMs during fuel cell operation. We thus have been developing an in-situ visualization technique using magnetic resonance imaging (MRI) for measurement of water content distribution in PEMs in through-plane and in-plane direction under fuel cell operation. We succeeded in visualization of transversal water content distributions in a membrane during fuel cell operation by designing a fuel cell that can operate in an MRI system [4]. It was shown that water concentration gradient established in the membrane with increase of cell current due to an electro-osmotic effect. This MRI observation was also compared with numerical simulation for validation [5]. We also examined lateral water content distributions with different flow pattern, *i.e.* a parallel flow and a serpentine flow by using three-dimensional (3D) MRI visualization. We confirmed that a parallel flow configuration shows different membrane hydration from a parallel flow [6].

<u>High-resolution MRI</u>

An especially challenging issue in MRI visualization for PEMFCs is achievement of higher spatial resolution, which is necessary to obtain fundamental insights into water transport processes in PEMs that are practically used for industrial applications. Figure 2 shows high-resolution MRI results of transversal water content distribution in a 117-μm-thick membrane. We achieved MRI visualization of 10-μm-boxel width along the through-plane direction in the membrane using a high-sensitivity radio frequency (RF) coil system and a specially designed PEMFC for MRI measurement.



(a) 0 [A/cm^2] (b) 0.1 (c) 0.2 (d) 0.3 (e) 0.4

Figure 2. MRI visualization of transversal water content distribution in a polymer electrolyte membrane with 117 μm-thickness under fuel cell operation

Reduction of the membrane thickness might flatten the water content profile in the membrane because of enhancement of water back-diffusion from the cathode to the anode. However, MRI visualization shows partial dehydration at the membrane's anode side with increased cell current, as observed in the 340-μm-thick membrane, which reflects that electro-osmotic drag remains influential on water content profiles in the membrane during fuel cell operation. Our next target for development of MRI visualization techniques is 5-μm-boxel width in the 50-μm-thick membrane.

Nuclei-labeling MRI (NL-MRI)

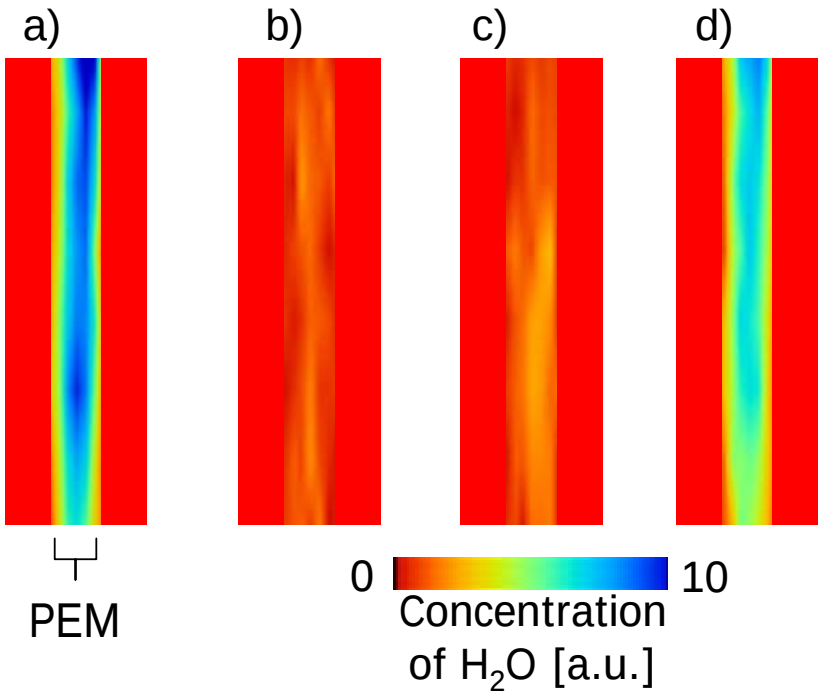


Figure 3. NL-MRI results in the membrane The anode is on the left side. (a) normal operation (b) effect of anode humidification (c) effect of cathode humidification (d) effect of supplied hydrogen.

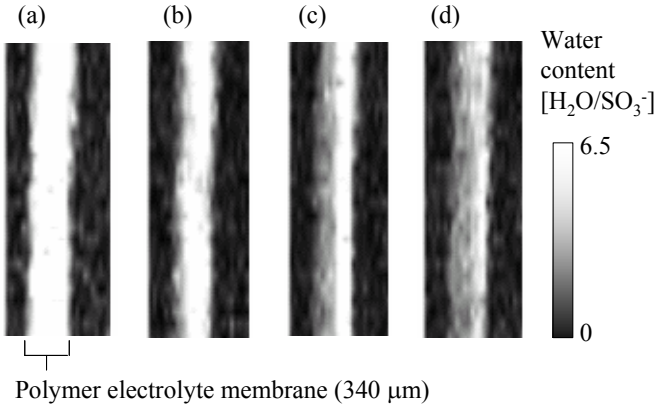
Our recent MRI application with isotope-labeling techniques enabled us to examine water sources for membrane hydration [7]. Neither D_2 nor D_2O is visible using ^{1}H-MRI, but fuel cell operation is not affected by the isotope. Using various combinations of D_2 fuel and D_2O for inlet humidification, it is possible to isolate each water source and transport mechanism.

Without nuclei labeling, a conventional MRI technique can only obtain overall water content distributions resulting from all water sources and transport processes. However, the water vapor in the cathode and fuel to the anode can be labeled with deuterium. Because deuterium can not be visualized by ^{1}H-MRI as a result of the difference of the nuclear magnetic resonance frequency, what is obtained using this technique is the distribution of water (H_2O) that has been absorbed in the anode side. In other words, we can ascertain the effect of water vapor from the anode side on hydration of PEM without disturbing the membrane's natural hydration state. Using other combinations of isotope-labeled fuel and humidification water, it is possible to isolate and study each water source and transport effect during PEMFC operation.

Figure 3 shows cross-sectional MR images of a membrane operated with different nuclei-labeling experiments. The fuel cell was operated at 60°C with 84% relative humidity maintained at the anode and the cathode inlet. As presented in Figure 2(d), water observed inside the membrane apparently originates in the supplied hydrogen, which indicates that supplied water vapor was not absorbed directly into the membrane and thus played a role in suppressing water discharge as vapor from the membrane. In fact, NL-MRI yields direct insight that is valuable for discussion of the membrane hydration path in operational PEMFCs.



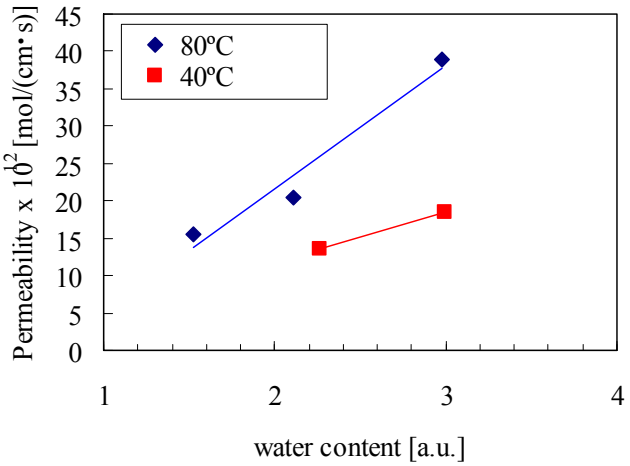


Figure 4. Hydrogen permeability under fuel cell operation at 0.1 A/cm^2 with water content measured by MRI.

Membrane degradation analysis using MRI

We also applied MRI for PEM degradation analyses. Actually, MRI was used to monitor water contents in the membrane during fuel-cell operation. We also used direct gas mass spectroscopy (DGMS) to investigate hydrogen crossover in the membrane. The averaged water content in the membrane was obtained from this MRI result. It is depicted along with hydrogen permeability through the MEA in Figure 4. Hydrogen permeability increases with water content in the membrane, suggesting that the hydrophilic domain of the membrane plays an important role for hydrogen permeation processes [8].

CONCLUSION

We described our research activities in CCS and fuel cells, focusing on mass transport process with advanced *in-situ* diagnostics, e.g. MRI, TDLAS and DGMS which are applied to acquire fundamental understanding on CO_2 and water transport.

RECENT ACHIEVEMENTS IN MULTI-SCALE MODELLING AND SIMULATIONS OF MAGNETOFLUIDDYNAMIC PHENOMENA:

FROM ORIGIN OF PLANETARY MAGNETIC FIELDS TO IMPROVED MAGNETIC DRUG TARGETING

S. Kenjeres[1, *]
[1]Department of Multi-Scale Physics, Faculty of Applied Sciences and J.M. Burgerscentre for Fluid Dynamics, Delft University of Technology, Delft, The Netherlands

ABSTRACT. The paper reviews some of the recent results in modelling and simulations of flow and heat transfer of the electrically conductive fluids interacting with electromagnetic fields. Despite the differences in flow geometries and huge disparity of the length- and time-scales, ranging from astrophysical to biomedical applications, it is demonstrated that magnetofluiddynamic (MFD) phenomena are characterised by two fundamental features – a time-dependent spiralling flow patterns and non-homogeneous distributions of the magnetic fields. Some representative examples of both one- and two-way coupled MFD phenomena are considered: electromagnetically driven vertical turbulent flows with and without heat transfer in a generic setup, turbulent magnetic dynamo under realistic experimental conditions (the Riga-dynamo experimental setup), and finally, simulations of the magnetic particle deposition in the realistic human blood vessels subjected to the locally imposed strong magnetic gradients (magnetic drug targeting). In all considered cases, a good agreement between available experimental results and numerical simulations is obtained, proving accuracy and potentials of the multi-scale modelling approach in simulating complex MFD phenomena.

Keywords: *fluid flow and turbulence, magnetic field, Lorentz force, magnetic dynamo, magnetic drug targeting;*

INTRODUCTION

In this paper, fundamental interactions between fluid flow, turbulence and electromagnetic fields are addressed. These interactions are essential for possible explanations of a fascinating number of phenomena in nature and technology, ranging from origin of magnetic fields in universe to the most recent advancements in medical applications through magnetic drug targeting techniques. Control of flow, turbulence and heat transfer of electrically conductive working fluids is a basic prerequisite for the design and optimization of many technological processes. Examples include electromagnetic braking of continuous steel casting, free-surface stabilization of the aluminum reduction cells, joining metals by arc welding, crystal growth, electromagnetic mixing and steering in metallurgy, and liquid metal blankets in new generation of fusion reactors, space craft-propulsion systems, satellite navigation, etc. The magnetofluiddynamics (MFD) (or traditionally called magnetohydrodynamics or MHD) is a typical example of the multi-physics phenomena – fluid flow, heat transfer and turbulent transport as a part of the fluid dynamics on one side, and on the other side, magnetic fields and electric currents as a part of the electromagnetism. We will demonstrate, that

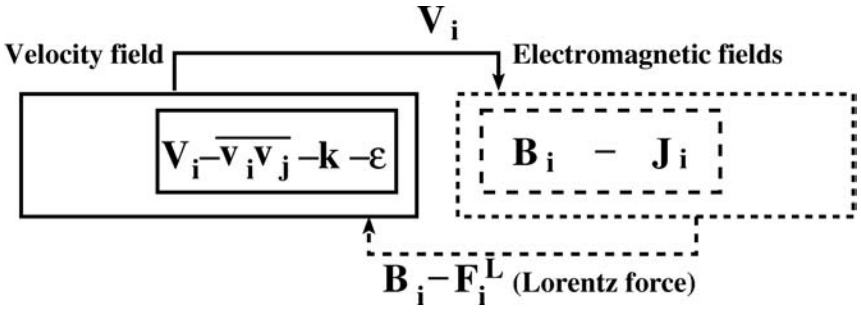

Figure 1. The general overview of the fluid flow, turbulence and electromagnetic fields interactions: the one-way interaction ($V_i \rightarrow B_i$) and the two-way interactions ($V_i \rightarrow B_i$, $B_i \rightarrow V_i$).

despite enormous disparity of characteristic length and time scales and intensity of interactions, all above mentioned phenomena are characterised by two essential features – time-dependent spiralling flow patterns and non-homogeneous distributions of electromagnetic fields.

General classification of electrically conducting fluid flows in the presence of electromagnetic fields can be based on the value of the Reynolds magnetic number $Re_m=V\,D/\lambda$, which represents the ratio between magnetic advection and diffusion, where $\lambda=1/(\mu_0\,\sigma)$ is magnetic diffusivity and μ_0 and σ are magnetic permeability and electric conductivity of the working fluid, respectively. The typical velocity and length scale (size of domain) are V and D, respectively. For $Re_m << 1$, the interactions between electromagnetic fields and fluid flow are one-way only, excluding the effects of the fluid velocity (V_i) onto the distributions of magnetic (B_i) and electric (J_i) fields. Under such conditions, the system of Maxwell's equations can be significantly simplified and only one additional equation for electric potential has to be introduced to fully close the system of equations. In contrast to that, two-way interactions occur for $Re_m > 1$, i.e. a fully coupled system of momentum and magnetic induction equations has to be solved. For both one- and two-way coupled systems, velocity and electromagnetic fields are interconnected through the Lorentz force ($F_L=J \times B$). In order to reach significantly large values of Re_m, the product V D has to be large, since the magnetic diffusivity is given as a property of fluid. By increasing a velocity and/or the dimension of the system, we are easily approaching a turbulent flow regime, characterized by a high hydrodynamic Reynolds number $Re = V\,D\,/\,\nu$ where ν is the fluid kinematic viscosity. The general overview of interactions between fluid flow, turbulence and electromagnetic field is shown in Fig.1.

Due to the fact that fluid flow will be primarily in the fully developed turbulent regime and because of our present inability to computationally resolve all characteristic flow and turbulence scales in time and space, the modelling of the unresolved scales remains one of the big challenges in the MFD phenomena. In this study we will adopt a multi-scale approach, i.e. the energetically most dominant flow and turbulence structure will be fully resolved by numerical mesh while the subscale structures will be represented by a turbulence model. The standard representation of the subscale turbulence structures primarily developed for the pressure driven flows is not suitable for the flows subjected to or driven by strong body forcing – as in case of the electromagnetic forcing. This required development of the novel electromagnetically extended subscale turbulence closures – and we will address some of our most recent achievement in this direction. In order to demonstrate recent achievements in mutually coupled magnetofluiddynamic phenomena of electrically conductive fluids, three examples are selected:

- Electromagnetically driven vortical turbulent flows with and without heat transfer,
- Turbulent Magnetic Dynamo,

- Magnetic Drug Targeting.

In the first example, a generic setup with imposed electromagnetic forcing is studied both experimentally and numerically. The electromagnetic forcing imposed by different combinations of permanent magnets and electrodes is constant in time, i.e. one-way interactions are considered. Flow and turbulence structure reorganization are analysed and their influence on the wall-heat transfer is studied. The second application addresses challenging magnetic dynamo phenomenon where by imposing mechanically driven turbulent spiralling flow of sodium, a self-generated and self-sustained magnetic field is created in laboratory conditions (the Riga-dynamo setup). Here, a fully coupled mechanism is considered, i.e. two-way interactions are simulated. The final example addresses application of a locally distributed magnetic field (originating from the permanent magnets or the state-of-art superconductive magnets) in capturing small (nano- or micro-scale diameter) magnetic particles released in a blood stream. Here, in addition to solving the fluid flow equations, equations describing the distributions of magnetic particles are introduced too. In this case we are dealing with one-way coupled phenomena. The major challenge (in addition to the complex geometry of typical blood vessels) lies in necessity to include combined effects of the magnetization and Lorentz force on blood flow because of the non-negligible electric conductivity of blood.

MATHEMATICAL EQUATIONS AND SUBSCALE/SUBGRID TURBULENCE CLOSURE

The governing fluid momentum, temperature and magnetic induction equations together with divergency-free conditions for velocity (**U**) , magnetic field (**B**) and total electric current (**J**) that describe the two-way coupled fluid flow/electromagnetic interactions can be written as:

$$\frac{\partial \widehat{U}_i}{\partial t} = \frac{\partial}{\partial x_j}\left[\nu\left(\frac{\partial \widehat{U}_i}{\partial x_j}+\frac{\partial \widehat{U}_j}{\partial x_i}\right)-\widehat{U}_i\widehat{U}_j\right]-\frac{1}{\rho}\frac{\partial \hat{P}}{\partial x_i}+\frac{1}{\rho}\varepsilon_{ijk}\widehat{J}_j\widehat{B}_k-\beta g_i\left(\hat{T}-T_{REF}\right) \quad (1)$$

$$\frac{\partial \hat{T}}{\partial t}=\frac{\partial}{\partial x_j}\left(\frac{\nu}{\mathrm{Pr}}\frac{\partial \hat{T}}{\partial x_j}-\hat{T}\widehat{U}_j\right),\quad \frac{\partial \widehat{B}_i}{\partial t}=\frac{\partial}{\partial x_j}\left(\frac{1}{\mu_0\sigma}\frac{\partial \widehat{B}_i}{\partial x_j}-\widehat{B}_i\widehat{U}_j+\widehat{U}_i\widehat{B}_j\right),\quad \frac{\partial \widehat{U}_i}{\partial x_i}=0,\quad \frac{\partial \widehat{B}_i}{\partial x_i}=0,\quad \frac{\partial \widehat{J}_i}{\partial x_i}=0 \quad (2)$$

Here "^" stands for the instantaneous variables. Any instantaneous variable can be expressed as a sum of an averaged (mean) and a fluctuating contribution (Reynolds decomposition). The last two terms in Eq.(1) represent the Lorentz (electromagnetic) and the thermal buoyancy (gravitational) force, respectively. By performing filtering of the equations above, i.e. by performing ensemble or time-averaging of equations in the case of Reynolds-Averaged Navier-Stokes (RANS) approach or by performing spatially averaging over a control volume in the case of Large-Eddy Simulations (LES), additional terms representing subscale (RANS) or subgrid (LES) contributions will appear. Since in the present study we will deal primarily with the turbulence associated with the velocity and turbulence fluctuations, the higher order moments associated with the velocity and temperature fields will be modelled, whereas the magnetic field fluctuations will be directly resolved. This approach is justifiable for the working regimes characterised by high Re and small or moderate values of $\mathrm{Re_m}$. For situations with high $\mathrm{Re_m}$ additional models dealing with magnetic stresses and cross-correlations between velocity and magnetic fields should be introduced.

Large-Eddy Simulation: Subgrid Turbulence Model

Expressions in the subgrid turbulence contributions in the momentum and temperature equations must be provided in order to have a fully closed system of equations. In the present investigations, the subgrid turbulent stress and subgrid turbulent heat flux are evaluated from the magnetically extended

Table 1
Specification of the T-RANS model coefficients

$C_{\varepsilon 1}$	$C_{\varepsilon 2}$	C_L	σ_k	σ_ε	C_μ
1.44	1.92	0.025	1.0	1.3	0.09

eddy-viscosity based Smagorinsky [1] model of Shimomura [2] and a simple gradient diffusion of temperature, Kenjeres [3], respectively:

$$\tau_{ij} = \frac{1}{3}\tau_{kk}\delta_{ij} - \nu_t S_{ij},\ S_{ij} = \frac{1}{2}\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right),\ \nu_t = \nu_s \exp\left[\frac{-\frac{\sigma}{\rho}\left(C_m\Delta\right)^2 \mid B_0 \mid^2}{\nu_s}\right],\ \nu_s = \left(C_s\Delta\right)^2\left(S_{ij}S_{ij}\right)^{1/2} \quad (3)$$

$$C_s = C_{s0}\left[1 - \exp\left(\frac{-x_i^{N+}}{25}\right)\right]^2,\ \mid B_0 \mid = \sqrt{B_i^2},\ \tau_{\theta i} = -\frac{\nu_t}{\mathrm{Pr}_t}\frac{\partial T}{\partial x_i} \quad (4)$$

Here, U_i and T are resolved velocity and temperature fields, respectively. The van Driest [4] damping function based on the non-dimensional wall distance is introduced in order to provide a proper near-wall behaviour of the turbulent viscosity. The standard values of the SGS model coefficients are used, C_{s0}=0.1, C_m=1.4, Pr_t=0.86. The characteristic spatial filter Δ is calculated as $\Delta = \Delta V^{1/3}$ where ΔV is the control volume.

Transient Reynolds-Averaged Navier-Stokes: Subscale Turbulence Model

In cases where the application of LES is not possible, for example for flows characterised by high Re or where the accurate predictions of the wall-heat transfer will require full resolving of the near-wall regions, application of the transient Reynolds-Averaged Navier-Stokes (T-RANS) approach is only viable option, Kenjeres and Hanjalic [5], Hanjalic and Kenjeres [6]. Now, a subscale model of unresolved (subscale) flow and turbulence structures needs to be introduced. The eddy-viscosity based two-equations k-ε model is introduced with additional source/sink terms representing the electromagnetic contributions, Kenjeres and Hanjalic [7]. The equations of the T-RANS model with specification of model coefficients are given next:

$$\tau_{ij} = \frac{3}{3}k\delta_{ij} - \nu_t\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right),\nu_t = C_\mu\frac{k^2}{\varepsilon} \quad (5)$$

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial x_j}\left(\nu\frac{\partial k}{\partial x_j} + D_k^t - U_j k\right) - \tau_{ij}\frac{\partial U_i}{\partial x_j} - \varepsilon - P_k^b \quad (6)$$

$$\frac{\partial \varepsilon}{\partial t} = \frac{\partial}{\partial x_j}\left(\nu\frac{\partial \varepsilon}{\partial x_j} + D_\varepsilon^t - U_j\varepsilon\right) - C_{\varepsilon 1}\tau_{ij}\frac{\partial U_i}{\partial x_j}\frac{\varepsilon}{k} - C_{\varepsilon 2}\frac{\varepsilon^2}{k} - P_\varepsilon^b \quad (7)$$

$$D_k^t = \frac{\nu_t}{\sigma_k}\frac{\partial k}{\partial x_j},\ D_\varepsilon^t = \frac{\nu_t}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial x_j},\ P_k^b = \frac{\sigma}{\rho}B_0^2 k\exp\left(-C_L\frac{\sigma}{\rho}B_0^2\frac{k}{\varepsilon}\right),\ P_\varepsilon^b = P_k^b\frac{\varepsilon}{k} \quad (8)$$

Here, $(P_k - P_\varepsilon)^b$ are the electromagnetic source/sink terms and turbulent diffusion terms $(D_k - D_\varepsilon)^t$ are calculated by applying simple gradient hypothesis.

NUMERICAL METHOD

The above presented set of equation is discretized by applying a finite-volume approach. The recently developed finite-volume based Navier-Stokes/Maxwell's solver can be applied for any three-dimensional non-orthogonal geometry distributed over many multi-blocks (locally structured) or on a fully unstructured mesh. The local grid refinements can be activated in the pre-specified blocks. The solver can be executed in serial or parallel mode. The latter involves the domain decomposition based message passing interface (MPI) directives. All transport variables are located in the geometrical centre of such control volumes (collocated variable arrangement). In order to prevent a decoupling between the velocity and pressure fields (checkerboard pressure oscillations) the Rhie–Chow interpolation is used in the pressure-correction equation. The corrected velocity and pressure fields are iteratively calculated by the semi-implicit method for pressure-linked equations (SIMPLE) algorithm. The numerical accuracy of the entire discretized system is of the second-order. The time integration is performed by the fully implicit second order scheme based on three consecutive time steps. The diffusive terms are discretized by the second-order central differencing scheme. The remaining convective terms are calculated by the monotonicity preserving total variation diminishing (TVD) schemes. The linearized system of equations is then solved using Stone's strongly implicit procedure (SIP) based on an incomplete lower-upper (LU)-factorization. Additional numerical details are given in Kenjeres and Hanjalic [8], [9], [10].

ELECTROMAGNETICALLY DRIVEN VORTICAL FLOWS

One of the most beautiful examples of mutual interdependency between flow, turbulence and electromagnetic fields can be found inside of whirlpool galaxies, Soward *et al.* [11]. Based on astrophysical observations and satellite measurements a link between spiralling pattern of the dust clouds inside of galaxy and underlying magnetic field is confirmed. This fundamental paradigm connecting spiralling flows (in both laminar and turbulent flow regimes) with electromagnetic fields will be in focus of our investigations. As an example, the spiral arms and dust clouds inside of whirlpool galaxy M51 are shown in Fig.2a. Inspired by this beautiful example from nature, a similar attempt in generating swirling flows by imposed electromagnetic forcing is performed on a laboratory scale. By imposing different configuration of arrays of permanent magnets of opposite polarities and oppositely charged electrodes, different multi-vortex patterns of electrically conductive working fluid confined in a simple rectangular tank can be easily generated.

An example of such an electrically driven flow that closely resembles above mentioned whirlpool galaxy is shown in Fig.2b,c. Here, flow is visualised by a laser induced fluorescence (LIF) technique of a dye colour released in an electrically conductive fluid (water with electrolyte solution), Verdoold *et al.* [12]. The Lorentz force is generated by combining two permanent magnets with opposite polarities that are located below the lower wall of the rectangular tank and two oppositely charged (with DC current) electrodes that are located in the upper part of the side walls. The dimensions of the tank are 0.6x0.6x0.155 m^3.The permanent magnets have dimensions 0.084x0.040x0.040 m^3 and are arranged in arrays of alternating polarity. The distance between each magnet is 0.040 m, resulting in a maximum magnetic field strength of 1.0 T inside the tank. The controllable DC current could be varied between 0.5 and 10 A. Due to the relatively large electrical current, induction effects can be neglected and Ohm's law can be approximated by $J \sim \sigma E$. Then, the resulting Lorentz force for the present range of experiments can be expressed as $F^L = ExB$, which is constant in time. Water with 7% Na_2SO_4 electrolyte solution is used as a working fluid, with electric conductivity $\sigma = 5.5$ S/m.

The sketch of this combination with applied DC current of I=10 A is shown in Fig.3-above. The value of the Reynolds number based on the maximum velocity reaches value of Re=8000 indicating

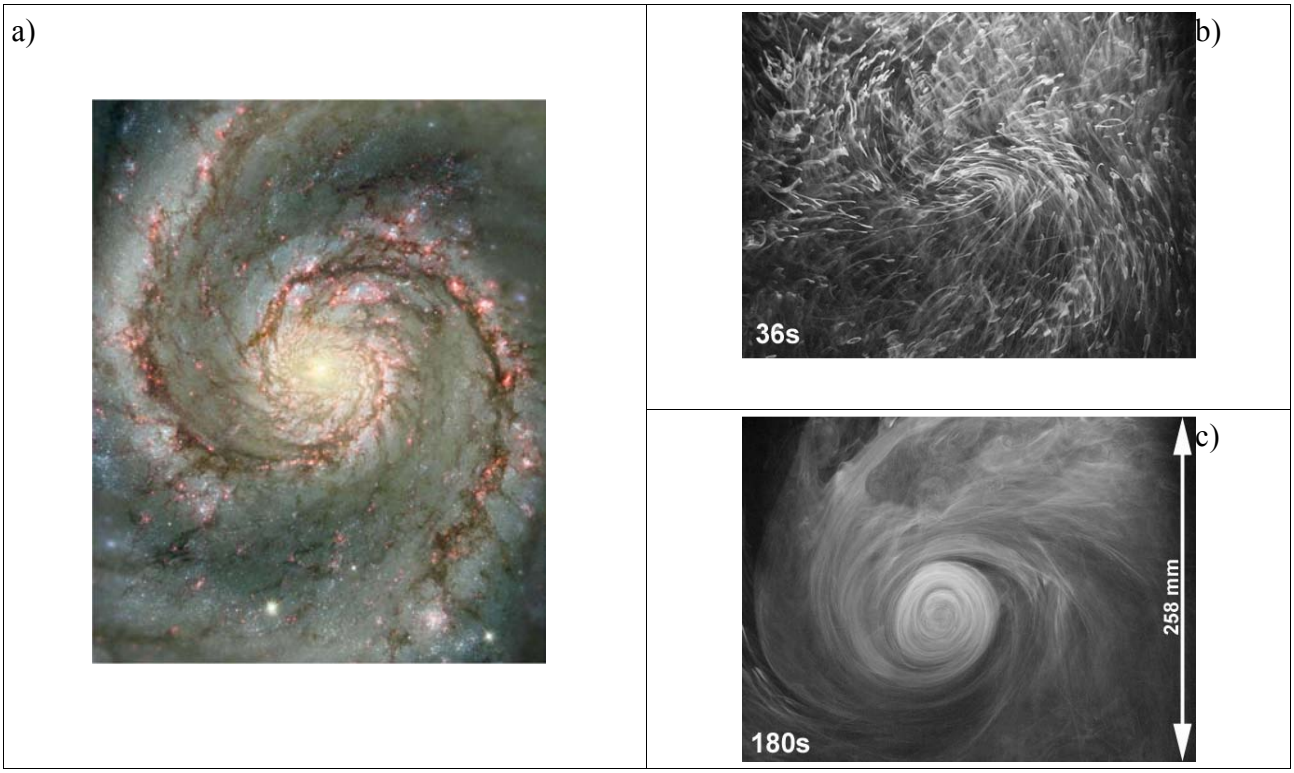

Figure 2. Left- The spiral arms and dust clouds inside of whirlpool galaxy M51 (radius ~38000 light years), image credit NASA and The Hubble Heritage Team (STScI/AURA); Right- a laser induced fluorescence visualisation of the electromagnetically driven draft-tornado (radius ~130 mm) in laboratory conditions (generated by a combination of 2-permanent magnets with |B|=1 T below lower wall and 2-electrodes with I=10 A along the side walls): initial (-b) and fully developed state (-c), Verdoold *et al.* [12].

turbulent flow regime (at least in regions with the intensive forcing). In the early stage of the forcing, some of the initially created spiralling arms of the centrally created vortex start to be visible, Fig.2b. In the fully developed state a very close resemblance with a whirlpool galaxy is obtained, Fig.2c. Note that these visualisations were performed in the top plane of the setup – providing just two-dimensional flow imprints (in the top plane). In order to be able to provide full three-dimensional time-dependent insights into flow and turbulence of such electromagnetically driven vortical flows under different forcing conditions, series of LES are performed, Kenjeres *et al.* [13]. Results of the above analysed configuration with 2-permanent magnets and 2-electrodes are shown in Fig. 3-below. The time-averaged resolved velocity and pressure fields are used for depicting three-dimensional flow structure. The velocity vectors in the central horizontal plane together with isosurfaces of pressure are shown in Fig.3a. The centrally located low-pressure regions indicate intensive swirling fluid motion. Similarly, a stream-traces coloured with velocity magnitude are shown in Fig.3b. A typical tornado-like structure is clearly visible. The high velocity in the proximity of the lower wall is simply result of the strong electromagnetic forcing that decays as the distance from the wall increases. Also the presence of the spiralling arms is nicely visible in the lower part of the centrally located vortex. In addition to the qualitative observations, numerical simulations are also validated against flow measurements obtained by particle imaging velocimetry (PIV) technique. The profiles of the circumferentially averaged magnitude of the horizontal velocity along the vortex diameter at two characteristic vertical locations (z=0.025 and 0.040 m) are shown in Fig.4-left. It can be seen that the peak value stays approximately constant with wall distance, whereas its location gradually moves towards the outer edge of the vortex. A good agreement between PIV and LES is obtained, especially with respect to the exact peak value, while some discrepancies are visible at locations towards the vortex edge. The time-averaged vertical profiles of the horizontal velocity at two different locations are shown in Fig.

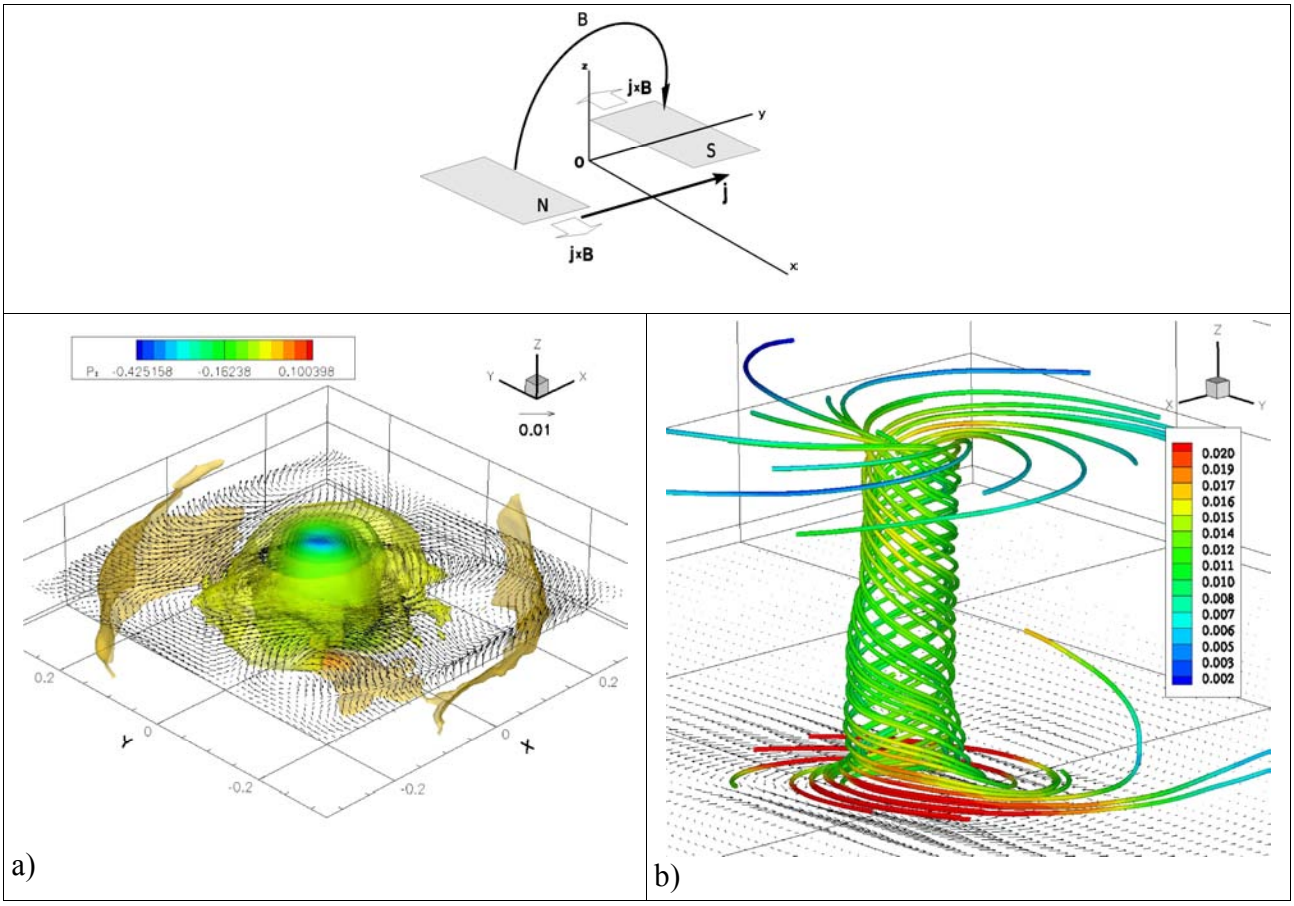

Figure 3. Sketch of distributions of magnetic and electric field lines as well as of resulting Lorentz force for configuration with 2-permenent magnets (B=1 T) and 2-electrodes (I=10 A) distributed along the side walls (x=-0.3 and 0.3 m) – above; Time-averaged LES results of the velocity vectors in the central horizontal plane and isosurfaces of low-pressure region (in Pa) (below-a) and zoom-in of the stream-traces coloured by the velocity magnitude (in m/s) (below-b), Kenjeres *et al.* [13].

4-right. Note that the measured vertical profiles do not span the entire height of the setup. The locations of the velocity peak values in the proximity of the lower wall are nicely captured at both locations. At x =-0.05 m some deviations between PIV and LES can be observed in the upper part for z > 0.075 m. The velocity peak value is slightly underestimated at x = 0.05 m, but the qualitative shape of the profile is well captured. It can be concluded that combined experimental and numerical studies of the electromagnetically driven flows in a generic setup proved that despite its geometrical simplicity, this setup can be used for fundamental studies of the interactions between flow, turbulence and electromagnetic fields. By changing the intensity of the applied DC electric current, different flow regimes (laminar, transitional or fully turbulent) can be achieved in different parts of the setup. Generally very good agreement between measurements and simulations is obtained for velocity field components at different locations proving validity of the preformed LES.

After this initial validation, the studies of the heat transfer are performed next, Kenjeres [3]. In addition to the supplying the heat flux through the lower hot wall and by cooling the upper wall, also a multi-array of the permanent magnets with opposite polarities is imposed. This is done in order to effectively control the wall-boundary layers along the lower horizontal thermally active wall. In total 35 magnets of opposite polarities (of identical specification as already mentioned for the isothermal studies) are used. The different intensities of supplied electric current through electrodes are applied, i.e. I=0, 1 and 10 A. The temperature difference between lower hot and top

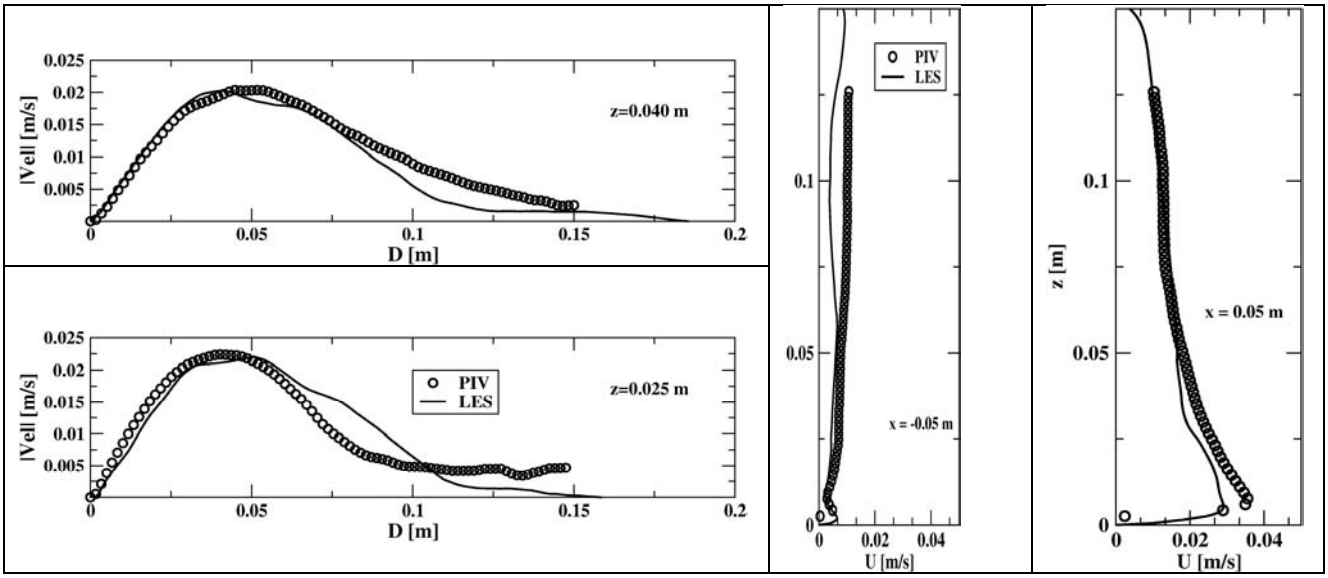

Figure 4. Comparison between PIV measurements and LES results for electromagnetically driven draft-tornado situation presented in previous figure; Left- circumferentially averaged modulus of velocity profiles at two characteristic vertical locations, z=0.025 and 0.040 m; Right- the vertical profiles of horizontal velocity component at two characteristic locations, x=-0.05 and 0.05 m, Kenjeres *et al*. [13].

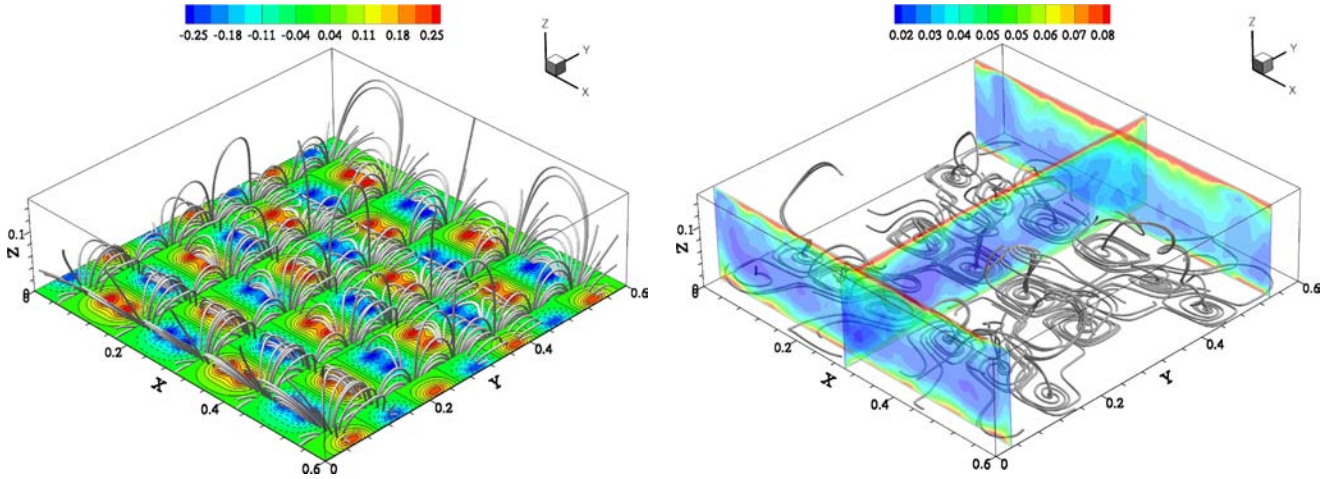

Figure 5. A wall-bounded [4:4:1] aspect ratio enclosure heated from below and cooled from top, filled with an electrically conductive locally fluid (electrolyte solution) subjected to locally generated Lorentz force originating from a multiple-array of the permanent magnets located below the lower wall and two electrodes along the side walls (x=0 and 0.6 m); Left- magnetic flux lines (gray lines) and the contours of the horizontal magnetic field at the lower wall (in T); Right- the stream-traces (gray lines) of the resolved velocity field and contours of the non-dimensional temperature variance in characteristic vertical planes, Kenjeres [3].

cold wall generates Ra=10^7 and Pr=7. An impression of the flow structures and imposed magnetic field is shown in Fig. 5. The magnetic field is visualized by plotting the spatial distributions of the magnetic flux lines, Fig.5-left. It can be seen that the strongest concentration of the flux lines is in the proximity of the lower horizontal wall and that gradually decays as the distance from wall increase. It indicates that the strongest forcing will occur in the regions close to the lower wall, i.e. the wall boundary layers will be mostly affected by imposed electromagnetic forcing. The generated flow structures are shown in Fig.5-right. The multiple spiraling vertical structures generated by strong shearing in horizontal planes are dominant flow structures. The strong temperature

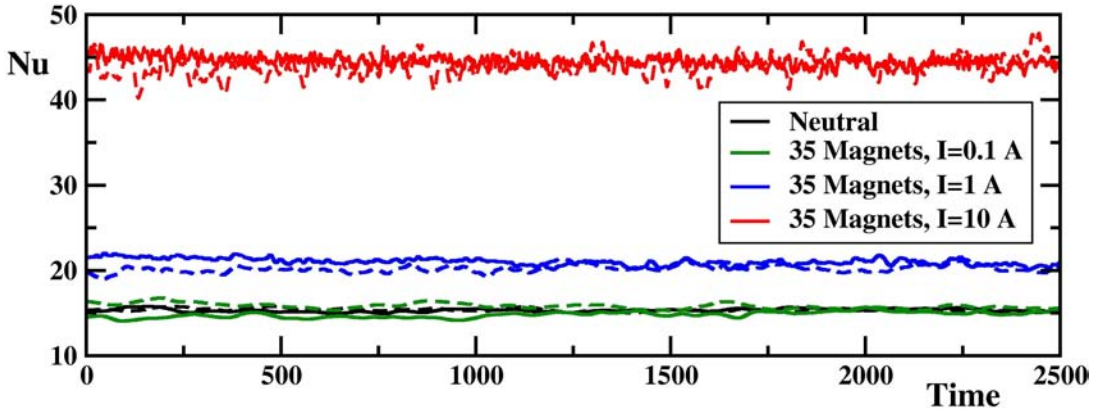

Figure 6. Time evolution of the Nusselt numbers along the top- (dashed lines) and bottom-wall (solid lines) for configuration shown in previous figure for different strengths of the imposed DC current, I= 0, 0.1, 1 and 10 A, Ra=10^7, Pr=7, Kenjeres [3].

fluctuations are located in the thin thermal boundary layers along the thermally active walls, as indicated by contours of the temperature variance in characteristic vertical planes, Fig.5 -right.

The time-evolutions of the Nusselt number along the top- and bottom-wall are shown in Fig. 6. The value of Nu=15.35 for the neutral situation agrees well with experimentally obtained correlations Nu =$0.145Ra^{0.29}$=15.54 (Tanaka and Miyata [14]) and Nu=$0.183Ra^{0.278}$=16.1 (Chu and Goldstein [15]). Also good agreement is obtained with DNS results of Nu =15.75 (Kerr and Herring [16]). It can be seen that flow and turbulence reorganization in the presence of external electromagnetic fields has a significant impact on the wall-heat transfer. The imposed current of I=1 A (that generates mean motion with Re=1300) gives 34% enhancement of the total heat transfer coefficient, while I=10 A (that generates mean motion with Re=4500) gives an impressive 188% increase. The significance of the obtained heat transfer enhancement can be compared with values obtained in Uda *et al.* [17] where an enhancement of 5–10% was experimentally obtained in annular turbulent flow $5x10^3<Re<10^5$ of lithium subjected to a magnetic field B_0=0.8 T.

MAGNETIC DYNAMO

The process of partial conversion of the mechanical energy of the moving electrically conductive fluid into magnetic energy is called magnetic dynamo. It is believed that ability of the turbulent motion of an electrically conductive fluid to generate and to maintain a magnetic field against its natural decay is the crucial mechanism responsible for generation and sustenance of magnetic fields in galaxies, stars and planets (including Earth's magnetic field creation), Soward *et al.* [11], Busse [18].

A validation of realistic simulations of the Earth's magnetic field generation can be only indirect, e.g. by comparing the recorded magnetic field distributions at the Earth surface. In order to provide direct and valid proofs of the magnetic dynamo mechanism, it is necessary to have well-defined and controlled working conditions, while retaining the basic physics of the dynamo phenomenon. A general concept of the magnetic dynamo inside of the simplified vertical column of an electrically conductive fluid (that is present in the liquid metallic outer core) driven by combined effects of thermal and concentration (composition) buoyancy, as well as subjected to the rotational effects due to the rotation of Earth, are shown in Fig. 7-left, Busse [18]. This simplified concept is mimicked by the Riga-dynamo setup shown in Fig.7-right, Gailitis *et al.* [19], [20]. Here, the mechanical forcing of working fluid by thermal and concentration (composition) buoyancy is simply replaced by strong

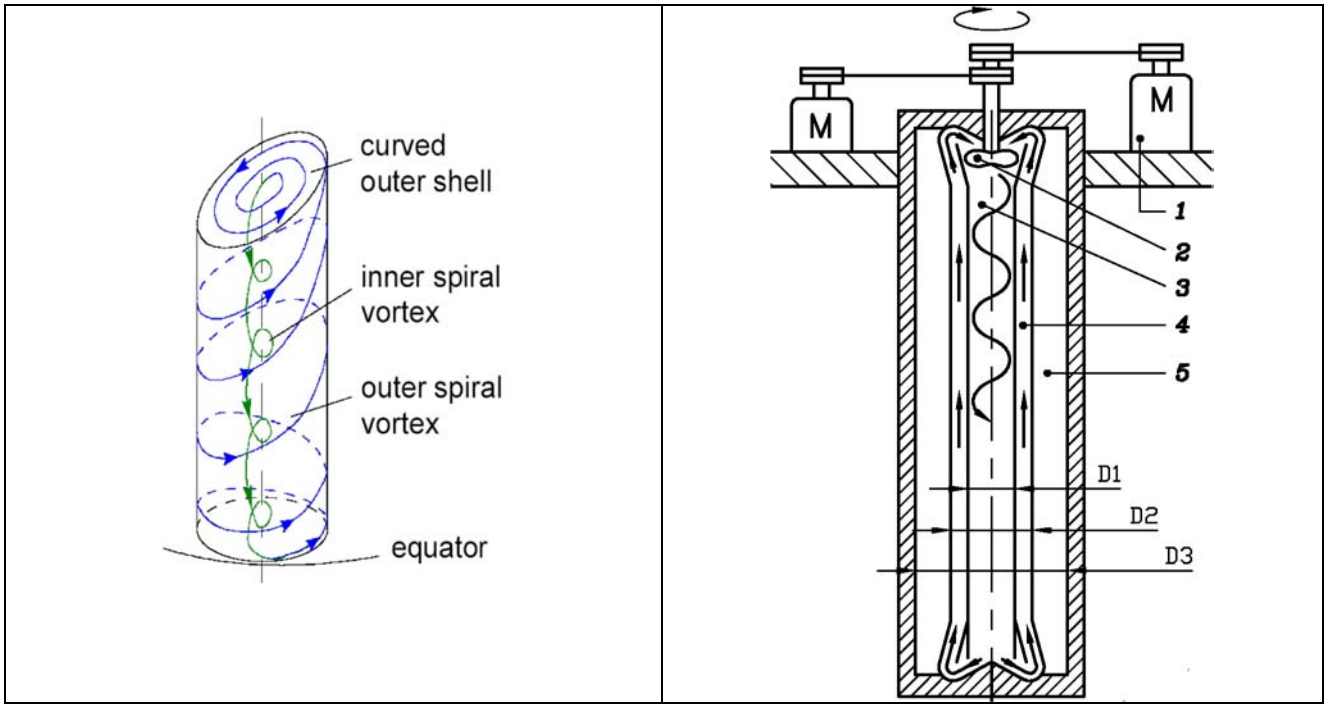

Figure 7. Left- a concept of the magnetic dynamo inside of the simplified vertical column of a conductive fluid driven by thermal and concentration buoyancy inside of Earth; Right- sketch of the Riga-dynamo experimental setup, Gailitis et al [19], [20]: 1- two engines (M) with 100 kW to drive propeller; 2- propeller; 3- inner cylinder with intensive swirling motion; 4- outer passage with back-flow; 5- surrounding ring of sodium at rest; D1=0.21 m, D2=0.4 m, D3=0.8 m are characteristic dimensions of the inner, outer and surrounding cylinder, respectively. The typical vertical length is L=3 m.

mechanical forcing by a centrally located propeller in the upper part of the inner cylinder. The propeller is driven by two electric motors with a power up to 100 kW each. The sodium is used as a working fluid because of its excellent electric conductivity properties, i.e. its use will provide the best probability to reach critical dynamo threshold under experimental conditions. After strongly swirling flow in the inner cylinder, fluid turns in a 180 degrees bend and reaches the outer cylinder and a closed loop of fluid motion is established. All around this central annular passage there is an additional ring of sodium at rest. Its role is to reduce possible escaping of the self-generated magnetic field in the surrounding environment.

It is recalled that the flow inside of the setup is in highly turbulent regime ($Re=3.5x10^6$) so it is necessary to simulate this flow with a turbulence model. Since the both direct numerical (DNS) and large-eddy simulation (LES) are out of reach for such high values of Re, we applied a novel electromagnetically extended subscale model in transient mode (T-RANS approach), Kenjeres and Hanjalic [7], [9], [10]. On other hand, the estimated range of $15<Re_m<20$ makes it possible to fully numerically resolve self-generated magnetic field in time and space – so no additional modelling of the magnetic turbulence is needed. This hybrid T-RANS/DNS approach for simultaneous solving of the two-way coupled fluid flow, turbulence and self-generated electromagnetic fields made it possible to simulate realistic experimental working conditions for the first time. Before performing the fully coupled two-way interactions, validity of the eddy viscosity based two equations k-e turbulence model (EVM) is tested by simulating a 1:2 scale-down experimental setup with water as working medium and results are compared with available experimental measurements and results obtained by more advanced full second moment closure (SMC) model. The axial and tangential velocity profiles at three characteristic vertical locations (y=+0.5, 0, -0.5 m) are shown in Fig.8. It

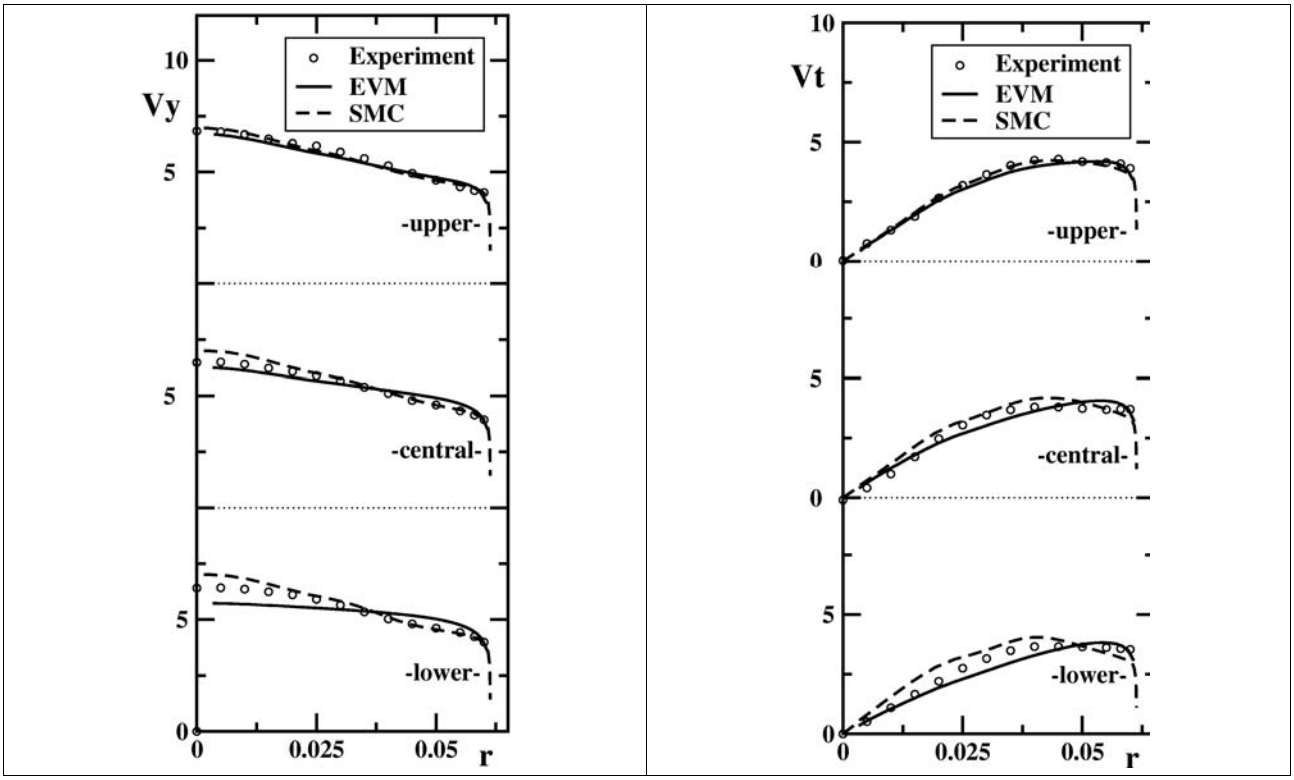

Figure 8. Comparison of experimental (LDA) and numerically obtained (with eddy-viscosity EVM and second-moment-closure SCM) velocity profiles in a 1:2 scaled-down Riga-dynamo setup with water as working medium; Left- axial velocity, Right- tangential velocity (both in m/s), Kenjeres and Hanjalic [10].

can be seen that the EVM performs quite well under defined working swirling conditions at all three locations giving good agreement with both experimental and SMC data. Since the more advanced SMC model requires solving 6 additional PDEs, the simpler EVM proved to be the best compromise between accuracy of the physical representation and numerical robustness and efficiency. Based on this performance, this model is used for the follow-up simulations. After this preliminary validation, a fully coupled solver is activated and results of simulations are shown in Fig.9. A snapshot of the intensive swirling flow pattern in the inner cylinder generated by propeller and visualised by stream-traces coloured by the axial velocity component is shown in Fig.9-left. The corresponding structure of the self-generated magnetic field (visualised by magnetic flux lines coloured by the axial magnetic field component) is shown in Fig.9-right. While the flow pattern is confined in the inner and outer cylinders, the self-generated magnetic field is allowed to leave the computational domain as indicated by the open magnetic flux lines. It is important to note differences in flow and magnetic field distributions – if magnetic filed will be simply driven by convective contribution of the velocity field, they will exhibit very similar spatial distributions. In contrast to that, very different structures are observed indicating importance of the magnetic flux stretching term as a primary mechanism behind the self-generation of magnetic field. Contours of the self-generated and self-sustained magnetic field components (tangential and radial) in the central horizontal (x-z) plane at the characteristic time instant during saturation regime are shown in Fig.10.

The resulting self-generated and self-sustained magnetic field profiles are shown in Fig.11. Here, the symbols represent the experimentally recorded maximum values at the particular radial locations for different propeller rotation rates - ranging from 1900 to 2500 rpm, Gailitis *et al* [19], [20]. All profiles are rescaled with the maximum value along the radial direction. It can be seen that

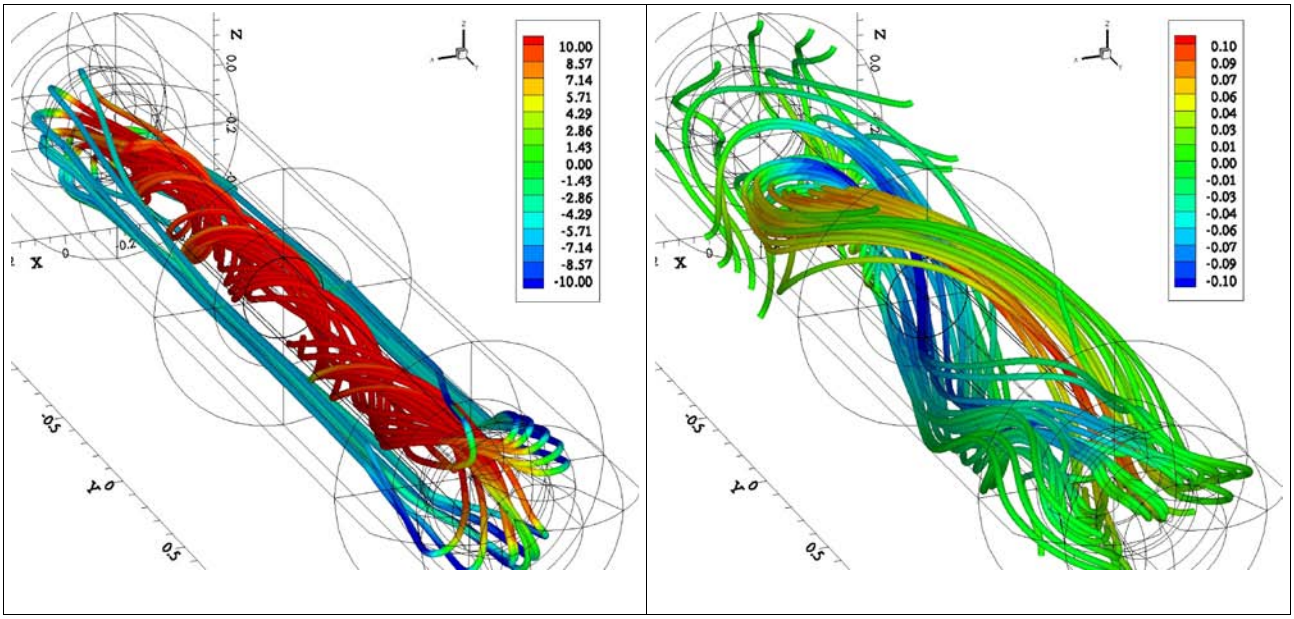

Figure 9. Left- Swirling flow pattern in the inner cylinder generated by propeller (stream-traces coloured by axial velocity, in m/s); Right- self-generated magnetic field magnetic (magnetic flux lines coloured by the axial magnetic filed, in T) – a snapshot of the simulated three-dimensional fields, $Re=3.5x10^6$, $Re_m=18$, Kenjeres and Hanjalic [10].

for both the axial and radial magnetic field component, the experiments show a slight deviation in the profile symmetry. In contrast to the experimental profiles, the numerical results show perfect symmetry indicating full convergence of the magnetic induction equation. The magnetic field profiles indicate that after t=5.5 sec, a fully saturated regime is achieved. A very good agreement between the experiments and simulations is observed for the axial magnetic filed component, Fig.11-left. The results for the radial magnetic field component show a larger scatter, but again, agreement can be considered as good, Fig.11-right. In contrast to the zero axial magnetic fields at the outer boundary of the surrounding sodium at rest, the radial component correctly shows a final value. This boundary value is slightly under-predicted as compared with measurements, but shows clearly that the boundary condition for the vertical magnetic field is properly imposed. In contrast to the monotonic time evolution of the axial magnetic field profiles, the radial profiles show an interesting variation in the radial location of the peak value. The peak value travels from the centre of the outer cylinder for earlier time instants (cycle 10–cycle 15) and finally settles at the middle radial distance in the inner cylinder, Fig.11-right.

In contrast to the measurements of magnetic field components that are restricted to one-dimensional recordings (time dependency), the numerical simulations can provide full three dimensional spatial distributions. Kenjeres and Hanjalic [9], [10]. In Fig.12-left, the isosurfaces of the radial magnetic field of opposite signs (red and blue) are shown together with stream-traces of the instantaneous velocity field (grey tubes) at different time instants, i.e. t= 2, 2.5 and 7.5 s, respectively. The strongest self-amplification takes place in the lower part of the set-up and then it moves upwards. In order to demonstrate effects of the generated Lorentz force on turbulent kinetic energy (TKE) of underlying velocity field, three dimensional distribution of TKE is shown in Fig.12-right. It can be clearly observed that a 'gap' is appearing in the lower part of the inner cylinder as time progress. This indicates that the levels of the turbulent kinetic energy are reduced in this region by an active action of the Lorentz force. In contrast to that, TKE levels in the outer cylinder show periods with suppression or enhancement – depending for which selected time instants these values are shown.

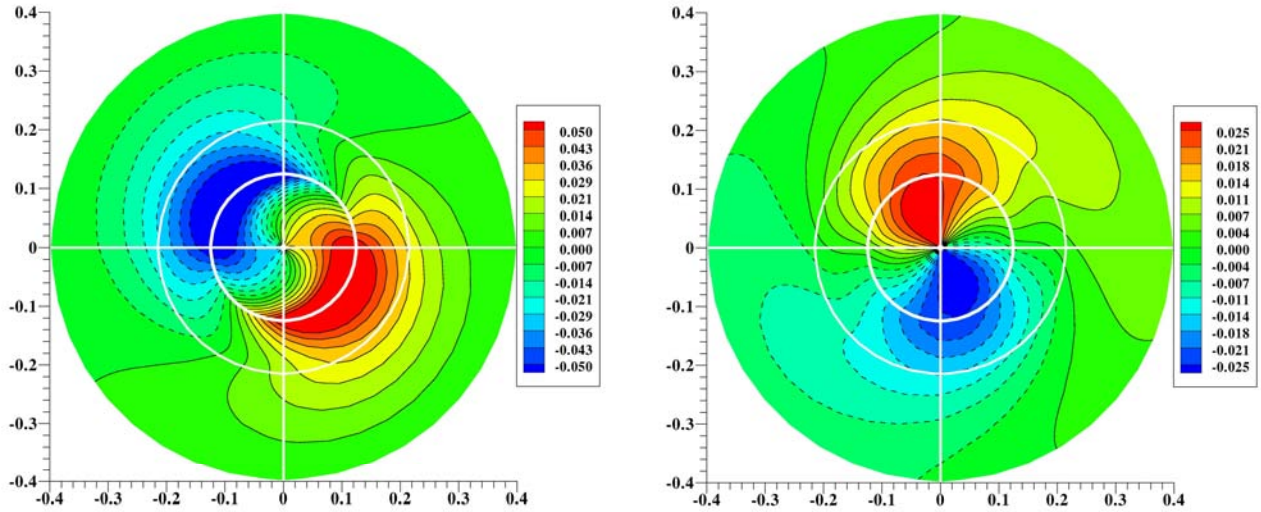

Figure 10. Contours of the self-generated and self-sustained magnetic field at particular time instant during saturation regime in the central horizontal (x-z) plane (y=-0.5 m): tangential (-left) and radial (-right) magnetic field component (in T), Kenjeres and Hanjalic [10].

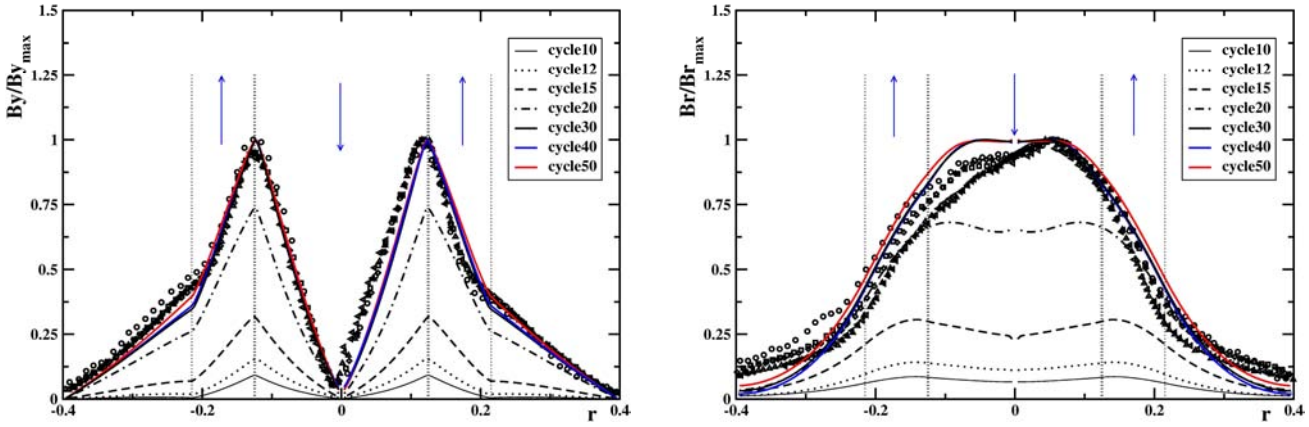

Figure 11. Time-evolution of the magnetic field component profiles in the central horizontal (x-z) plane (y=-0.5 m): axial (-left) and radial (-right) component (in T). Note that the cycle time instants actually correspond to the following time instants: cycle 5 = 1 s, cycle 10 = 2 s, cycle 15 = 2.85 s, cycle 20 = 3.5 s, cycle 30 = 5.5 s, cycle 40 = 7.5 s, cycle 50 = 9.5 s, respectively, Kenjeres and Hanjalic [10].

Finally, it can be concluded that presented numerical simulations based on a hybrid T-RANS/DNS approach for velocity (T-RANS) and magnetic field (DNS) succeeded in replicating numerically a magnetic-dynamo mechanism in a turbulent flow regime as observed in the Riga-dynamo experimental setup. This was achieved without imposing any external excitation or artificial inputs for electromagnetic fields. It is shown that such an approach clearly demonstrated not only its potentials to reproduce process of the self-generation and self-sustenance of a magnetic field, but also captured distributions and magnitude of the magnetic field components in close agreement with available experimental data.

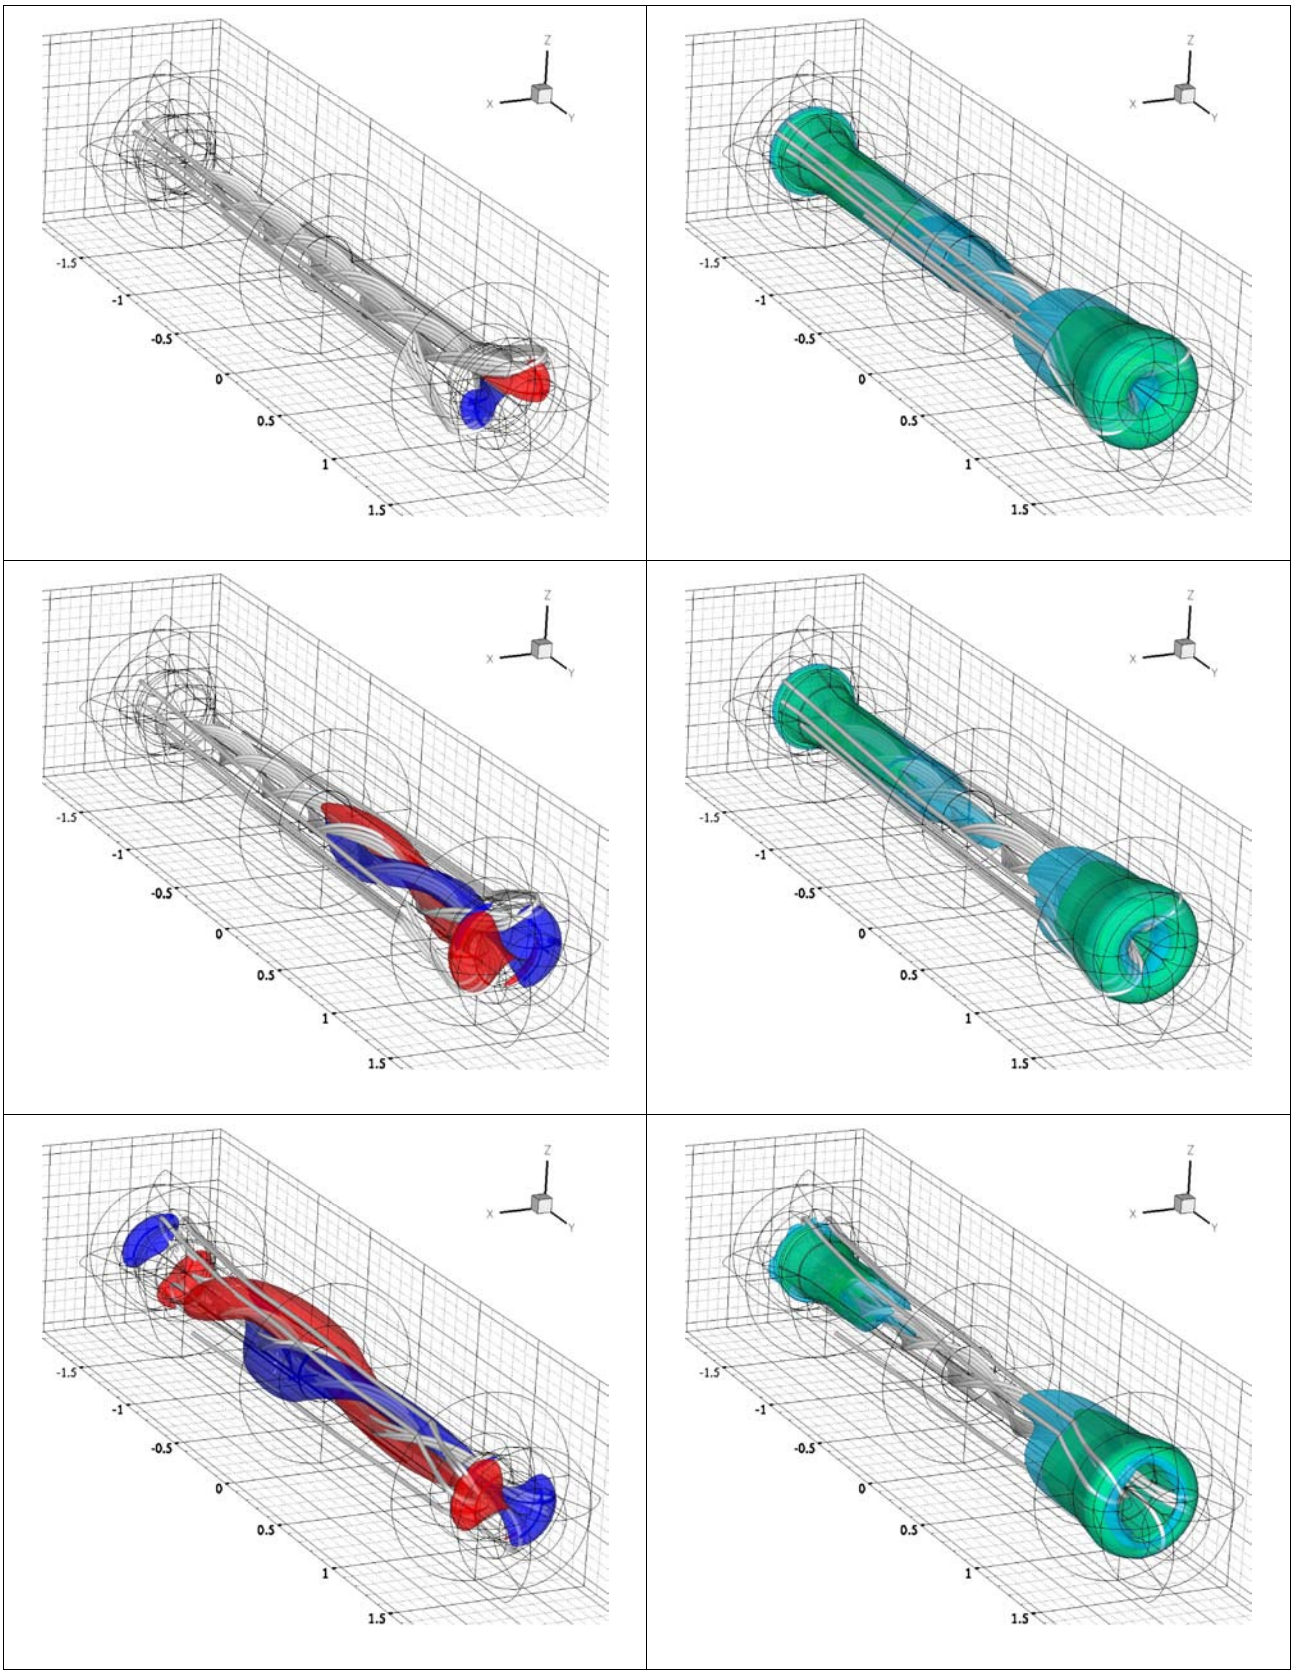

Figure 12. Time evolutions (from top to bottom, Time= 2, 2.5 and 7.5 sec, respectively) of the radial magnetic field component (B_r= + 0.05 T – red, -0.05 T – blue) (-left) and of the turbulent kinetic energy (iso-surface k= 2.5 m^2/s^2 is light blue and k= 1 m^2/s^2 is light green (-right).

MAGNETIC DRUG TARGETING

At present, one of the main problems of chemotherapy is often not the lack of efficient medical drugs, but our inability to precisely deliver these drugs in sufficiently high concentrations in areas affected by disease. The concept of the magnetic drug targeting (MDT) is to insert a small magnetic particles as carriers of medical drug into blood flow and to locally apply magnetic field gradients over an area of interest that these particle will be locally captured and accumulated in these regions, Alexiou [21], [22], [23], Torchilin [24]. Two major goals can be achieved: a huge (tenfold) increase in local concentrations of medical drugs and significant reduction of the freely circulating drugs. Due to latter, toxic effects of medical drugs on healthy organs will be drastically reduced. It is not difficult to imagine that blood flow in realistic blood vessels will exhibit complex three-dimensional patterns with characteristic imprints of spiralling motion, Kenjeres [25]. Distribution of magnetic particles released in blood flow will strongly depend from the underlying flow patterns. By imposing external magnetic field gradients, through generated magnetization force, distributions of the magnetic particles can be significantly affected. For sufficiently strong magnetization force, magnetic particles can be efficiently captured from the blood flow and deposited along the blood vessel walls at the pre-defined locations in desired regions. In contrast to the previously analysed cases where the underlying fluid flow was affected by magnetic fields, here we introduce additional equation for the magnetic particle trajectories in presence of magnetization force:

$$m\frac{d^2r}{dt^2} = F_D + F_M \tag{9}$$

where r(t) is the particle location and F_D and F_M are the drag and magnetization forces, respectively. The drag force is defined by Stokes expression (that is valid for $Re_p=\rho \mid u_p - u_f \mid D / \mu << 1$) as

$$F_D = 3\pi\mu D\left(u_p - u_f\right) \tag{10}$$

where u_p and u_f are velocity of the particle and fluid, respectively. The magnetization force acting on particles can be expressed as

$$F_M = \mu_0 M \cdot \nabla H \cdot V_P \tag{11}$$

where M is the magnetization, H is the auxiliary magnetic field, μ_o is the magnetic permeability of vacuum and V_p is the volume of the particle. The particle velocity (under assumption that the particle inertia can be neglected) can be estimated as a sum of the fluid velocity u_f and a 'magnetic velocity' u_m as

$$u_p = u_f + u_m = u_f + \frac{F_M}{3\pi\mu D} \tag{12}$$

The capture efficiency of magnetic particles by an imposed magnetic field is simply calculated as a ratio between number of particles deposited along the vessels walls and total number of the released particles

$$\eta = \frac{n_{dep}}{n_{in}} = \frac{n_{in} - n_{out}}{n_{in}} \tag{13}$$

In order to demonstrate basic concepts of the magnetic drug targeting technique, we simulated a realistic case of blood flow inside of human left coronary artery (LCA) where magnetic particles with different diameters were released, Haverkoort and Kenjeres [26]. A magnetic field distribution from a recently developed superconducting magnet that generates sufficiently strong gradients was imposed and capturing efficiency for different particle diameters is analyzed. Numerical mesh used for computations is shown in Fig.13-left. This geometry was created by averaging angiograms (medical imaging technique to obtain geometry of the blood vessels) of 83 healthy patients in order to get a single representative dataset, Giannoglou *et al.* [27].

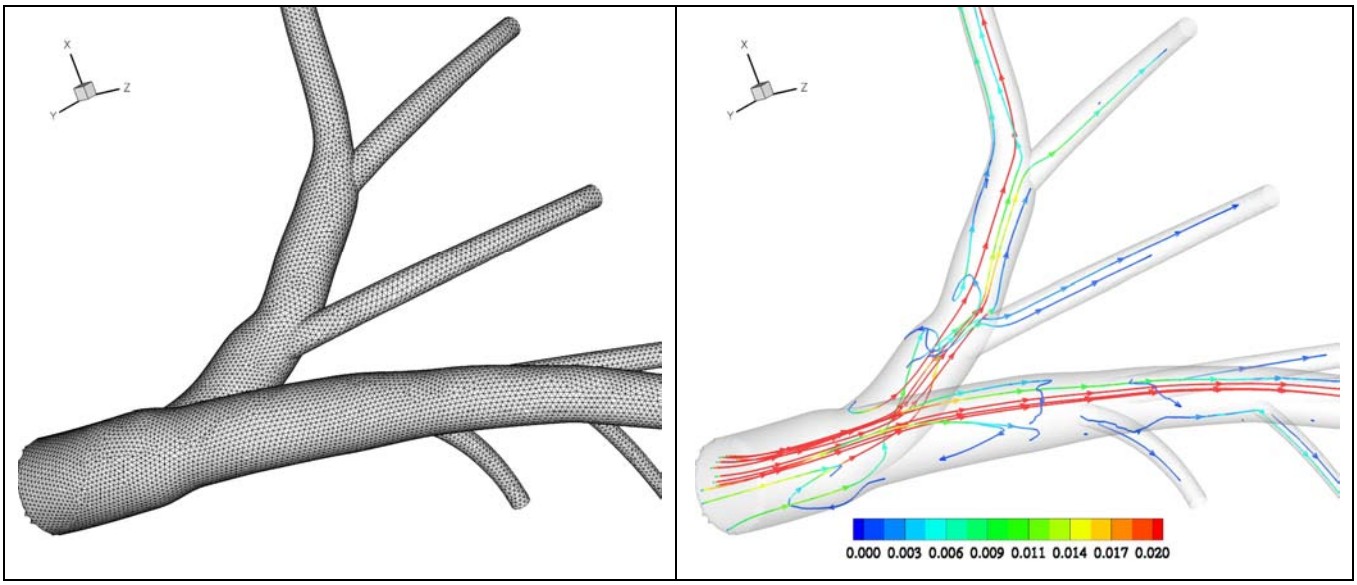

Figure 13. Numerical mesh used for computations of blood flow inside a simplified model of the multi-branching left-coronary artery (LCA) (generated as a typical configuration by averaging geometrical data of 83 healthy patients) (-left) and visualization of the flow pattern at particular time instant of the pulsating heartbeat cycle (stream-traces coloured by magnitude of the velocity), Haverkort and Kenjeres [26].

Characteristic heartbeat cycle was simulated by imposing a periodically changing (with a characteristic time period of t = 1s that corresponds to the real cardiac cycle) flattened inlet radial velocity profile at the inlet plane of the coronary artery:

$$u_f(r,t) = \frac{4}{3} u_{in}(t) \left[1 - \left(\frac{r}{R} \right)^6 \right] \tag{14}$$

The average Reynolds number based on inlet parameters is estimated to be in 100< Re<500 range. The flow rate was forced to distribute over the several outlets according to Murray's law (proportional to r^3 – where r is the outlet radius). The initial diameter of the left coronary artery is ~4.5 mm while the multiple outlets reduce their diameters up to 0.9 mm and total length of approximately 12 cm. Eqn.(9) is numerically integrated using the forth-order Runge-Kutta scheme. The momentum equation is integrated in time with a typical time step corresponding to $1/100^{th}$ of the characteristic period of the cardiac cycle (t=0.01 s). A snapshot of the characteristic flow pattern that corresponds to a period of deceleration of blood flow is shown in Fig.13-right. It can be seen that due to multi-branching geometry and adverse pressure gradients (during the period of deceleration in the cardiac cycle) flow reversals with already mentioned spiralling imprints are clearly visible. In parallel with solving the time-dependent velocity and pressure fields, distributions of the different classes of magnetic particles are also tracked and their deposition along the artery walls is analyzed. The imposed magnetic field originates from a state-of –the-art superconducting magnet that gives $|B|_{max}$~2.5 T at a distance of approximately 4.5 cm from the patient chest – mimicking a real application. In Fig.14-above, contours of the magnetisation force are shown. Fur such an imposed magnetic field, deposition efficiency is calculated and shown in Fig.14-below – for different time instants. It is immediately clear that the magnetic field significantly increases the deposition efficiency compared to the neutral situation (magnetic field off), Fig.14-left and Fig.14-right. The capturing efficiency for different particle diameters is shown in Fig.15. Different lines indicate different orientation of the superconducting magnet. Compared to the neutral case for which practically no significant levels of the deposition rates are observed, the case with active magnet reaches capturing efficiencies between 10 and 35 %- for the biggest particle diameters in 2 to 4 μm range. This result is very encouraging for possible future medical applications

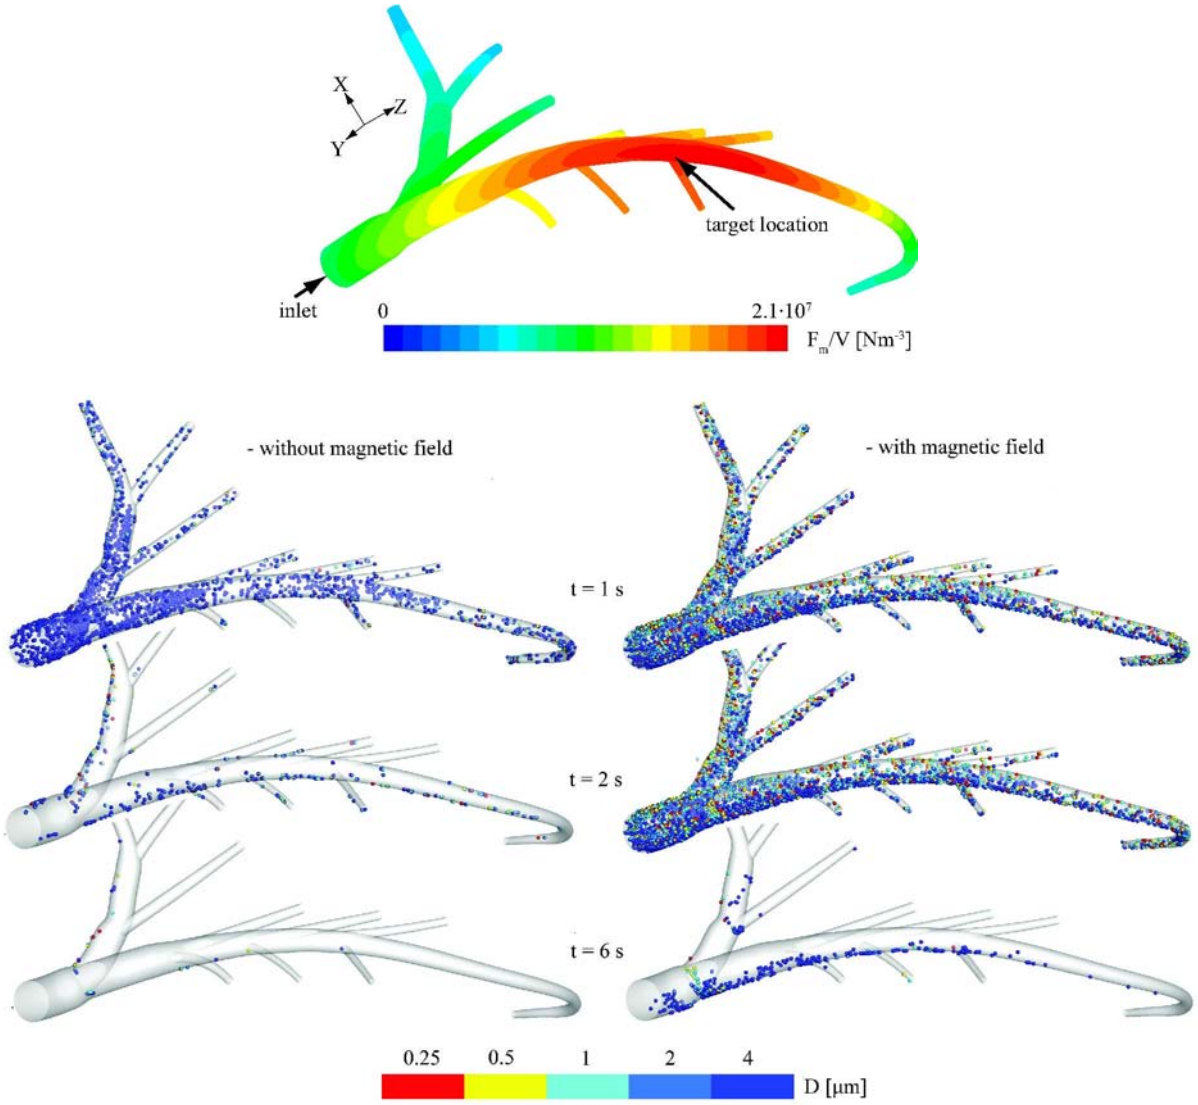

Figure 14. Simulations of the time dependency of magnetic particles depositions along the walls of the left coronary artery (LCA) subjected to an external magnetic field originating from a state-of-the-art superconducting magnet (with $|B|_{max}$~2.5 T) (different colours indicate different particle diameters – not to scale), Haverkoort and Kenjeres [26].

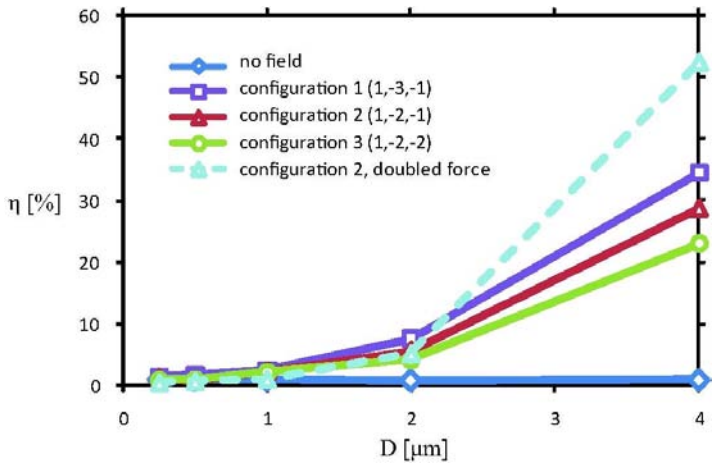

Figure 15. The capturing efficiency of magnetic particle carriers released in the left-coronary-artery (LCA) as a function of a particle diameter D for various superconducting magnet orientations, Haverkoort and Kenjeres [26]

of the magnetic drug targeting approach in fighting arteriosclerosis even for such challenging flow situations as occurring in the coronary arteries.

CONCLUSIONS

An overview of the recent achievements in the multi-scale modelling and simulations of complex interactions between fluid flow, heat transfer, turbulence and electromagnetic fields is presented. Three different classes of problems are considered including both the one- and two-way coupled interactions: 1- the single and multiple vortical flow patterns (draft tornados) generated by imposed electromagnetic field in a generic setup with and without heat transfer; 2- the mechanism of the self-generation of the magnetic field by turbulent swirling flow of liquid sodium in the Riga-dynamo experimental setup; 3- the magnetic capturing of nanoparticulates as a medical drug carriers released in a time-dependent pulsating blood flow inside of the left coronary artery. For first two applications, an extensive validation of the adopted multi-scale modelling approach is performed against available experimental results. A good agreement with available flow and magnetic field profiles are obtained for both configurations proving accuracy and potentials of the numerical simulations. The simulations also revealed some interesting phenomena for the very first time. A significant wall-heat transfer enhancement is obtained (up to 200%) in turbulent flow regime caused by targeted electromagnetic control of the wall-boundary layers. A fully integrated two-way coupled simulation of the experimental magnetic dynamo revealed process of the self-generation and self-sustenance of magnetic field under realistic working conditions. In contrast to the experimental data that are usually limited to the single point measurements in time, the numerical simulations provided a complete three-dimensional picture of flow and magnetic structures and their dynamical (time-dependent) evolutions. The last application demonstrated potentials of using numerical simulation in optimising the process of the local delivery of the medical drugs carried by magnetic nanoparticulates. The capturing efficiency is significantly increased when strong magnetic gradient are imposed even in such challenging case of the left coronary artery, demonstrating potentials of magnetic drug targeting technique in treating cardiovascular diseases.

DROPLET MICROFLUIDICS: FUNDAMENTALS AND APPLICATIONS

P. Garstecki, Krzysztof Churski
[1]Institute of Physical Chemistry, Polish Academy of Sciences,
Kasprzaka 44/52, 01-224 Warsaw, Poland

ABSTRACT. Microfluidic systems offer perfect control over formation of bubbles and droplets. In my lecture I will discuss the physical mechanisms underlying this control and the use of multiphase microfluidic systems for preparation of droplets, compound droplets, capsules and particles. Microfluidic systems allow also for a control of transport of droplets through topologically non-trivial microfluidic networks of channels. In such systems the droplets present in the network affect their trajectories via long-range interactions mediated through the pressure field in the channels. These interactions lead to fascinating dynamic behaviours. The recently developed techniques for computer controlled formation of droplets and guiding them through the channels open up completely new possibilities for constructing automated chips for analytical and synthetic chemistry.

Keywords: *microfluidics, droplets, automated systems, lab on chip*

Microfluidic systems offer perfect control over the processes of formation of droplets and bubbles. In the microfluidic devices it is possible to precisely tune all important characteristics of the emulsions: the volume, volume fraction and the frequency of formation [1-3] of droplets. It is also possible to form bimodal, multimodal and continuous distributions [4,5] of sizes, or to prepare emulsions comprised of distinct families of droplets of different sizes and chemical composition, and to tune their ratios of sizes and stoichiometry [6]. Also the architecture of individual droplets can be tuned: from multiple emulsions (i.e. drops-in-drops), with tuned hierarchy and stoichiometry [7,8], to preparation of capsules and solid particles [9,10].

These characteristics, coupled with a detailed understanding of break-up in confined systems [11-14], prompt for applications in i) preparation of 'perfect' emulsions and their derivatives for use in pharmacology, cosmetics, and food industries, and ii) use of droplets as micro-reaction-beakers for automated, parallel chemical and biochemical analyzes and for chemical synthesis.

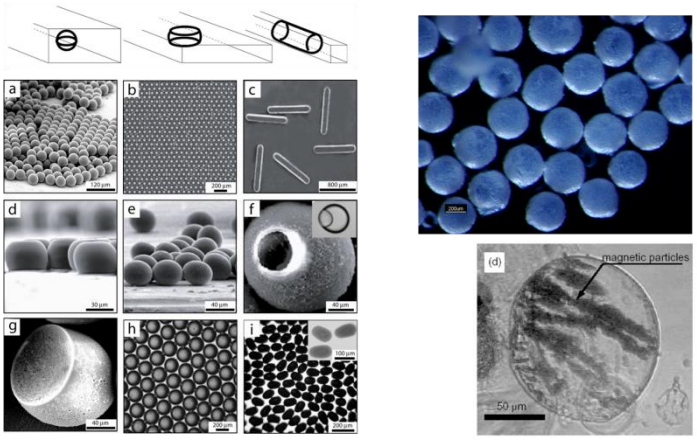

Figure 2. Examples of use of microfluidic methods of forming droplets for formulation of new materials: anisotropic particles [10] (left pane) and polymeric capsules [9] (right pane).

In the lecture I will discuss the mechanism behind the observed monodispersity of the droplets and bubbles formed in microfluidic systems. This mechanism rests on the stability of interfaces in confined geometries of microfluidic junctions [11, 12, 15] and on the separation of time-scales between fast equilibration of the interface and disturbances in the pressure field, and slow progression of the flow (as reflected by usually small values of the capillary number). The ability to form perfectly monodisperse foams and emulsions [11,12,15] and further particles [10], capsules [9] and compound droplets [16-18] may lead to applications in formulation of new materials for use in pharmacy, cosmetics and food industries.

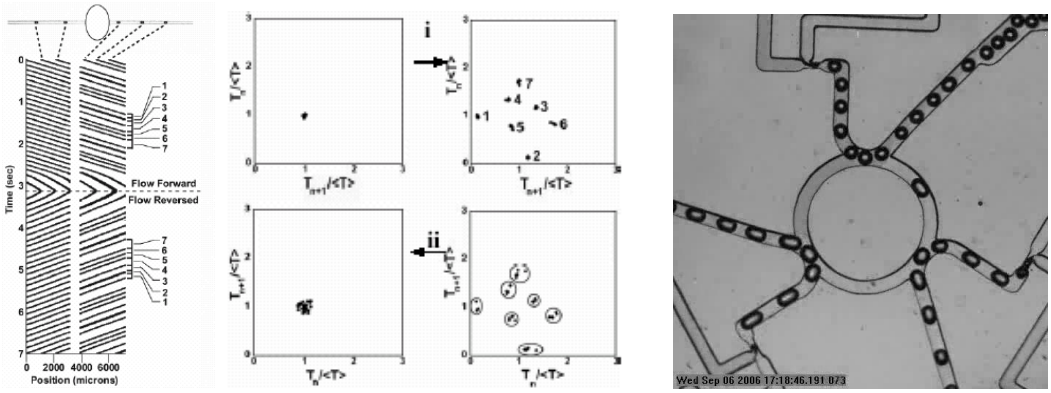

Figure 3. (left) demonstration of reversibility of the complex flows of droplets in microfluidic networks [21], (right) a microfluidic ring oscillator [22]

Another use of microfluidic droplet systems is to perform reactions within droplets [19]. Several simple demonstrations of analytical, and synthetic screens have been reported [19]. Extending the current capabilities of microfluidic droplet based systems for more advanced applications in chemistry requires i) understanding of the dynamics of transport of droplets through networks of microchannels [20-23]., and ii) construction of tools for computer controlled formation and guiding of droplets. Recent experiments [20] have demonstrated that the properties of flow of droplets in capillaries (e.g. the increased resistance to flow introduced by the droplets) can be used to perform elementary but non

trivial schemes of processing of sequences of droplets, as for example coding and decoding [21] or logic operations [22]. These demonstrations, together with the apparent robustness of such operations to experimental disturbances or noise [21] suggest that it should be possible to design and operate automated chips performing non trivial operations (e.g. merging, splitting, distributing in the network) on the micro reaction vessels (droplets). I will describe the current state of art in formation of droplets on demand in microfluidic systems and the prospects for designing fully automated combinatorial lab-on-chip systems.

ABSTRACT. It is thought that the skin texture on human skin influences its appearance and a fine texture of skin makes the skin beautiful. However, it has not been clarified how the skin texture influences its appearance. In this study, to clarify the scattering characteristics at the skin surface, an experimental study using an optical prism with skin structure has been performed, and to understand the experimental results, three numerical models have been developed. A model takes into account comparatively large skin structure, which is called "skin texture," and another model considers the finer structure called "microstructure." The other is a combined model of the two models. The results predicted by the models that consider the microstructure are in good agreement with the experimental one. This reveals that the skin texture does not affect the light scattering by skin surface, but the microstructure finer than the skin texture.

Keywords: *Radiation, Radiative Properties, Human skin, Skin Texture, Appearance*

INTRODUCTION

A phrase "kime komayakana" is one of expressions to describe beautiful human skin in Japan. The word "kime" represents grooves on the skin surface, and the word "komayaka" means that the grooves or the structure confined by grooves are fine or small. Since a skin with the fine structure looks beautiful, the phrase "kime komayakana" may be used for representing beautiful skin. We are not sure of this, however, it is empirically thought the structure on skin surface affects appearance of human skin. Therefore, many studies have been carried out so far.

In those studies, researchers try to clarify the effect of the surface structure on appearance for human skin. However, since the reflection by human skin contains surface reflection at the skin surface and internal scattering inside the skin, the appearance does not depend on only the skin surface but also inside optical characteristics of human skin. This means that observation or experimental study using actual human skin cannot clarify the effect of the surface structure of the skin on its appearance.

The final goal of this study is to clarify what and what optical characteristics beautiful skin comes from, and to develop cosmetics that reproduce the optical characteristics of beautiful skin. To do this, it is necessary to individually evaluate how the surface reflection and the internal scattering influence the appearance of human skin. The purpose of this study is to experimentally investigate the optical characteristics of skin surface and to clarify the effect of the surface structure on the optical characteristics by using numerical models.

In this study, to set the surface reflection by the skin structure apart from the internal scattering inside the skin, an optical prism having a surface structure of skin is prepared and a scattering characteristic is measured. In order to understand what the measured scattering characteristic comes from, three models are proposed and compared with the measured results. A model taking into account microstructure much smaller than the skin grooves is in good agreement with the measured results.

SCATTERING CHARACTERISTICS OF SKIN SURFACE

To avoid the effect of the internal scattering inside the skin and to evaluate the effect of the surface reflection at the skin surface, an optical prism on which a surface structure of skin was printed was fabricated (Fig. 1). When the skin surface on the prism is irradiated by incident light, a part of the light penetrates into the prism. However, the light is not scattered in the prism because the prism is transparent. Using this prism, the scattering characteristics of the skin surface can be evaluated.

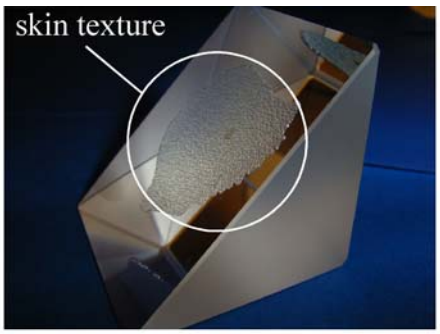

Fig. 1 Surface Structure of Skin Printed on an Optical Prism

The prism is made of BK7, and its reflective index is close to the refractive index of human skin, which depends on the water content and is around 1.5. The surface structure of skin is fabricated by UV light curable resin AT3925M (NTT Advanced Technology, Co., LTD.) on the prism surface. The refractive index of this resin can be controlled. In this study, the refractive index of the resin is adjusted to that of prism so that difference in refractive index between the resin and the prism is not given rise to. The skin structure printed on the prism is taken from an inner arm of man aged 22 years.

In the experiment, the skin surface on the prism is irradiated by parallel beam having a diameter of 5 mm and the light reflected by the surface structure is measured. A He - Ne Laser (632.8 nm) is used as the incident beam, and an optical fiber with a receiving lens having narrow view angle (0.6×10^{-3} sr) is used to detect the reflected light. The measurements are performed 6 times at different positions.

To evaluate the appearance of skin, the bi-directional reflectance is adopted. The definition of the bi-directional reflectance, ρ'', is [1]

$$\rho''(\theta_{in},\theta_r,\phi_r) = \pi I(\theta_r,\phi_r)/q_{in}(\theta_{in}) \tag{1}$$

where q_{in} is the radiative flux of the incident light, and I is the intensity of reflected light. θ_{in}, θ_r, ϕ_r are the polar angles of incident light and reflected light, and the azimuthal angle measured from the direction of the incidence, respectively. The measured results are converted to the bi-directional reflectance. The profiles of the bi-directional reflectance on the incident plane, which contains both the axis of the incident beam and the axis normal to the surface, are shown in Fig. 2.

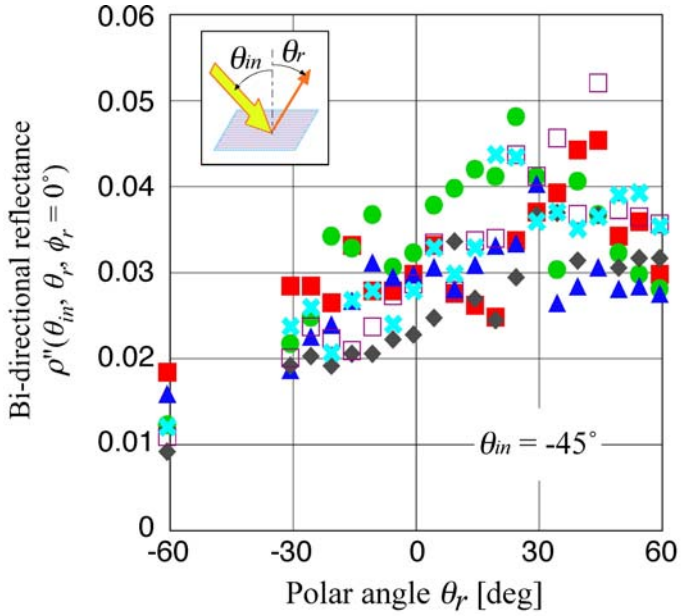

Fig. 2 Experimental results for Reflection by Surface Structure of Skin

The results of θ_{in}, = -45˚, which is the incident angle of light, are shown in this figure. Any peak cannot be seen around 45˚ in θ_r, which is the specular direction corresponding to the incident direction. This means the skin surface diffusely reflects the incident light, and it is found that the skin surface has an optical characteristic that the strongly reflection occurs in the direction along the surface (large θ_r).

In this study, to understand what these scattering (reflection) characteristics come from, three models are proposed and compared with the measured results. The numerical models will be described in the following.

NUMERICAL MODELS FOR SKIN STRUCTURE

Geometric configuration for the surface structure is measured using a confocal laser-scanning microscope (CLSM) to construct the numerical models. The result is shown in Fig. 3. The imaged area of skin is about 2.5 x 2.5 mm^2. Brightness in this figure represents depth of structure. Deep grooves are brightly shown. It can be seen that there are comparatively larger grooves configuring

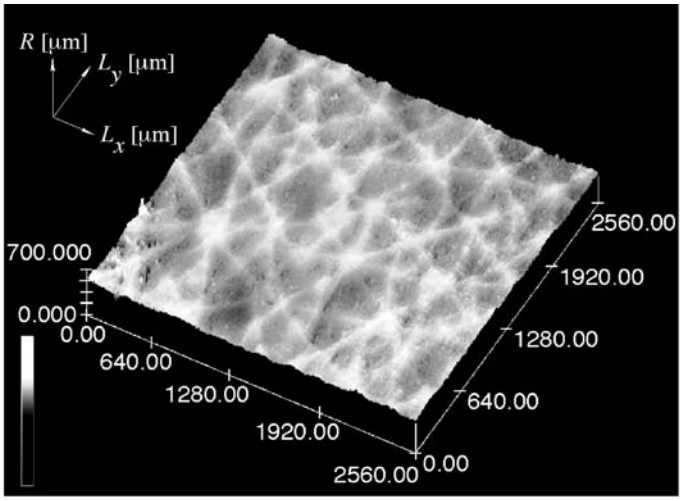

Fig. 3 Surface Structure of Skin Imaged by a Confocal Laser-scanning Microscope

triangle networks and smaller structures over the surface. In this study, larger groove structure is called "skin texture" and smaller structure is called "microstructure."

Numerical models have been constructed based on the CLSM image. Figure 4 shows a model (Model A) that takes into account only the "skin texture." The "microstructure" is not considered in this model. The depth of grooves and the size of the triangle network have determined from the CLSM image. It is assumed that the scattering at the surface is induced by the reflection and the refraction at the interface between the two media that have different refractive indexes. The reflection and the refraction are assumed to follow the geometric optics governed by Fresnel's relations.

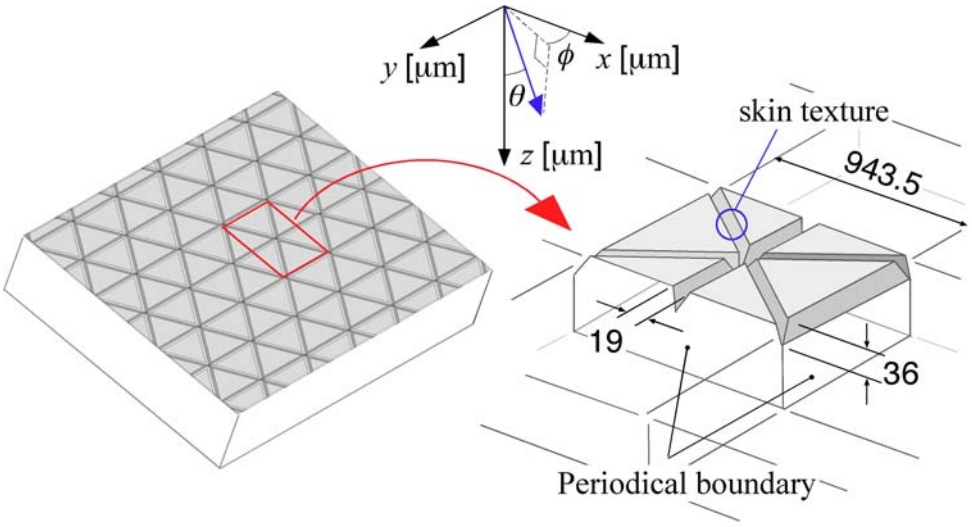

Fig. 4 Model A: Numerical Model Taking into Account "Skin Texture"

Another model (Model B) does not take into account the " skin texture" but the "microstructure." In this model, it is assumed that the scattering at the surface with the "microstructure" is induced by the reflection and the refraction at the interface. This is the same as Model A. However, the actual microstructure is not placed on the surface. The microstructure is treated statistically. The concept and the feature of this model are as follows.

When an ideally fine beam of light hitting on the skin surface meets a small element of surface on microstructure, the light is reflected by or transmitted through the small surface element. If it is assumed that the reflection and/or the transmission follow geometric optics, as mentioned before, only the direction of the small surface element is necessary to determine the reflected or transmitted direction. Generally, since the skin surface is widely irradiated, the incident radiation hits many small surface elements on microstructure that are oriented at varied directions, if we know the directions of the small surface elements, we can evaluate the radiation scattering. Therefore, we propose a method for statistically determining the directions of small surface elements on microstructure. In this study, we give the probability for the direction of the small surface element that the incident light hits.

To give the probability for the direction of the small surface elements, we utilize the geometric configuration of the microstructure measured by the CLSM. The CLSM image stores digital data for height of the surface structure every 2.5 μm. When a surface element is taken by neighboring three data points, as shown in Fig. 5, the direction, the polar and the azimuthal angles, θ_e and ϕ_e of the surface element can be determined. We checked up on the directions of the whole surface elements imaged by the CLSM and derived the probability density function for the direction of the surface elements, $p(\theta_e, \phi_e)$. When $\Delta M(\theta_e, \phi_e)$ is the number of surface elements that face to a

small solid angle, $\Delta\Omega_e$ around θ_e and ϕ_e, and the total number of the surface elements is M_{tot}, the probability density function, $p(\theta_e, \phi_e)$ is determined by

$$p(\theta_e, \phi_e) = \lim_{\Delta\Omega_e \to 0} \frac{\Delta M(\theta_e, \phi_e)}{M_{tot}\Delta\Omega_e} \tag{2}$$

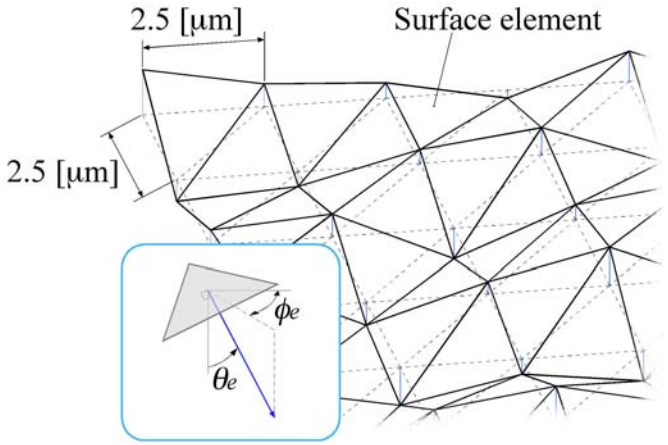

Fig. 5 Model B: Numerical Model Taking into Account "Microstructure"

When the incident light hits a surface element, the direction of the surface element is not determined by the above probability density function, because it also depends on the projected area to the incident direction of the surface element. Therefore, by taking into account the projected surface area, the probability density function for the incident light with the incident angle of θ_{in} is given by,

$$f(\theta_e, \phi_e, \theta_{in}) = \lim_{\Delta\theta_e \to 0, \Delta\phi_e \to 0} \frac{\int_{\Delta\Omega_e} p(\theta,\phi)\, A(\theta,\phi,\theta_{in})\, d\Omega}{\sin\theta_e \Delta\theta_e \Delta\phi_e} \cdot \frac{1}{\oint_{\Omega=2\pi} p(\theta,\phi) A(\theta,\phi,\theta_{in}) d\Omega} \tag{3}$$

where $\Delta\theta_e$ and $\Delta\phi_e$ are the small increments of angle around θ_e and ϕ_e, respectively, and $\Delta\Omega_e = \sin\theta_e \Delta\theta_e \Delta\phi_e$.

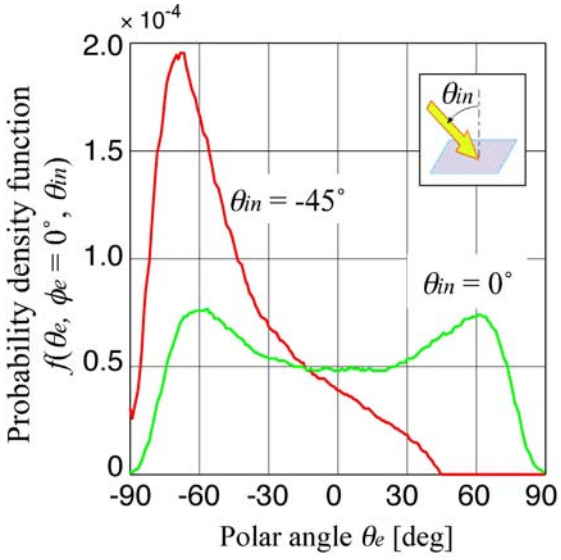

Fig. 6 Probability Density Function for Orientation Angle of Surface Elements on Microstructure

The probability density functions for θ_{in} = 0˚ and -45˚are shown in Fig. 6. It is found that the function is symmetric for the normal incidence of light (θ_{in} = 0˚) because the surface elements are randomly oriented in the azimuthal direction and is azimuthal symmetric. It is also found that the function is zero for 45˚ < θ_e when θ_{in} = -45˚. The reason for this is the incident light does not hit surface elements oriented to a polar angle larger than 45˚.

The third model (Model C) is a combined model of Model A and Model B. This model takes into account both the "skin texture" and the "microstructure."

RESULTS AND DISCUSSION

The bi-directional reflectances of the three models are numerically evaluated using a Monte Carlo method. The results are shown in Fig. 7. In this calculation, it is assumed that the incident light is parallel and uniform and has an incident angle of 45˚ so that the results can be compared with the experimental results.

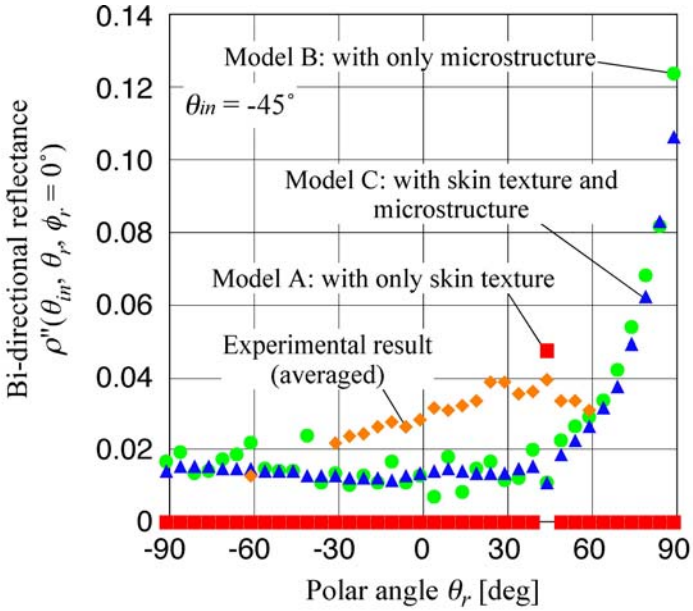

Fig. 7 Comparison between Numerical Results and Experimental Results

For Model A, the profile of reflected light depends on the incident axis of light and the orientation of the skin texture. Although the skin texture on an actual skin is randomly oriented, the skin texture in the model is not. Therefore, in the calculation, we calculate the profiles of reflected light varying orientation of the skin texture all over the azimuthal directions and average the calculated profiles. The resultant profile is shown in Fig. 7 with red square symbols.

Figure 7 reveals that the numerical results using Model A does not agree with the experimental result at all. Since we do not consider the "microstructure" in this model, only the strong specular reflection occurs. A peak in the numerical results represents the strong specular reflection. On the other hand, it is found that the numerical results for Model B and C, shown with green circle and blue triangle, respectively, are in good agreement with the experimental results in magnitude, although the profiles are not. Furthermore, it is found that the numerical results of Model B and C are almost the same. This means the scattering by the skin surface does not depend on the "skin texture" but the "microstructure."

There are discrepancies between the numerical results and experimental ones in profile of the bi-directional reflectance. Especially, the increase at large polar angles in the numerical results cannot

be seen in the experimental results. This can be due to diffraction effects that are not considered in the numerical models.

CONCLUSIONS

To clarify the scattering characteristics at the skin surface, an experimental study using an optical prism with skin texture has been performed, and to understand the experimental results, three numerical models have been developed in this study. A model takes into account comparatively large skin structure, which is called "skin texture," and another model considers the finer structure called "microstructure." The other is a combined model of the two models. The results predicted by the models that consider the microstructure are in good agreement with the experimental one. This reveals that the skin texture does not affect the light scattering by skin surface but the microstructure finer than the skin texture.

EXPERIMENTAL SIMULATION OF A THERMALLY SIGNIFICANT BLOOD VESSEL IN A TISSUE SUBJECTED TO CRYO-SURGERY

N. Rybko, A. Shitzer*, D. Degani
Department of Mechanical Engineering
Technion, Israel Institute of Technology, Haifa, Israel 32000

ABSTRACT. The influence of a thermally significant blood vessel on a tissue phantom, during freezing by a liquid Nitrogen operated, circular, surface cryo-probe was investigated. The medium used in the experiments was a 0.2% mass concentration Bacto Agar/distilled water solution. The blood vessel was simulated by a 5.4/6 mm ID/OD brass-alloy tube. The experiments were conducted under several flow rates of constant temperature water in the embedded tube: no flow, 30, 100 and 200 ml/min. Cryo-probe cooling rates applied on the surface of the medium varied from -4.4°C/min to -9.2°C/min. The advancement of the frozen front was tracked by thermocouples placed in the medium. Results indicate reductions in the extents of the total frozen areas under the cryo-probe of about 42% due to the highest flow rate vs. no-flow in the tube, and 53% by applying the highest vs. the lowest cryo-probe cooling rate.

INTRODUCTION

Cryo-surgery is a medical technique used for destroying undesired tissues by the application of controlled localized freezing. The treatment is performed by a cryo-probe, which may be placed either in contact with the tissue surface, or inserted into the targeted tissue. The treatment can be applied as a stand-alone or in conjunction with other conventional surgical techniques. Current applications of cryo-surgery include the treatment of a variety of malignancies in the liver, prostate, skeleton bones, womb, skin and benign hemorrhoids. Although this technique has many advantages, it still falls short of being the treatment of choice, especially because of the uncertainty regarding its long term effects and success rate.

Investigators suggest several criteria for the success of the treatment. Apparently, the most important of these is the cooling rate maintained at the tissue freezing front [1]. Experimental evidence obtained from tissue cultures, suggests that at both very high cooling rates, of hundreds of degrees Celsius per minute, and at very low cooling rates, of up to several degrees Celsius per minute, the tissue may be lethally damaged as a result of two different mechanisms. Another important criterion for the success of the cryo-surgical procedure is the minimal temperature reached in the tissue during the treatment. Current practices assume maximal tissue-specific "lethal" temperatures of -5°C to -50°C [2].

Thermal perturbations which are present in the treated region, e.g., large blood vessels (artery or vein) that traverse the targeted area, may distort the temperature field and modify the rate and extent of freezing. This thermal perturbation could affect the achievement of the desirable end result, or it could prevent parts, or even the whole volume of the malignant tissue from being frozen. Thus,

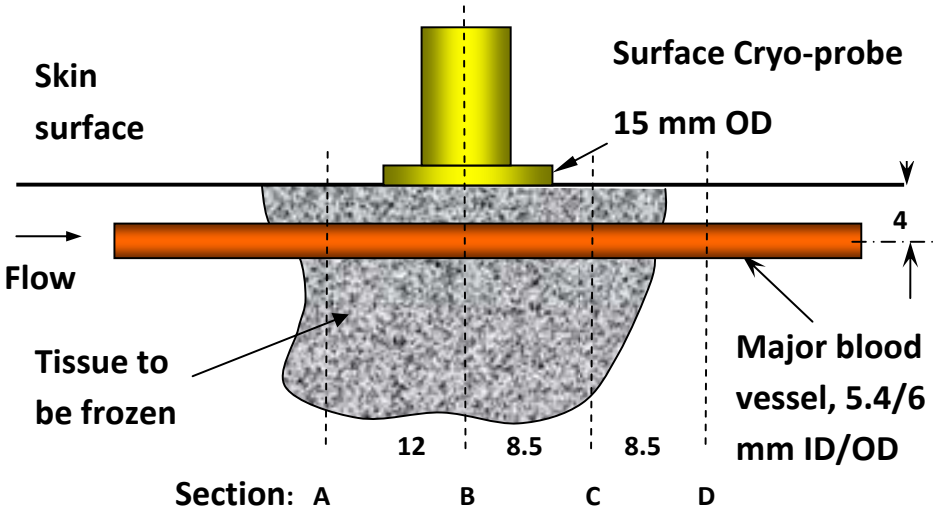

Figure 1. Schematic view of the tumor, blood vessel and surface cryo-probe

understanding the evolution of the temperature field that develops in the vicinity of a cryo-probe in the presence of such a thermal perturbation could be useful in the design and application of a cryo-surgical procedure and increase its probability for greater success.

The purpose of this study is to investigate experimentally the influence of a simulated thermally significant blood vessel on a tissue phantom, while it is being frozen by a circular, liquid Nitrogen operated, surface cryo-probe (Figure 1). The medium used in the freezing experiments was a 0.2% mass concentration Bacto Agar/distilled water solution. The thermo-physical properties of this solution closely approximate those of a biological tissue. The blood vessel is simulated by a 5.4/6 mm ID/OD brass-alloy tube.

EXPERIMENTS

Experimental setup

Detailed description of the experimental setup is given by Rybko [3] and by Massalha and Shitzer [4]. Only essential details are repeated here. The setup consisted of the following four subsystems (see Figure 2):

Liquid nitrogen (LN_2) freezing system. The cryo-surgical system (Model CS-13-A, RICOR, Israel) consisted of an LN_2 storage Dewar, a flat, circular, surface cryo-probe (brass, 15 mm OD) connected to an insulated, flexible delivery tube and a PC-based control system.

Test section. A rectangular support frame, made of two plexiglass plates, held both the embedded tube (the "heat source") and the thermocouple wires. The embedded tube, simulating large blood vessels in the human body, was made of a thin wall circular brass-alloy tube 5.4/6 mm in diameters. The tube was placed at a centerline depth of 4 mm parallel to the surface of the PCM on a plane coinciding with the centerline of the cryo-probe. The tube was perfused by 26ºC constant temperature water. The test section was filled with the phase-changing medium (PCM, 0.2% mass concentration Bacto Agar/distilled water solution) and was placed in an inner cylindrical container which was fitted, flush at the top, inside an insulated, outer cylindrical container. The free volume between the bottoms and sides of the two metal containers was used for circulating temperature-controlled water to maintain a constant temperature at the outer surfaces of the PCM contained

inside the inner container. A schematic layout of the test section is shown in Figure 2.

The water circulating system. Constant temperature water was supplied to the embedded tube and into the volume between the outer and inner containers. Water flow rate in the embedded tube was continuously monitored by a turbine flow meter.

Temperature measuring system. A total of 40 Teflon-coated, Type K (chromel-alumel) thermocouples (TCs), made of 0.25 mm wires with 0.076 mm coating (OMEGA Engineering), were used: 7 to measure the temperatures of the water flowing through the embedded tube (Figure 3) and the remaining 33 to monitor the temperatures of the PCM (Figure 4). The thermocouple junctions were welded by an electrical arc and were placed in the PCM on four separate planes perpendicular to the
embedded tube (Sections A to D in Figure 1). Placement was done at alternate lateral locations on a 5x5 mm grid to minimize thermal perturbations, as shown in Figure 4. Two additional Type T (copper- constantan) TCs were inserted into the bottom part of the cryo-probe. The thermocouple wires were

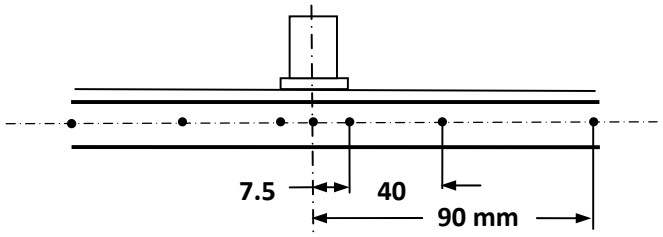

Figure 3: Thermocouple placements in the embedded tube

connected to a PC through a multiplexer and were scanned every 1 sec with a sampling rate of 25 samples/sec.

Experimental procedure

The experiments were conducted under several flow rates of constant temperature water in the embedded tube: without flow, 30, 100 and 200 ml/min. Cooling rates applied on the surface of the PCM by the cryo-probe varied from -4.4°C/min to -9.2°C/min. Tracking the advancement of the frozen front was done by the aforementioned TCs. Each experiment was performed with the same initial and boundary conditions, which were achieved by circulating water at a uniform temperature of 26°C through the system for several hours prior to the initiation of the freezing process.

RESULTS

Figure 5 shows the effects of the highest flow rate used in the embedded tube, 200 ml/min, on the propagating temperature fronts at the various measuring sections in the PCM. These fronts were drawn by interpolating the readings of the various TCs. Results are shown at 1055 seconds after the initiation of the cooling process when the cryo-probe temperature reached -95ºC. Section B, which coincides with the cryo-probe centerline, and which was instrumented with the most thermocouple junctions, exhibits temperature regions from 20ºC to -60ºC. A symmetrical pattern is established in

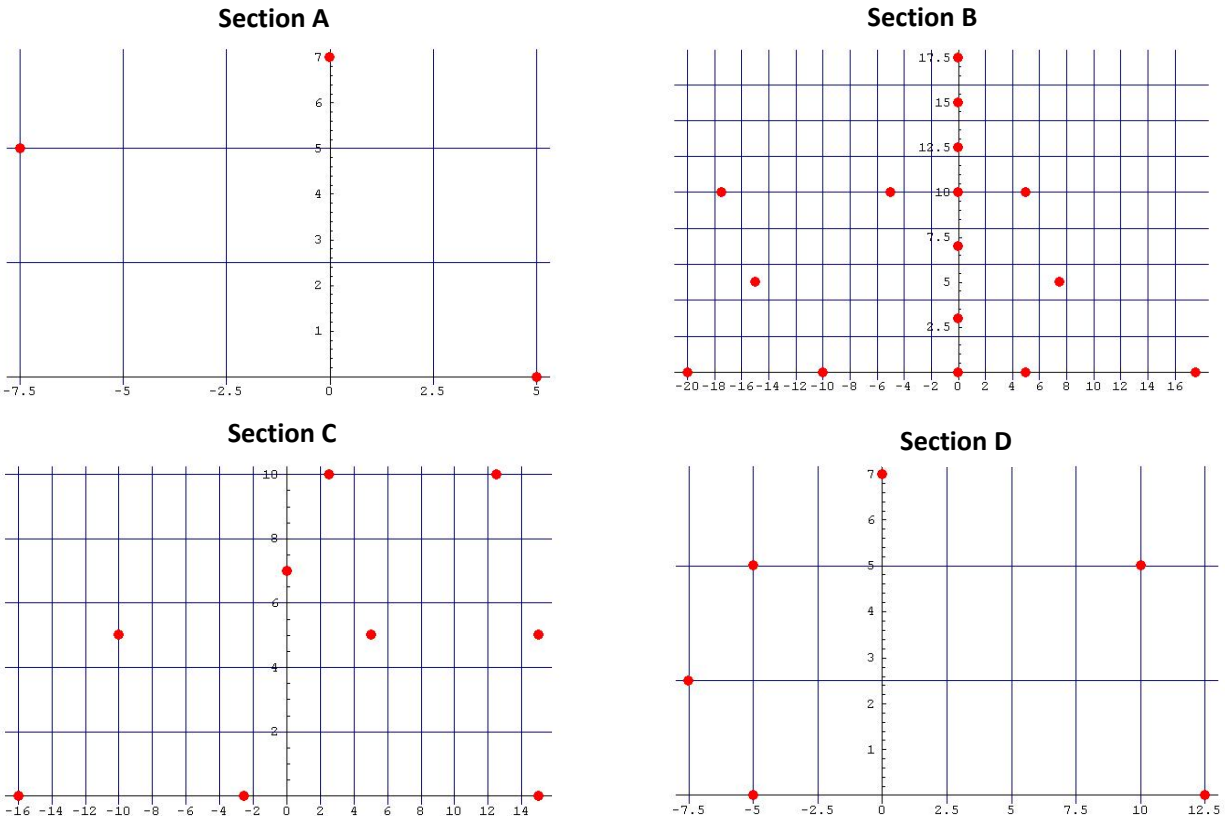

Figure 4. Thermocouple placement in the PCM (hereinafter cryo-probe placed at (0,0))

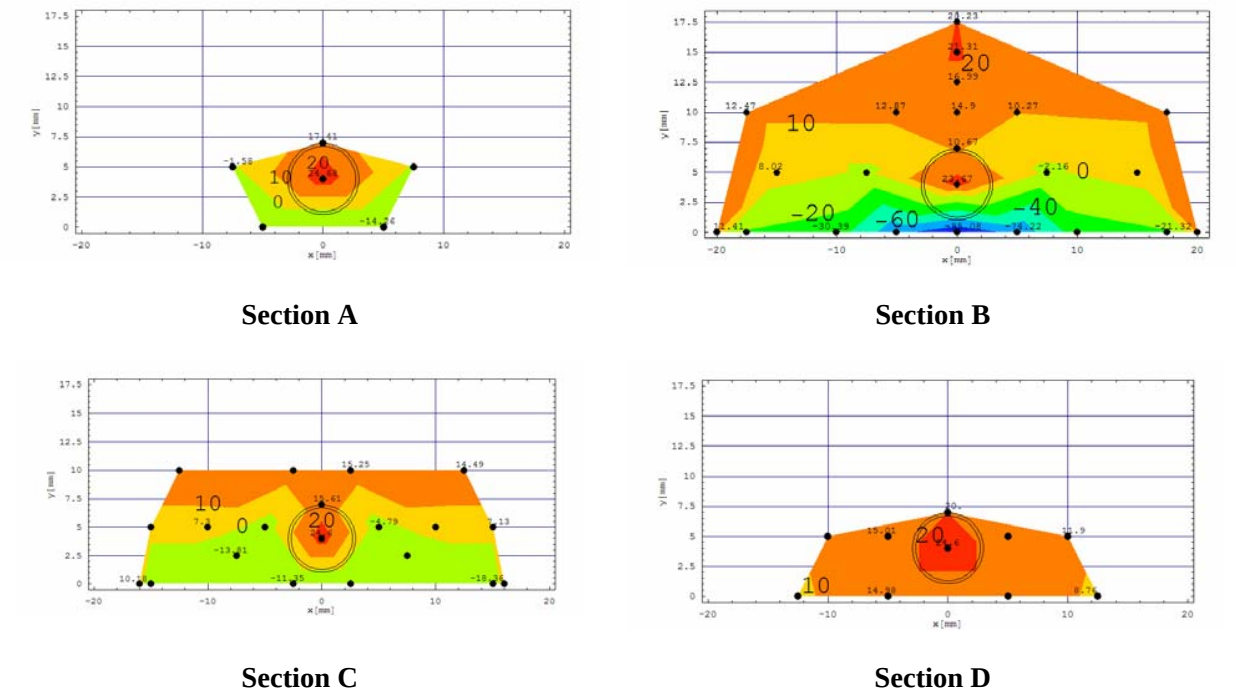

Figure 5. Effect of 200 ml/min flow rate in the tube on temperature distributions in the PCM at the various measuring sections. Cryo-probe temperature -95ºC after 1055 seconds

the PCM with the isothermal boundaries spreading sideways due to the heating effect of the embedded tube. No temperatures below freezing are observed above the tube (figures 4 to 7 are inverted with the cryo-probe assumed to be placed at (0,0), as per Figure 4). Temperature variations in the other sections are less pronounced with temperatures staying above -20ºC in Sections A and C. Temperatures below 0ºC were not detected in Section D located 17 mm from the cryo-probe centerline.

The effects of the various flow rates in the tube on temperature distributions in Section B of the PCM are shown in Figure 6. In the experiment without flow in the tube, the area that reached temperatures lower than -40°C (considered as “lethal” temperature in certain applications) was about 30% of the total frozen area at that Section. This area was smaller, at about 16 to 20% of the total frozen area, in the experiments with the various flow rates in the tube. At the lowest flow rate used, 30 ml/min, partial freezing was observed to occur inside the tube. As was to be expected, the experiment without flow in the tube differed significantly from the other experiments. In this experiment, the tendency of the frozen region to form a spherical-like ice ball was clearly seen (top left, Figure 6) and the stagnant water in the tube froze completely. Seen clearly in this figure are also the "suppression" and sideways spreading effects of the increased flow rates on the advancement of the freezing front into the PCM.

The effects of cryo-probe cooling rates on the temperature distributions in Section B in the PCM are shown in Figure 7. Three cooling rates were employed: -9.2, -6.6 and -4.4°C/min. In all cases the final cryo-probe temperature was -95ºC and the flow rate in the tube was 200 ml/min. This condition dictated different experimental times for the various cooling rates; the lower the rate the longer the application time. Due to this operational strategy, the largest frozen area was obtained

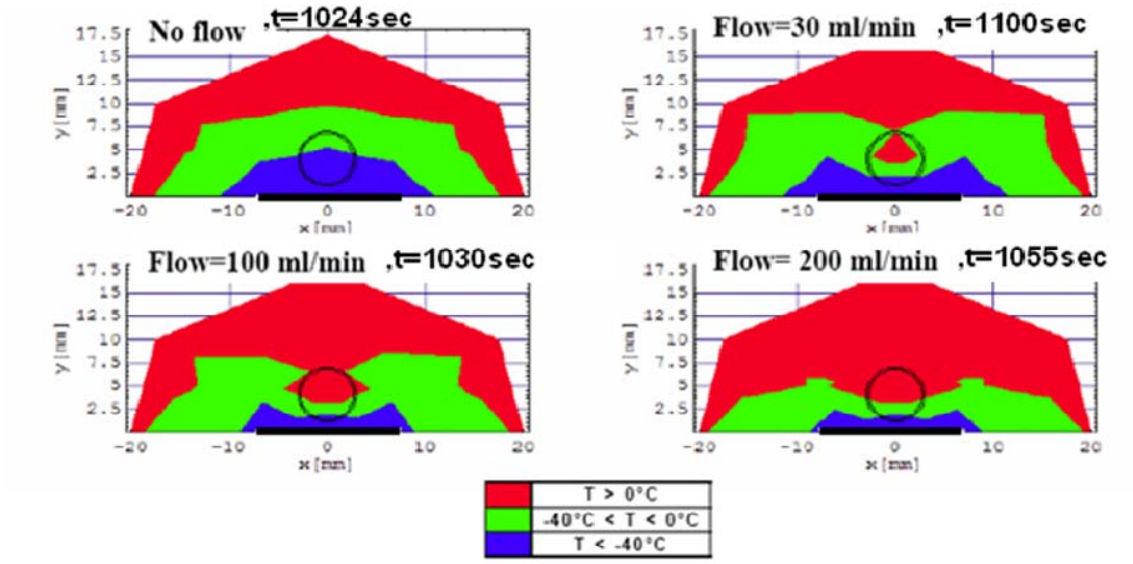

Figure 6. Effects of flow rates in the tube on temperature distributions in the PCM. Section B.

for the lowest cooling rate used which was operated for the longest time. Table 1 summarizes the total frozen areas, and the relative areas that reached the "lethal" -40ºC observed in Section B for all flow and cooling rates employed.

Finally, Figure 8 shows temperatures measured along the centerline of the embedded tube for the various flow rates. Connecting lines are drawn for illustration purposes and do not reflect actual variations. Data are shown after about 1000 seconds of operation when the temperature of the cryo-probe had reached -100ºC. It is seen that for both the case without flow in the tube, and the lowest flow rate used (30 ml/min), water temperatures fell below freezing in the tube. The higher flow rates used prevented this from occurring and, furthermore, resulted in essentially constant water temperatures in the tube.

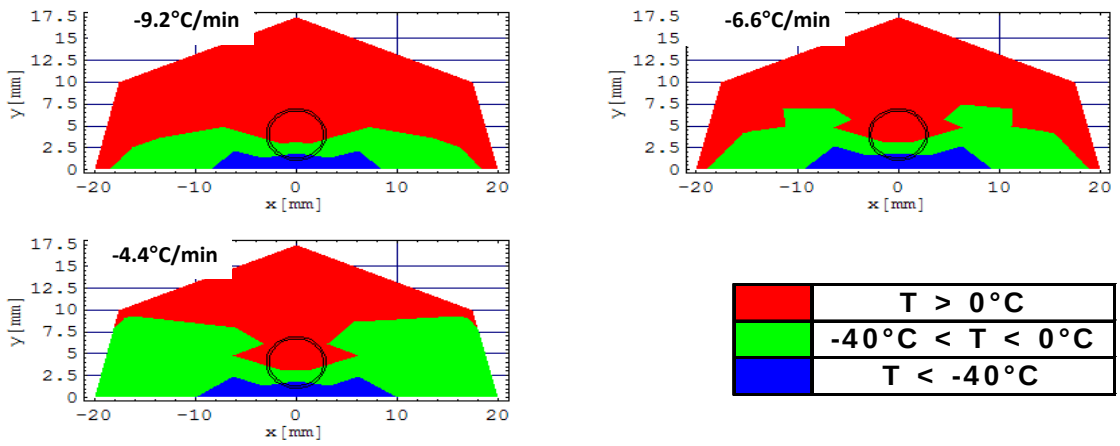

Figure 7. Effects of cryo-probe cooling rates on temperature distributions in the PCM. Section B.

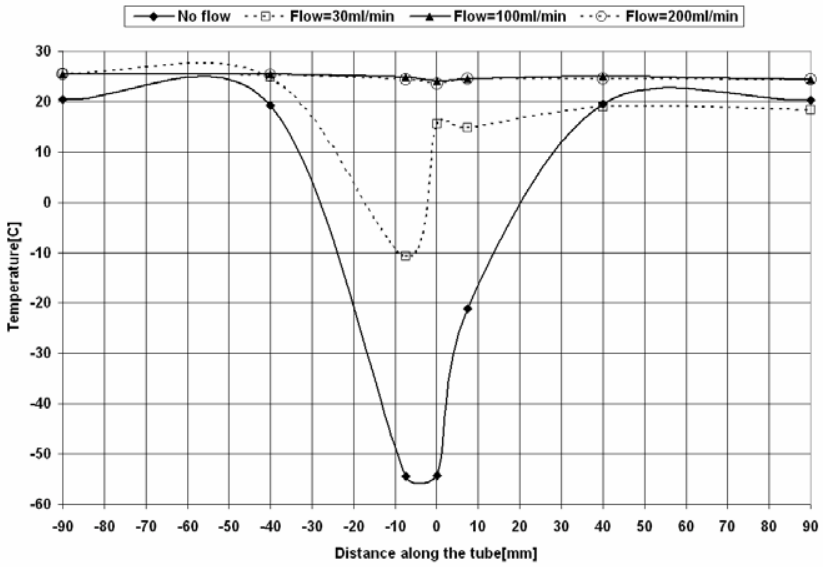

Figure 8. Temperature distributions along the centerline of the embedded tube for the various flow rates when the cryo-probe temperature reached -100ºC (after about 1000 seconds).

TABLE 1
Total frozen areas and areas below -40ºC in Section B for different flow and cooling rates.

	Total frozen area (mm^2)	*Frozen area below -40ºC (mm^2)*	*Percentage frozen area below -40ºC (%)*
Flow rate (ml/min)		Cooling rate = - 9ºC/min	
0	257	76	30
30	270	54	20
100	216	35	16
200	148	28	19
Cooling rate (ºC/min)		Flow rate = 200 ml/min	
-9.2	131	26	20
-6.6	175	33	19
-4.4	281	30	17

CONCLUSIONS

The effects of an embedded, warm-fluid carrying tube during freezing of a phase-changing medium (PCM) were studied experimentally. Freezing was performed by a surface cryo-probe operated by liquid Nitrogen. Two parameters were varied: (a) flow rate in the embedded tube, and, (b) cooling rate of the cryo-probe surface. In the first series of experiments cryo-probe cooling rate was maintained at -9ºC/min. As was to be expected, increasing the flow rate of the warm fluid in the tube, diminished the extent of the total frozen volume in the PCM. In the plane coinciding with the tube centerline, total frozen area decreased from about 257 mm^2 for no flow in the tube, to 148 mm^2 for

200 ml/min flowing in the tube, a 42% area reduction. Similar frozen area reduction proportions were obtained for the areas bounded by -40ºC which is considered to be the "lethal" temperature for cell destruction in certain cryo-surgical applications. The second series of experiments consisted of a constant flow rate of 200 ml/min in the tube. Cooling rates applied by the cryo-probe until the final cryo-probe temperature reached -95ºC, ranged from -4.4ºC/min to -9.2ºC/min. Under these conditions the largest frozen area in the above plane was obtained for the lowest cooling rate, which was operated for the longest time, at some 281 mm^2. The highest cooling rate produced only 131 mm^2 of frozen area, a 53% area reduction. Results for the areas bounded by the "lethal" temperature were significantly different with only a 13% area reduction for these two cooling rates. Results of this study quantify the effects of both these parameters which should be considered during the planning and application of cryo-surgical procedures.

ELECTRICAL CLASSIFICATION OF SINGLE RED BLOOD CELL DEFORMABILITY IN HIGH SHEAR MICRO-CHANNEL FLOWS

Y. Katsumoto, K. Tatsumi*, T. Doi, K. Nakabe
Kyoto University, Kyoto, Japan

ABSTRACT. Measurement of human red blood cell (RBC) deformability in a micro-channel using electric micro-sensors is proposed and carried out in this study. The time series of the electric resistance is measured using an alternative current vs. voltage (I-V) method as the RBCs deformed by high shear flows individually pass between the electrodes. The resistance distributions vary in relation with the RBC shape, which depends on the cell deformability under the condition of a constant shear stress produced by the flow. Experiment is carried out with the samples of normal and glutaraldehyde treated (rigidized) RBC to evaluate the feasibility of the present method.

Keywords: *Micro-channel, Red blood cell, Deformability, Micro electric resistance sensor*

INTRODUCTION

Measurement of the deformability of a red blood cell (RBC) is an important issue in terms of not only investigating the hydrodynamic characteristics of the blood such as fluid viscosity and electric permeability[1], but also diagnosing initial symptoms of diseases in clinical investigation. For example, in *Plasmodium falciparum*, which is one of the most virulent diseases causing severe anaemia in number of tissues and organs[2], the deformability of the RBC is significantly reduced due to the increase of the internal viscosity and rigidization of the cytomembrane caused by having the plasmcytoskeleton of the RBC bounded with the neoantigens during the parasite, even in the early 'ring' stage[3]. Therefore, developing a technique which can evaluate the deformability of the RBC with low cost, short time and simplified procedure would provide a large contribution in the medical fields particularly in clinical testing[3,4].

There are several typical measuring schemes to evaluate the RBC deformability. The one using viscometer[5] evaluates the deformability of the bulk RBC solutions from the fluid viscosity. The one using a rheometer with coaxial rotating cylinder applies shear stress on the RBC and measures the deformability visually[6]. Measurement using optical tweezers[7] or micro-glass pipettes[8] stretches single RBC and evaluates the extension rate. However, the accuracy of the former two measuring schemes is low especially when the number density of infected RBC is small. This is not preferable for clinical test of diseases in the early stages. On the other hand, the latter two can evaluate the deformability of each single RBC whereas the available sampling number of RBC is limited.

The motivation of the present study is to develop a micro sensor which can measure the deformability of a single RBC using hydrodynamic stresses and electrical sensors applied in a micro-channel. Recently, Korin et al.[9] visualized the behaviour of RBCs in a micro-channel and measured the cell deformation by analysing the images of the cells stretched by the high shear flow. The usage of the micro-channel has the advantage in reducing the cost, measuring time, and sample volumes. Their method, however, requires high spatial resolution image recording equipment, which may increase the cost and impair the compactness of the application. In contrast, the sensor proposed in the present study is based on an electrical measurement to evaluate the RBC deformation. Namely, micro platinum membrane electrodes are attached to the channel bottom wall

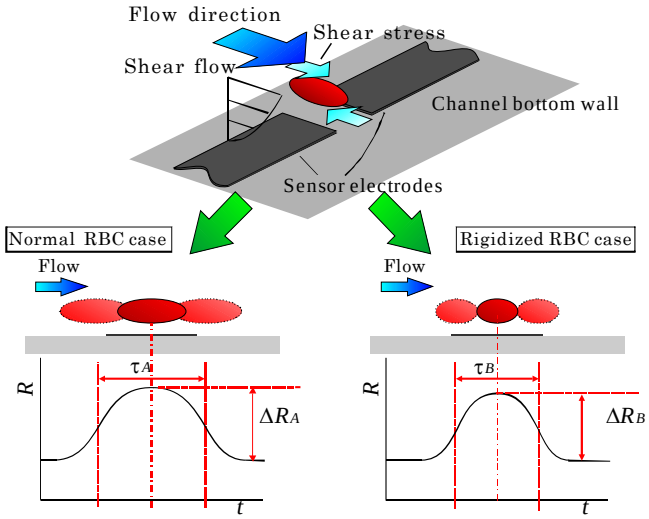

Figure 1. Concept of the measuring method of RBC deformability.

of the sensor, and the time-sequential signals of electric resistance are measured as the RBC crosses the electrodes. Compared with the aforementioned optical measurements, the present method can decrease the size and cost of the device markedly. A higher affinity to the existing RBC counting equipments is also another advantage. In this paper, experiment is carried out to evaluate the feasibility of the sensor proposed in this study. Micro-channel with the micro membrane electrodes is fabricated, and the electric resistances of the RBC crossing the electrodes are measured and analysed using the samples of normal human RBC and glutaraldehyde-treated rigidized RBC.

MEASUREMENT PHYSICS

The electric conductivity of the RBC cytomembrane is approximately 1×10^{-6}S/m, which is small enough to be considered as an insulating material compared with the cytoplasm and normal saline solution. When a low frequency AC electric field is applied around the RBC suspended in a solution, the current is interfered mainly by the cytomembrane. In this case, the cell shape also affects the distribution of the current density, in other words, the electric resistance monitored between the electrodes changes depending on the cell shape.

Figure 1 shows the schematic of the measuring method proposed in this study. A pair of platinum membrane electrodes is attached to the bottom wall of a micro-channel, and the time-sequential signals of the electric resistance between the electrodes are measured. When RBCs are suspended in the micro-channel flow, the resistance between the electrodes increases significantly as the RBC passes between them due to its high electric insulating property. While the RBCs flow in the channel, they are stretched and deformed attributed to the high shear stress provided by the steep velocity gradient of the flow. The profile of the measured resistance is affected not only by the fluid properties but also by the size, position and shape of the RBC. If the position of the RBC passing between the electrodes can be precisely controlled, then the shape of the RBC, which also represents the deformability of the RBC, can be evaluated by analysing the resistance signals.

When an electric field is, thus, applied to the RBC by using the sensor shown in Fig. 1, the parallel circuit between the electrodes consists of cytoplasm, cytomembrane, solvent, and the electric double layer formed at the electrode surface as shown in Fig. 2(a). This circuit can also be simplified as parallel components of variable resistance and capacitance connected in series with the component of the electric double layer, presenting the change in the electric characteristics as the RBC passes between the electrodes.

As one can see, the accuracy of the measurement largely relies on how large the difference between the resistances of the buffer solution and the RBC membrane is. If a solution of high ionic concentration, such as isotonic sodium chloride solution, is used, however, the effect of the electric double layer cannot be neglected. This problem can be solved by applying a high frequency AC electric field to the electrodes and reducing the capacitance of the electric double layer. In contrast,

since the cell membrane has electrically insulation properties, an increase in the frequency of the electric field can incur a decrease of the cell resistance. Therefore, there is a trade-off problem in determining the frequency range to be applied on the electrodes.

The maximum limit of the frequency is obtained from the numerical simulation calculating the impedance characteristic of RBCs suspended in the solution using the model proposed by Katsumoto et al.[10]. This model treats the RBC as a 6μm diameter sphere shown in Fig. 2(b) having the frequency-dependent complex permittivity derived form from the Maxwell-Wagner equation.

Figure 3(a) depicts the results of the computation showing the effects of the frequency, f, on ε and κ, respectively. κ increases with f in the area above several MHz in the figure showing the relaxation behaviour of the solution. This indicates that the cytomembrane acts as an insulator when the frequency is low, while the cytoplasm is directly measured when the frequency is high. As mentioned above, the present sensor shows a higher performance with larger difference in the solution and RBC. Therefore frequency of several tens of kHz is suitable for the sensors. The lower limit of the frequency to be applied will be discussed shortly.

EXPERIMENTAL SETUP

Figure 4 and Table 1 show the schematic and dimensions of the channel and sensor electrodes used in this study, respectively. The channel width is 1mm and is much larger than the channel heights H_1 and H_2. Therefore, the channel flow can be considered as two-dimensional flow, and the RBC is deformed receiving the shear stress in the streamwise direction.

The channel has three inlets, and RBCs suspended in phosphate buffer saline (PBS: Amresco) solution are supplied from the center inlet while PBS solution only is supplied from the side ones. Due to the low Reynolds number of the flow in the micro-channel, the flow is in laminar regime and the molecular diffusion of the flow supplied from the center inlet becomes small. Therefore, by

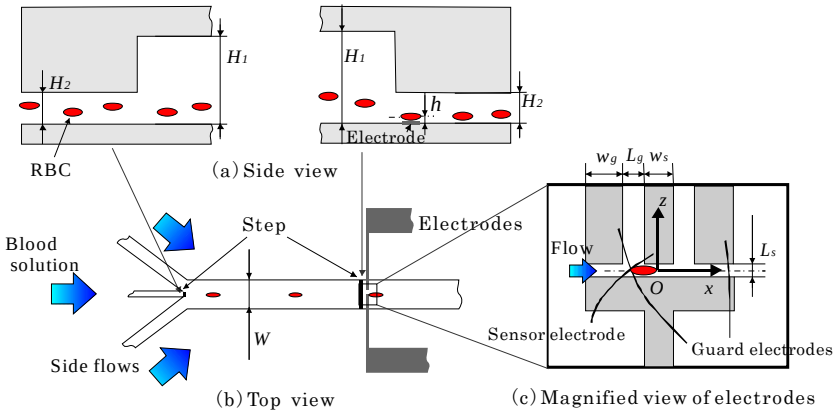

Figure 4. Schematic of the micro-channel and sensor electrodes.

Table 1. Parameters of the micro-channel and electrodes (μm).

W	H_1	H_2	L_s	L_g	w_s	w_g
1000	52	10	5.2	2.3	14.8	14.6

changing the flow rate of each side flow, the spanwise position of the RBC passage can be controlled to pass the center of the electrodes. These fluids are supplied by syringe pumps (Nihon Kohden: CFV-3200, Harvard Apparatus: econoflo) with flow rates of 0.01 and 1.0μl/min.

When the RBC is placed in the channel shear flow, the RBC receives a lift force attributed to the so-called Fåhraeus effect[11]. This lift force moves the RBC away from the channel wall on which the sensor electrodes are embedded. Apparently, this leads to a decrease of the measuring resistance and the sensor S/N ratio. To tackle this problem, the channel heights at the center inlet and at the electrodes are smaller than the other parts of the channel, i.e. backward-facing and forward-facing steps are installed in the downstream of the center inlet and immediately upstream of the electrodes, respectively. The RBC is, thus, supplied from the inlet in a lower position, and the downwash flow at the forward-facing step carries the RBC toward the bottom wall. This spanwise and downward positioning of the RBC passage can control the relative distance between the RBC and electrodes.

The micro-channel illustrated in Fig. 4 is made of poly-dimethylsiloxane (PDMS) and is fabricated by using SU-8 (MicroChem) as a casting mold. To fabricate the SU-8 mold, an optical mask, on which the channel pattern is printed, is prepared first. Then, SU-8 layer spincoated on a slide glass is exposed to the UV light through the mask. After the post baking and etching processes, an SU-8 mold is obtained. PDMS in liquid phase is then poured over the SU-8 mold, and is rigidized and ripped off. The PDMS channel is then attached to a slide glass, on which the platinum membrane patterns of electrodes are formed. These electrodes are fabricated through a sputtering and lift-off processes using a sputtering equipment (ULVAC KIKO: SCOTT-C3) and ZPN (ZEON) resist.

The electrodes are serially connected to the shunt resistance for detection. Sinusoidal wave of AC voltage is applied to these resistances under the condition of 10kHz using a function generator (NF: WF-1973). By measuring the phases of the shunt resistance and applied voltages, the resistance measurement accuracy is enhanced.

As shown in Fig. 4, guard electrodes are placed on both sides of the sensor electrode (the one used for detection). Voltage is charged to these guard electrodes through an FET input Op-amp possessing the same electric potential with the sensor electrode. The electric fluxes from the guard electrodes will suppress the fringe effect of the fluxes from the sensor electrode. This leads to a narrow distribution of the current density in the streamwise direction and enhances the sensitivity.

To evaluate the impedance characteristic of the electrodes, the electric resistance between the electrodes embedded in the channel filled with PBS solution is first measured by using an impedance analyser (Agilent: 4294A). Figure 3(b) shows how the frequency of the applied AC voltage, f , affects the resistance, R. The open and solid circles in the figure present the results using platinum bare electrodes and platinum black plated ones, respectively. The Pt-plated electrodes represent those with Pt nano particles attached on the surface using the following plating process.

Namely, first filling the channel with a solution of hexachloroplatinic (H_2PtCl_6) 30mg/mL and lead acetate $(CH_3COO)_2Pb$ 0.3mg/mL, and then applying 2V DC voltage between the electrodes.

As shown in Fig. 2(a), when f is not sufficiently high, an electrical double layer is formed at the electrode surfaces, which leads to a reduction in the resistance measurement performance. This can be observed in Fig. 3(b), where the resistance R plotted with the open circles decreases as f increases and then becomes constant. As mentioned above, 10kHz AC electric field is applied in this study. This is, however, not large enough to suppress the appearance of the electric double layer as can be found in Fig. 3(b), i.e. R measured under the condition of f = 10kHz is larger than the values in higher frequency region. To tackle this problem, the aforementioned Pt-black plating is conducted on the electrode surface in this study. A layer of Pt nano-particles will be formed on the surface as a porous media, and the surface area is increased by this structure resulting in the reduction of the electric double layer effect. In this case, the frequency range from which R begins to increase is shifted toward the lower f side and R is small and uniform under the condition of f = 10kHz compared with the case of bared electrodes. It should be noted that the reason why the resistance in the plated case are lower than those of the bare electrodes is attributed to the fact that the plate is formed uniformly on the surface and the distance between the electrodes is decreased.

Along with the above electric measurements, optical measurement is carried out using a microscope (Olympus: IX-71) and halogen lamp as the light source for the purpose of verifying the position and shape of the RBC when passing between the electrodes. An objective lens (Olympus: LMPLFLN100X, ×100 magnification and NA = 0.8) and a high speed camera (Vision Research: Phantom V7.3) are used to record the images. The frame rate of the camera is 1000 frames/s and the CCD resolution is 800×650 pixels. The optical resolution of the image is 0.21μm/pixel. The focusing depth of the image Δz is 1.669μm calculated from the following equation:

$$\Delta z = \frac{\lambda_0 n}{NA^2} + \frac{n}{MNA} e \tag{1}$$

e and M are the smallest distance that can be resolved by the detector, and lateral magnification, respectively. λ_0 and n are the wave length of light in air and refraction index.

Korin et al. [13] reported that shear stress required to deform an RBC with a deformation index DI=0.5 in a micro-channel is approximately 15Pa. Here, DI is defined as $DI = (a-b)/(a+b)$, where a and b are the long and short axes of the RBC, respectively. When water is used as the working fluid, it is not suitable to obtain this value of shear stress by increasing the flow rate because of the time resolution of the measurement using the high-speed camera and electric sensors. Polyvinylpyrrolidone (PVP: MW 3.6×10^5, Nacalai tesque) is, therefore, mixed with the working fluid to increase the viscosity, by which sufficient shear stress is achieved to deform the RBC.

RBC treatment is carried out by the following procedure. 10μl sample blood is collected from a healthy human volunteer. The blood is first suspended in 1ml PBS, and then centrifuged during 10min with 1000G to separate the RBC from other substances, i.e. plasma, plaque and leucocytes. Supernatant solution is removed, and 0.1ml PBS is added to the collected RBC. 0.4ml PBS with 10wt% PVP is added to the solution, and RBC suspended solution of PBS with 8wt% PVP is prepared and used as the normal RBC suspended working fluid.

Rigidized RBCs are prepared by treating the cells with glutaraldehyde. Glutaraldehyde (Nakalai tesque: 25% solution) is first diluted with PBS by 0.025wt%. The RBC separated from other substances in the same way shown above is then added to this solution and settled for 30min under room temperature. The solution is, then, centrifuged during 10min with 1000G. After removing the supernatant solution, 1ml PBS is added. Once again the solution is centrifuged and the supernatant solution is removed. Finally, 0.1ml PBS and 0.4ml PBS with 10wt% PVP are respectively added to the solution, and, thus, PBS solution of 8wt% PVP with rigidized RBC is prepared.

EXPERIMENTAL RESULTS

Figures 5(a) and (b) show the snapshots presenting the behaviour of the normal and rigidized RBCs passing between the electrodes, respectively. The flow direction is from the left to the right, and the

b [μm]	4.65	7.35
DI	0.52	0.00

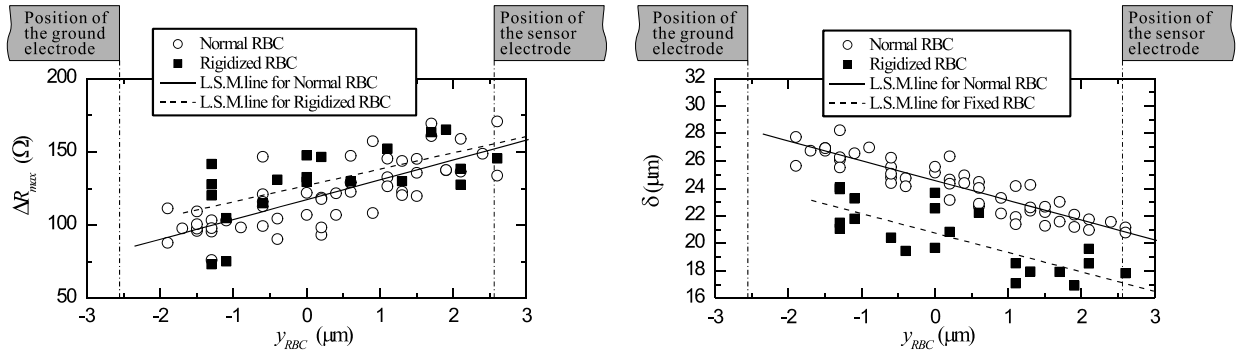
arrow indicates the location of the forward-facing step. Although not shown here, the height of the RBC passage, *h*, was obtained visually by measuring the distance between the points focused on the RBC and bottom wall. *h* was nearly constant for all RBC measured as h=5μm. It should be noted that the degree of the error in *h* is approximately equal to the aforementioned focusing depth Δz.

In the figure, the RBC is deformed and stretched in the streamwise direction owing to the two-dimensional shear flow in the channel. In Fig. 5(a), the RBC deforms most when passing the forward-step. This is due to downward flow generated at the step by which not only the shear stress is increased, but also the RBC is carried to the area of larger shear stress located close to the bottom wall. The deformation rate gradually decreases as the RBC flows to the downstream. This can be attributed to the Fåhraeus effect[11], namely, a lift force works on the RBC and the RBC moves toward the channel center resulting in a reduction of the shear stress.

In contrast with the normal RBC case, the rigidized RBC shown in Fig. 5(b) maintains a biconcave surface and no deformation of the cell is observed. The RBC rotates as it flows, which is a motion so called 'flipping'. When a normal RBC is suspended in a shear flow, the cytomembrane not only deforms but also rotates together with the cytoplasm. This is called 'tank treading motion' of the cell, which prevents the cell to flip[12]. Since the shape of the cytomembrane in the rigidized RBC case is fixed, the tank treading motion cannot be generated and the flipping motion takes place.

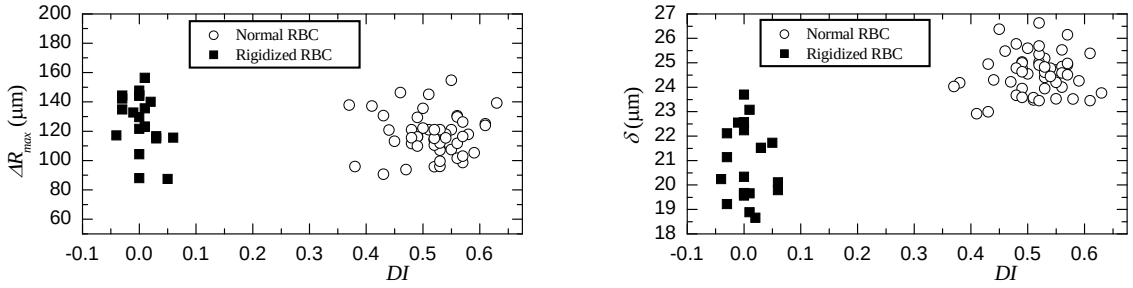
Table 2 shows the averaged value of the long and short axes of the RBC, *a* and *b*, and the deformation index, *DI* , obtained from the visualization results. As mentioned above, rigidized RBCs show no deformation and have a circle projection shape. Therefore *a* and *b* are identical in this case. On the other hand, since the normal RBC is deformed, *a* is almost three times larger than *b*. *DI* is approximately 0.5 in the normal RBC case.

Figure 6 shows the distributions of ΔR_{max} and δ of the normal and rigidized RBCs. ΔR_{max} and δ are the maximum value and half bandwidth of the resistance peak distributions obtained when each RBC passes the electrodes, respectively. During the experiment, variation in the RBC spanwise position when passing the electrodes is observed. This is attributed to the width of the center inlet of the channel, which is 50μm and is much larger than the gap between the electrodes, L_g =5μm . To discuss this effect, the spanwise position of the cell, y_{RBC}, is taken as the abscissa in the figure. The lines in the figure present the results obtained by using the least-square method (L.S.M.) in each RBC case.



(a) Relation between ΔR_{max} and y_{RBC} (b) Relation between δ and y_{RBC}

Figure 6. Distributions of peak resistance ΔR_{max} and half bandwidth δ against spanwise location of RBC, y_{RBC}.



(a) Relation between ΔR_{max} and *DI* (b) Relation between δ and *DI*

Figure 7. Distributions of modified ΔR_{max} and δ against deformation index *DI*.

In Fig. 6 (a), ΔR_{max} decreases as the RBC position y_{RBC} is closer to the ground electrode. On the other hand, δ increases as y_{RBC} decreases as shown in Fig. 6(b). This can be attributed to the following reason: As seen in Figs. 4 and 5, the sensor side consists of three electrodes, the sensor and guard electrodes, while the ground side has a single electrode. The effect of the guard electrodes reducing the fringe components of the electric flux deteriorates in the ground side. Namely, the current density distribution becomes wide and the value decreases in the position close to the ground electrode. The amount of electric flux blocked by the RBC, therefore, decreases, which leads to a decrease in the resistance particularly the maximum value, ΔR_{max}. On the other hand, since the current density distribution is wider at the location close to the ground electrode, δ increases.

As shown in Fig. 6, y_{RBC} appears to affect ΔR_{max} and δ linearly. Therefore, the linear component using the L.S.M. line in the figure is subtracted from each value, and is shown in Fig. 7 in relation with *DI*. Since only two kinds of RBCs, normal and glutaraldehyde-treated ones, are measured in the experiment, two large groups are found in the area close to *DI* = 0.0 and 0.5.

To evaluate the variation of the samples in each RBC case, coefficient of variance, $Cv=\sigma/m\times100$, is shown in Table 3. σ and m are the standard deviation and arithmetic average of the distributions, respectively.

In Fig. 7(a), ΔR_{max} of both RBCs show similar values and overlap with each other. Furthermore, *Cv* of ΔR_{max} shown in Table 3 is relatively large in both RBC cases, indicating that the variation of the samples is large.

On the other hand, a difference in the groups of δ for the normal and rigidized RBCs is recognizable in Fig. 7(b) indicating the fact that there is a correlation between δ and *DI*. Furthermore, *Cv* shown in Table 3 is small compared with those of ΔR_{max} . These results point out that the half bandwidth δ is more reasonable as an index to evaluate the shape, i.e. deformability of the RBC, than ΔR_{max}.

The reason why δ shows a better characteristic than ΔR_{max} is due to current density distribution between the electrodes. ΔR can be more sensitive with the RBC height position *h*. Therefore, even when the RBC height position is controlled by the step flow, small variation in *h* can vary ΔR_{max}

Table 3. Coefficient of variance for ΔR_{max} and δ

	ΔR_{max}		δ	
	Normal RBC	Rigidized RBC	Normal RBC	Rigidized RBC
Cv (%)	12.1	15.4	3.42	7.39

largely enough to make the difference of the RBC shape ambiguous. δ, however, depends more on the current density distribution in the streamwise direction, which is less affected by other parameters.

CONCLUSIONS

A micro sensor consisted of micro-channel and electric sensors, which can measure the deformability of a single RBC was proposed and evaluated in this study. The sensor was fabricated and its feasibility was examined using normal and rigidized human red blood cells. The major results are stated as follows:

1. The frequency of the sensor AC voltage was determined numerically and experimentally. Together with the Pt-black plated on the electrodes, frequency specification of 10kHz reduced the influences of the electric double layer formed on the electrodes and dielectric relaxation appearing around the cell membrane, which led to the increase of the sensor sensitivity.
2. The backward- and forward facing steps, and the side flows applied in the micro-channel were effective to control the height and spanwise positions of the RBC in order to closely pass the area between the sensor electrodes.
3. A good correlation was observed between the half bandwidth of the time-sequential signals of the resistance and the deformation index. In contrast, the correlation between the peak value of the resistance and deformation index was considerably small. This characteristic was strongly attributed to the current density distribution formed between the electrodes. Consequently, the feasibility of the present sensor was verified from the results.

IN VIVO MEASUREMENT OF BLOOD FLOW IN MICRO-CIRCULATION SYSTEMS OF A CHICKEN EMBRYO

S. J. Lee[1, *], J. Y. Lee[1]
[1]Center for Biofluid and Biomimic Research, Dept. of Mechanical Eng., Pohang, Republic of Korea.

ABSTRACT. The micro-circulation system of a living biological creature plays an important role in maintaining the metabolism and transport nutrients and wastes. In addition, the hemodynamic characteristics of blood flow such as wall shear stress and flow rate are important factors that affect angiogenetic process and control the vasomotion and dilatation of the vessel adaptively. These governing factors of blood flows in the micro-circulation system are crucial in the development of the cardiovascular system as well as for the proper functioning of an organism, especially when the blood flow is related to circulatory vascular diseases. Moreover, the structural characteristics of blood vessels (Murray's law and bifurcation pattern) are significantly influenced by the hemodynamic characteristics. Therefore, it is important to measure the blood flow *in vivo* and determine its relation to the structural rules of the vessel. In this study, we measured the blood flow in the extraembryonic arterial blood vessels of chicken embryos and investigated the hemodynamic characteristics and the structural rules of the vessels along the bifurcation cascade. Velocity field information of the blood flow was measured using a micro-PIV technique and the temporal characteristics were obtained using a high-speed CMOS camera. The mean velocity in the arterial blood vessels decreased and Womersley number (α) calculated based on the pulsating frequency and diameter of the vessel also decreased, as the bifurcation cascaded. The ratio of Murray's law was very close to the theoretical value of 1 when the vessel diameter was small (50 μm ≤ D_0 ≤ 100 μm). However, the value deviates from 1 as D_0 increases. The bifurcation angles are wider when the D_0 is smaller and becomes narrower as D_0 increased.

INTRODUCTION

Arteries are important in the cardiovascular system and easily adapt to varying flow and pressure conditions by enlarging or shrinking to meet hemodynamic demands. Blood flow in arterial blood vessels is basically an unsteady pulsatile flow, with flow characteristics becoming more complicated due to the non-Newtonian properties of blood [1-3]. In addition, the hemodynamic characteristics of blood flow change significantly in the arterial bifurcation cascade, and these changes play a major role in the pathology of atherosclerosis [4].

Over the past 80 years, several studies have been conducted to test Murray's law [5,6] as well as different minimum principles. Nonetheless, only a few have focused on the bifurcation angle as a geometrical governing factor. The bifurcation angle of the vascular system is an important geometric factor that affects hemodynamic properties, flow conditions and other transport

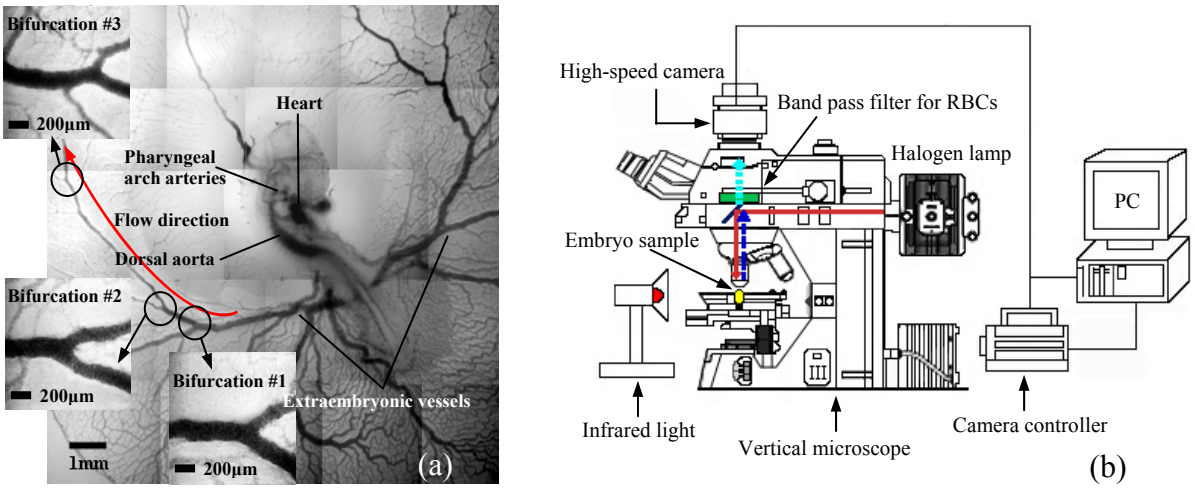

Figure 1. (a) Chicken embryo after approximately 72 hours of incubation, (b) schematic diagram of a micro-PIV system used for *in vivo* measurement of arterial pulsatile blood flow

phenomena in blood flows [7]. In addition, their effects on blood flow are believed to play a major role on developmental growth, angiogenesis, and vascular networking.

We therefore have used the micro-PIV technique to measure quantitative velocity fields of pulsatile blood flow in the extraembryonic arterial blood vessels of Hamburger and Hamilton [8] (HH)-stage 18 chicken embryos with high spatial and temporal resolutions, especially in the arterial bifurcation cascade. We have analyzed the complex pulsatile flow phenomena in the arterial bifurcation cascade. In order to understand the cardiovascular circulation system in detail, it is necessary to investigate the design rules related to the bifurcation angle and its relationship to the diameter of blood vessels. For this reason, we measured not only the diameters of blood vessels to test Murray's law, but also the angles of the arterial bifurcations. The bifurcation angle (θ) was analyzed according to the diameter of the parent vessel (D_0) and the diameter ratio of the daughter branches (D_2/D_1). The bifurcation angle was used to compare the measured diameter of the vessel with the theoretically optimal diameter estimated from the principle of minimum work.

METHODS AND MATERIALS

Chicken Embryos

Chicken embryos were obtained at early stages of development, within the first 3 days of incubation. Since these embryos are very sensitive to variations in temperature, humidity and environmental conditions, all experiments were performed in a room maintained at constant temperature and humidity, and infrared light was applied to maintain each embryo at a constant temperature of 37ºC. To prevent desiccation of the embryos, the vitelline surface region of each, containing the extraembryonic blood vessels, was covered with a thin film of sterile-filtered mineral oil [9]. Fig. 1(a) shows a typical chicken embryo after 72 hours of incubation; each sectional image was taken with a 4× objective lens. Although the embryo and the extraembryonic blood vessels were small, the components of the circulatory system, including the chambered heart, arterial vessels and venous vessels, could be visualized clearly on the vitelline surface. Blood flow inside the extraembryonic blood vessels of a chicken embryo at an early developing stage can be visualized clearly by optical methods *in vivo* and the whole velocity fields of the unsteady pulsatile blood flow in extraembryonic arteries can be measured non-invasively using the temporally-

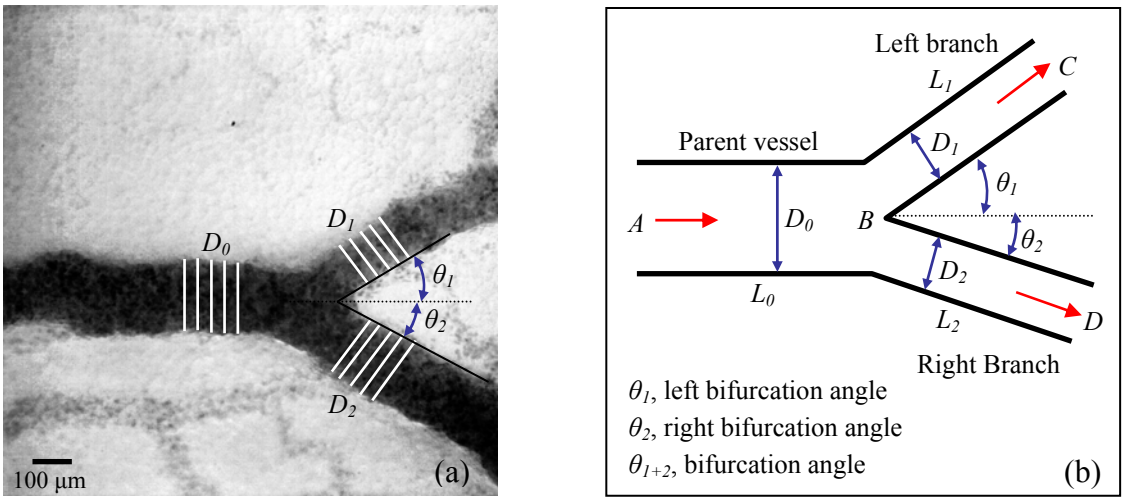

Figure 2. A typical microscopic image of extraembryonic arterial bifurcation (a) and geometric parameters of the branching pattern of vessel (b)

resolved *in vivo* micro-PIV system (Fig. 1(b)). The main target of this study, the arterial bifurcation cascade, is also shown in Fig. 1(a) along the main lumen.

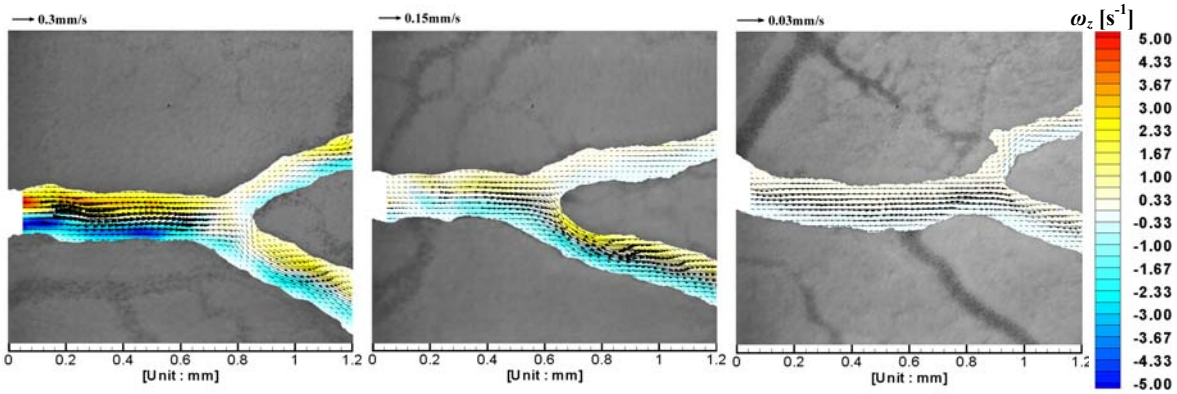
Measurement Technique and Experimental Set-up

Fig. 1(b) shows a schematic diagram of the micro-PIV system used in this study. The *in vivo* micro-PIV system used in this study consists of a vertical microscope (*Nikon Eclipse 80i*), a high-speed CMOS camera (*PCO 1200hs*), a halogen lamp and a PC for data processing and control. RBCs inside blood vessels were used directly as tracer particles, making the injection of chemical tracers unnecessary.

To analyze the unsteady pulsatile flow, blood flow images of red blood cells (RBCs) were captured using a high-speed CMOS camera at 250 fps (frames per second) to achieve sufficiently high temporal resolution with a spatial resolution of 14.6 μm × 14.6 μm. To obtain an instantaneous velocity field from two consecutive flow images, the fast Fourier transform (FFT) based cross-correlation PIV algorithm was applied. The size of the interrogation window was 24 × 24 pixels, with a 50% overlap. The spacing between two adjacent vectors was 12 pixels, corresponding to about 14.6 μm. In this experimental condition, we were able to measure the dimensions very precisely because 1 image pixel captured by the CMOS camera corresponded to 1.219 μm. Figs. 2(a) and (b) show a typical microscopic image of the arterial bifurcation and the schematic diagram for geometric parameters of the branching pattern, respectively. The dimensions were measured at five different locations near the bifurcation in each blood vessel to smooth out the nonuniformities as did by Taber et al. [10]. In order to avoid undesirable effects such as shrinkage and deformation of blood vessels accompanied by desiccation, the vitelline surface was covered with a thin film of sterile-filtered mineral oil because the configuration and dimension of the blood vessels are the most important factors in this experiment. In addition, the lower part of the egg was submerged in a constant-temperature bath to maintain the temperature within the range of 37-38ºC, the same temperature range as in the egg incubator.

RESULTS AND DISCUSSION

Fig. 3 shows the time-averaged mean velocity vector fields and vorticity contours at each bifurcation. The vorticity (ω_z) was calculated from velocity field data using the secondary data



(a) Bifurcation #1 (b) Bifurcation #2 (c) Bifurcation #3

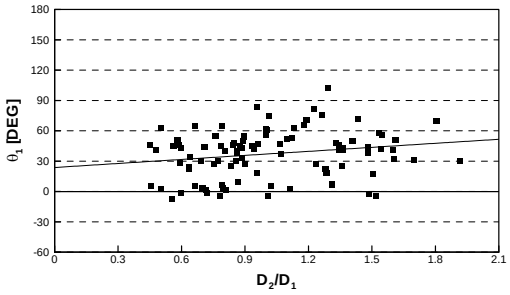
Table 1
Global average of bifurcation parameters

Bifurcation parameter	Global dimension
Ratio of Murray's law α (= $D_0^3/(D_1^3+D_2^3)$)	1.053 ± 0.188
D_2/D_1	1.001 ± 0.349
Left bifurcation angle θ_1 (degree)	37.434 ± 23.689
Right bifurcation angle θ_2 (degree)	39.726 ± 22.506
Bifurcation angle θ_{1+2} (degree)	77.161 ± 26.171

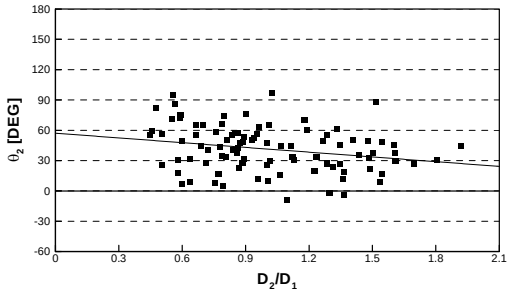
reduction procedure. Although the blood vessels were bifurcated and the instantaneous flow showed noticeable pulsatility, the time-averaged velocity vectors were distributed smoothly in the mean velocity field without any noticeable flow separation or secondary flow, even in the regions of bifurcation. These hemodynamic characteristics can be mainly attributed to the basic properties of low-Reynolds number flow (Re « 1).

As the bifurcation cascaded, the magnitudes of the local mean velocity ($U_{L,mean}$, in mm/s) rapidly decreased from 0.475 ± 0.538 mm/s to 0.020 ± 0.230 mm/s. This was due to the increase in total cross-sectional area of the vessels and the accumulation of pressure loss due to flow resistance along the blood vessels. Vorticity (ω_z, in s^{-1}) was higher in regions near the vessel wall due to large velocity gradients (Fig. 3), but relatively low at the central regions of the blood vessels. In the human blood circulation system, the total cross-sectional area of capillaries is about ten times larger than that of arterial blood vessels. The mean velocity and pulsatility must therefore be reduced significantly to satisfy the continuity of the blood flow through bifurcations. This causes unsteady pulsatile flow in arterial blood vessels to be altered gradually to a slow steady flow, as blood flow approaches the capillary blood vessels. This may be a type of natural physiological regulation, because gases, nutrients and waste materials can be exchanged efficiently through the thin permeable walls of the capillaries under these flow conditions.

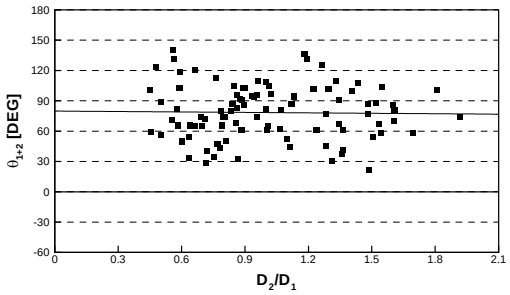
The global average of the geometric parameters of the arterial bifurcations is listed in Table 1. For the HH-stage 18 chicken embryos tested in this study, the mean value of the ratio of Murray's law ($\alpha = D_0^3/(D_1^3 + D_2^3)$) was 1.053 ± 0.188. This value is very close to the theoretical value of unity given by Murray's law. In addition, the branch diameter ratio $D_2/D_1 = 1$, indicating that the global bifurcation system is symmetric ($D_2 = D_1$). Therefore, the bifurcation angle θ_{1+2} (≈ 77º, also see Fig. 4(c)) is also close to the theoretical value of the symmetric bifurcation (≈ 75º; Murray



(a) Bifurcation angle of the left branch



(b) Bifurcation angle of the right branch



(c) Combined bifurcation angle

Figure 4. (a)~(c) Bifurcation angle of the left branch (θ_1), the right branch (θ_2) and the combined bifurcation angle (θ_{1+2}), respectively

[5,6]). However, the right bifurcation angle θ_2 is slightly larger than the left bifurcation angle θ_1. Other geometrical parameters such as D_1/D_0, D_2/D_0 and γ (cross-sectional area ratio) also have similar values of symmetrical bifurcation ($D_1/D_0 = D_2/D_0 = 2^{-1/3} \approx 0.794$ and $\gamma = 2^{1/3} \approx 1.260$).

Fig. 4 shows the variations of measured bifurcation angles (θ_1, θ_2 and θ_{1+2}) according to the diameter ratio (D_2/D_1). As the diameter ratio D_2/D_1 increased, the left bifurcation angle θ_1 slightly increased, while the right bifurcation angle θ_2 slightly decreased. Therefore, due to mutual compensation, the combined bifurcation angle θ_{1+2} is maintained at a nearly constant value of 77º, close to the theoretical bifurcation angle of 75º for a symmetric bifurcation, as shown in Table 1. From Figs. 4(a) and 4(b), we can see that the bifurcation angle (θ_1 or θ_2) of a branch vessel is larger when the diameter of the corresponding branch (D_1 or D_2) is small. The most common approach to testing the validity of Murray's law is to utilize the dependence of branching angle at a branch point on the relative size of the daughter vessels. A number of alternative formulations of the relation are possible; all predict that daughter vessels with smaller radii should make steeper angles to the parent vessels. The results shown in Figs. 4(a) and 4(b) support well the predictions on the bifurcation angle relation of daughter vessels. In addition, the combined bifurcation angle (θ_{1+2}) is nearly constant, regardless of the ratio of the branch's diameter (Fig. 4(c)). These results indicate that the geometric parameters of the vascular system are strictly regulated by the constructal rules of morphogenesis.

CONCLUSION

In this study, we obtained the velocity field information in the extraembryonic blood vessels of chicken embryos under *in vivo* condition. As bifurcation cascades, the mean velocity and pulsatility in the arterial vessel decrease, indicating flow becomes steady state apparently as the vessel diameter decreases. This flow phenomenon satisfies the Murray's law because it is based on the Hagen-Poiseuille's law. This is attributed to the fact that Poiseuille's formula postulated in the derivation of Murray's law is best approximated for vessels of smaller diameter. The unsteady pulsatile flow in arterial blood vessels becomes a slow steady flow or suppressed to a laminar flow, as the blood flow approaches capillary blood vessels.

The structural characteristics follow well the constructal rule (Murray's law), especially when D_0 is small. The bifurcation angle increased as D_0 decreases. It seems reasonable to utilize geometric information of the vascular system and its rules for the design of fluid transport systems, especially for micro-scale fluidic devices. The structural design of microchannels with bifurcation or confluence and complicatedly-connected microchannel networks in Lab-on-a-chip and μ-TAS (total analysis system) would be potential applications.

ABSTRACT. This paper reports an experimental study of skin cooling for precise cryosurgery. The Peltier cryoprobe developed in the previous study has facilitated accurate control of heat transfer for precise cryosurgery. Cooling performance of the cryoprobe was estimated through the experiment utilizing pig skin. The maximum cooling rate (255°C/min) was found at −40 °C, and this value was found adequate for the skin cryosurgery. Thermophysical characteristics of different parts of the skin were found to be different. Thermophysical characteristics between after and before the freezing/thawing cycle were also observed to be different. However, these differences were not significant. Experimental results were found to be in a good agreement with the numerical results.

INTRODUCTION

Cryosurgery is one of the treatment methods in which undesired tissue such as a cancerous tissue is frozen and destroyed. The advantages of the cryosurgery are: (i) focal and central application causes less damage to the normal tissue than resection, (ii) operation time is short, (iii) tissue recovery time is relatively short (iv) retreatment is highly feasible and (v) tumors near large blood vessels can be treated [1]. Despite these advantages, owing to the uncertainty and less repeatability, applications of the cryosurgery have been limited. In the skin surgery, cryosurgery is applied only to an early stage cancer or verruca. The main problem in the existing cryosurgery cooling methods is associated with an inadequate control of the cooling sequence. Therefore, development of a cryoprobe with precise control of heat transfer would allow precise treatment and, thereby, widen the application of the cryosurgery.

For precise control of heat transfer as well as rapid cooling, Maruyama et al. [2, 3] used the Peltier element, which is normally used as a device for actively controlling heat transfer in the steady-state. They found that both precise control of heat transfer and rapid cooling could be realized by utilizing the Peltier effect and by maintaining the heat sink at the cryogenic temperature. They developed a cryoprobe using Peltier elements and dry ice (solid carbon dioxide) as the low temperature heat sink [4]. Takeda et al. [5] developed the model of the cryoprobe in which cooling performance was improved utilizing Peltier module and liquid nitrogen as a cryogen. To control surface temperature precisely, they also developed a control system [5]. Through the experiment utilizing an agar, it was shown in the previous study [4, 5] that the cryoprobe can control imperceptible frozen region even thinner than 300μm and it can prevent freezing of the peripheral region of the affected tissue.

Because of its porous structure and water transportation, as far as thermal response is concerned, the skin tissue is different from an agar. Therefore, the estimation of the Peltier cryoprobe has to be conducted utilizing skin tissue for the application to an actual operation.

The first objective of this study is to estimate the cooling performance and controllability of the cryoprobe by utilizing a piece of pig skin. The suitability of the cryoprobe for actual cryosurgery is then discussed in accordance with the experimental results. Since effective thermophysical properties may change with repeated freezing/thawing and they may be different for different position in the skin, the second objective is, therefore, to evaluate the effect of the locations in the biological tissue.

EXPERIMENTAL METHOD

The cooling experiment was conducted utilizing the Peltier cryoprobe and the jig for injection of thermocouples. Principal concepts of the Peltier cryoprobe and the jig are explained in the following sections.

Peltier Cryoprobe

The schematic diagram and photograph of the cryoprobe are shown in Figs. 1(a) and 1(b), respectively [10]. Utilizing the Peltier effect and cryogenic heat sink, the cryoprobe can control heat transfer precisely and achieve rapid cooling. The Peltier module (KSMH01031F-ABE, KELK Ltd.) of 8 mm long × 8 mm wide and 1.65 mm high is attached between the heat sink and the cooling section. The diameter of the cooling section is 5 mm and the T-type thermocouple is attached to monitor the surface temperature for feedback control. To maintain a constant low temperature, the volume of the heat sink is a comparatively large. Liquid nitrogen is employed as a refrigerant in the cryoprobe and it cools the heat sink by pool boiling. The vessel is insulated by vacuumed co-axial pipes. Therefore, the side wall of the vessel is thermally insulated. The surface of the handle was found so warm that the operator could grab it with his hand. The vessel, in which liquid nitrogen can be maintained for about 30 minutes during the operation, has a volume of about 250 ml.

(b) Photograph of the Peltier cryoprobe

Figure 1. Peltier cryoprobe

Experimental Procedure

In order to measure the temperature variations in the skin block, thermocouples were installed to the points beneath cooling point utilizing the jig developed in this study. Figure 2(a) shows schematic diagram of the jig. The L-shaped jig has 5 guide holes of diameter $\phi = 0.5$ mm at 1 mm, 3 mm, 5 mm, 7 mm and 10 mm depths, respectively. Injection needles were installed into the specimen until the tops of the needle reached beneath the cooling point. After that, T-type thermocouples ($\phi = 0.050$ mm) covered with $\phi = 0.28$ mm × $\phi = 0.20$ mm of polyimide tubes were installed through the injection needle. After that, as shown in Fig. 2(a), injection needles were pulled backward to keep the thermocouples embedded in the meat. By utilizing the jig, thermocouples were installed parallel precisely beneath the cooling points. Schematic diagram of the cross section around the periphery of the cooling section of the cooling experiment is shown in Fig. 2(b). Although thermocouples were installed through the guide hole, the depths of the thermocouples were not exactly the same as the depths of the guide hole because the skin surface was distorted by the pressure of the injection needles. Therefore, after the cooling experiment, the skin was cut and depths of the thermocouples were measured.

In order to estimate the cooling performance of the Peltier cryoprobe and evaluate thermophysical characteristics of the human skin, we utilized the pig skin. This was done for the reason that many characteristics such as structure, mechanical properties and thermophysical properties of the pig skin are similar to those of the human skin. Several blocks of the pig skin were picked up from buttocks and shoulders of the pig. Cross sectional of each block of the pig skin was 50 mm ×50 mm square and its thickness was 10 mm. The skin blocks were shaved and according to the procedure explained above, thermocouples were installed. Next, the cooling section was attached and cooling sequence was applied to the skin surface. The sequence of the experiment was controlled by the PID controller. In the initially, heat flux from the cooling section into the heatsink was cut off by setting the temperature of the cooling section equal to the surface temperature of the specimen. After the cooling started, temperature of the cooling section was controlled so as to maintain it at a set value. The cooling rate, end temperature (lowest temperature during the operation), hold time (time period for which the surface temperature was maintained at the end temperature) and heating rate could be set during the operation. Cooling was obtained by applying constant electric current on the Peltier module or by the PID controller. In order to estimate the cooling performance, the cooling experiment by applying constant electric current was also conducted. After the experiment, the blocks were cut and the depths of the thermocouples were measured.

RESULTS AND DISCUSSIONS

In the cooling experiment utilizing PID controller or constant electric current, cooling performance of the Peltier cryoprobe and the characteristics of the pig skin were estimated. To assure reliability, experimental results were compared with those of the numerical simulation.

Estimation of Cooling Performance

Our previous results [5] utilizing an agar indicated that the cooling rate and the lowest temperature were maximized when an electric current of 1.0 A was applied to the Peltier module. In the present work, therefore, in order to estimate maximum cooling performance for the skin tissue and to measure the variation of the surface temperature with time, measurements were made by applying 1.0 A electric current. Variation of temperature with time is shown in Fig. 3. Solid line shows average temperature over 4 experiments and broken lines show the maximum and the minimum errors assuming that all data distributes as t-distribution. It is observed from the figure that the dispersion of temperature variation increased gradually after the freezing. Such a dispersion was not observed in the experiment of the cooling of an agar. This difference is because water component of the skin tissue is different at different positions, and after the freezing, latent heat of water strongly affects temporal variation of temperature of the cooling section. Therefore, it is impossible for the feed forward cooling system such as the conventional cooling method utilizing cotton or cooling probe with liquid nitrogen to conduct repeatable cooling sequence. It indicates that the Peltier cryoprobe with a PID controller has advantages for precise operation.

Figure 4 shows the relationship between the surface temperature and the cooling rate applying constant 1.0 A current that provides the maximum cooling rate of the Peltier cryoprobe. It is seen from the figure that the cooling performance decreases with decrease in temperature of the cooling section. This is for the reason that the temperature gradient in the Peltier elements becomes small as the surface temperature decreases. The cooling rate reaches 0 °C/min at –120 °C, so the cryoprobe cannot cool the skin tissue lower than –120 °C. Around –10 °C, there is a discontinuity of the cooling rate because there was immediate temperature increase due to ice nucleation in the skin. The graph also shows that the cooling rate lower than the maximum cooling rate (colored region in Fig. 4) can be controlled freely by applying appropriate electric current higher than 1.0 A. In cryosurgery, lethal temperature is in the range from -20 °C to -40 °C [6] and the cooling rate in this temperature range is very important. In this temperature range, our cryoprobe the cooling rate ranges from 360 °C/min to 255 °C/min. This cooling rate is sufficient for the cryosurgery [6, 7].

Figure 5 shows one of the results of the controlled cooling sequence (180 °C/min cooling to –30 °C, holding 120 s, and heating by 300 °C/min, in this case). It is seen from the results that a precise control of the cooling sequence can be achieved when the overshoot at the cooling is lower than 2 °C. Except the data logger's inherent error, the error at the steady-state was found to be less than ±0.1 °C. The same experiments were repeated and the difference of surface temperature of each experiment was found to be lower than 0.2 °C in the steady-state as well as in the transient state. Therefore, unlike a feed-forward cooling systems, with the present cryoprobe, the cooling sequence is repeatable. The figure also shows temperature variation with time of every location including the surface. During 100 s of the cooling time, the temperature difference between any two depths is found to be very high, even higher than 10 °C. This situation is advantageous for controlling the imperceptible necrotized area because it means that a high temperature difference can be achieved in a thin region. For example, assuming the lethal temperature is –20 °C, necrotized area is around 1.0 mm in this experiment. There is a little possibility for temperature of 2.0 mm depth to decrease lower than –20 °C even in the case having the maximum error. Therefore, we consider that the necrotized area can be controlled precisely less than mm order.

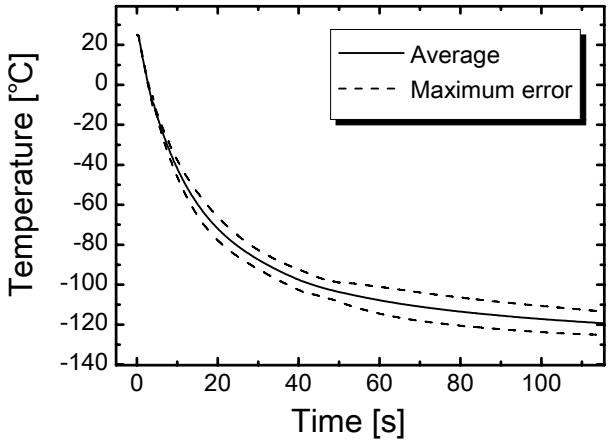

Figure 3. Surface temperature variation of pig skin with time of the cooling section at -1.0A

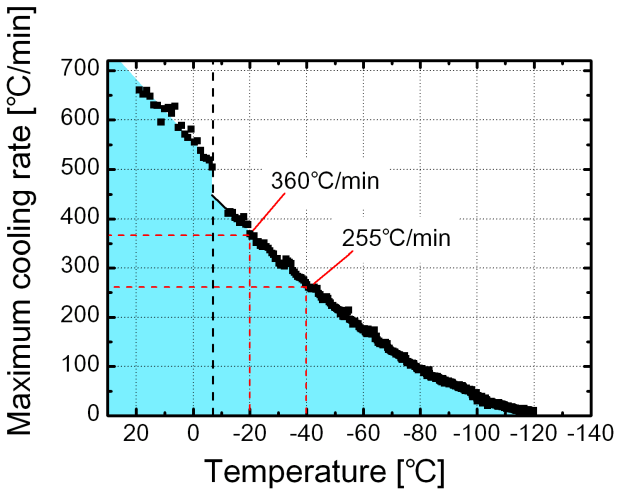

Figure 4. Relationship between temperature and maximum cooling rate

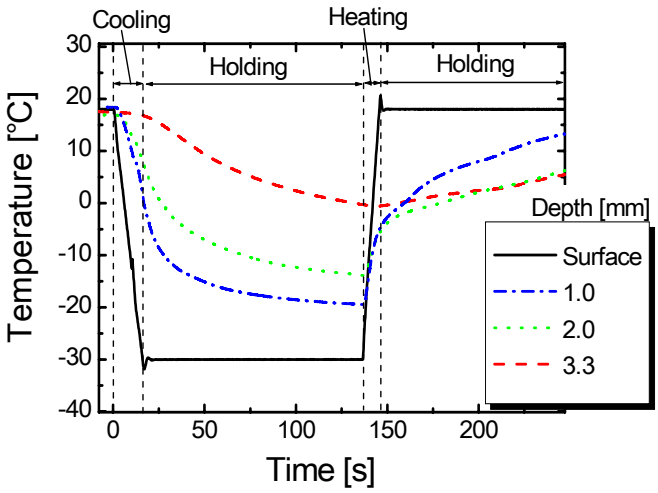

Figure 5. Temperature variation of pig skin at a several depths with time of cooling sequence

Estimation of the characteristics of the skin tissue

Second objective of the experiment of the skin cooling is to estimate the characteristics of the skin tissue. For the precise and repeatable cryosurgery, it is important to know the repeatability of the cooling sequence and the difference between skins of different parts. An agreement of the numerical simulation with the experimental results means that the frozen depth and inner temperature can be predicted before the operation and an appropriate cooling sequence can be decided before the actual operation.

In order to evaluate the difference of the thermophysical properties between skins of different parts, during the cooling, by applying constant 1.0 A current, surface temperature variation with time was compared. Results are shown in Fig. 6. As observed and explained in Fig. 3, temperatures at different locations are different. However, comparing the temperature profiles between different parts, e.g. shoulder and buttock in this case, we could not find significant difference. From the results, we can expect that thermophysical properties of different parts of the skin are similar and we can measure thermophysical properties of the skin from different parts. To confirm this assumption, evaluations of more samples of different parts are needed, but at least in the case of shoulder and buttock, the difference between local positions was more dominant than the difference between other parts.

In the research by Bischof et al. [8], the latent heat of tissue was observed to become higher once the tissue underwent freezing/thawing cycle because of the destruction of the cell membrane. In order to destroy undesired tissue, certainly it is necessary to repeat freezing/thawing cycle in cryosurgery. Therefore, it is important to investigate how large the change of latent heat affects temperature variation of the inner part of the skin. In the present experiment, controlled cooling and heating sequence was repeated several times and results are presented in Fig. 7. In the graph, the solid lines show temperature variation at 1 mm depth and the dashed lines show the same at 3 mm depth. From the figure, it is observed that temperature during the 3rd cooling is slightly higher than during the 1st cooling. However, the difference was less than 2°C at 1 mm depth. This difference can be neglected in the actual cryosurgery because there are many other factors such as anisotropy and random structure of the skin which make it difficult to predict frozen region or inner temperature.

Finally, temperature distributions of each cooling time were compared with numerical results. For the comparison, experimental results are from the controlled cooling and heating experiment for which the results are shown in Fig. 5. The computational results are based on the enthalpy method for the frozen region [9], and relationship between temperature and enthalpy in the mushy region was reconstructed from the experimental results through tissue cooling [5]. Thermophysical properties utilized in the calculation were that of a general tissue. The calculation did not consider matter diffusion or nano-scale structure but utilized effective thermophysical properties. Surface temperature measured in the experiment was utilized as boundary conditions. Axisymmetric numerical calculation was applied in this study. The results are shown if Fig. 8. Calculation results and experimental results are found to reasonably agree quantitatively. However, to see qualitatively, some results had difference more than 5 °C. Considerable reasons of the difference are, (1) the depths of the thermocouples were not accurate because of deformation of the skin and (2) thermophysical properties utilized in the calculation was not accurate. We could not clarify which result (experiment or calculation), or neither of them, is reliable. In order to realize more precise operation, we need further research such as measurement of thermophysical properties of the skin or more accurate temperature measurement. If we can predict temperature profile precisely, the precise control of freezing region or necrotized region will be predicted in actual cryosurgery by combining heat transfer control by the Peltier cryoprobe and the numerical calculation.

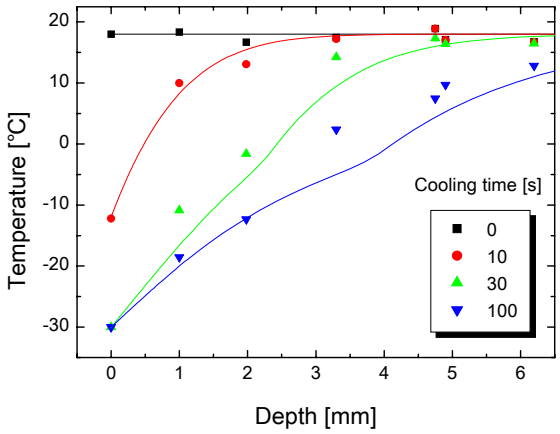

Figure 8. Comparison of numerical simulation and experimental results in temperature distribution of the skin for each cooling time (plots are experimental results and lines are numerical result)

CONCLUSIONS

The cooling performances of the Peltier cryoprobe were estimated utilizing pig skin blocks. The experiment utilizing constant electric current showed sufficient cooling rate and the lowest temperature for the cryosurgery. The cooling rate was up to 255 °C/min at -40 °C and the lowest temperature was -120 °C. The controllability of the cooling sequence was also confirmed and the temperature variation of the points beneath the cooling surface indicated the possibility to control imperceptible necrotizing thickness. Thermophysical characteristics were also evaluated and the results showed that thermophysical properties were not significantly different between the parts (shoulder and buttock) and between freezing times. Experimental result agreed well with numerical simulation developed in the previous study. It indicates that the freezing region or necrotized region can be predicted and controlled precisely by combining heat transfer control with the Peltier cryoprobe and numerical simulation.

ACOUSTIC CHARACTERISTICS OF ULTRASOUND IN WATER CONTAINING LIPID MICROBUBBLES

R. Imai, H. Nakagawa, T. Kanagawa, M. Watanabe and S. Fujikawa*
Division of Mechanical and Space Engineering,
Graduate School of Engineering, Hokkaido University, Sapporo, 060-8628, Japan

ABSTRACT. The resonant frequencies of lipid bubbles are measured from attenuation of ultrasound pulse propagating through the test cell filled with normal saline or lipid bubble solution. The attenuation spectrum has two dominant peaks in the frequency range of 0 through 15 MHz due to the energy absorption by lipid bubble resonant oscillations. The two peaks of attenuation spectrum are observed near the bands of 1.4 MHz and 11.5 MHz, respectively. The peaks of attenuation spectrum decrease with the decrease in the concentration of the lipid bubble solution. Furthermore, the strong attenuation is confirmed to be hardly affected by the length through the lipid bubbles. We conclude that the two peaks in the attenuation spectrum obtained are related to the effect of the existence of lipid bubbles.

INTRODUCTION

Bubbles have been widely used in various fields, for instance, from marine engineering to medical engineering. One of the most characteristic features observed in the practical bubble application is a wide range of bubble diameter. Diameters of bubbles are of the order of millimeters when bubbles are used for the drag reduction of large vessel. On the other hand, they are of the order of nanometers when bubbles are used for clinical applications such as the contrast agents.

In the field of medical engineering, the application of bubbles to Drug Delivery System (DDS) has attracted great attention as the administration of next generation. DDS with bubbles of nanometer size is expected to be a noninvasive clinical treatment. Capsules of nanometer size, which contain exogenous gene such as anticancer drug, are administered in blood. These capsules are transported to target sites and impregnate in the disorder cells efficiently.

There exist bubbles wrapped in biomedical materials, i.e., lipid. The lipid bubbles are used as the transport carrier of DDS. However, dynamic properties of these lipid bubbles are not yet made clear. DDS with lipid bubbles uses actively the resonance of bubbles in order to increase the efficiency of gene injection in the disordered cell, because oscillations of lipid bubbles are easily excited with sufficiently small driving forces at resonant conditions.

In this study, acoustic characteristics of lipid bubbles are experimentally investigated in the vicinity of the resonance. The resonant frequencies of lipid bubbles are evaluated by measuring the attenuation of the propagating broadband ultrasound waves through the water containing lipid bubbles.

EXPERIMENTAL METHOD

Lipid bubble

We use lipid bubbles in a liquid. A lipid bubble is composed of a kind of shell made of lipid layer, in which both gas and liquid are contained. The lipid bubble is made from a liposome. Figure 1 shows schematic diagrams of a lipid bubble. The liposome used in the present experiment is first made of lipid with DSPC (DiStearoyl Phosphatidyl Choline) and then modified by PEG (PolyEthlen Glycol Distearate). With the treatment, the liposome can exist stably in blood. The liposome becomes easily incorporated with ligand that is able to bind disease-related markers on bubble surfaces.

The liposome is produced by the reverse phase evaporation method. The inside of liposome produced by this method is liquid phase (Figure 1 (a)); hence liquid should be replaced by C_3F_8 (Perfluorocarbon) gas (Figure 1 (b)). The C_3F_8 gas is first injected into a glass receptacle containing a liposome solution, and then the receptacle is wobbled using an ultrasonic cleaner (Ultrasound cleaner 2510-J-DTH, Bransonic Co., Ltd.) until the solution in the receptacle becomes opaque. As shown in Figure 1 (b), it is supposed that replacement from the contained liquid to the gas within the liposome is attained by micelle formation inside the liposome [1]. The C_3F_8 gas enables lipid bubbles containing this gas to be used as an ultrasound contrast agent [2]. It is also necessary to equalize the size distribution of lipid bubbles by using the 20 kHz ultrasound probe. The lipid bubbles with larger diameters are assumed to be destroyed by this procedure. Figure 2 shows the distribution of lipid bubble diameter.

The solution containing lipid bubbles is diluted with the PBS (Phosphate Buffered Saline), and thus, solutions of different concentrations are obtained. The stock solution of lipid bubbles before diluted contains DSPC of 1 mg in its 1 ml. In this study, lipid bubble solutions with the concentration of 1000 ppm, 1333 ppm, 2000 ppm, and 4000 ppm are used. The experimental test cell which is the container made of the Polyvinylidene Chloride film (Saran Wrap, Asahi Kasei Co., Ltd.) is filled with lipid bubble solution. Ultrasound passes through this film.

Figure 3 shows the scanning electron micrograph of the liposome.

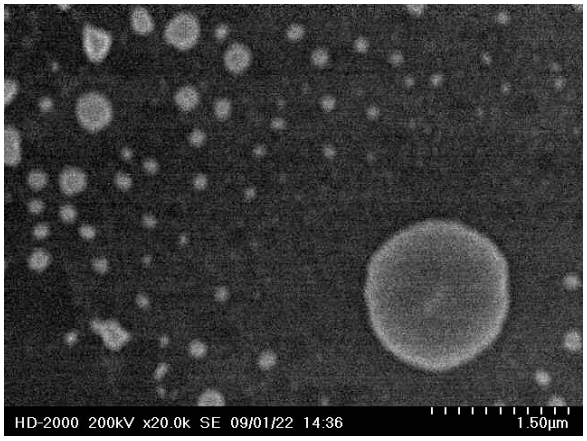

Figure 3. The scanning electron micrograph of the liposome.

Experimental apparatus and method

Experimental apparatus

Figure 4 shows the experimental apparatus, which is similar to that used by Hoff et al. [3]. This apparatus consists of a pulser/receiver, a coaxial cable relay for selecting transducers, four transducers (Panametrics Videoscan V306-SU, V382-SU, V326-SU and V312-SU), and a digital oscilloscope (LeCroy9410, LeCroy Co., Ltd.). The pulser/receiver and oscilloscope were connected to a PC.

Central frequencies of four types of broadband ultrasound transducers are 2.25MHz, 3.5MHz, 5.0MHz, and 10.0MHz, respectively. The four transducers are unfocused, 2.25 MHz with 13 mm aperture diameter, 3.5 MHz with 13 mm aperture, 5.0 MHz with 10 mm aperture, and 10.0 MHz with 6 mm aperture diameter. They are mounted in parallel in a water tank made of acrylic.

The test cell is filled with normal saline or the diluted lipid bubble solution. The lengths of the cell are 31.5 mm or 15.0 mm, and the distances from transducers to the experimental cell are 100 mm. The back wall of the water tank acts as an acoustic reflector, and is placed 150 mm from the transducer faces as shown in Figure 4. This acoustic reflector is made of steel.

Experimental method

The transducers are excited by the pulser which sends broadband ultrasound short pulses at 50 pulses per second. These pulses propagate through the experimental cell containing a lipid bubble solution separated from the ambient water by a very thin plastic film. These pulses are reflected at the back wall of the water tank, and then received by the transducer again. That is, the pulses pass through the cell twice; hence the total sound path lengths through the cells of 31.5 mm and 15.0 mm become 63.0 mm and 30.0 mm, respectively. The received pulses are amplified by the receiver and transferred to the oscilloscope. The oscilloscope is set to display only the reflection off the back wall of the chamber. The pulses are digitized in the oscilloscope at a sampling rate of 20 GS/s, and transferred to PC.

Signal processing of the received pulses is carried out using MATLAB software (The Math Works, Inc., Natick, MA). The power spectra are calculated by the Fast Fourier Transformation of received pulses in the cases of with and without lipid bubbles in the cell, respectively. Figure 5 shows an example of received pulses and their power spectra, without and with lipid bubbles in the cell with 31.5 mm in length. The attenuation spectra are calculated by the normalization, i.e., dividing the difference of power spectra both with and without lipid bubbles by the total sound path length through the cell, which is either 63.0 mm or 30.0 mm.

The evaluation ranges of broadband ultrasound transducers are from 1.4 to 3.0MHz, from 2.0 to 5.0MHz, from 3.0 to 8.0MHz, and from 6.0 to 14.0MHz, respectively, which correspond to their central frequencies 2.25MHz, 3.5MHz, 5.0MHz, and 10MHz. The overlaps of the curves obtained by different transducers assure the consistency of the experiment.

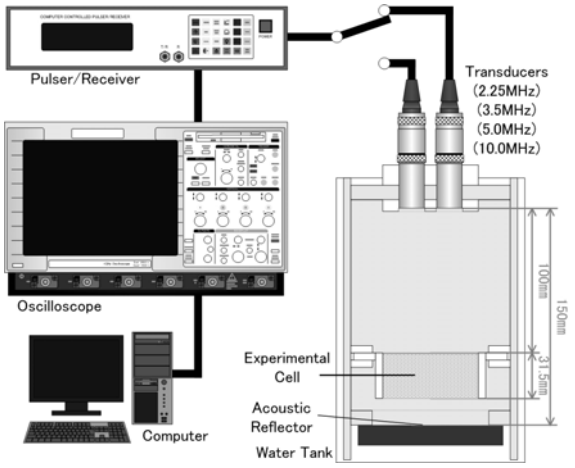

Figure 4. Schematic of the experimental apparatus.

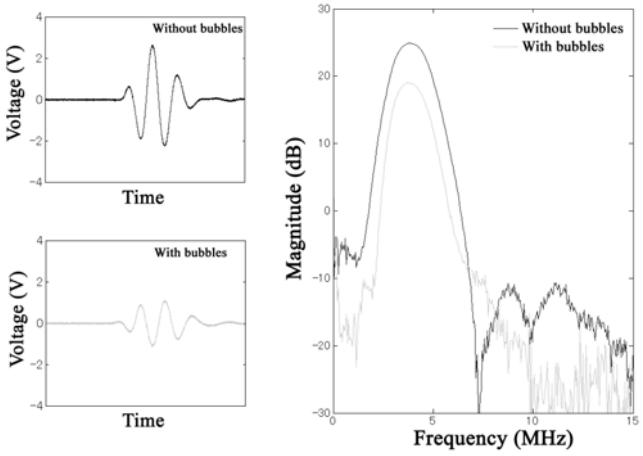

Figure 5. An example of received pulses and their power spectra measured with 3.5 MHz transducer. The left diagrams show received pulses passed through the cell twice: The upper and lower figures shows received pulses without and with lipid bubbles, respectively. The right diagram shows their power spectra, without and with lipid bubbles in the experimental cell.

RESULTS

First, we measured power spectra both with and without lipid bubbles, and calculated the attenuation spectrum, which is defined as the division of the difference between them by the total sound path length through the experimental cell, with both acoustic energy and the path length of the experimental call fixed as 100 μJ and 31.5 mm, respectively. The attenuation spectrum, which is used as the index of the difference of the acoustic characteristics between with and without lipid bubbles, is shown in Figure 6 in the case of the lipid bubble solution concentration of 1333 ppm.

Figure 6 is a typical example of the attenuation spectrum. It should be emphasized that, in this frequency range (0-15 MHz), this attenuation spectrum has two peaks. The larger attenuation is observed around the frequency of 1.4 MHz, the other is observed around the frequency of 11.5 MHz. It is understood that the existence of these peaks in the attenuation spectrum is due to the acoustic energy absorption by the lipid bubbles with resonant oscillations; hence the resonant frequencies of the solution of lipid bubbles are evaluated as approximately around the frequencies of 1.4 MHz and 11.5 MHz. These two peaks should be closely related with the distribution characteristics of the lipid bubble diameter, as already shown in Figure 2. Thereafter, these two peaks of the attenuation spectrum are discussed in the context of the acoustic characteristics of the lipid bubbles.

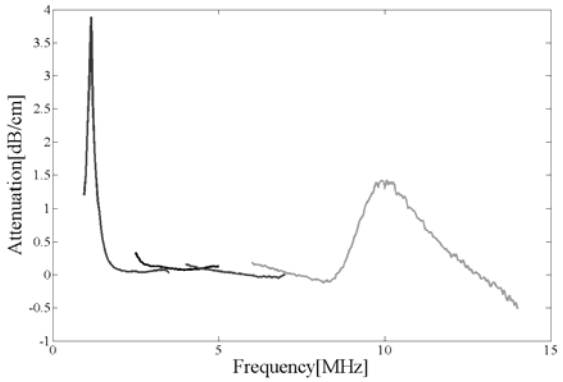

Figure 6. Acoustic attenuation spectra: with acoustic energy of 100 μJ, cell thickness of 31.5 mm, concentration of 1333 ppm.

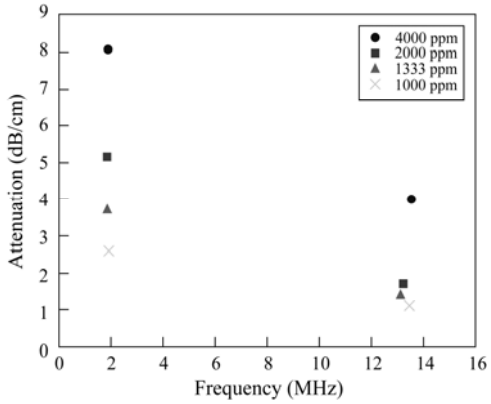

Figure 7. Peak attenuation with acoustic energy of 100 μJ, cell thickness is 31.5 mm, concentrations of 1000 ppm, 1333 ppm, 2000 ppm, and 4000 ppm.

Figure 7 shows the effects of concentration of the lipid bubble solution on the magnitudes of the attenuation at the two peaks of the attenuation spectrum. Here, the acoustic energy and the length of the experimental cell are fixed as 100 μJ and 31.5 mm, as before. Four types of lipid bubble solutions with the concentration of 1000 ppm, 1333 ppm, 2000 ppm, and 4000 ppm are used. It should be noted that the magnitudes of the attenuation at both of the two peaks decrease with the decrease in the concentration of the lipid bubble solution. The concentration of the solution is proportional to number of lipid bubbles per unit volume, and consequently to the amount of energy absorbed by the resonant frequencies of the lipid bubbles.

In order to discuss the effects of the total sound path length, we compare the attenuation spectra obtained by using two cells with different lengths of 31.5 mm and 15.0 mm, respectively. Figure 8 shows the effects of cell length on the magnitude of the attenuation at the two peaks of the attenuation spectrum, in the case that the acoustic energy is 100 μJ and the concentration of the lipid bubble solution is 2000 ppm. There exist little influences of the difference in the cell length; hence the magnitude of the attenuation peak is independent of the total path length through the lipid bubble solution.

As has been already discussed, the two dominant peaks in the attenuation spectrum obtained by this experiment are related to the resonance of the lipid bubbles. A resonant frequency increases with the decrease in the diameter of bubbles. Therefore, the resonant frequency observed in the vicinity of 1.4 MHz and 11.5 MHz may be contributed by lipid bubbles with diameter of 1.5 μm of 200 nm, respectively. It should be noted that this discussion should be improved by incorporating the multiple bubble effects.

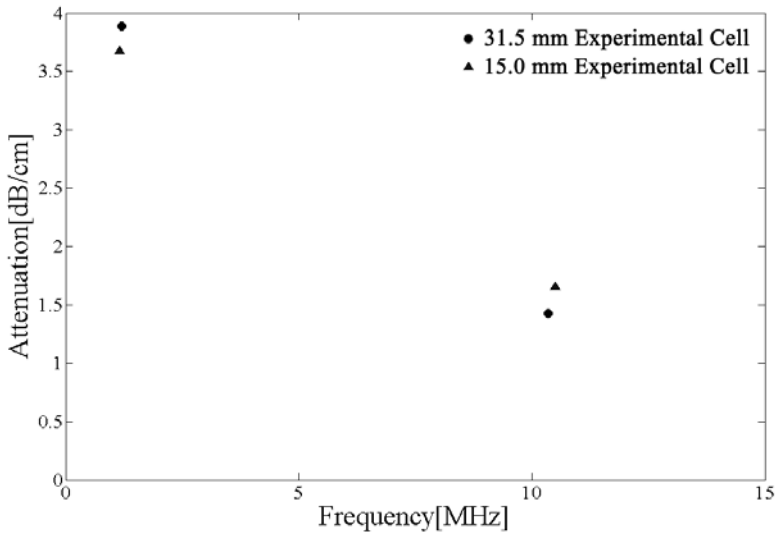

Figure 8. Acoustic attenuation spectra with acoustic energy of 100 μJ concentration of 1333 ppm, cell thickness of 31.5 mm and 15.0 mm.

CONCLUSIONS

We have experimentally studied the resonant frequencies of the lipid bubbles and obtained the following results:

(1) The attenuation spectrum, which is defined as the division of the difference of power spectra between with and without lipid bubbles by the total sound path length through the experimental cell, has two dominant peaks.

(2) The strong attenuations are observed at two different frequencies, around 1.4 MHz and 11.5 MHz, respectively.

(3) The strong attenuation decreases with the decrease in the concentration of the lipid bubble solution.

(4) The strong attenuation is independent of the path length through the lipid bubbles.

ABSTRACT. Boiling heat transfer experiment for the development of ultrafine cryoprobe was conducted. The structure of ultrafine cryoprobe which is the co-axial double tube was simulated. To visualize the phenomena, water under the low pressure condition was used as working fluid. The inner diameter of needle section is 1.2mm. Two types inner tube were made and it was evaluated the effect obtained by the difference of inner tube diameter. The emission of small bubbles from inner tube to glass tube was observed by visualization experiment. Furthermore temperature measurement with heat flux obtained on the needle surface was conducted. The relationship between needle surface temperature and heat flux elucidates that needle surface temperature of thinner inner tube is lower despite lower flow rate. This fact indicates that pressure drop of inner tube or the state of water at the exit of inner tube is important for cooling needle.

INTRODUCTION

Cryosurgery is one of the surgical treatments, which utilize frozen phenomena of the tissue for removing lesions. The advantages of cryosurgery are minimal invasiveness, low bleeding, and short period for recovery[1]. Cryoprobe that is the cooling equipment for cryosurgery is usually cooled by Joule-Thomson effect of the high pressure refrigerant and its outer diameter is 3-8mm. Conventional cryoprobe has enough cooling power but poor heat transfer controllability. To overcome this problem, our group has developed novel type cryoprobe which can control heat transfer precisely by utilizing Peltier module[2]. The treatment effect of this cryoprobe was confirmed by animal experiment[3]. Furthermore less invasiveness and application to small lesion which can not be treated by conventional method are required for the development of cryosurgery. To satisfy these requirements, downsizing of cryoprobe is focused as one of the solution. On the other hand, cooling power of cryoprobe decreases as downsizing. Because surface area of cryoprobe and flow rate of refrigerant decreases. Therefore downsized cryoprobe using Joule-Thomson effect might generate insufficient cooling power for cryosurgery[4]. Therefore large heat transfer coefficient is required to downsizing cryoprobe to obtain sufficient cooling power.

To overcome these problems, we consider the concept of novel type cryoprobe “cooling needle” which has less than 1mm diameter and uses boiling heat transfer. We investigated the relationship between heat transfer coefficient of cooling needle and frozen region in biological tissue when the diameter of cooling needle is 0.5mm. As a result, large heat transfer coefficient which is equivalent to outer boiling heat transfer coefficient is required to generate the sufficient frozen region[5].

The knowledge of boiling heat transfer in microchannel is important for the development of cooling needle because the size of fluid channel inside cooling needle is small. Many investigations

about boiling heat transfer in microchannel have been conducted. A criterion to differentiate between macroscale and microscale of two-phase flow and heat transfer was discussed by Kew et al[6]. and Kandlikar et al[7]. Kew et al. defined threshold diameter by using confinement number *Co* When confinement number becomes less than 0.5, the two-phase flow and heat transfer is classified into microscale phenomena. Confinement number is expressed as;

$$Co = \sqrt{\frac{\sigma}{g\left(\rho_L - \rho_V\right) D_h^{\,2}}}\,, \tag{1}$$

where σ [N/m], g [m/s^2], ρ [kg/m^3] and D_h [m] are surface tension, gravitational acceleration, density and hydraulic diameter, respectively. Subscript L and V are liquid and vapor, respectively. On the other hand Kandlikar et al. classified scale effect by hydraulic diameter of channel: conventional channel (> 3mm), minichannel (200μm-3mm), microchannel (10μm-200μm), transitional channel (0.1μm-1μm) and molecular nanochannel (< 0.1μm). Many experiments of boiling heat transfer in microchannel was conducted[8][9] and various correlations were proposed by using these experimental data. Chen proposed a correlation[10] which uses Lockhart and Martinelli parameter[11] to judge the laminar or turbulent flow in the both of liquid and gas phase. This correlation was improved by Zhang et al[12]. On the other hand Kandliker et al. also proposed a correlation[13] which used liquid phase Raynolds number to judge the flow condition. The both correlations define that two-phase flow heat transfer coefficient consists of nucleate boiling and single phase forced convective heat transfer coefficient. Furthermore Thome et al. analysed theoretically heat transfer phenomena of two-phase slug flow in microchannel[14]. However the boiling heat transfer mechanism in microchannel has not been fully understood. Additionally the correlations of boiling heat transfer which are given so far might not apply to cooling needle because experimental conditions of these studies are different from cooling needle. Therefore boiling phenomena in cooling needle should be clarified experimentally.

The final goal of our study is to conduct the cryosurgery by using cooling needle which has sufficient cooling power and to achieve the heat transfer control of cooling needle by controlling boiling phenomena in cooling needle. For that purpose, the behaviour of boiling flow and its heat transfer in cooling needle has to be clarified at first. The objective of this study is to evaluate the transient temperature response and transient boiling characteristics of cooling needle. As a first step, water with low pressure is used for refrigerant of cooling needle. The effects obtained by the difference of inner tube diameter are evaluated by visualization of boiling flow and measurement of temperature of cooling needle.

PRINCIPLE OF HEAT TRANSFER IN COOLING NEEDLE

Cooling needle has the co-axial double tube structure as shown in Fig.1. When refrigerant which is high pressure, high temperature and liquid state comes into inner tube, large pressure drop occurs. Furthermore the refrigerant expands on the exit of inner tube. This process is isenthalpic expansion therefore temperature and pressure decreases. The refrigerant becomes two-phase flow in the outer tube. This boiling phenomenon forcibly occurs due to the pressure difference between inlet and outlet tube. Therefore refrigerant absorbs the heat equivalent to evaporative latent heat which is required for phase change of refrigerant. As a result, surrounding of cooling needle is cooled. Its cooling power depends on the state of refrigerant (subcooled or saturated) or the flow state (single or two phase). The boiling phenomenon in cooling needle is different from boiling phenomena in conventional boiling experiment in microchannel in several points as follows;

1. Condition to reach saturation state in outer tube is not increment of quality by input heat flux but pressure drop by thin inner tube.
2. The enthalpy of refrigerant on the exit of inner tube is not corresponding of enthalpy on the inlet due to heat exchange to fluid flow in outer tube and frictional pressure drop in inner tube.
3. Boiling phenomena around tip of needle is the most important to use in cryosurgery.

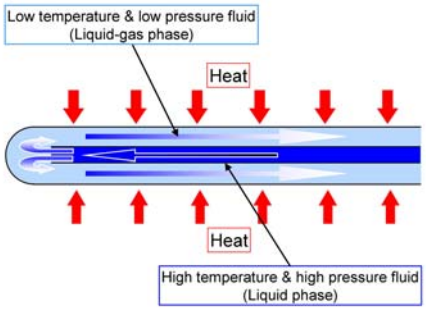

Figure 1. The cooling mechanism in cooling needle

EXPERIMENTAL APPARATUS

Figure 2 shows the schematic of the experimental apparatus. Working fluid is water. The apparatus consists of temperature-controlled reservoir, electromagnetic valves, needle section, liquid nitrogen (LN2) trap and oil-sealed rotary vacuum pump. Temperature-controlled reservoir is heated by the electrical heater to keep the temperature at 100°C. Therefore the pressure in the reservoir is kept at 0.1 MPa which is saturation pressure of water at 100°C. The oil-sealed rotary vacuum pump is used for keeping low pressure at nearly 0 Pa in outlet and LN2 trap avoids of indraft of water to vacuum pump. The electromagnetic valves can open the both of upstream and downstream flow pathes at a time. Temperature, pressure and flow rate were measured by thermocouple, bourdon tube pressure gauge and rotameter, respectively.

The needle section consists of glass pipe (1.2mm inner diameter, 2mm outer diameter) and nylon inner tube as shown in Fig. 3. Figure 4 shows the threshold diameter between microscale and macroscale two-phase calculated by Eq. (1). PROPATH[15] was used for the thermophysical properties of water. According to classification proposed by Kew et al., two-phase flow in glass pipe which is used in this experiment is classified into microscale phenomena. In addition, according to classification proposed by Kandlikar[7], this glass pipe is classified into minichannel. By using glass pipe, the flow pattern of boiling flow can be observed by digital high-speed microscope (KEYENCE Co., Ltd. VW-6000). Two types nylon inner tube were made by extending with heating. The dimensions of inner tubes are listed in Table 1. The values of the dimension of inner tube were determined by digital high-speed microscope. The needle section is partially heated as constant heat flux condition by nichrome wire supplied DC current as shown in Fig. 3. The length of heated area is 5mm. Thermocouple for measurement of needle surface temperature was set between glass pipe surface and nichrome wire. When temperature of the needle surface was measured, glass pipe was insulated thermally.

RESULT AND DISCUSION

Visualization result -bubble generation process

Figures 5 and 6 show the visualization results of boiling flow pattern. These snapshots were taken by digital high-speed microscope. The frame rate and shutter speed were set 1000 fps and 1/4000 s, respectively. The differences of inner tube influence on boiling flow pattern as shown in Figs. 4 and 5. The flow rates of inner tube A and B are 5.0 ml/min and less than 0.5 ml/min, respectively. The flow rate in the case of inner tube A was much larger than inner tube B because of the difference of inner diameter. The value of flow rate in the case of inner tube B was not determined because the minimum range of flowmeter is 0.5 ml/min. In the both cases, the emission of small bubbles from inner tube was observed. This phenomenon indicates that water became the saturation state on the exit of inner tube. In the case of inner tube A, the bubble was released from the tip of needle in 40ms. However, in the case of inner tube B, the bubble expanded on the tip of needle. Furthermore the quantity of liquid in glass pipe in the case of inner tube B was less than the case of inner tube A because of the difference of flow rate as shown in Figs. 5 and 6. In addition, small bubbles were observed in the liquid slug in the both cases. This phenomenon also indicates that water in glass pipe became saturation condition.

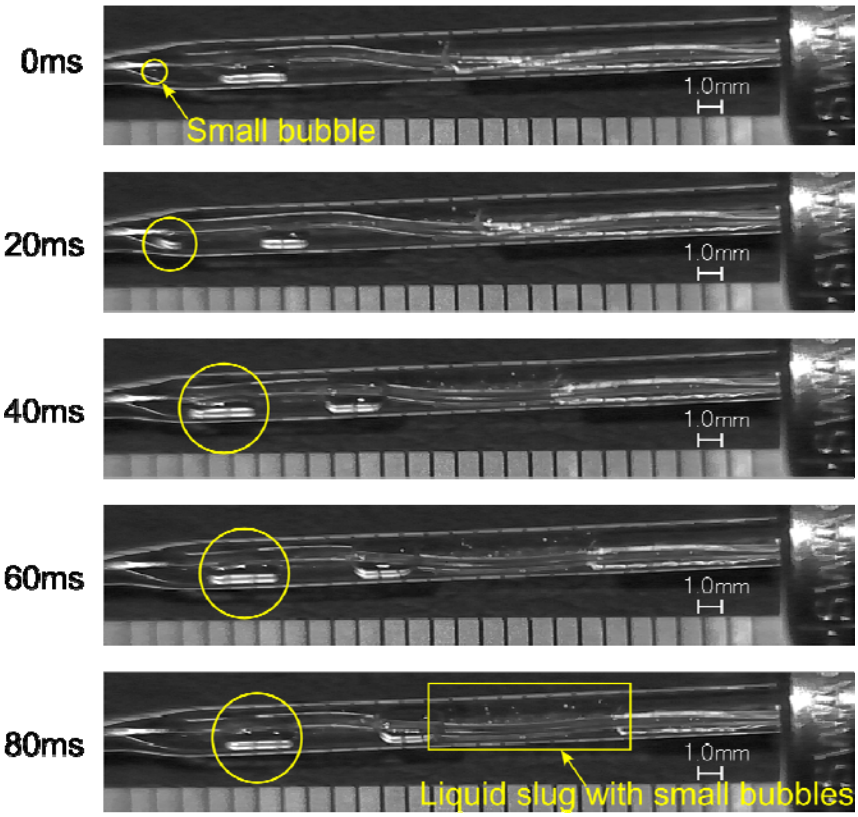

Figure 5. Visualization of bubble generation process in the case of inner tube A

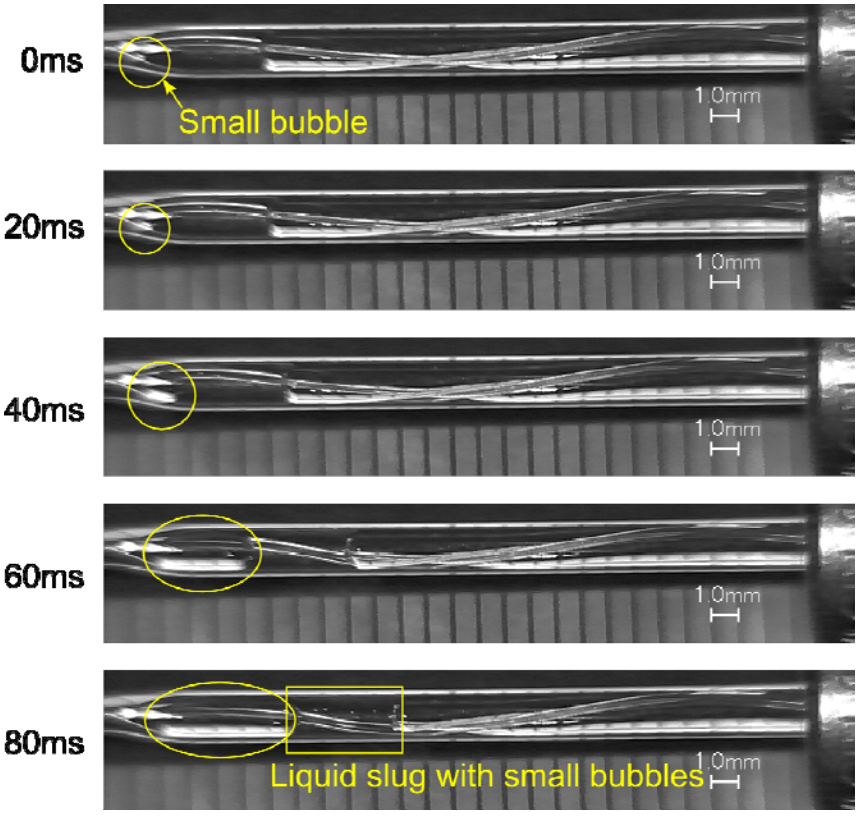

Figure 6. Visualization of bubble generation process in the case of inner tube B

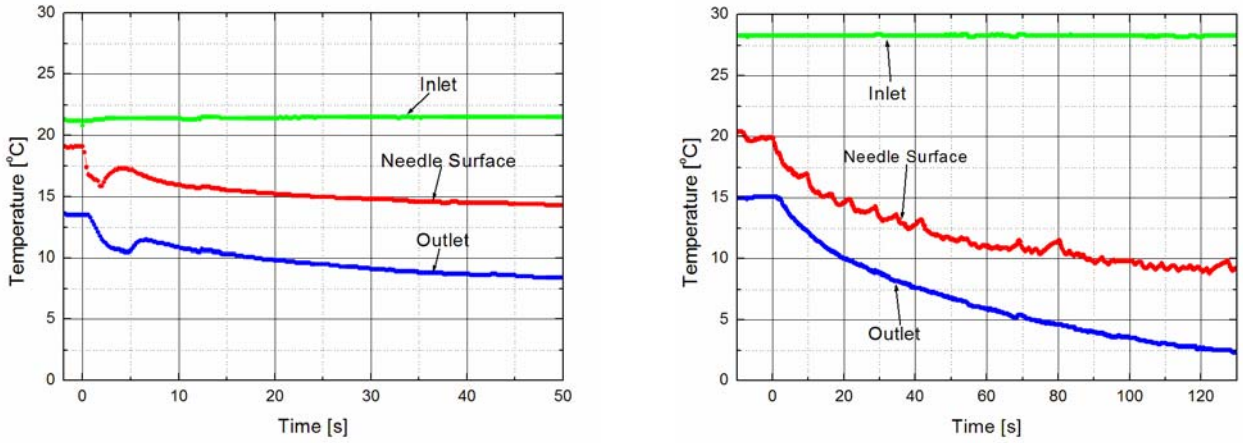
Temperature measurement without heating

Figure 7 shows the time variation of temperature of inlet, outlet and needle surface in the case of inner tube A and B, respectively. Needle surface temperature was measured with insulating around the needle. The time 0 s was defined as the moment when valve was opened. In spite of higher inlet temperature in the case of inner tube B than inner tube A, needle surface and outlet temperature of inner tube B was lower than inner tube A. Here it is assumed that convergence temperature of needle surface in Fig. 7 is the saturation temperature of the water in the tip of needle. By this assumption, the properties of saturated water on the exit of inner tube can be calculated.



(a) inner tube A (b) inner tube B

Figure 7. Time variation of temperature without heating on the needle surface

Temperature measurement with heating

Figure 8(a) shows transient temperature response of needle surface under various heat fluxes in the case of inner tube A. In this experiment, needle surface was heated before opening the electromagnetic valves. Afterward both of electromagnetic valves were opened. Figure 8 shows cooling process by boiling heat transfer. Furthermore needle surface temperature converges at constant value. This steady state temperature depends on the heat flux. During experiment needle surface temperature was controlled without exceeding 100°C because heat-resisting temperature of nylon tube is around 100°C. In addition, Fig. 8(b) shows transient temperature response under the various heat fluxes in the case of inner tube B. In the case of inner tube B, needle surface temperature did not increase by heat flux like the case of inner tube A because boiling phenomena even continued after valve close. Therefore transient process could not be observed. As a consequence, only steady state temperature of needle surface was measured under various heat fluxes as shown in Fig. 8(b). The needle with inner tube B could absorb larger heat flux than inner tube A.

Figure 9 shows the relationship between needle surface temperature, heat flux and vapor quality at the tip of needle. Thermodynamic equilibrium vapor quality x is defined as follows,

$$x = \frac{h - h_L}{h_{LV}}, \tag{2}$$

$$h = h_{in} + \frac{1}{\dot{M}} \int_S q dS , \tag{3}$$

where h [J/kg], $\dot{M}$ [kg/s], q [W/m^2] and S[m^2] are enthalpy, mass flow rate, heat flux and heat transfer area, respectively. In addition, h_L, h_{LV} and h_{in} are the enthalpy of saturated liquid, the latent heat of vaporization and the enthalpy of the fluid at inlet condition. In this study, h_{in} means the enthalpy of water on the exit of inner tube, therefore it corresponds to h_L. Heat transfer area S denotes the heating

area as shown in Fig. 3. It is assumed that flow rate of inner tube B is 0.5ml/min and saturation temperature of water in outer tube is equivalent to measured temperature in Fig. 7. It is obvious that needle surface temperature of inner tube B is lower than inner tube A. Flow rate of inner tube B is much smaller than inner tube A. However cooling power of inner tube B is larger than inner tube A. Futhermore vapor quality at the tip of needle in the case of inner tube B is much larger than inner tube A. The differences of needle surface temperature and vapor quality between inner tube A and B is caused by the difference of flow rate. This fact indicates that pressure drop of inner tube or the state of refrigerant at the exit of inner tube is important for cooling needle. Therefore the design of inner tube is one of significant factors to realize cooling needle for cryosurgery.

CONCLUSION

Boiling heat transfer experiment for developing cooling needle was conducted. The effect that the difference of inner tube diameter obtains was considered. Several results as follows are obtained.

- The emission of small bubbles from inner tube to glass tube was observed by visualization experiment. This phenomenon indicates that water became the saturation state on the exit of inner tube.
- Time variation of temperature of inlet, outlet and needle surface was measured. The needle surface and outlet temperature of thinner inner tube was lower.

- Temperature measurement with heat flux obtained on the needle surface was conducted and vapor quality was calculated. The relationship between needle surface temperature and heat flux elucidates that needle surface temperature of thinner inner tube is lower despite lower flow rate. This fact indicates that the pressure drop of inner tube or the state of refrigerant at the exit of inner tube is important for cooling needle.

DYNAMICS OF NANOFIBERS CONVEYED BY LOW REYNOLDS NUMBER FLOW IN A MICRO-CHANNEL

K. Sadlej*, E. Wajnryb, M.L. Ekiel-Jezewska, T. A. Kowalewski
IPPT PAN, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT. In this paper we aim on creating an experimental and numerical model of nano and microfilaments suspended in a confined Poiseuille flow. The experimental data obtained for short nanofibres will help elucidate fundamental questions concerning mobility and deformation of biological macromolecules due to hydrodynamic stresses from the surrounding fluid motion. Nanofibres suspended in the microchannel flow are obtained by electrospinning polymer solutions. Their typical dimensions are 100-1000μm (length) and 0.1-1μm (diameter). Typical for macromolecules, folding and unfolding sequences are observed and correlated with local flow gradients. This behaviour is compared with predictions of the Stokesian bead-spring model modelling dynamic behaviour of the fibre suspended in a Poiseuille flow between two infinite parallel walls.

Keywords: nanofibres suspension, microchannels, filaments dynamics, Stokesian dynamics

INTRODUCTION

Microfluidics is a rapidly growing field of basic and applied research, predominantly driven by the tight demands of biotechnology [1]. The well-known "lab-on-a-chip" (LOC) concept embraces the goal of integrating a bio-laboratory on a single microfluidic chip. Recent developments of the LOC technology provide possibility for handling not only single cells but to use the microfluidic systems for manipulating, sorting and analysing individual biomolecules. Devices consisting of nanoscale pores are being pursued as probes of molecular structure [1,2]. Single, double or triple DNA strands passing nanopores are observed to extract the identity of DNA bases [3,4]. Rapid measurements of DNA fragment size, of their folding and unfolding sequences represent challenging target for present single molecule studies. Development and availability of highly sensitive experimental tools permits to follow transient behaviour of single macromolecules in nearly native environment. However, such studies are still very tedious and expensive, and available experimental data are mostly quantitative, not accurate enough to be used for validating numerical models. In addition modelling of microbiological processes involve complex molecular interactions difficult for direct modelling due to prohibitive number of molecules involved and time scales far beyond those available for simulation methods at molecular level [5,6]. On other hand coarse, long time scale behaviour of macromolecules can be usually relatively well described using simple Stokesian fluid dynamics. Understanding slender filament dynamics in Stokesian flow may elucidate fundamental questions about mobility and deformation of biological macromolecules due to hydrodynamic stresses from the surrounding fluid motion. Moreover, by combining hydrodynamic interactions with molecular models one may aim to achieve a multiscale description of biologically driven process.

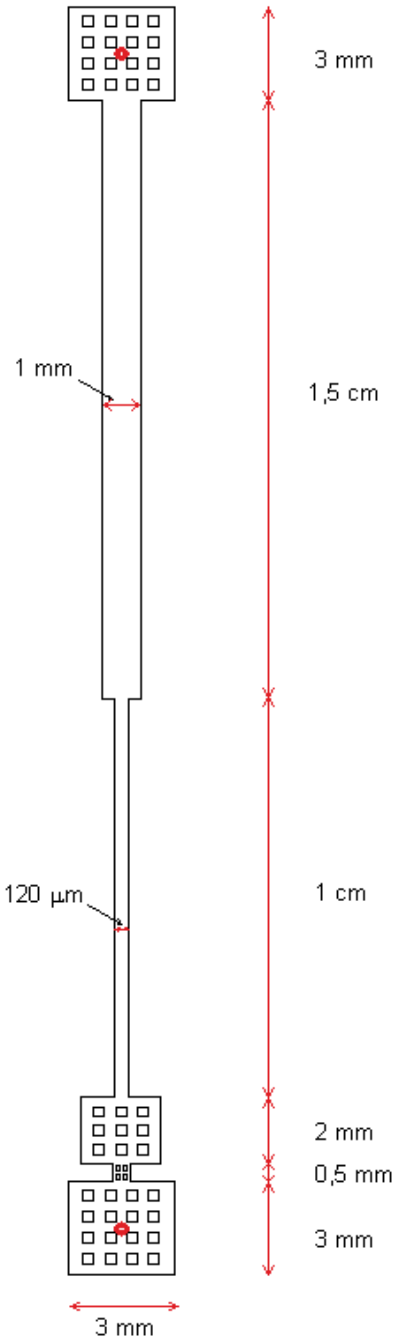
Having all above arguments in mind the present paper aims on creating an experimental and numerical model allowing to obtain quantitative data on hydrodynamics of nano and microfilaments suspended in a confined Poiseuille flow. Microscopic data are obtained for the fluid - filament interactions, including their lateral migration, wall effects, and folding-unfolding sequences. To evaluate the importance of hydrodynamic interactions a macroscopic model is developed for modelling dynamic behaviour of a single fibre in a Poiseuille flow.

EXPERIMENTAL



The main part of the experimental set-up consists of a microscope, a laser light source and a high speed digital camera. The flow is observed using a 10x (NA 0.3 / WD 17.30 mm) microscope lens covering an area of *854 µm x 683 µm.* Short illumination time is achieved by using a single pulsed Nd:YAG laser, delivering 1 mJ energy at 532 nm wavelength and 1kHz repetition rate (Ekspla Ltd). The flow is illuminated and observed through the upper wall of the channel. By traversing the field of observation in the horizontal and vertical direction, the position of the interrogated flow plane is selected. For the recording of images a high-speed 10bit *PCO 1200HS* camera with 1280 x 1024 pixels resolution is used. In most cases the flow was driven by syringe micro-pump permitting flow rate variation from 1 $\mu m^3/s$ to 1 mm^3/s.

The micro and nano filaments used in the experiment are produced by electrospinning polymer solutions [7]. Two types of polymers, polycaprolactone (PCL) and poly-L-lactide (PLLA), are used to form short, insoluble in water filaments. Small amount of rhodamine is added to the polymer solution to make produced filaments visible under a fluorescence microscope. By modifying electrospinning parameters, it is possible to produce filaments of diameters varying from 100 nm to 5 µm. The aspect ratio of filaments is then in the range from 50 to several thousands. In fact it is difficult to obtain short pieces of filaments and several scenarios of microfluidic separators are applied to preselect randomly chopped continuous nanofibres before they are used for the experimentation. The flow is studied in different channels created in a PDMS mould. The typical channel dimension is 100µm. Fluorescence of filaments suspended in the flow is excited by Nd:Yag laser and emitted red light (610nm) is collected by the camera using appropriate filters. Translocation of filaments within the channel and their shape evolution are evaluated using image processing software.

Fig. 1 Schematic of the microchannel used for studying nanofibre translocation in the flow.

Figure 1 shows typical shape of microchannel used for investigating single fibre dynamics. The straight parts of the microchannel allow for studying fibre interaction with a Poiseuille flow, structured obstacles in form of pillars are used to analyse possibility of fibre sorting.

NUMERICAL

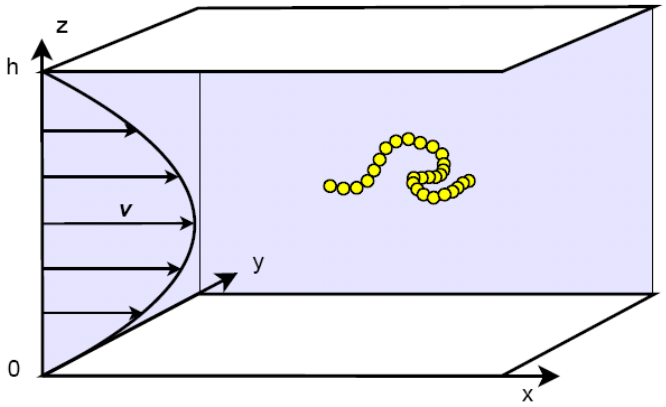


Fig. 2. Coordinate system of the numerical model

The bead-spring model is used for modelling the dynamic behaviour of fibres in a Poiseuille flow inside a microchannel modelled by two infinite parallel walls (Fig. 2). The regime of low Reynolds number of a particle is considered and the Brownian motion of particles is neglected resulting in a description based on the stationary Stokes equations

$$\begin{aligned} \eta\nabla^2\mathbf{v} - \nabla p &= \mathbf{0}, \\ \nabla\cdot\mathbf{v} &= 0, \end{aligned}$$

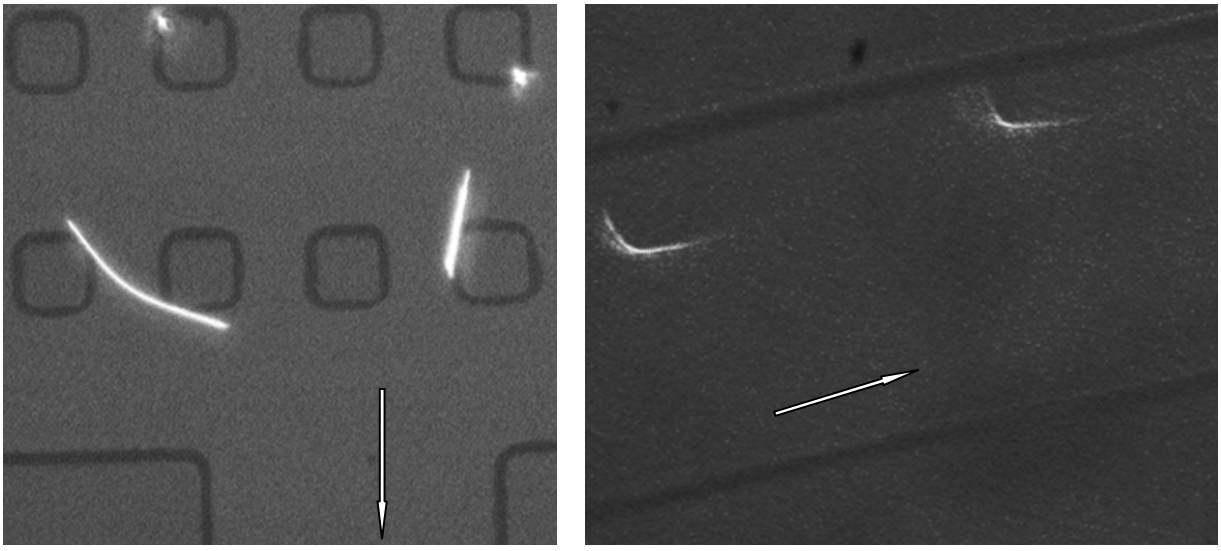
where η is the fluid viscosity, p is the pressure and **v** is the fluid velocity field. These equations must be supplemented by stick boundary conditions for the fluid velocity field on fibre and wall surfaces, as well as the condition of vanishing fluid flow disturbance far away from the fibre. In the model adopted, each fibre strand is constructed out of N solid non-deformable spherical particles which can move with respect to each other [8]. The spheres are lined up and connected by fictitious springs with equilibrium length l_0, a parameter of the model. Although external, non-hydrodynamic forces or torques applied to the fibre are absent, each segment of it feels elastic and bending forces defined for each fibre conformation and forces resulting from hydrodynamic interactions between segments of the fibre and with the flow itself. The derivation of the dynamical behaviour of the fibre realizes the following procedure. For each fixed configuration the instantaneous hydrodynamic forces exerted by the fluid on the particles are calculated. Then the velocity of each bead is linearly proportional, through the mobility matrix dependent on the exact position of all fibre segments, to the sum of these forces and the elastic and bending forces exerted on each fibre segment. Both the hydrodynamic forces and the mobility matrix are determined numerically by the HYDROMULTIPOLE algorithm [9], which implements the theoretical multipole method [10] of calculating hydrodynamic interactions between bodies within Stokesian dynamics. In this particular case, the wall effects where evaluated by the single-wall superposition. The evolution of the fibre is then determined by time stepping the set of coupled differential equations for each fibre-segment position. The calculations have been performed for several initial configurations, different fibre aspect ratios (number of beads) and different flexibilities.

RESULTS

Preliminary experiments with single nanofibres are performed to collect knowledge about different flow scenarios. Steady and pulsating flow is generated to analyze behaviour of suspended

nanofibres. In most cases after single nanofibre is localized in viewing area of the camera, the flow is stopped and reversed. Such push-pull motion permitted to observe selected object without changing position of the channel. Figures 3 and 4 show examples of collected images of nanofibres acquired under fluorescent microscope. The motion of short (0.1 mm) fragments through the multi pillar structure (Fig. 3a) exhibits characteristic fibre bending.
For longer fragments (above 0.5 mm) looping of the fibre tails is observed. Long fragments are often trapped or their relative motion is slowed down. This effect can be used to sort out selected fibre fragments before they enter the straight part of the microchannel (comp. Fig. 1). Fibres conveyed through the straight channel are usually deformed by flow shear stress (comp. Fig. 3b, Fig. 4). This behaviour shows several similarities to confinement-induced coiling-recoiling of DNA molecules.

The sequence of images shown in Fig. 4 is extracted from the longer movie illustrating complex dynamics of nanofibre fragment located about 40μm from the channel wall. It is interesting to note that average velocity of the fibre is similar to that of tracer particle located close to the flow axis (Fig. 4). By tracing displacement of both tails of the tangled fibre it is found that its part being closer to the wall is apparently nearly 20% faster than the other one. This striking behaviour seems to be confirmed by our numerical model (comp. Fig. 5).



a b

Fig. 3. Fluorescent filaments passing multi-pillar separator (a), and conveyed close to the channel wall (b). Image width corresponds to 0.3mm.

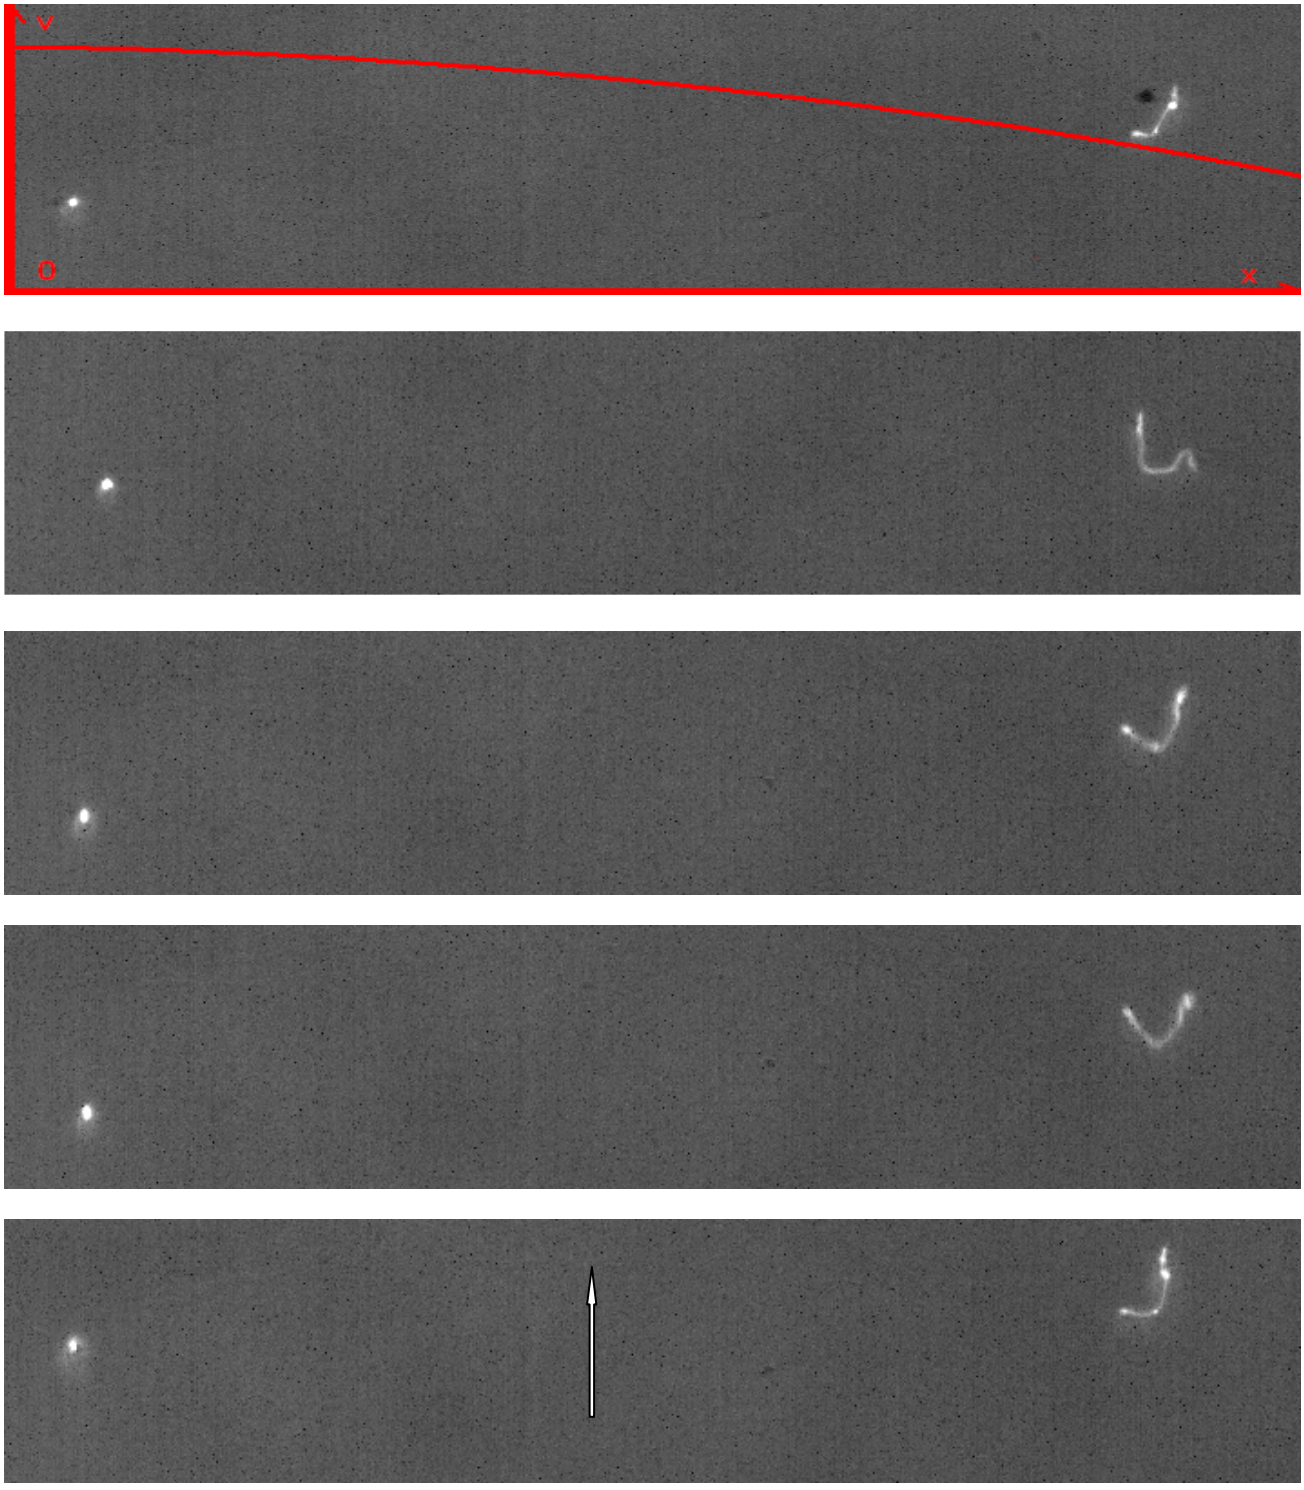


Fig. 4. A sequence of images of a nanofibre conveyed by a pulsating Poiseuille flow. The microchannel width is 2mm and the mean flow velocity is 40μm/s. Channel axis is on the left side, less than one half of the channel is visible. Poiseuille velocity profile is indicated by the red line. The bright spot on the left is a fluorescent particle used to measure local flow velocity.

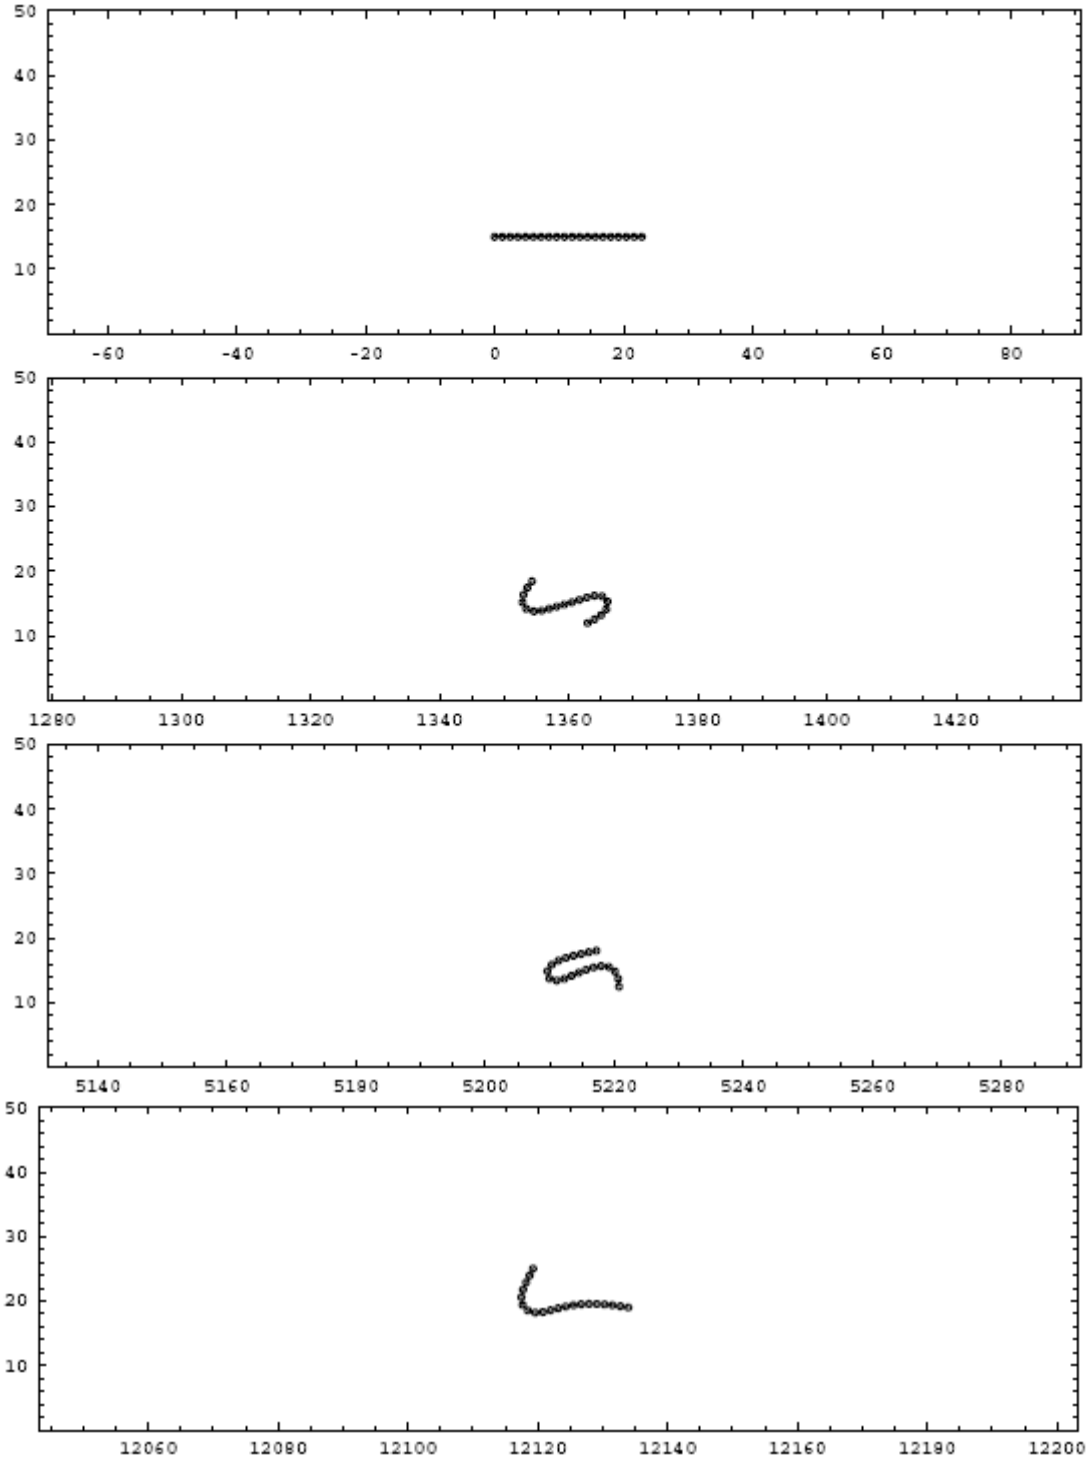

Fig. 5. Numerical modelling: flipping/tumbling motion of a fibre conveyed along the channel wall. Travelled distance given in fibre diameter units; initial fibre position $z = 15$. Number of beads $N = 20$, distance between walls $h = 50$ (fibre diameter units).

Several simulation runs performed for short "strings of beads" conveyed by Poiseuille flow gave us very promising results, reproducing the typical evolution of a fibre shape observed in the experiment. However, at the moment quantitative comparison with the experiment is limited by lack of elastic data for the available filaments. Hence, the present aim is to estimate unknown elastic properties of the physical filament by try-and-error simulation of observed filament. We have therefore preformed simulations for fibres of different length and flexibility. These have provided some interesting conclusions summarized below:

1. The motion of a single fibre strand in Poiseuille flow shows a generic behaviour. Independently of the initial configuration, it fairly rapidly (depending on its length and degree of entanglement), straightens out along the streamlines. It then begins a flipping or tumbling motion, which is almost periodic. Almost, not exactly, because the fibre has a tendency to migrate toward or away from the wall, moving through areas of different flow velocities.
2. Migration of fibres towards the centre of the channel is present only when the initial distance from the wall is large enough (typically larger then approximately 5 fibre diameters). The migration speed then decreases with distance from the wall.
3. Greater stiffness of the fibre hinders flipping on small distances from the wall and increases the flipping period elsewhere.
4. Longer fibres migrate faster towards the middle of the channel and take much longer time to flip while bending. This is shown in Fig. 6, where the distance between the first and last segment of the fibre is plotted for the whole flipping period. The short fibre (5 beads) behaves as a solid rod rotating in the flow, whereas for the long fibre (40 beads) nearly periodic stretching and winding is visible.

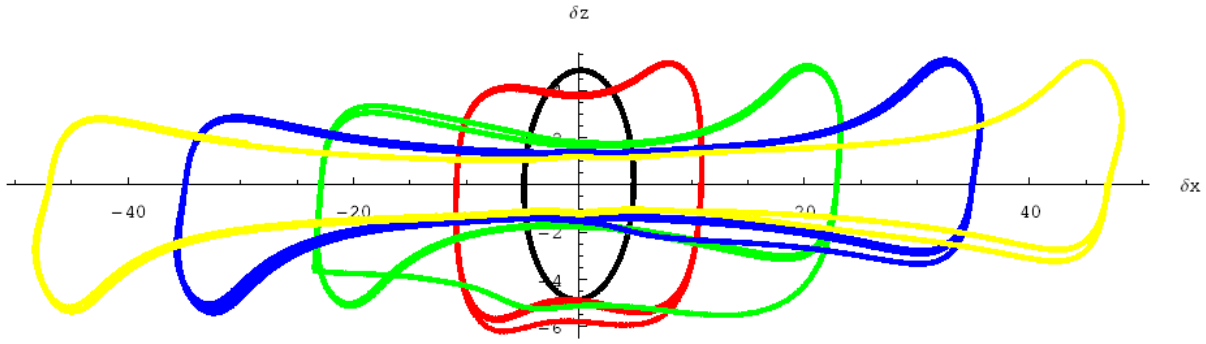

Fig. 6. Numerical modelling: evolution of the distance (δx , δz) between both ends of the fibre conveyed by the flow in x direction. Initially fibre is aligned with the flow (δz =0). The equilibrium distance between fibre segments is $l_0 = 1.2$. Five different fibre lengths marked by colours: black: N = 5, red: N = 10, green: N = 20, blue: N = 30, yellow: N = 40. Shorter fibres tend to stay straighter during flipping. In particular, for N = 5 the fibre virtually does not fold at all. The plotted evolution curve (black) is then almost a perfect circle.

CONCLUSIONS

Our preliminary experimental and numerical studies demonstrate the possibility of evaluating the dynamics of long filaments conveyed in the Poiseuille flow. Several observed features show convincing similarities to confinement induced deformations of biopolymers or DNA strands. Further study is planned to elucidate details necessary for quantitative analysis of this phenomena.

NOMENCLATURE

h	distance between walls, fibre diameter units
N	number of beads, relative length of the fibre.
x, z	coordinates along the channel and across the channel, distance in fibre diameter units.
δx , δz	distance between both ends of the fibre, fibre diameter units

ABSTRACT. Application of a two-phase slug flow in side-stream membrane bioreactors (MBRs) has proven to increase the permeate flux and decrease fouling through a better control of the cake layer. Literature has shown that the hydrodynamics near the membrane surface have an impact on the degree of fouling by imposing high shear stress near the surface of the membrane. An experimental program was developed to investigate the shear stress imposed on the surface of a membrane under different two-phase flow conditions (gas an liquid), by varying the flow of each phase. Due to the random behaviour of the shear stress values, caused by the continuous passing of bubbles and difference in size (coalescence), the results were analysed using histograms of shear stress distributions (SSD). A bi-modal SSD was observed, with one peak corresponding to the shear induced by liquid flow, and the other induced by gas flow. This distribution could be modelled using two Gaussian relationships. Literature suggests that fouling control is expected to be optimal when the shear induced by liquid flow is approximately equal to that induced by gas flow. Therefore, the Gaussian relationships could be used to identify the two-phase flow conditions that optimize fouling control.

Keywords: *Side-stream membrane bioreactor, gas-liquid slug flow, wall shear stress, bi-modal distribution*

INTRODUCTION

Bearing in mind the more stringent effluent quality standards imposed by the EU Water Framework Directive (EU-WFD), treatment efficiencies need to be improved. These improvements can be achieved both in terms of biological removal efficiency as well as in the sludge-water separation step. For the last step two types of technologies exist, the Conventional Activated Sludge (CAS) systems where the separation is brought about by gravity (Figure 1, a) and the Membrane Bioreactors (MBR) where the separation is achieved by filtration (Figure 1, b and c). The latter has proven to be a good alternative to achieve high effluent quality compared to the CAS. However, a common problem encountered with MBR systems is fouling of the membrane resulting in a frequent need for membrane cleaning to remove the accumulate foulants [1], making it a less appealing alternative in terms of cost-effectiveness. This has been the limiting factor in the full-scale application of these systems. There are two types of MBR, one has the membrane inside the bioreactor, commonly called immersed membrane bioreactor (iMBR) (Figure 1, b); and the other has the membrane outside the bioreactor, named side-stream membrane bioreactor (sMBR) (Figure 1, c). This work focuses on the latter type.

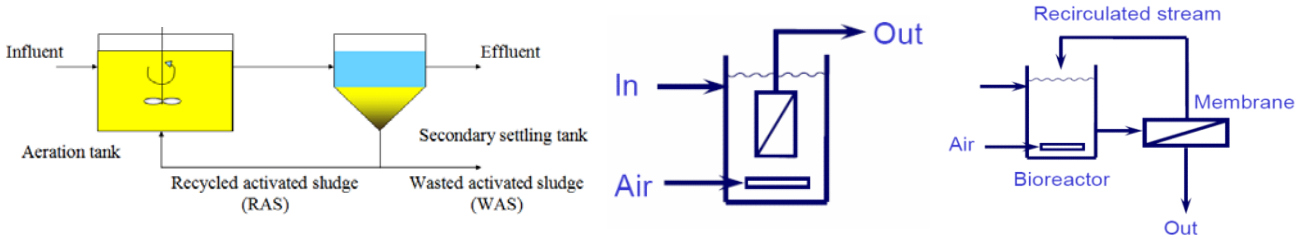

Figure 1. (a) Conventional Activated Sludge (CAS), (b) Immersed and (c) side-stream MBR [1]

The hydrodynamics near the membrane surface play an important role in fouling control. To reduce the fouling near the membrane surface, air is often introduced in the sludge flow to create a gas-liquid two-phase slug flow [2], which increases the surface shear stress. These shear stresses increase the mass transfer of foulants away from the membrane surface. However, the mechanism governing the mass transfer of foulants under two-phase flow conditions are poorly understood, and therefore, a trial-and-error approach is used to optimize the hydrodynamics of two-phase flow near a membrane surface.

In the slug flow that typically builds up, three different zones can be distinguished (Figure 2): 1) the falling film zone, i.e. the zone where the bubble is passing, 2) the wake zone, i.e. the zone just behind the bubble where mixing of liquid and gas takes place and 3) the liquid slug zone.

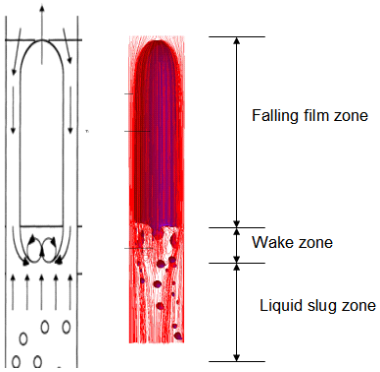

Figure 2. Zones in the slug flow [3] (left) and numerical simulation of a Taylor bubble rising through stagnant glycerine in a vertical tube [4] (right)

Experimental studies on hydrodynamics of two-phase flow have been reported in literature using shear probes [5, 6]. The method uses an electrolyte solution with a well known stoichiometry reaction which allows to correlate the diffusion (mass transfer) with a difference in electrical potential [7]. However, a more comprehensive hydraulic model of two-phase flow along a membrane is needed to better understand the mechanisms and allowing for better control of the fouling phenomenon.

MATERIALS AND METHODS

Description of the Setup

A description of the setup is given in Figure 3. For the present study, a Plexiglas tube, similar in geometry to the airlift tubular membranes of interest, was used. The tube has a length of 2 m with an inner diameter of 9.9 mm. In the middle of the tube (1 m) a flow cell is present which contains 2 electrochemical shear probes (cathode). A stainless steel pipe fitting is located downstream of the pipe

(at top of the pipe apparatus, anode). A temperature controlled water bath (20°C) is used to keep the temperature of the electrolyte solution flowing through the system constant. A MasterFlex pump is used to recirculate liquid in the system and a rotameter (range 0 to 1 L min^{-1}) is used to measure the liquid flow rate, whereas a gas flow meter (range 0 to 0.33 L min^{-1}) is used to measure the flow rate of the nitrogen gas. Nitrogen gas was used instead or air to avoid the oxidation of the electrolyte solution. A gas-liquid separator tank, which is used to store the electrolyte solution, feeds the tube with liquid and closes the loop.

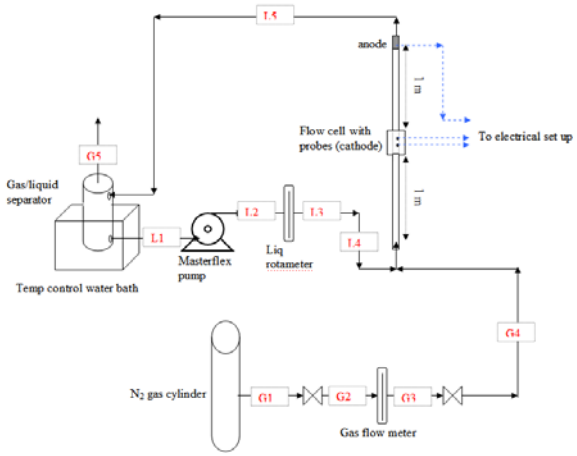

Figure 3. Description of the electrochemical shear measurement.

The electrolyte solution is pumped to the tube with specific flow rates (0.1, 0.2, 0.3, 0.4 and 0.5 L min^{-1} or 0.022, 0.043, 0.065, 0.087 and 0.108 m s^{-1}), which are monitored with the liquid rotameter. The nitrogen gas is pumped to the tube directly from a gas cylinder at different flow rates (0.1, 0.2 and 0.3 L min^{-1} or 0.022, 0.043 and 0.065 m s^{-1}), monitored by the gas flow meter. Water with the electrolyte solution and nitrogen are pumped inside of the tube at the bottom. This leads to a total of 15 possible gas-liquid flow rates, corresponding to the expected operating range in full-scale airlift tubular membrane systems, that were investigated. For each combination, surface shear stresses were measured for a period of 10 seconds, and recorded at a frequency of 1000 Hz [8]. For each combination six repetitions were performed. The flow cell has two shear probes to allow determination of the direction of the flow. When both probes in the flow cell are connected to the circuit simultaneously, the probe that is upstream (relative to the direction of flow) measures a higher magnitude of shear signal compared to the probe that is downstream of the flow. This occurs because the downstream probe is in the diffusional wake of the upstream probe [9].

Shear probes and shear stress

The shear signals recorded in Labview are in units of Voltage. This voltage can be transformed into shear stress (τ) using the following relation [7]:

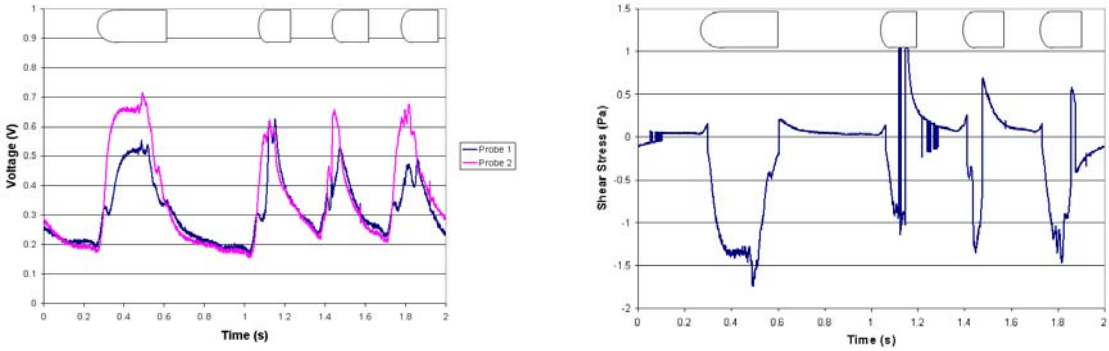
$$\tau = \mu_L \left[\frac{4.64\,V}{\nu_e F \pi d_e^{\frac{5}{3}} C_o D^{\frac{2}{3}} R G} \right]^3 \qquad (1)$$

where V is the voltage signal (V), R is the resistance (Ω), G is the amplifier gain (=1000), ν_e is the number of electrons involved in the reaction (=1), F is the Faraday constant (=96 500 C mol^{-1}), d_e is the diameter of the probe (m), C_o is the bulk concentration of ferricyanide (=3 mol m^{-3}), D is the diffusion coefficient of ferricyanide ($7.14 \cdot 10^{-10}$ m^2 s^{-1}) and μ_L is the dynamic viscosity of the solution (= 0.001 Pa s).

RESULTS AND DISCUSSION

Shear profiles in two-phase vertical pipe flow

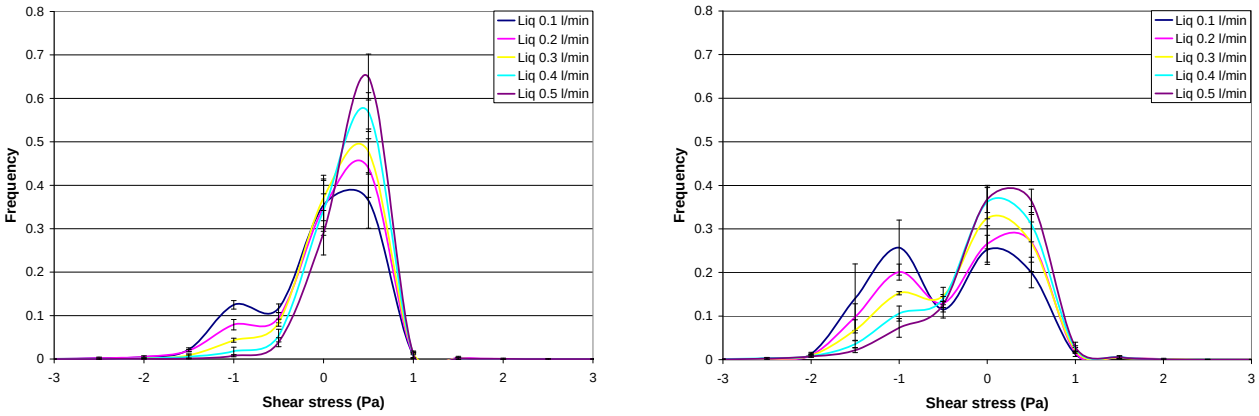
Typical results obtained using the electrochemical shear probes, and the corresponding shear stresses, are presented in Figure 4 a and b, respectively.



(a) (b)

Figure 4. a) Raw voltage signal for the two probes and b) conversion to shear stress for a water-N_2 combination of 0.1-0.1 L min^{-1} during a period of 2 s. (Note that the figure contains schematics of the slugs and their impact on the shear stress)

In Figure 4, the valleys in the shear stress are the bubbles and the plateaus are the liquid slug. Gas slugs rising in the vertical tubes were observed to periodically coalesce when downstream slugs 'catch-up' with upstream slugs. The coalescence occurs because two bubbles join together when the space between them gets shorter and the trailing bubble reaches the wake of the leading bubble, which makes the trailing bubble accelerate and finally coalesce with the leading bubble. This is the reason why the shear stress patterns induced by successive slugs are not similar. As a result, the pattern of shear forces in successive shear events, induced by rising gas slugs by the electrochemical shear probe, varied considerably over time. In addition to being used to validate the CFD model, shear stress distributions (SSD) were used to explore the effect of the different experimental conditions investigated on the resulting shear stresses. The SSDs with bins of 0.5 Pa were derived in the range -3 and 3 Pa (Figure 5). The histograms summarise two things: 1) the range of SSD that the membrane surface experiences and 2) the frequency or the duration of this exposure. SSD for the different gas-liquid flows are shown in Figure 5.



(a) (b)

Figure 5. SSD for two different gas flow rates (a) 0.1 and (b) 0.3 l min^{-1} with five liquid flow rate combinations.

For all cases, it is possible to distinguish clearly two peaks in the distributions (bi-modal distribution): a first peak occurs at a marginally positive shear value and is caused by the liquid slug; whereas a second peak occurs at a negative shear value and is caused by the gas slugs. The magnitude of the frequency for both peaks is, however, different for the different gas-liquid flow rate combinations. At low gas flow rates, the liquid slug peak is more pronounced (Figure 5a) and the magnitude of the frequency of the liquid peaks increase with the liquid flow rates. Similar findings can be observed in Figure 5b. However, at higher gas flow rates, the peaks become more balanced.

A number of studies have suggested that fouling control can be correlated to the variability in the magnitude of surface shear stresses [10]. Therefore, conditions that maximize the occurrence of both positive (liquid flow) and negative (bubble flow) shear conditions are likely to promote better fouling control. For all experimental conditions investigated, a bi-modal SSD was observed (Figure 5). An empirical relationship was developed to model the bi-modal SSD based on the Gauss distribution for the different experimental conditions investigated using the following equation:

$$f(\tau) = \underbrace{\frac{A_1}{w_1\sqrt{0.5\pi}}\exp\left[-\frac{(\tau-\tau_1)^2}{w_1^2}\right]}_{Gas\ slug} + \underbrace{\frac{A_2}{w_2\sqrt{0.5\pi}}\exp\left[-\frac{(\tau-\tau_2)^2}{w_2^2}\right]}_{Liquid\ slug} \quad (2)$$

The parameter $A_i / w_i\sqrt{0.5\pi}$ is the height of the curve's peak, τ_i is the position of the centre of the peak, and w_i controls the width of the curve. From the previous equation, there are six parameters that need to be defined (A_1, A_2, w_1, w_2, τ_1 and τ_2). The 15 SSD that were obtained from the different combinations investigated were fitted by equation (2) using Sigmaplot v10 obtaining an R-squared of 0.999 for all the combinations. Linear correlations for the different parameters were tested based on the liquid (u_{SL}) or gas (u_{SG}) superficial velocity as follows:

$$A_1 = m_1 u_{SG} + b_1 \quad (3) \qquad w_1 = m_3 u_{SL} + b_3 \quad (5) \qquad \tau_1 = m_5 u_{SL} + b_5 \quad (7)$$

$$A_2 = m_2 u_{SG} + b_2 \quad (4) \qquad w_2 = m_4 u_{SG} + b_4 \quad (6) \qquad \tau_2 = m_6 u_{SL} + b_6 \quad (8)$$

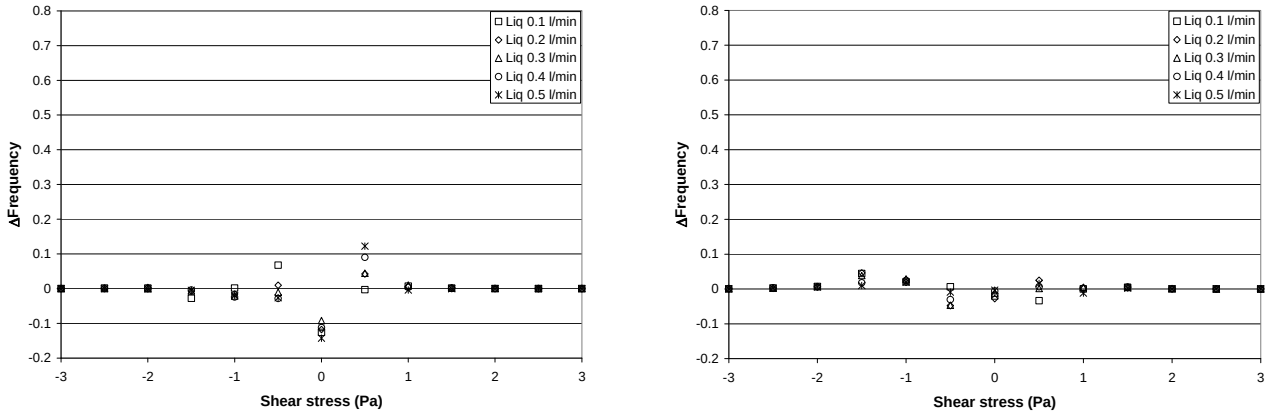
The coefficients of the slope (m_i) and intercept (b_i) are presented in Table 1.

Table 1.
Slope and intercept coefficients for equations (3) to (8)

	m_i	b_i	r^2
A_1	2.4122 ± 0.4593	0.0606 ± 0.0215	0.6797
A_2	-4.1921 ± 1.1033	0.5387 ± 0.0516	0.6104
w_1	5.3298 ± 0.8327	0.6167 ± 0.0598	0.7591
w_2	3.9621 ± 1.3383	0.3413 ± 0.0626	0.7103
τ_1	9.8327 ± 1.6658	-1.2210 ± 0.1196	0.7283
τ_2	0.5881 ± 0.2629	0.2135 ± 0.0189	0.2965

The correlations obtained are shown in Table 1, and present low R-squared values. This was due to the fact that the six parameters in equation (2) were modelled with a linear relationship, and each parameter was defined in terms of the superficial liquid or gas velocities (no combinations). This was done on purpose to keep the model structure simple.

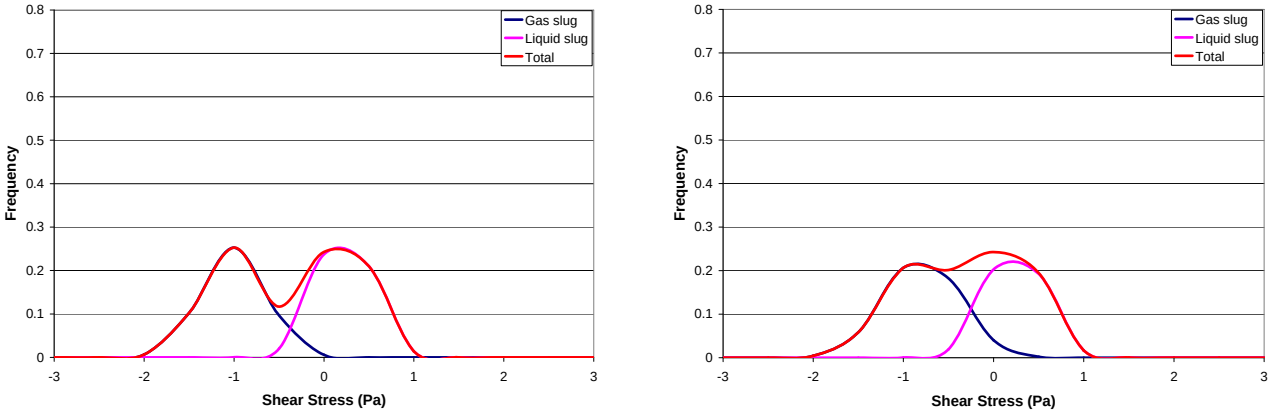
The SSD obtained using equations 2 to 8 were compared to those obtained experimentally (Figure 6). At relatively high gas flow rates, the frequencies obtained using equations (2) to (8) and experimentally were relatively similar, deviating by less than approximately 5 %. However, at relatively low gas flow rates, the differences were slightly higher, exceeding 10 %.



(a) (b)

Figure 6. Difference in frequency from SSD between experimental and correlations for two different gas flow rates (a) 0.1 and (b) 0.3 L min^{-1} with five liquid flow rate combinations.

The results suggest that equations (2) to (8) were able to predict the experimental data accurately. Therefore, these equations can be used to identify one exact set of operating conditions that make the gas and liquid flow rates generate similar peaks in the bi-modal SSD. The balance of the liquid and gas peaks are in terms of the curve height ($A_i / w_i \sqrt{0.5\pi}$), the width (w_i) and the centre of the peak (τ_i). However, the last term (τ_i) cannot be fixed in the equation due that the centre of the positive and negative peaks occurs in different places (positive and negative shear stress). Therefore, two velocities combinations were identified within the range of the operational conditions investigated and used to reproduce the SSD. They are presented in Figure 7.



(a) (b)

Figure 7. SSD for different liquid-gas flow rates: (a) 0.10-0.32 and (b) 0.20-0.36 L min^{-1}

From Figure 7, it is possible to observe three curves, derived from equation (2). Where the first peak is the gas slug, the second is the liquid slug and the third line is the sum of both. Similar values were found between the height and the width of these curves to have a balance liquid and gas slug

peaks in terms of frequency. Nevertheless, a perfect match was not possible within the experimental range and a slightly extrapolation for the gas flow rate was made. From Figure 7a, the ratio between the liquid and the gas flow rate is 3.2 times, which means that to equilibrate the peaks at this specific liquid flow rate it is necessary to have 3.2 times more flow rate of the gas compared to the liquid. For Figure 7b, a ratio of 1.3 was found, where the flow rate of the liquid was double but the gas flow rate kept almost similar as for the case of Figure 7a. From these results, it is possible to observe that the liquid flow rate doubled but that the gas flow rate increased only 10 % to balance the two peaks.

Another factor to consider in optimising fouling control is the energy consumption, which can be expressed in terms of pressure drop using the correlation developed by [11] for two-phase flow. These equations will not be discussed further in the paper. A sum up of the pressure drop in function of the gas-liquid flow rates is presented in Table 2.

Table 2.
Two-phase pressure drop

Liquid flow rate L min^{-1}	Gas flow rate L min^{-1}	Pressure drop kPa	Liquid flow rate L min^{-1}	Gas flow rate L min^{-1}	Pressure drop kPa	Liquid flow rate L min^{-1}	Gas flow rate L min^{-1}	Pressure drop kPa
0.1	**0.32**	**4.89**	0.2	0.2	10.12	0.4	0.2	13.48
0.1	0.3	5.16	0.3	0.3	10.19	0.5	0.2	14.45
0.1	0.2	6.78	0.4	0.3	11.63	0.3	0.1	15.07
0.2	0.3	8.17	0.3	0.2	12.13	0.4	0.1	16.08
0.2	**0.36**	**9.36**	0.5	0.3	12.71	0.5	0.1	16.76
0.1	0.1	10.06	0.2	0.1	13.40			

When the pressure drop is low the energy requirements to pump the liquid and gas through the tube are lower. From Table 2, the highlighted values correspond to the liquid-gas combinations that were found as optimal combinations. From this analysis the optimal combinations result in lower pressure drop in the tube. For instance, comparing the use of liquid-gas 0.1-0.32 l min^{-1} requires 5 % less energy than 0.1-0.3 l min^{-1} and has a better remove of particles due to the balance of shear stress in the membrane surface. Finally, this correlation can be used to determine the more efficient liquid-gas ratio to increase the removal of particles at the membrane surface and to optimize the energy consumption in terms of pressure drop.

CONCLUSIONS

Due to the coalescence of bubbles, the shear stress is excessively random; therefore, SSDs are used to quantify the shear stress the tube surface is exposed to. Two peaks were found, one due to the liquid and a second due to the gas slugs. At different gas-liquid flow rates combinations, these peaks change in terms of frequency. At high liquid flow rates the liquid peak increases and the gas peak decreases. At high gas flow rates, the gas peak increases, however the liquid pick does not disappear. The bi-modal behaviour was correlated with two Gauss distributions, one for each peak. A total of six parameters were needed to describe the two Gauss distributions, each of these parameters were correlated with a linear regression function of the superficial liquid or gas velocity. A comparison between the numerical correlation and the experimental data was made and presented an error less than 15 %. The numerical correlation was used to find balanced peaks in the Gauss distribution in terms of

height and width. It was found that this new correlation can help to identify the optimal gas and liquid flow rates that minimize fouling and decrease energy requirements in terms of pressure drop.

NOMENCLATURE

A_i	height of the peak in the Gauss curve
C_o	bulk concentration of ferricyanide ions (mol m^{-3})
d_e	diameter of the probe (m)
D	diffusion coefficient of ferricyanide (= $7.14 \cdot 10^{-10}$ m^2 s^{-1})
F	Faraday constant (= 96 500 C mol^{-1})
G	amplifier gain (= 1000)
R	resistor in the circuit (Ω)
$u_{SL,G}$	superficial velocity of liquid or gas (m s^{-1})
v_e	number of electrons involved in the reaction (= 1)
V	measured shear signal (V)
w_i	width of the Gauss curve.
τ	wall shear stress (Pa)
τ_i	position of the centre of the peak in the Gauss curve

SCREENING DIAGNOSTICS OF ERYTHROCYTIC SOLUTIONS BASED ON DISSIPATIVE PATTERNS BEHAVIOUR IN THE PRESENCE OF A MAGNETIC FIELD

A.A. Bozhko[1, *], G. Kirko[2]

[1] Perm State University, Perm, Russia
[2] Perm State Academy Medical, Perm, Russia

ABSTRACT. The influence of a uniform magnetic field on the behaviour of erythrocyte solutions made of fresh blood samples is investigated. It is found that the dissipative structures in these solutions taken from different donors differ from each other. Subsequently, it is shown that the application of a magnetic field parallel to the surface of a solution can be successfully used for express screening diagnostics of samples.
Keywords: *erythrocyte solution, dissipative patterns, magnetic field, express diagnostics*

EXPERIMENTAL APPARATUS

Observations of the qualitative state of erythrocytes can be used to conduct a rapid analysis of blood samples including different kinds of anaemia whose presence may change the size and shape of erythrocytes. The erythrocytes typically have the shape of a disk with the diameter of 7.2-7.9 μm and the mean thickness of 2 μm. Erythrocytes consist mainly of hemoglobin. It is composed of one albumen molecule of globulin and four molecules of iron-bearing compound of hem. That is why the solution of erythrocytes is very sensitive to an imposed magnetic field. It is known that the increase in erythrocyte size is indicative of the deficiency of vitamin B_{12}, while the prevalence of small size erythrocytes may be a symptom of iron-deficiency anaemia and inborn microspherocytosis. The current paper reports an experimental study of the response of dissipative patterns in thin layers of erythrocyte solution to the applied magnetic field.

Experiments were performed in a layer of erythrocytes suspended in 0.9% solution of *NaCl*. Fresh blood samples were used. In order to obtain stable solutions blood was centrifuged at 3000 rpm in a salt solution. Subsequently, a few heparin crystals were added to prevent fibrin formation. Such erythrocyte solutions remain stable for up to an hour i.e. much longer than the duration of the conducted experiments typically running for about three minutes.

Small volume of erythrocyte solution (0.2-0.4 ml) was poured in a Petri dish (with the diameter of 9.5 cm and the height of 1.5 cm) filled with *NaCl* solution so that the thickness of a resulting mixture did not exceed 3.5 mm. The vessel was fixed in the center of two Helmholtz pairs of coils that were oriented orthogonally to each other. Helmholtz coils were able to create magnetic field of up to 10 mT perpendicular or parallel to the open surface of a Petri dish. The arising flow structures were filmed using a video camera, which was placed 1 meter away from the surface of a Petri dish so that it occupied the complete video image. A lighting unit was placed under the dish.

EXPERIMENTAL RESULTS

Dissipative structures in erythrocite solution were first experimentally observed in absence of a magnetic field [1]. A close-up of such structures is shown in Figure 1. The light regions in the photograph correspond to high density of erythrocytes. Erythrocytes are virtually absent along the dark lines and their intersections (symbol EL). The observed structures were similar to Benard convection cells [2] with a characteristic size of the order of the layer thickness.

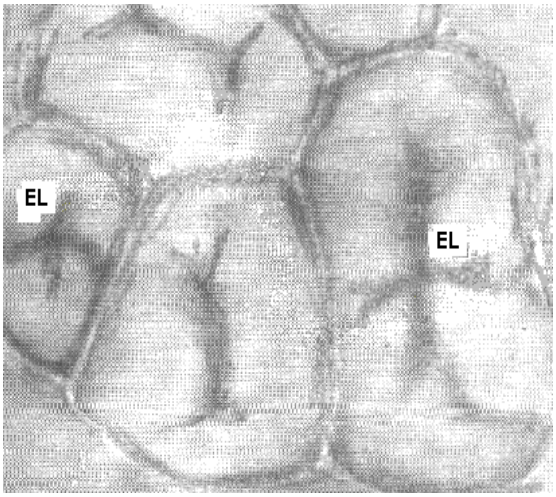

Figure 1. Dissipative patterns in an erythrocyte layer observed in absence of magnetic field. View from above. The characteristic cell diameter is about 7 mm.

Further experiments showed that convection patterns in erythrocyte solution are influenced strongly by a magnetic field which is parallel to the free surface. Typical non-stationary dissipative patterns observed in this case are shown in Figure 2. When magnetic field is just switched on small cells and narrow winding rolls with the width of about 2 mm are observed. As time progresses cells merge into rolls which align with the applied magnetic field. The transverse size of rolls increases more than four times during the exposure to magnetic field. The optimal alignment of initially disordered patterns with the direction of magnetic field is achieved at magnetic field strength of 10 mT. Similar patterns arising when the horizontal component of magnetic field is increased were reported in [3] for a free-surface layer of a colloidal dispersion of magnetic nanoparticles (also referred to as magnetic fluid [4]) placed in a magnetic field of nearly the same strength (7.7 mT): once the magnetic field is applied the hexagonal convection patterns stretch and finally form ridges aligned with magnetic field. The observed spatio-temporal patterns were correlated with the erythrocyte sizes found in blood samples received from different donors.

The same experimental set up was used to study flow patterns in magnetic fluids. In this case salt solution was replaced with kerosene. A Petri dish then was placed in the center of Helmholtz coils and a few droplets (0.2-0.4 ml) of a ferrofluid were added to kerosene. Over the time of about 5 minutes ferrofluid formed a layer of uniform thickness. Subsequently, a magnetic field of a similar strength to that used in the erythrocytic solution experiments was applied. The structures observed in a magneto-colloid mixture were found to be very similar to those seen in Figure 2.

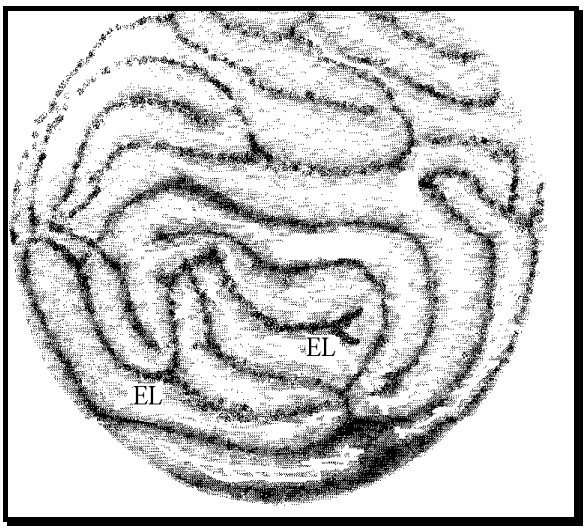

Figure 2. Dissipative structures observed in an erythrocyte layer 70 seconds after the magnetic field of 6.4 mT was applied in the plane of the photograph. View from above. The diameter of the observed area is 9.5 cm.

CONCLUSIONS

At present we are conducting systematic experiments aiming at compiling a comprehensive catalogue of patterns which would enable preliminary diagnostics of a human condition. Similarities between the patterns arising in erythrocytic and ferromagnetic mixtures indicate that the previously accumulated knowledge in the area of ferrohydrodynamics [4] can provide valuable guideance for accomplishing this task.

ACKNOWLEDGEMENTS

al. Mickiewicza 30, 30-059 Kraków, Poland

ABSTRACT. In this article distribution of the electromagnetic field components and temperature are calculated. Knowledge of temperature distribution in human body is of great importance in hyperthermial treatment of tumors. First distribution of induced current density in tissues is calculated and next bioheat equation is solved. Computed temperature distribution allow as optimal determination of electric parameters exciting coil in such a way that temperature attain its maximum value in the tumor and surrounding tissues. At the end sensitivities of the maximum temperature distribution in the body from different model parameters are calculated.

Keywords: *hyperthermia, Specific Absorption Rate, finite element method.*

INTRODUCTION

Hyperthermia is a medical therapy of tumor treatment through increasing the tissue temperature in specific part of the human body, which can have fewer side effects than other traditional methods as chemotherapy or radiotherapy. It is well known that continuous temperature in range 42–46 C will cause necrosis of living cells, resulting in a permanent damage cell functions, or at least increasing heat-induced sensitization of tumor cells to ionizing radiation and to certain chemical drugs. Up to now, many different methods have been devised to raise temperature either locally in selected parts of particular organs or over the whole body. A main advantage of electromagnetic (EM) hyperthermia is its ability to control the destruction process by a single electromagnetic applicator. In ideal case, concentrating power on a tumor selectively heats it to temperatures high enough to destroy cancerous cells without overheating and damaging the surrounding healthy tissues. Different heating methods are used to heat the superficial and deep placed tumors. Resistive heating with external electrodes, microwaves or ultrasound are usually used. Such techniques, however, may cause problems in heating deeply situated tumors, due to unavoidable overheating adjacent healthy tissues. In recent years interest in improving hyperthermia techniques has gained substantial attention in searching for new methods that can result in depth and uniform tissue heating. Invasive methods include heating with deep implanted electrodes, invasive microwave antennas, thermal seed heating, etc. To avoid pain caused by such methods, great efforts have recently been made to use radio frequency (RF) tissue heating.

Electromagnetically induced current in radiofrequency range has recently become the preferred mode of energy delivery for the tumor destruction or sensitization. The high current density near the tumor generates heat which rapidly increases the tissue temperature, causing desiccation and protein structural change in macromolecules. In comparison with other methods as, for example, high-

E-mail address: kurgan@agh.edu.pl, piotr.gas@agh.edu.pl

energy direct-current, the advantages of radiofrequency radiation therapy are that energy can be delivered in a graded manner by changing exciting current density, it does not require general anesthesia, it can produce a homogeneous region of necrosis. The synergistic behavior between hyperthermia and chemo- and radiotherapy is a well-known phenomenon and in the last time hyperthermia experiences increasing attention of medical world.

This paper describes, through numerical finite element modeling and computer simulation, distribution of electromagnetic variables such as magnetic vector potential, electric field strength, induced current density, which are used next as starting point in calculation of heat sources in human body. In order to calculate a full investigation of the temperature variation in human tissues, one needs to take into account tissue composition, blood perfusion rate, heat conduction effects of various tissues, and heat generation due to metabolic processes. All these factors are covered in bioheat equation.

In regional hyperthermia systems, low frequency radio waves are employed to obtain significant penetration depths to heat deep-seated tumors. In this publication, inductive noninvasive applicators are employed what is highly desirable in clinical applications. The current applicators using in this study have circular shape and are placed around a patient. However, it is extremely difficult to design general-purpose antenna which can heat a tumor located anywhere within the body. The heat generation can one control with adequately placed thermometer. On the other hand, the temperature measurements also have severe problems. From one side only invasive methods are available today to measure the temperature distributions inside tissues and from the other side thermometers themselves can significantly change heat generation.

In this article distribution of the electromagnetic field components and temperature are calculated. Knowledge of temperature distribution in human body is of great importance in hyperthermial treatment of tumors. First distribution of induced current density in tissues is calculated and next bioheat equation is solved. Computed temperature distribution allow as optimal determination of electric parameters exciting coil in such a way that temperature attain its maximum value in the tumor and surrounding tissues.

MAIN EQUATIONS

Around the human body a cylindrical coil with excitation current is placed as in Figure 1.

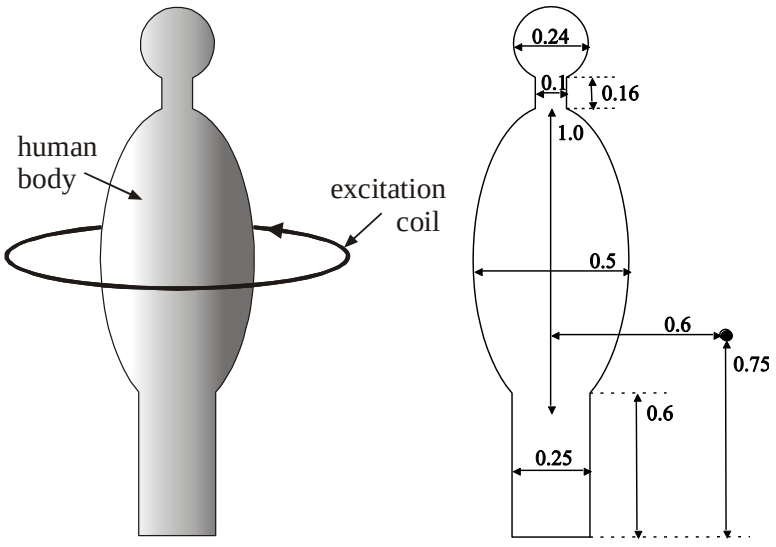

Figure 1. Schematic view of human body surrounded by wire with excitation current. Dimensions are given in meters.

The human body is considered as homogeneous medium with averaging material parameters. The current is flowing in clock-wise direction. The radius of this coil has value r_1. The exciting current in the coil generates sinusoidal electromagnetic field, which next induces eddy currents in human body. These currents are sources of heat and after some transient time, a temperature distribution in body is established. In order to calculate temperature, first distribution of electromagnetic field generated by circular coil with exciting current has to be calculated. Let us start with Maxwell's equations in time domain:

$$\nabla \times \mathbf{H} = \mathbf{J}_\mathrm{i} + \mathbf{J}_\mathrm{c} + \frac{\partial \mathbf{D}}{\partial t} \tag{1}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{2}$$

where $\mathbf{J}_\mathrm{i}$ is an impressed current, which can be treated as a source of the electromagnetic field, and which results from charges placed outside computational domain, $\mathbf{J}_\mathrm{c}$ is a conduction current caused by electric field strength accordingly with differential Ohm's law, and other vectors have their usual meaning. Magnetic vector potential is defined as

$$\mathbf{B} = \nabla \times \mathbf{A} \tag{3}$$

Introducing (3) into (2) (3)we get

$$\nabla \times \mathbf{E} = -\frac{\partial}{\partial t}\left(\nabla \times \mathbf{A}\right) = -\nabla \times \frac{\partial \mathbf{A}}{\partial t} \tag{4}$$

and finally

$$\nabla \times \left(\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} \right) = 0 \tag{5}$$

We can introduce potential V as

$$-\nabla V = \mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} \tag{6}$$

Field intensity can be express now as

$$\mathbf{E} = -\nabla V - \frac{\partial \mathbf{A}}{\partial t} \tag{7}$$

In two dimensional problems we can assume that $\nabla V = 0$, so in this case

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} \tag{8}$$

Taking into account, that $\mathbf{J}_\mathrm{c} = \sigma\,\mathbf{E}$, and $\mathbf{D} = \varepsilon\mathbf{D}$ and introducing (8) into (1) yields

$$\nabla \times \mathbf{H} = \mathbf{J}_\mathrm{i} + \sigma\mathbf{E} + \varepsilon \frac{\partial \mathbf{E}}{\partial t} \tag{9}$$

and

$$\nabla\times\left(\frac{1}{\mu}\nabla\times\mathbf{A}\right)=\mathbf{J}_{\mathrm{i}}-\sigma\frac{\partial\mathbf{A}}{\partial t}-\varepsilon\frac{\partial^2\mathbf{A}}{\partial t^2} \tag{10}$$

If in time domain in sinusoidal steady state magnetic vector potential is given by function

$$\mathbf{A}(\mathbf{r},t)=A_m(\mathbf{r})\cos[\omega t+\varphi(\mathbf{r})] \tag{11}$$

then we can introduce complex amplitude

$$\tilde{\mathbf{A}}(\mathbf{r},t)=\hat{\mathbf{A}}(\mathbf{r})e^{j\omega t} \tag{12}$$

where phasor $\hat{\mathbf{A}}(\mathbf{r})$ is a complex number dependent from spatial coordinates $\mathbf{r} = (x, y, z)$. Magnetic vector potential in time domain $\mathbf{A}(\mathbf{r}, t)$ is related with complex amplitude $\tilde{\mathbf{A}}(\mathbf{r},t)$ by

$$\mathbf{A}(\mathbf{r},t)=\mathrm{Re}\left[\hat{\mathbf{A}}(\mathbf{r})e^{j\omega t}\right] \tag{13}$$

Introduction (13) into (10) gives

$$\nabla\times\left(\frac{1}{\mu}\nabla\times\hat{\mathbf{A}}\right)-\left(\omega^2\varepsilon+j\omega\sigma\right)\hat{\mathbf{A}}=\hat{\mathbf{J}}_{\mathrm{i}} \tag{14}$$

In two dimensions we assume symmetry with respect to coordinate φ, so magnetic vector potential can be written as

$$\hat{\mathbf{A}}=A_\varphi(r,z)\mathbf{e}_\varphi \tag{15}$$

Because also

$$\hat{\mathbf{J}}_{\mathrm{i}}=J_{\mathrm{i}}\mathbf{e}_\phi \tag{16}$$

thus equation (14) can be written in simpler form

$$-\left[\frac{\partial}{\partial r}\left(\frac{1}{\mu r}\frac{\partial\left(rA_\phi\right)}{\partial r}\right)+\frac{\partial}{\partial z}\left(\frac{1}{\mu r}\frac{\partial\left(rA_\phi\right)}{\partial z}\right)\right]-\left(\omega^2\varepsilon+j\omega\sigma\right)A_\phi=J_{\mathrm{i}} \tag{17}$$

As boundary condition we assume zero potential no symmetry axis z. The above equation is solved by finite element method over given computational domain. If $\sigma >> \omega\varepsilon$ then displacement current can be neglected.

Unlike the computation of the electric currents in body, for which agreement exists accordingly a derived physical model, no clear consensus exists for an appropriate mathematical model for the evaluation of temperature field distribution in biological tissues. An extremely important work in the modeling of heat transfer in biological tissues was done over half a century ago by Pennes. The equation, which he derived, is named bioheat equation, and it can be derived from the classical Fourier law of heat conduction. This model is based on the simple assumption of the energy exchange between the blood flowing in vessels and the surrounding the tumour tissues. Pennes model may provide suitable information on temperature distributions in whole body, organ under consideration, and tumour analysis under study.

Pennes model states, that the total heat exchange between tissue surrounding a vessel and blood flowing in it, is proportional to the volumetric heat flow and the temperature difference between the blood and the tissue. The expression of Pennes bioheat equation in a body with uniform material properties in steady state is given by

$$\nabla\left(-k\nabla T\right)=\rho_b C_b \omega_b (T_b - T) + Q_{ext} + Q_{met} \tag{18}$$

where T is temperature [K], k − the tissue thermal conductivity [W/(m·K)], ω_b − the blood perfusion rate [1/s], C_b − the blood specific heat, T_b − the blood vessel temperature, Q_{met} − the metabolic heat generation rate [W/m^3], and Q_{ext} − the external heat sources [W/m^3].
The usual boundary condition associated with the heat transfer process in the context of hyperthermia can be given by

$$\mathbf{n}\cdot\left(-k\nabla T\right)=h(T_{air} - T) \tag{19}$$

on boundary Γ, where h is the heat transfer coefficient [W/(m^2·K)], T_{air} is the temperature of the surrounding air [K].

The limitations associated with bioheat equation were pointed out in [17]. One of the most serious limitations results from the fact that the perfusion rate is not generally independent from temperature. Instead, the human thermoregulatory system generally responds to increased heat generation in an tissue by attempting to increase blood flow to that part of body. In regional hyperthermia, the most common modelling choice is to assume that the blood perfusion rate in the Pennes model is constant. Several experiments, however, have shown that the response of organ to heat generation is dependent, even at moderate temperatures in the range 41–43°C. Nevertheless, we further assume constant value of blood perfusion rate. Both equations (17) and (18) are simultaneously solved by finite element method.

COMPUTATIONAL RESULTS

The hyperthermia arrangement in two dimensions as given in fig.1 is considered. The dimensions and physical parameters of the model are given in following tables (Tables 1 – 2):

Table 1
PHYSICAL PARAMETERS OF TISSUES
TAKEN INTO NUMERICAL MODEL

Tissue	ε_r	σ [S/m]	k [W/(m·K)]	Q_{met} [W/m^3]
Human body	29.6	0.053	0.22	300

Table 2
PHYSICAL PARAMETERS OF BLOOD
TAKEN INTO BIOHEAT EQUATION

Tissue	ρ_b [kg/m^3]	C_b [J/(kg·K)]	T_b [K]	ω_b [1/s]
Blood	1060	3639	310.15	in body 0.005

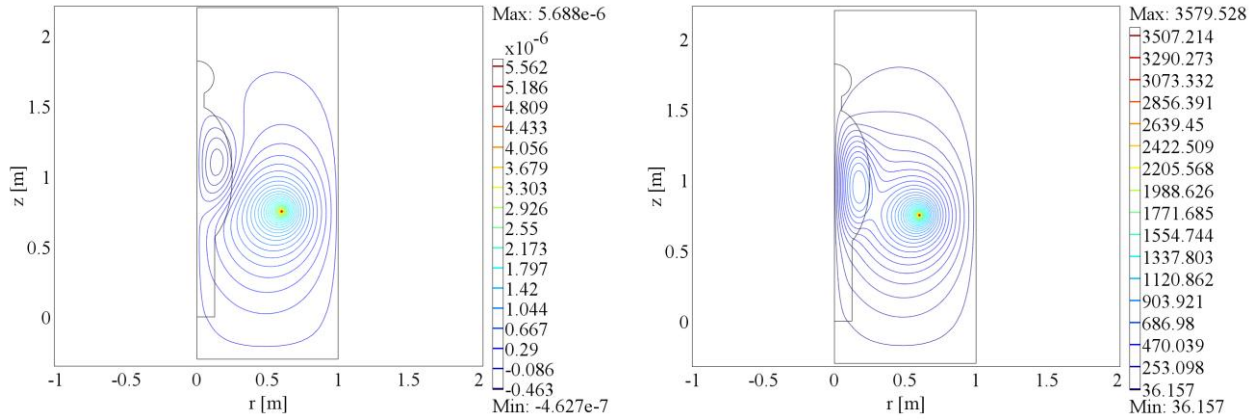

Figure 2. Equipotential lines of magnetic vector potential A_ϕ (left)
and equipotential lines of modulus of the electric field strength E_ϕ (right).

The whole computational domain was divided into triangular finite elements and appropriate boundary conditions were introduced. The exciting current in the coil is I_{max} = 4.5 [A], and frequency is f = 100 [MHz]. Moreover, the heat transfer coefficient is h = 10 [W/(m^2·K)] [25], and the air temperature surrounding the body is T_{air} = 293.15 [K]. Radius of the exciting coil with current I_{max} has value r = 0.6 [m].

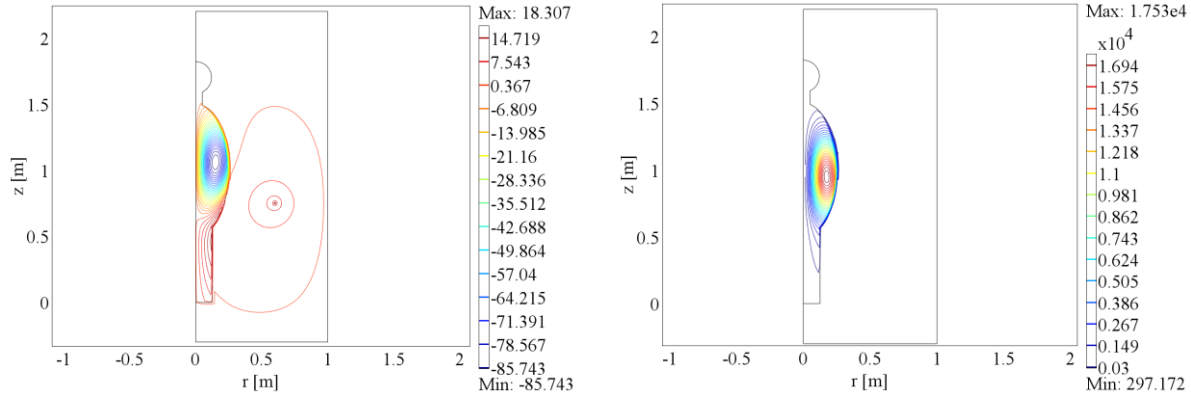

Figure 3. Equipotential lines of total current density (left)
and equipotential lines of resistive heating (right).

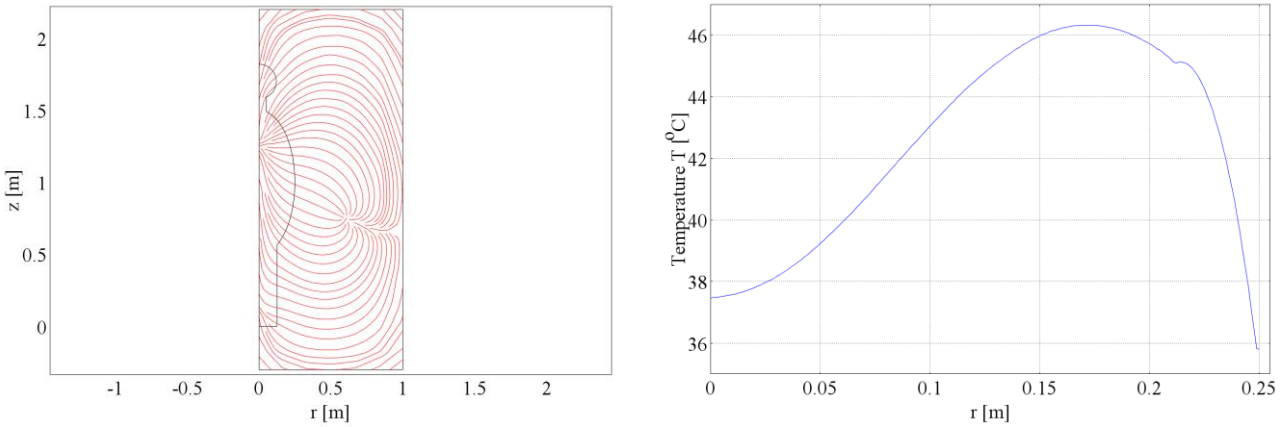

Figure 4. Streemlines of the total energy flow (left) and temperature distribution
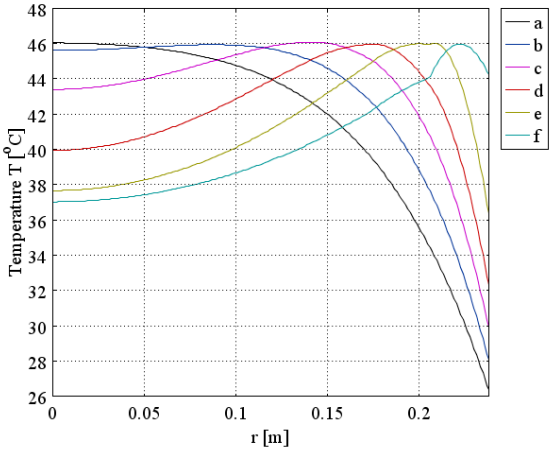
along line from point (0,0.95) to point (0.25, 0.95) (right).

First magnetic vector potential A_ϕ is calculated from the equation (17), and next modulus of the electric field strength E_ϕ, computed with formula $E_\phi = j\omega \cdot A_\phi$ (Figure 2). Total induced current density in human body is calculated from the equation $J_z = (\omega^2\varepsilon + j\omega)\cdot A_\phi$ and then resistive heat source $Q_{ext} = 0.5\ \mathrm{Re}[J_\phi (E_\phi^* + \sigma^{-1} J_{i\phi}^*)]$ (Figure 3). At the end bioheat equation was solved. Figure 4 shows power density streamlines from field source to human body. One can see that energy really flows from energy source, in this case exciting coil, to human body.

At Figure 5 six temperature distributions for different blood perfusion rates ω_b and exciting current I_{max} are shown. Calculations were made for frequency f = 500 [kHz] with condition that in every case maximal temperature has the value T_{max} = 46°C. When blood perfusion rate is increased exciting current should be also adequately corrected as it is shown in Figure 5.



Lines	ω_b [1/s]	I_{max} [A]
a	0.000005	545
b	0.00001	720
c	0.00002	925
d	0.00005	1240
e	0.0002	2060
f	0.005	8450

Figure 5.Temperature distribution along path from (0, 0.85) to (0.2386, 0.85).

In Fig. 6 and 7 sensitivities of the maximum temperature T_{max} along path from (0, 0.85) to (0.2386, 0.85) from exciting frequency f, exciting current in the coil I_{max}, perfusion rate ω_b and surface heat transfer coefficient h are shown.

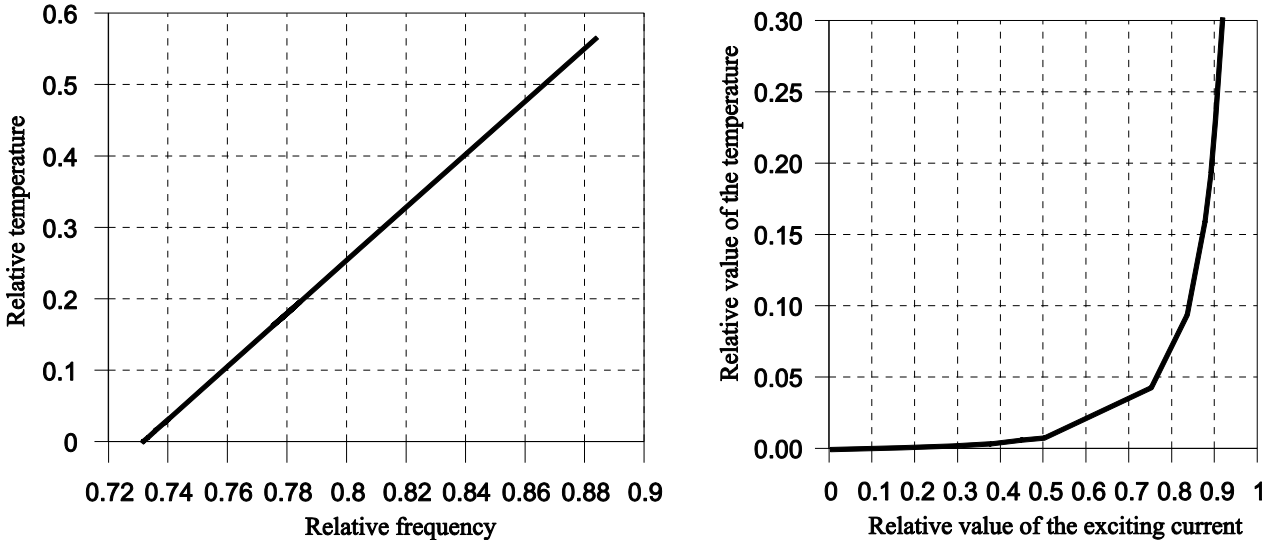


Figure 6. Relative maximum temperature distribution along path from (0, 0.85) to (0.2386, 0.85) from relative frequency (left) and relative value of exciting current I_{max} (right).

All four figures present dependence between relative maximum temperature in human body in relation to relative values of model parameters:

$$\frac{\Delta T_{\max}}{T_{\max}} = f\left(\frac{\Delta\omega}{\omega}\right) \tag{20}$$

where ω is here any model parameter.

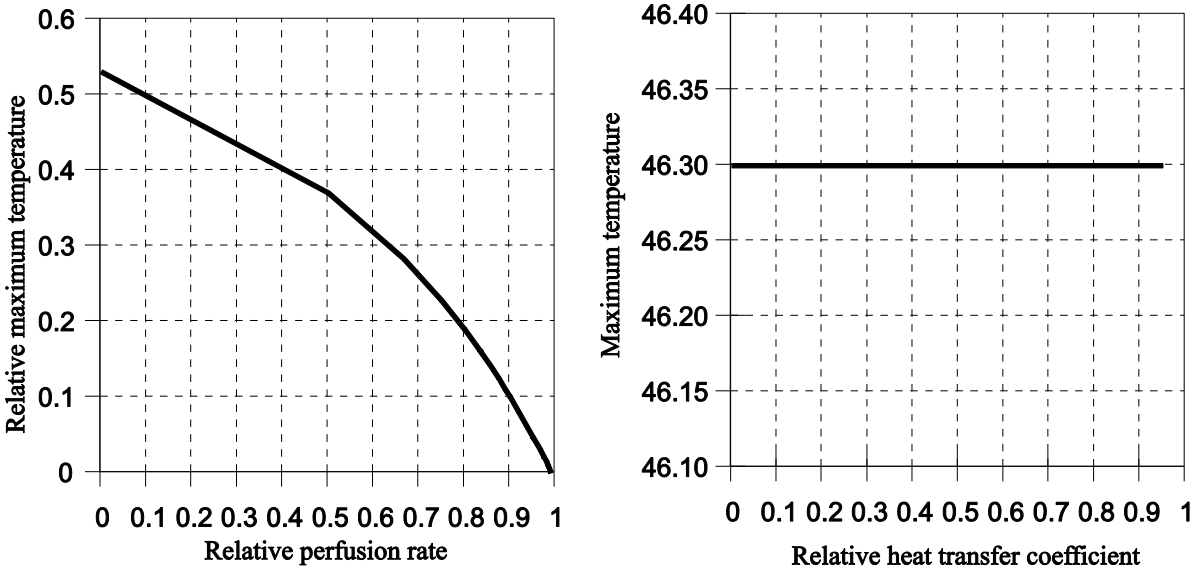

Figure 7. Relative maximum temperature distribution along path from (0, 0.85) to (0.2386, 0.85) from relative perfusion rate (left) and maximum temperature from relative heat transfer coefficient (right).

CONCLUSIONS

In this study, numerical simulations electromagnetic field and temperature distribution in human tissues was performed. A two-dimensional analysis has been applied to compute the electric current fields and the temperature distributions inside tissues. The developed procedure is general and could be used to evaluate temperature distributions for arbitrary coils configurations, also in the case when coils are placed at different angels compared with human body, have different radius and different conducting currents. The described method could be used to optimize the position, exciting current amplitude and phases of coils, and to give better control to the temperature distributions throughout the tumor volume. Numerical results show that there is a considerable variation of the temperature parallel to the coil plane, which signifies the importance of the two-dimensional model employed in this paper. This approach is expected to be valuable in improving optimal distribution of the temperature in tumor and surrounding tissues when tumor is placed deep in body. There is direct proportionality between relative temperature and exciting frequency ω. Thus through frequency change one can adjust temperature in the body (Fig.6). Exciting current $I_{\max}$ has influence on body temperature, when it is greater than 0.3. Blood perfusion rate generally diminishes body temperature (Fig 7) and heat transfer coefficient h has not visible influence on temperature distribution.

HYDROGEN STORAGE PROPERTIES OF GRAPHITE INTERCALATED WITH LITHIUM BY MECHANICAL ALLOYING

A. Takasaki* and, R. Era
Shibaura Institute of Technology, Tokyo, Japan

Abstract. We attempted to intercalate lithium, which has a strong chemical affinity with hydrogen, in graphite structure by mechanical alloying (MA). The graphite powders were firstly mechanical alloyed with lithium hydride (LiH) powders, and then were dehydrogenated in a vacuum. The amount of lithium was varied from $C_{92}Li_8$ to $C_{88}Li_{12}$ by changing the amount of LiH. Although the graphite structure turned into a turbostratic one after earlier MA, the aromatic carbon layers still remained even after longer MA. The graphite interlayer spacing increased with increasing MA time. The interlayer spacing for the $C_{92}Li_8$ powders varied largely, that were about 0.665 nm before MA and about 0.725 nm after MA for 40 h, showing the intercalation of lithium between the graphite interlayers after dehydrogenation. After rehydrogenation at a temperature of 303 K and an initial hydrogen pressure of 4 MPa, the $C_{92}Li_8$ powders absorbed about 1.6 wt.% hydrogen, while the pure graphite, the $C_{90}Li_{10}$ and the $C_{88}Li_{12}$ powders absorbed only about 0.6 wt% hydrogen. No formation of LiH was observed after rehydrogenation. Hydrogen desorption for the $C_{92}Li_8$ powders occurred at 469 K, while those for the $C_{90}Li_{10}$ and the $C_{88}Li_{12}$ powders occurred at more than 473 K. The $C_{92}Li_8$ powders exhibited the best hydrogen storage properties among the powder mixtures.

Keywords: *hydrogen storage, graphite, lithium hydride, mechanical alloying*

INTRODUCTION

Hydrogen storage is one of important technological issues for the application of the fuel cell. Several kinds of hydrogen storage methods are now being proposed, in which the storage in a high-pressure tank seems to be most simple and convenient, but there are potential problems, i.e. very low volumetric density for hydrogen storage and dangerousness. The hydrogen storage in solid materials such as metal hydrides, which has been studied actively by materials scientists and engineers, is very safe and normally shows high volumetric density, but suffer from lower gravimetric density.

Hydrogen storage in carbonaceous materials has firstly been reported by Dillon et. al.[1] for single walled nanotubes. Since then study for hydrogen storage in carbonaceous materials, like carbon nanofibers [2] and nanostructured graphite produced by mechanical milling in hydrogen atmosphere [3], etc., has been widely performed. However, there is still controversy about the hydrogen capacities. Because carbon is one of light elements, higher hydrogen capacities that are the amount of hydrogen stored per unit weight is expected, even if it takes some hydrogen atoms.

Mechanical alloying (MA) of Mg with graphite (approximately $C_{47}Mg_{53}$) in nitrogen atmosphere was reported to result in the generation of large amounts of dangling carbon bonds in the graphite, providing suitable sites for hydrogen atoms, in which at least two hydrogen states have been

reported to exist; one in the form of C-H bonding in the nanostructured graphite and the other as a hydride in Mg [4]. We have previously reported that the graphite interlayer (graphene) spacing in the graphite structure was expanded by a combination of addition of small amount of Mg and MA, leading the hydrogen capacity about 1 wt.% at 308 K [5]. This suggests that Mg atoms were intercalated between the graphite interlayer in the graphite structure and attracted hydrogen into the interlayer. In this study, we attempted to substitute Li for Mg, and mechanically alloy and hydrogenate the graphite/Li powder mixtures after MA because the Li is a lighter element than Mg so that higher hydrogen capacity in weight percent would be anticipated.

EXPERIMENTAL PROCEDURES

Commercially pure graphite and LiH powders were used as starting materials in this study (Li powders were not used because they are very active in an atmospheric condition). The purities of graphite and LiH powders were 99.9 % and 95 % respectively, and the mean grain diameters were 20 μm and 30 μm respectively.

By adjusting the powder mixtures with a final chemical composition of $C_{100-x}Li_x$ ($0 \leq x \leq 12$) after dehydrogenation of LiH, the powder mixtures were poured into stainless-steel vials ($45cm^3$) with some stainless-steel balls. The ball-to-mixture weight ratio was approximately 20:1. The vials containing the powder mixtures and the balls were evacuated by a rotary-pump and then back-filled with an argon gas (99.99999 %) several times in a glove box, and the final argon gas pressure was kept to be 0.1 MPa. MA was carried out by a Fritsch Pulverisette 7 planetary ball mill. The maximum ball acceleration was 15g. To avoid any temperature increases during MA, the alloying period of 0.5 h was alternated with an equal rest time.

After MA the powder mixtures were dehydrogenated in a vacuum at an elevated temperature, and then rehydrogenated at 308 K at an initial hydrogen pressure of 4 MPa in a pressure-composition-isotherm (PCT) equipment (Sieverts type apparatus). The hydrogen capacities of the powder mixtures after dehydrogenation were calculated from the pressure change in the PCT measurement. Thermal analyses such as thermogravimetry/differential thermal analysis (TG/DTA) and differential scanning calorimetry (DSC) were also performed for the powder mixtures after rehydrogenation to investigate the hydrogen desorption properties. X-ray diffraction measurements were made with Cu-Kα radiation to identify the phases before and after MA for several times, and before and after rehydrogenation.

RESULTS AND DISCUSSION

Figure 1 shows X-ray diffraction patterns for $C_{88}Li_{12}$ powder mixtures before and after MA for several MA times. The X-ray intensity of the prominent peak for the graphite, (002), decreases with increasing MA time up to 40 h, although other peaks for the graphite and LiH almost disappear after earlier MA (about 8 h). The graphite structure seems to be decomposed and turned into a turbostratic structure (i.e. structure whose chemical bonding between the graphite interlayer are broken because of a weak van der Waals' secondary bonding but the bonding in the aromatic carbon layers (graphene) still exits because of a strong covalent bonding) by MA process. The (002) peak for the graphite also shifts to lower angles with increasing MA times, indicating an expansion of the graphite interlayer spacing. The graphite interlayer spacing as a function of MA time for all powder mixtures are shown in Figure 2. The interlayer spacing seems to increase with increasing MA time up to 40 h. The spacing for the $C_{92}Li_8$ powders, particularly, varied largely between before and after MA, which was about 0.665 nm before MA and about 0.725 nm after MA for 40 h (about a 9 % increase). The spacing for $C_{92}Li_8$ after MA for 40 h is the highest among the powder mixtures. An expansion of

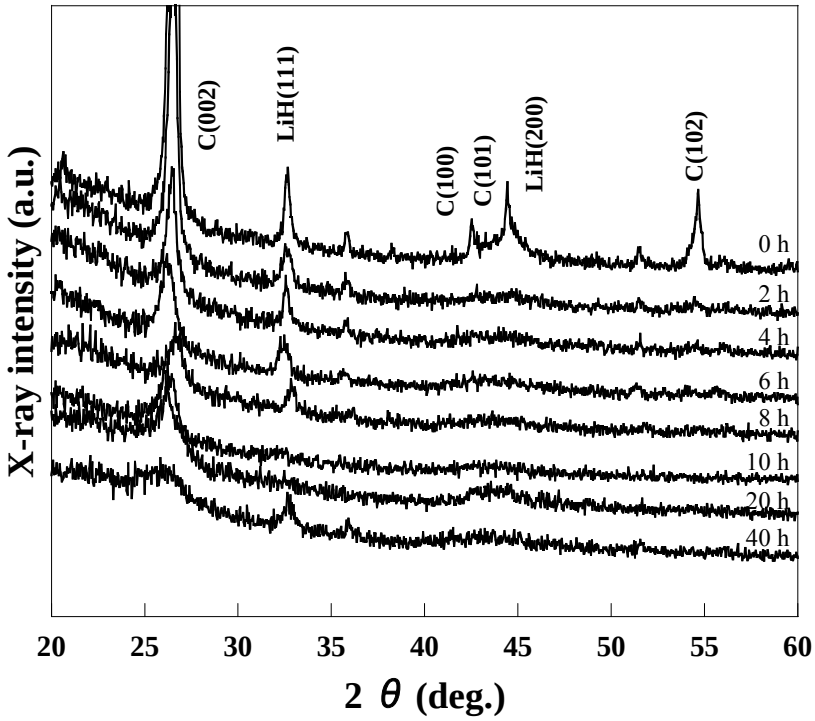

Figure 1. X-ray diffraction patterns for for $C_{88}Li_{12}$ powder mixtures before and after MA for several MA times.

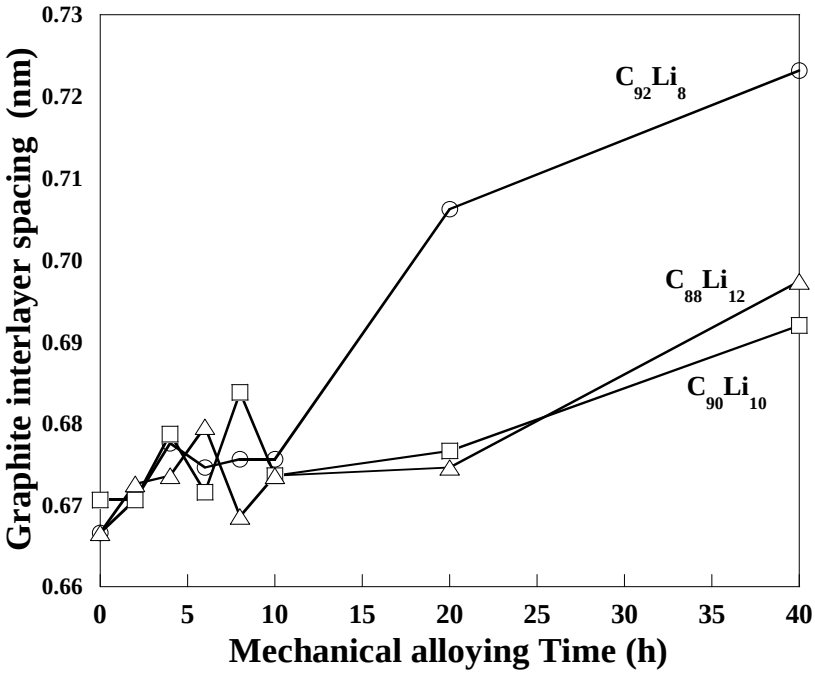

Figure 2. The graphite interlayer spacing as a function of MA time for all powder mixtures.

graphite interlayer was reported for graphite without any additives after MA under hydrogen atmosphere for earlier milling time [3]. However, it is suggested that the Li must be intercalated

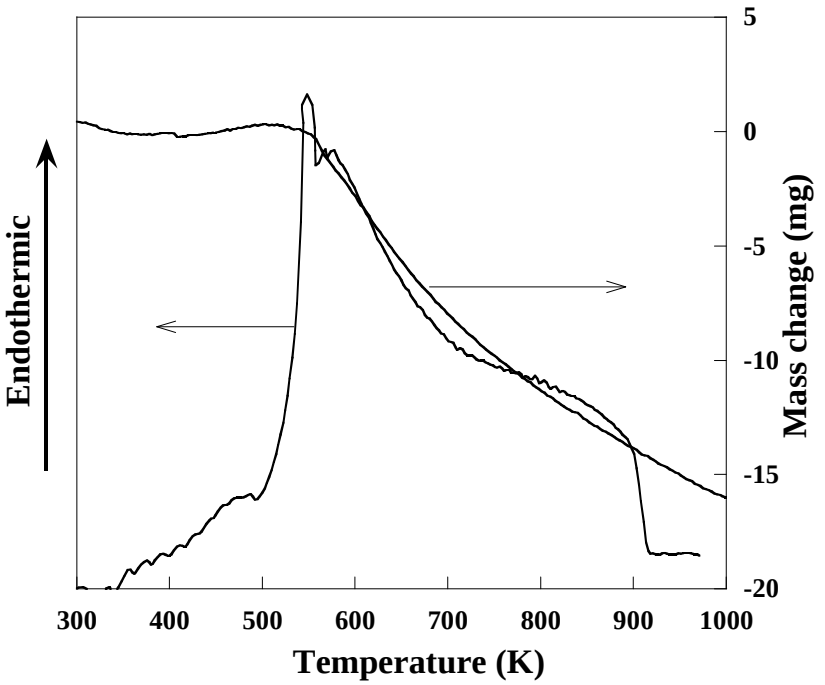

Figure 3. Thermogravimetry/ differential thermal analyses curves for $C_{92}Li_8$ powder mixture after MA for 40 h.

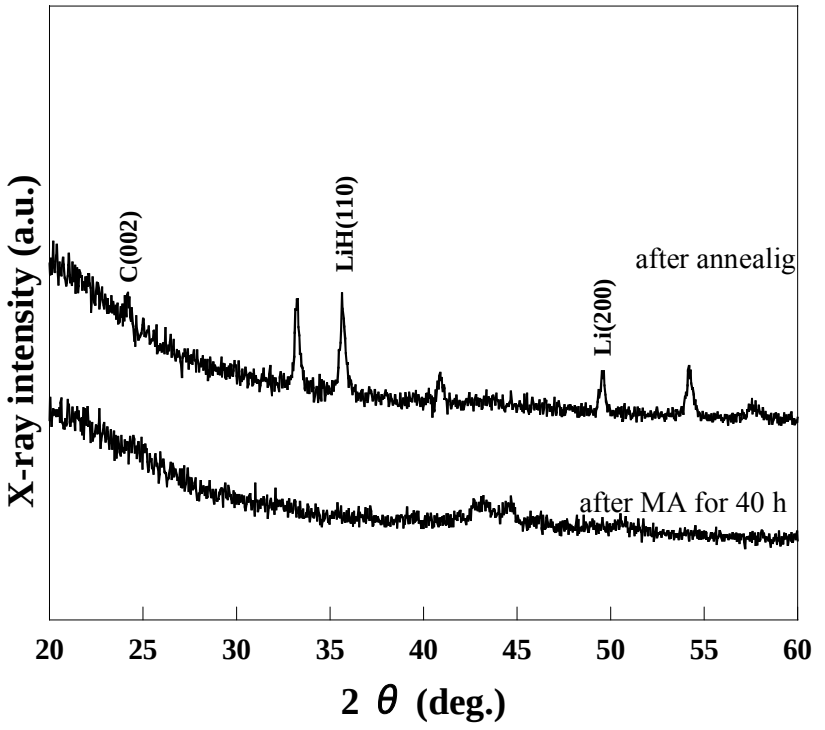

Figure 4. X-ray diffraction patterns for $C_{92}Li_8$ powder mixture before and after the first dehydrogenation after MA.

between the graphite interlayers after dehydrogenation process of the powder mixtures, because the interlayer spacings are dependent on both the chemical composition and MA time in this study.

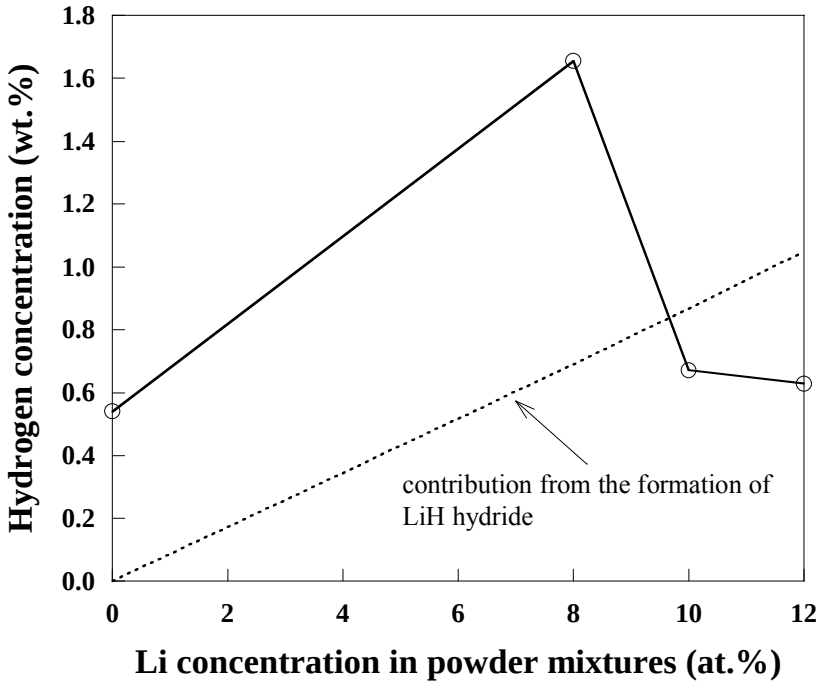

Figure 5. Hydrogen concentration (open circles) in the powder mixtures as a function of Li concentration in the powder mixtures after MA for 40 h. The data shown with dashed line indicate the hydrogen concentration in the powder mixtures if Li existed in the powders is assumed to turn back into LiH hydride.

Figure 3 shows TG/DTA curves for $C_{92}Li_8$ powder mixture after MA for 40 h. The mass of the powder mixture initiates to decrease at a temperature of about 573 K with an endothermic reaction, indicating the decomposition of LiH in the powder mixtures. From these results, all the powder mixtures after MA were dehydrogenated at a temperature of 773 K for 5 h in a vacuum. Figure 4 shows X-ray diffraction patterns for $C_{92}Li_8$ powder mixture before and after the first dehydrogenation after MA. No X-ray diffraction peaks for LiH were observed even before hydrogenation, and several peaks for Li were observed after dehydrohenation, indicating that the dehydrogenation was performed sufficiently at 773 K for 5 h in a vacuum. Some peaks which are not indexed seem to be due to an oxide formation during heating.

After dehydrogenation of the powder mixture, all powders were rehydrogenated in a PCT apparatus to investigate their hydrogenation properties at a temperature of 308 K and an initial hydrogen pressure of 4 MPa. Figure 5 shows hydrogen concentration (open circles), measured from pressure change, in the powder mixtures as a function of Li concentration in the mixtures after MA for 40 h. The $C_{92}Li_8$ powder absorbed about 1.6 wt.% hydrogen whereas the pure graphite, $C_{90}Li_{10}$, $C_{88}Li_{12}$ powders absorbed about 0.6 wt% hydrogen. The data shown with dashed line in Figure 5 indicate the hydrogen concentration in the powder mixtures if one assumes that the Li existed in the powders turned back into LiH hydride during rehydrogenation (although we did not observe a LiH formation (see Figure 6)). Even if we assume the formation of LiH, $C_{92}Li_8$ mixture absorbed more than the level of hydrogen capacity due to the LiH formation, suggesting that hydrogen absorption occurred in the graphite structure. Fig. 6 shows X-ray diffraction patterns for $C_{90}Li_{10}$ powder mixtures before and after hydrogenation in PCT apparatus. Even after rehydrohenation, no X-ray diffraction peaks corresponding to the LiH hydride are observed for all the powder mixtures. Thus it is implied that hydrogen absorption was occurred in the graphite structure by extending the graphite interlayer spacing.

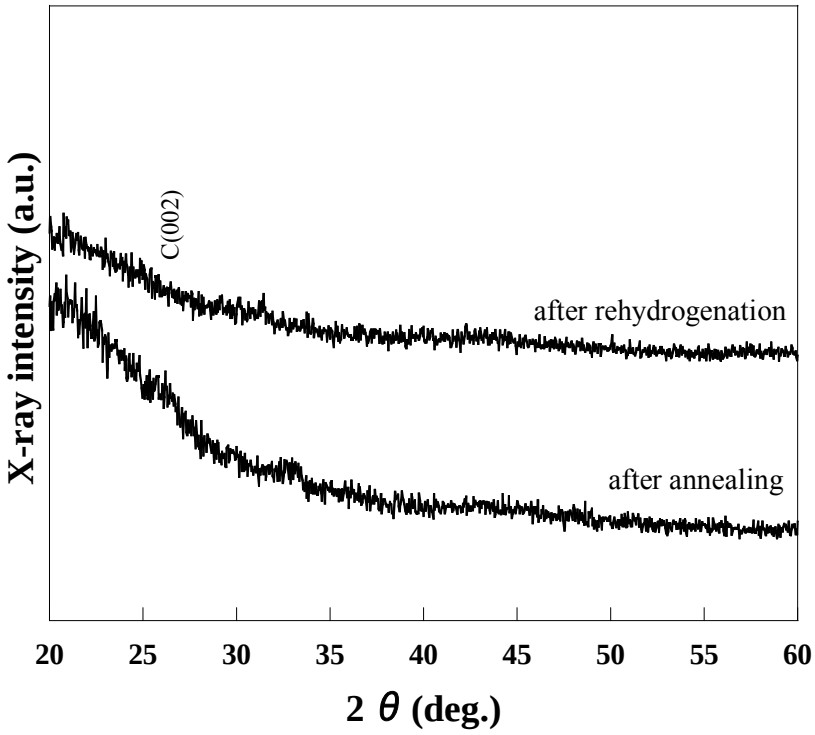

Figure 6. X-ray diffraction patterns for $C_{90}Li_{10}$ powder mixtures before and after hydrogenation.

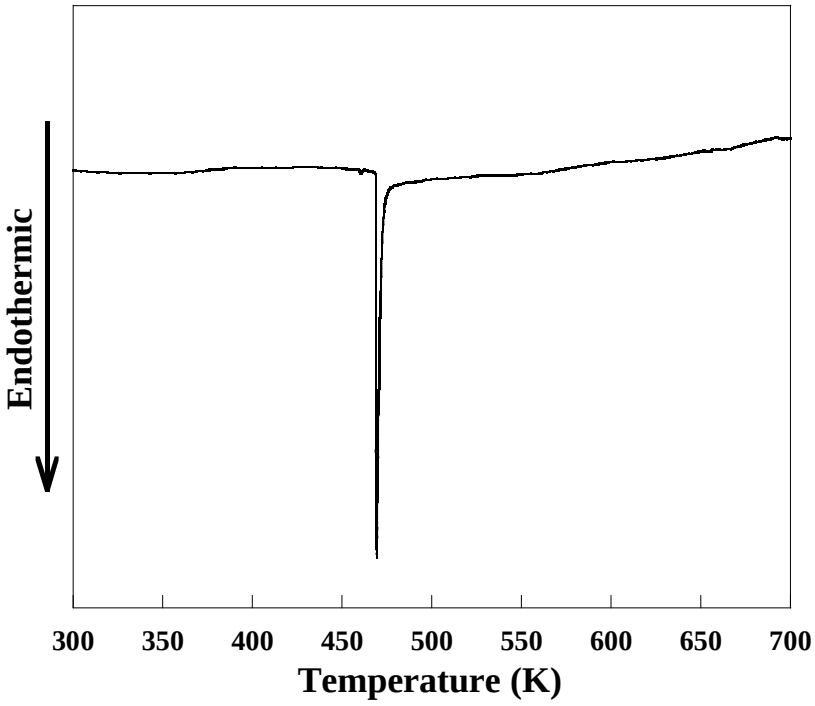

Figure 7. Differential scanning calorimetry curve for $C_{92}Li_8$ powder mixtures mechanically alloyed for 40 h after rehydrogenation.

Figure 7 shows DSC curve for $C_{92}Li_8$ powder mixtures, which were mechanically alloyed for 40 h, after rehydrogenation. The $C_{92}Li_8$ powder seems to desorb hydrogen at temperatures lower than 473 K. However, the $C_{90}Li_{10}$ and the $C_{88}Li_{12}$ powder mixtures desorbed hydrogen much higher

than that for $C_{92}Li_8$ mixtures, which were about 530 K and 490 K respectively, indicating that the $C_{92}Li_8$ powders exhibit the best hydrogen storage properties among the powder mixtures in this study. Two types of hydrogen coordinations, hydrogen in the graphite layers and that with the C-H covalent bonding, were reported for graphite after MA under hydrogen atmosphere [3]. At least two types, C-H bonding and hydriding of Mg, were also reported for nanocomposites obtained by MA of graphite and Mg [4]. Because the C-H bonding and Mg-H hydriding are due to strong chemical bonding, their hydrogen desorption normally occurred at higher temperatures. The hydrogen deosprtion temperature for the present powder mixtures, particularly for $C_{98}Li_8$, is lower than those, suggesting strongly that hydrogen absorption occurred in the graphite interlayers.

CONCLUSIONS

Mechanical alloying (MA) for the powder mixtures consisted of graphite and lithium hydride (LiH) powders ($C_{100-x}Li_x$ ($0 \leq x \leq 12$)) was attempted to intercalate lithium in graphite structure after dehydrogenation. The results obtained are summarized as follows;

1. Although the graphite structure turned into a turbostratic structure after earlier MA, aromatic carbon layers still remained even after MA for 40 h because of the strong covalent bonding. The graphite interlayer (graphene) spacing increased with increasing MA time. The interlayer spacing for the $C_{92}Li_8$ powders after MA for 40 h, which was the highest among the powder mixtures, increased about 9 % from that before MA, indicating the intercalation of lithium between the graphite interlayer after dehydrogenation.
2. After rehydrogenation at a temperature of 308 K and an initial hydrogen pressure of 4 MPa, the $C_{92}Li_8$ powders absorbed about 1.6 wt.% hydrogen, but the pure graphite, the $C_{90}Li_{10}$ and the $C_{88}Li_{12}$ powders absorbed only about 0.6 wt% hydrogen. No formation of LiH was observed after rehydrogenation.
3. An accelerated hydrogen desorption occurred endothermically at 469 K for the $C_{92}Li_8$ powders, while those for the $C_{90}Li_{10}$ and the $C_{88}Li_{12}$ powders occurred at 530 K and 490 K respectively.

TRANSIENT THERMAL EFFECTS IN A FUEL PROCESSOR FOR HIGH TEMPERATURE SOFC STACKS

A. Ferretti[1], A. Traverso[1,*], G.J.Saunders[2]
[1]University of Genoa, Thermochemical Power Group (TPG), Genoa, Italy
[2]Rolls-Royce Fuel Cell Systems Limited, Loughborough, United Kingdom

ABSTRACT. Fuel processing is a fundamental step in any fuel cell system fuelled with hydrocarbons. This work focuses on the development of the model of one reactor of the Fuel Processor unit being developed by Rolls-Royce Fuel Cell Systems Limited: the SCSO (Selective Catalytic Sulphur Oxidation). The transient model has been validated against experimental data: attained results are shown to demonstrate both the accuracy of results and the validity of modelling approach.

Keywords: heat transfer modelling, transient, fuel processor, solid oxide fuel cells

INTRODUCTION

The Fuel Processor unit is complementary to the high temperature Fuel Cell system and its relevance should not be underestimated. The modelling activity, in which this work is placed, helps along the development of such system. The final purpose of this work was to build a transient model of the desulphuriser, suitable for the development of the control system of the actual Fuel Processor. More precisely it was thought as a predicting tool for tuning control parameters and strategies.
The model has been developed as a new component of Matlab-Simulink external library named TRANSEO, which is a comprehensive tool, built in the last ten years at TPG, and still growing. It is based on the C language and it has been used for previous works on microturbine-based energy cycles: accuracy of existing components has already been proved, hence the choice to continue developing it throughout this work.

SCSO SUB-SYSTEM MODELLING AND VALIDATION

System overview

The SCSO is one of the Fuel Processor subsystems and its task is to make the raw natural gas from the network consistent with the high temperature solid oxide fuel cell requirements in terms of composition, pressure and temperature. Two main requirements are pursued: reduction of sulphur and higher hydrocarbon contents in the pipeline natural gas. Sulphur is usually present as odorants, organic sulphur compounds like THT (tetrahydrotiophene) commonly used in most European countries, OBE (dimethyl and diethyl sulphide) used in UK and mercaptans used together with THT in the US. The level of sulphur varies from country to country and it is neither constant within the same country, ranging between 2 ppm and 16 ppm. From studies on the actual Fuel Cell system, it

E-mail address: alberto.traverso@unige.it

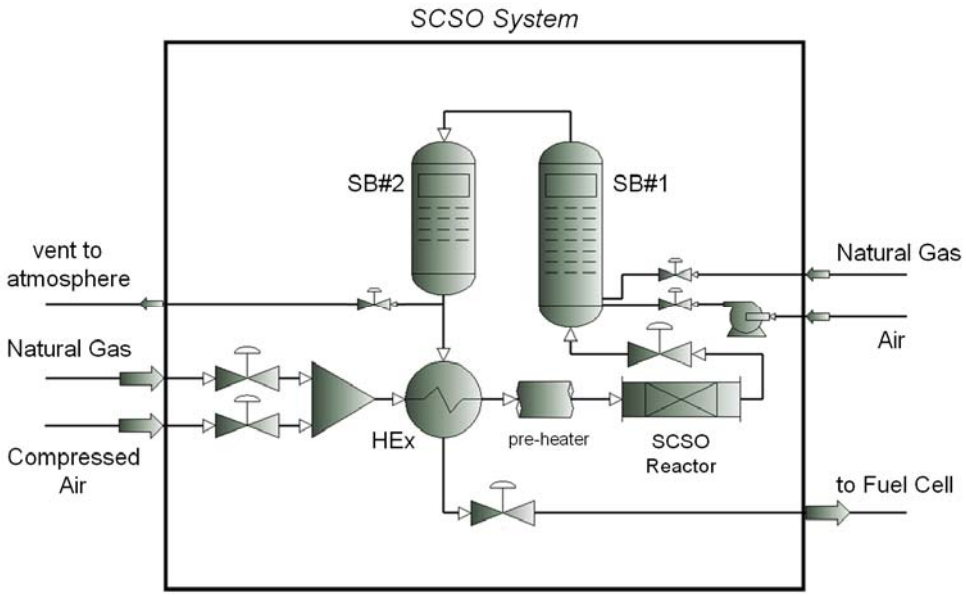

Figure 1. Simplified layout of the desulphurisation subsystem

resulted that a sulphur concentration of approximately 100 ppb has to be assumed as the target concentration in the fuel stream that must be achieved after the desulphurization process. Higher hydrocarbons (C_2-C_6) in the natural gas have a decomposition temperature much lower than methane: feeding a higher-hydrocarbons-rich natural gas to a high temperature SOFC system may result in carbon deposition in any point where thermal cracking temperature is exceeded. Therefore, for commercial systems, very low sulphur and higher hydrocarbons concentration in methane has to be obtained and natural gas has to be maintained below critical temperature before any mixing with a steam- or oxygen-rich stream. To overcome such problems, the SCSO technology combines the fuel with a sub-stoichiometric amount of oxygen and uses a sulphur tolerant monolith catalyst to oxidize selectively the sulphur compounds to sulphur oxides (SO_2 and SO_3 referred to collectively as SO_x). The SO_x species are then absorbed (chemical adsorption) downstream by two different inexpensive low capacity (6.5 gS/100g adsorbent) particulate adsorbents (SO_3 can displace SO_2 and therefore it has to be removed upstream on a different bed).
Sorbent beds are required to be warmed up with hot air during the start-up phase: two burners are placed inside the sorbent bed vessels to operate until the designed temperature is achieved. During such a warm-up the two vessels are being isolated from the rest of the system since burners are designed to operate at atmospheric pressure to reduce both costs and control issues.
The model refers to the actual layout of the SCSO subsystem from the 250kWe Fuel Processor. Most of control or safety components such as vents or check valves have been neglected, as the main goal was the validation against experimental data during normal operation.

STANDARD REACTING PIPE MODEL

The “Standard Reacting Pipe” TRANSEO component is a multipurpose time-dependent model, representing most of the actual parts of the system: empty pipes, electrical heaters and reactor itself. By now, only the selective catalytic sulphur oxidation and the catalytic partial oxidation are implemented but other reactions/reactors will be added soon. The “Standard Reacting Pipe” model can be used to predict the transient behaviour of an empty pipe, in its simplest form, as well as a chemical reactor implementing user-defined reactions. The aim, in fact, was to create the transient model of a pipe with also the capability of calculating temperature and composition changes due to various reaction sets. Since the reduction of the calculation time was a necessary requirement, a “lumped-volume” model has been adopted [6]: it is a simplified scheme, based on

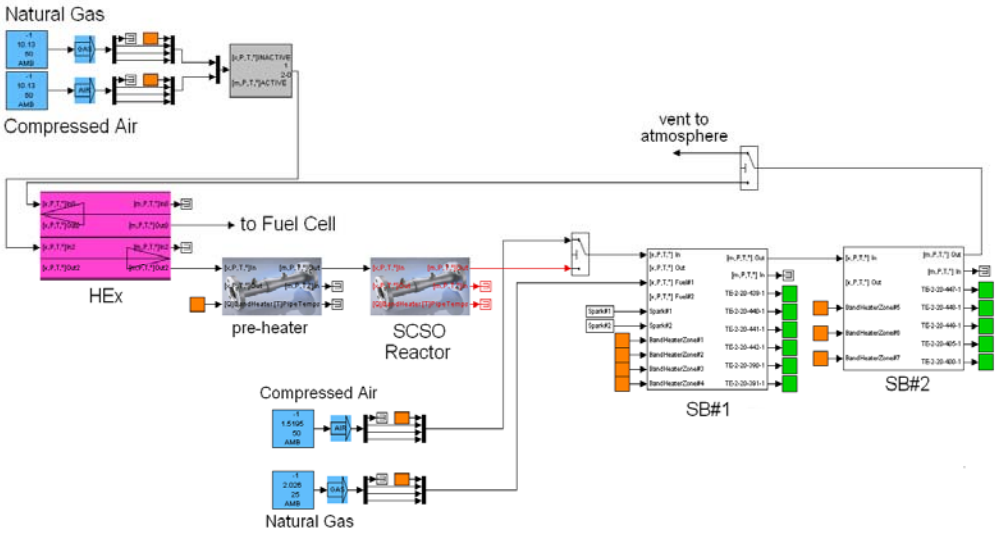

Figure 2. Matlab/Simulink model of the complete subsystem

the hypothesis of semi-ideal gas, that allows the use of large time steps. The lumped-volume model (Figure 3) is formed by an off-design model that behaves as an actuator disk, followed by a duct, with constant equivalent cross-sectional area and length, for the fluid dynamic delay. In this way, a sort of superposition of the effects is carried out: the actuator disk responds rigidly to the inlet and lumped-volume conditions (these represented its boundary conditions), while its effect is delayed by the equivalent duct that follows. The actuator disk is actually the place where the involved reactions happen. On the other hand, heat transfer is modelled with a more detailed approach in this work, since the heat transfer/storage/loss are the main phenomena to be captured by the model.

Heat Transfer Model

The heat transfer model adopted in the "Standard Reacting Pipe" was based on the one from the original pipe component of the TRANSEO library, which implemented a basic heat transfer: heat exchange between gas stream and wall, and heat losses towards the environment. In the "Standard Reacting Pipe" such model has been upgraded. As the real system involved not negligible catalyst and insulation masses, to best represent its behaviour, the transient effect due to the thermal capacitance of multiple layers of different materials has been implemented. While the real geometry for both the metal and insulation layers have been taken into account, for the catalyst the complex geometry of the real system had to be simplified. The SCSO reactor catalyst, in fact, implemented a micro channel geometry while the sorbent beds contained packed spheres. These two complex configurations have been simplified through the use of an additional concentric circular layer between the pipe and the gas stream. The thickness of such layer was determined spreading the calculated (from data) volume of catalyst onto the inner surface of the pipe (it acts as fixed external radius for the inner layer). The catalyst-fluid surface of heat exchange was not bound to this simplified geometry but it was left to be defined by the user as a parameter from the Simulink component mask. The heat transfer was modelled also considering the effect of the electrical band heaters: they are used to heat the gas stream and to keep the different components (i.e. reactor and sorbent beds) at operating temperature also in no flow conditions (zero space velocity).

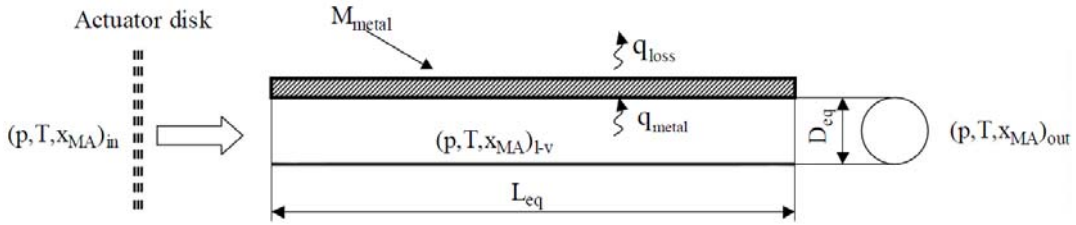

Figure 3. Lumped-volume model [6]

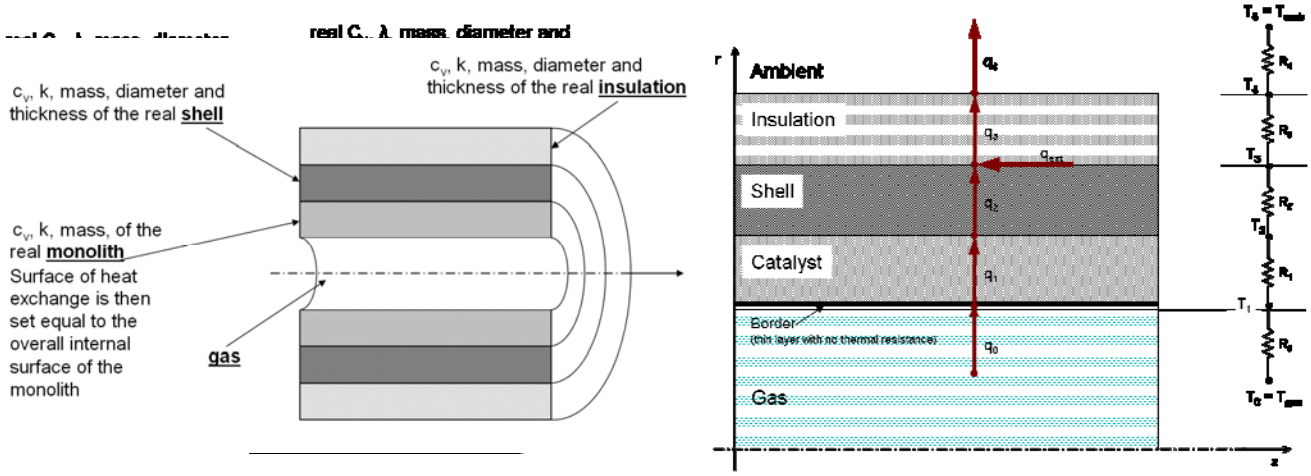

Figure 4. Simplified geometry adopted (left) and heat transfer model (right)

To simulate this effect an external heat rate in the heat transfer scheme has been added between the metal and insulation layers, where the heaters are actually placed.
A general relationship between Nu, Re and Pr numbers is adopted. Dividing the general relationship by the on-design values of Nu, Re and Pr numbers (i.e. the Nu, Re and Pr numbers calculated at on-design conditions), it is possible to derive (1). Such an equation expresses the relationship of the convective heat transfer coefficient h with the current and on-design values Re', Pr' and k'. The user only needs to introduce the reference value for the convective coefficient, that is h', and the exponents "a" and "b", together with the on-design operating parameters (mass flow or velocity, pressure, temperature). By assuming standard composition for the flow (air at ISO conditions), the tool is automatically capable of calculating the remaining on-design numbers to be employed in (1). Such an approach is employed here because the aim is to simulate the transient and off-design behaviour of the system, rather than designing it: thus, geometry and design operating conditions can be considered known.

$$h = h' \cdot \frac{k}{k'} \cdot \left(\frac{\mathrm{Re}}{\mathrm{Re}'}\right)^a \left(\frac{\mathrm{Pr}}{\mathrm{Pr}'}\right)^b \tag{1}$$

Energy equations for the gas stream and for the solid layers, considering the assumptions of the model and its geometry, reduce respectively to (2) and (3).

$$\frac{\partial\left(\rho c_v T A_c\right)}{\partial t} = -\frac{\partial\left(\dot{M} c_p T\right)}{\partial z} + q \tag{2}$$

$$\frac{\partial\left(M c_v T\right)}{\partial t} = q \tag{3}$$

In the following equations the calculation nodes (Figure 4) are referred to with the use of the subscript i. The heat exchange rates q_i must be explicitly indicated, as reported in (4).

$$q_i = \frac{1}{R_i}\left(T_i^{\,n+1} - T_{i+1}^{\,n+1}\right) \qquad \text{for } 0 \le i \le 4 \tag{4}$$

Thermal resistances R_i (5) for the solid layers are calculated consistently with the actual cylindrical geometry.

The inner resistance is calculated starting from the convective coefficient and area of heat exchange; the external resistance is derived from the thermal conductance parameter which is to be provided by the user from the component mask in Simulink.

$$\begin{cases} R_0 = \dfrac{1}{h \cdot A} \\ R_i = \dfrac{1}{2\pi\lambda_i L} \cdot \ln \dfrac{r_{i+1}}{r_i} \qquad \text{for } 1 \le i \le 3 \\ R_4 = \dfrac{1}{U_4} \end{cases} \tag{5}$$

Since the reduction of the calculation time is a necessary requirement when plant simulations are carried out, it was decided to adopt an implicit scheme for calculating the temperatures at the *n+1* (i.e. current, unknown) time, as it allows the use of greater time steps of integration without compromising the stability of the results. All the previous sets of equations are then being used in the system (6).

$$\begin{cases} \left[1 + \dfrac{m_{out} c_p dt}{c_{v0} M_0} + \dfrac{dt}{c_{v0} M_0 R_0}\right] \cdot T_0^{n+1} + \left[-\dfrac{dt}{c_{v0} M_0 R_0}\right] \cdot T_1^{n+1} = T_0^n + \left[\dfrac{m_{in} c_{pin} dt}{c_{v0} M_0}\right] T_{totin} \\ \left[-\dfrac{dt}{c_{vx} M_x R_0}\right] \cdot T_0^{n+1} + \left[1 + \dfrac{dt}{c_{vx} M_x R_0} + \dfrac{dt}{c_{vx} M_x R_1}\right] \cdot T_1^{n+1} + \left[-\dfrac{dt}{c_{vx} M_x R_1}\right] \cdot T_2^{n+1} = T_1^n \\ \left[-\dfrac{dt}{c_{v1} M_1 R_1}\right] \cdot T_1^{n+1} + \left[1 + \dfrac{dt}{c_{v1} M_1 R_1} + \dfrac{dt}{c_{v1} M_1 R_2}\right] \cdot T_2^{n+1} + \left[-\dfrac{dt}{c_{v1} M_1 R_2}\right] \cdot T_3^{n+1} = T_2^n \\ \left[-\dfrac{dt}{c_{v2} M_2 R_2}\right] \cdot T_2^{n+1} + \left[1 + \dfrac{dt}{c_{v2} M_2 R_2} + \dfrac{dt}{c_{v2} M_2 R_3}\right] \cdot T_3^{n+1} + \left[-\dfrac{dt}{c_{v2} M_2 R_3}\right] \cdot T_4^{n+1} = T_3^n + \left[\dfrac{dt \cdot q_{ext}}{c_{v2} M_2}\right] \\ \left[-\dfrac{dt}{c_{v3} M_3 R_3}\right] \cdot T_3^{n+1} + \left[1 + \dfrac{dt}{c_{v3} M_3 R_3} + \dfrac{dt}{c_{v3} M_3 R_4}\right] \cdot T_4^{n+1} = T_4^n + \left[-\dfrac{dt}{c_{v3} M_3 R_4}\right] \cdot T_5 \end{cases} \tag{6}$$

It is possible to write (6) as the product of a matrix representing the constant coefficients and the unknown term vector: the result is the vector of the known (i.e. at the previous time step) terms. The matrix turns out to be tri-diagonal and so it is possible to find the value of the T_i^{n+1} elements of the unknown vector using the Gauss method. The boundary conditions and the additional q_{ext} in (7) are being considered in the vector of the known terms.

$$\begin{bmatrix} [...] & [...] & 0 & 0 & 0 \\ [...] & [...] & [...] & 0 & 0 \\ 0 & [...] & [...] & [...] & 0 \\ 0 & 0 & [...] & [...] & [...] \\ 0 & 0 & 0 & [...] & [...] \end{bmatrix} \cdot \begin{bmatrix} T_0^{n+1} \\ T_1^{n+1} \\ T_2^{n+1} \\ T_3^{n+1} \\ T_4^{n+1} \end{bmatrix} = \begin{bmatrix} T_0^n + [...] \cdot T_{totin} \\ T_1^n \\ T_2^n \\ T_3^n + [...] \cdot q_{ext} \\ T_4^n + [...] \cdot T_5 \end{bmatrix} \tag{7}$$

VALIDATION

Approach

The model has been validated against experimental data retrieved from a representative test that took place in late 2007 in Canton, Ohio, at Rolls-Royce Fuel Cell Systems US laboratories. It was a 120h test on the 250kWe Fuel Processor and it included a complete test on the SCSO subsystem. Warm-up, part and full load operation and cool-down phases were tested and recorded with 2s sample time. During the first 27 hours of the test, the system was operating the warm-up cycle. Pressure was atmospheric and the two sorbent beds were isolated from the rest of the system (Figure 1). Two different ignitions of the burner (only one of the two burners was used) are visible at hour 2nd and 16th (Figure 6). At the hour 27th the burner was turned off and the band heaters temperature control loop started. It maintained the set-point temperature and at the hour 42nd the system pressurised: it was ready for the reactor light-off that took place in 90 minutes time. The system operated until the hour 82nd at various loads and then it was cooled down.
Validation has been performed in two steps: firstly, single blocks of the system layout have been verified, secondly the complete system layout has been tested. In such a way, in the first part of validation a number of unknown parameters could be assumed, while in the second part prediction of system behaviour could be verified. For brevity, since this paper mainly focuses on the heat transfer model, the results will be explained but the validating process will not be described. More details on the validating process and additional results will be included in [1].

Final Results

Once the validation of single components was carried out, the model of the entire subsystem layout was built (Figure 2). The inputs from experimental data (orange blocks in Figure 2) were the methane and main air streams, the methane and air streams to the burners and the output signal of the controllers to the electrical heaters (i.e. reactor pre-heater, sorbent bed #1 zones 1-4 and sorbent bed #2 zones 1-3). Results on the temperatures of the reactor are shown in Figure 5. The graph on top refers to the temperatures of the gas streams, except one (dotted line) that represents the measurement of the thermocouple placed on the outer shell: the matching with experimental can be

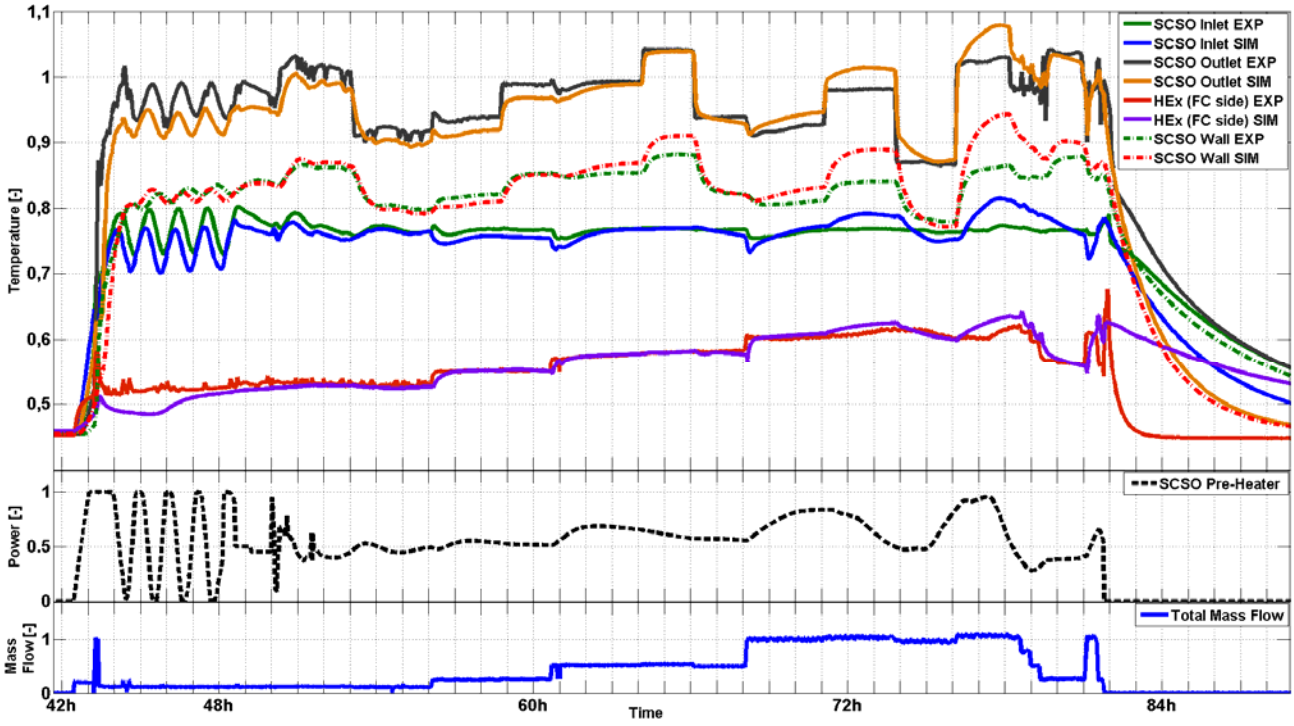

Figure 5. SCSO reactor gas and wall temperature validation

considered acceptable. It is worth saying that during the analysis of the reactor on its own, the model results were much closer to the experimental data: it is in fact easily noticeable that the calculated SCSO outlet temperature (orange) is largely affected by the upstream error from the recuperator and pre-heater components. The control signal of the SCSO pre-heater from the test is plotted below in Figure 5 and it explains the behaviour of the reactor inlet temperature in the last part of the chart: the value measured during the test (green) is almost constant while the model (blue) is prone to the heater effect. At the bottom the total flow rate during this part of the test (i.e. operation phase) is plotted. The validation of the SCSO wall temperature required an analysis on the flow regime (i.e. Reynolds number) as at first there was a significant mismatch between the model and experimental data. Such investigation revealed a laminar flow in every condition of the test. The Dittus-Boelter equation used for calculating the off-design convective coefficient was not valid anymore and Nu was instead considered constant [5]. The model with the new settings confirmed the analysis results and its wall temperature got closer to the experimental data.
Figure 6 shows the sorbent beds gas measurement points considered during the validation: the first just after the first burner, the second at the outlet of the first vessel and the third at the end of the second vessel. Results achieved show an acceptable overall behaviour of the model during the whole test length. Nonetheless a delay effect on the gas temperatures is visible in the second and third plot of Figure 6. The model yields a larger error when space velocity is negligible. This is reasonable as in such condition the influence of the free convection mechanism (not considered in the developed heat transfer model) become relevant. Also wall temperatures for all the sorbent beds heating zones have been validated, showing results consistent with those presented in this paper. They are plotted and discussed further in [1].

CONCLUSIONS

The validation of the model helped in better understanding and quantifying the phenomena undergoing in the different components of the rig: considering the test duration (120hours) and the variety of operating conditions (warm-up, hot stand-by, part and full load operation) the model prediction can be considered acceptable. Such validation confirms the validity of the heat transfer model adopted and also the effectiveness of the TRANSEO code as base for future developments.

ABSTRACT. The effects of cathode mesoscale structures on the SOFC performance are experimentally investigated. Preliminary scale analysis using the characteristic lengths based on the conservation equations for electron, ion and gas phases shows that the ionic transport is the rate-limiting process of the transport phenomena in electrode under a standard SOFC condition and thus the active reaction area exists in the vicinity of the electrode-electrolyte interface. The electrode-electrolyte interface is modified by introducing mesoscale structures to the electrode and its effects on the cell performance are examined by conducting power generation tests for the cells with two types of mesoscale grooves. Enhancement of the power generation performance was observed for the grooved cells.

Keywords: *SOFC, Power generation performance, Cathode mesoscale structure, Scale analysis*

INTRODUCTION

Enhancement of the power generation density is important for the development of solid oxide fuel cells (SOFCs). To increase the power generation density, there have been many investigations from various angles including thin-film electrolyte, development of high conductivity electrolyte materials [1], improvement of electrode [2] and multi-layer electrode for electrochemical reaction and gas diffusion [3, 4]. The key step in the electrochemical power generation of SOFCs is the electrochemical reaction at electrodes. It proceeds at three-phase boundary (TPB) where the oxygen ion, the electron and the reaction gas meet. TPB near the electrode-electrolyte interface is believed to be active and such region in the electrode is sometimes called as active reaction area. It is expected that such active reaction area could be expanded by modifying the electrode-electrolyte interface shape.

We have previously investigated the effects of anode mesoscale structures on power generation density of SOFC [5, 6]. The characteristic length of mesoscale structure is smaller than the macroscopic shape of a cell (~1mm) and larger than the microstructure of electrodes such as the grain size of the electrodes (~1μm). As one of the simplest mesoscale geometries we introduced small grooves machined on the electrolyte to enlarge the anode-electrolyte interface area and found that the anode with such mesoscale structure achieved larger power density compared with a standard flat anode. However it should be kept in mind that the enlargement of electrode-electrolyte interface by introducing mesoscale structures does not always give a positive result. The mesoscale structure causes the change of electrode and electrolyte thickness as well as the electrode-electrolyte interface area. The ohmic loss and concentration overpotential in the electrode increase with the increase of the electrode thickness. The ohmic loss for ionic conduction in the electrolyte is also increased with electrolyte thickness. The active reaction area is strongly affected by these changes of overpotentials, because it is

* Corresponding author: Mr. A. Konno

E-mail address: konno@t06.mbox.media.kyoto-u.ac.jp

directly related the ohmic loss of electrode and electrolyte, activation overpotentials and concentration overpotentials. From the previous numerical simulations [6, 7], it is found that the active reaction area distributes non-uniformly when the cell has mesoscale grooves and it expands into the groove bottom. Groove shape and depth are found to be very important parameters for discussions on the effective grooves to enlarge the active reaction area.

In this study, we firstly make a scale analysis using the characteristic lengths based on the conservation equations of electron, oxide ion and gas phase to estimate a suitable length scale of mesoscale structure. On that basis, we evaluate the cathode mesoscale structure by conducting power generation experiments of electrolyte supported button cells. Two types of the cathode mesoscale structures are realized by adopting different groove shapes on electrolyte surface. The power generation tests using each cell are conducted and the effects of the grooves on the power generation performance are discussed.

SCALE ANALYSIS

In this section we try to estimate the active reaction area in a simple analysis assuming an electrode consisting of three phases that are the electronic conducting phase, the ionic conducting phase and gas phase. The electrode reaction depends on the transport phenomena in three phases and the electrochemical reactions occur at three-phase boundary. It is believed that the electrochemical reaction is particularly prominent near the electrode-electrolyte interface. Costamagna el al. [8] and Chan and Xia [9] predicted the active reaction area and the electrode performance by the numerical analysis considering transport phenomena of two electrical potential phases or three phases. We try to estimate the active reaction area using the characteristic lengths from the conservation equation of these three phases. From each conservation equation (equation (1)), the orders of electronic, ionic and gas phase characteristic length can be expressed as equation (2).

$$\sigma_{el}\frac{\partial^2\phi_{el}}{\partial x^2}=i_{tpb},\quad \sigma_{io}\frac{\partial^2\phi_{io}}{\partial x^2}=i_{tpb},\quad D_{eff}\frac{\partial^2 C_j}{\partial x^2}=\frac{i_{tpb}}{nF} \tag{1}$$

$$l_{el}\sim\sqrt{\frac{\sigma_{el}\phi_{el}}{i_{tpb}}},\quad l_{io}\sim\sqrt{\frac{\sigma_{io}\phi_{io}}{i_{tpb}}},\quad l_{gas}\sim\sqrt{\frac{nFD_{eff}C_j}{i_{tpb}}} \tag{2}$$

where σ_i is effective conductivity at phase i, ϕ_i is electric potential at phase i, i_{tpb} is electrochemical reaction rate per unit volume, n is number of electron carried by chemical species, F is Faraday constant, D_{eff} is effective diffusivity of porous electrode, C_j is molar concentration of chemical species j at gas phase. Relative comparison among three characteristic lengths shows that oxide ion transport is the rate-limiting step in the electrodes. As the electrochemical reaction rate per unit volume is same in the formulas of the characteristic lengths (equation (2)), ratios of the characteristic lengths can be written as effective conductivities and diffusivity as follows.

$$\frac{l_{el}}{l_{io}}=\sqrt{\frac{\sigma_{el}\phi_{el}}{\sigma_{io}\phi_{io}}}\approx\sqrt{\frac{\sigma_{el}}{\sigma_{io}}},\quad \frac{l_{gas}}{l_{io}}\sim\sqrt{\frac{nFD_{eff}C_j}{\sigma_{io}\phi_{io}}}=\sqrt{\frac{nFD_{eff}P_j}{R_0T\sigma_{io}\phi_{io}}} \tag{3}$$

The values of these two ratios are estimated using electrical and thermo-physical properties of standard electrode materials [10-12]. Assumed electrode materials are Ni-YSZ cermets and LSM-YSZ composite as anode and cathode material, respectively. As the electrode is porous, the value of effective ionic conductivity is assumed to be one-tenth of ionic conductivity of a dense electrolyte. Effective diffusivity is calculated as $D_{eff}=\varepsilon/\tau\, D_{ij}$, where ε is porosity, τ is tortuosity factor and D_{ij} is the binary diffusivity between chemical species i and j ($\varepsilon = 0.3$, $\tau = 3$). ϕ_{io} uses 1V for the reference voltage. From the estimation of the ratios at general operating conditions of SOFC, the order of ratio l_{el}/l_{io} is 10^3 for anode and 10^2 for cathode, respectively. It shows that electron transport in the

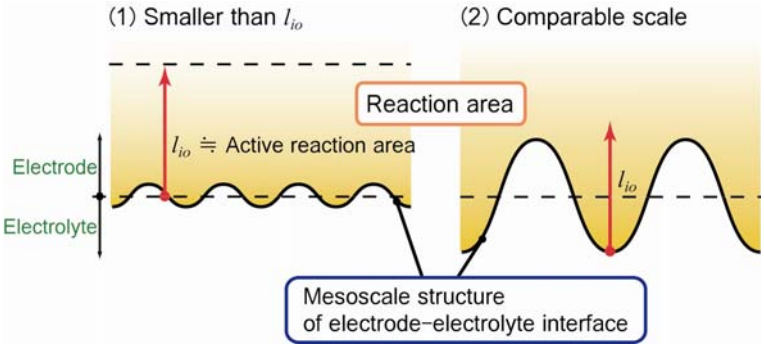

Figure 1. Active reaction area of the cells applied (1) mesoscale structure smaller than ionic characteristic length and (2) the structure comparable to ionic characteristic length

electrode is sufficiently fast and therefore it is not the rate-limiting process. On the other hand, the orders of l_{gas}/l_{io} is 10 for anode and 1~10 for cathode, respectively. It shows that the oxide ion transport is of the primary importance and probably the rate-limiting process yet the gas phase transport may affect the reaction area and the electrode performance depending on the operating conditions. The gas phase transport becomes important when the gas concentration is low and/or the gas diffusivity is low due to inefficient microstructure of electrode (equation (2)). When the oxide ion transport is the rate-limiting process, the active reaction area is limited to the neighboring area of the electrode-electrolyte interface. It is expected that the thickness of the reaction area is close to the ionic characteristic length.

In this study we apply mesoscale structure to enhance cell performance by increasing the electrolyte-electrode interface area. To improve cell performance, the scale of the electrode mesoscale structure should be larger than the ionic characteristic length. The mesoscale structure that is smaller than the ionic characteristic length will be buried in the active reaction area and therefore enlargement of electrolyte-electrode interface has little effect on the power generation performance as shown in Figure 1. Mesoscale structures larger than the characteristic length of ion transport are effective and suitable for the electrode performance enhancement.

In the following experiments, LSM cathode is used for electrode material. It is known that LSM is a mixed ionic and electronic conducting material but the ionic conductivity is negligibly small under a standard operating condition of SOFC [13]. Ionic characteristic length of LSM cathode is quite short and therefore it is expected that the cathode electrochemical reactions occur only in the vicinity of the electrode-electrolyte interface. Cathode mesoscale structures of tens of micron scale are employed in the experiment expecting structures of this size can improve the power generation performance by the electrode-electrolyte interface enlargement.

EXPERIMENTAL SETUP

Cell fabrication

Electrolyte-support button cells are used as test cells. Figure 2 shows the button type electrolyte made of Yttria stabilized Zirconia (YSZ, Tosoh, Japan). Its thickness is 0.5mm. The grooves are machined on one side of the electrolyte to realize the mesoscale structure. Two types of grooves are tested in this study, namely, large groove and small groove. The groove shape parameters are listed in Table 1. The area enlargement factor in the table is defined as a ratio of electrode-electrolyte interface area of grooved part to that of the flat part. Figure 3 shows cross sectional views of large and small grooves.

NiO-YSZ is used for the anode material. It is prepared from NiO powder (Wako Pure Chemical Industries, Japan) and 8mol% YSZ powder (Tosoh, Japan) by ball milling (Ni:YSZ=1:1, volume ratio) and pre-sintered at 1500°C for 5 hours. NiO-YSZ powder is mixed with poly-ethylene glycol, screen printed on the electrolyte surface and sintered at 1400°C for 5 hours. The cathode material is prepared using $La_{0.7}Sr_{0.3}MnO_x$ powder (AGC Seimi Chemical Co., Japan). It is mixed with

Table 1 Shape parameters of grooves

	Depth (μm)	Width (μm)	Interval (μm)	Area enlargement factor
Large grooves	210	210	220	1.58
Small grooves	60	60	50	1.72

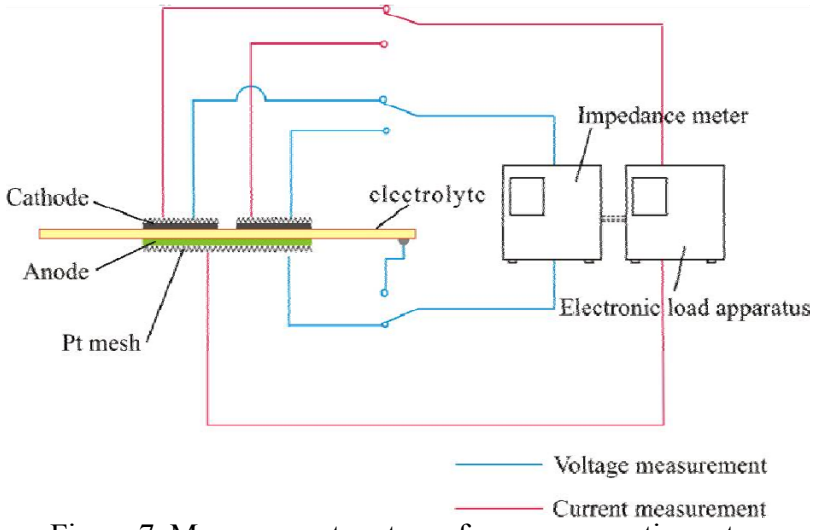

Figure 7. Measurement system of power generation setup

poly-ethylene glycol, screen printed on cathode side of electrolyte and sintered at 1150^{o}C for 5 hours. Figure 4 and 5 shows anode and cathode electrodes fabricated on each side of the test cells. As shown in Figure 5, cathode electrode is segmented into two parts. One side covers the flat surface and the other covers the grooved surface.

Power generation testing

Figure 6 shows the test section of the experimental button cell setup in this study. A button cell is sandwiched by co-axial ceramic tubes. On the anode side, the fuel is supplied through the inner tube. It turns and flow through the outer tube to be exhausted. On the cathode side, air as oxidant is supplied through the double tube and is directly exhausted in the furnace. The air flow rate is controlled by mass flow controller. The fuel is a mixture of hydrogen and nitrogen. Its concentration is controlled by mass flow controllers. Anode side outer tube is tightly connected to the cell by glass sealing to prevent gas leakage. The test section is placed in an electric furnace to maintain the operating temperature. It is confirmed prior to the experiments that the both fuel and air feeding tubes have enough length for preheating the flows.

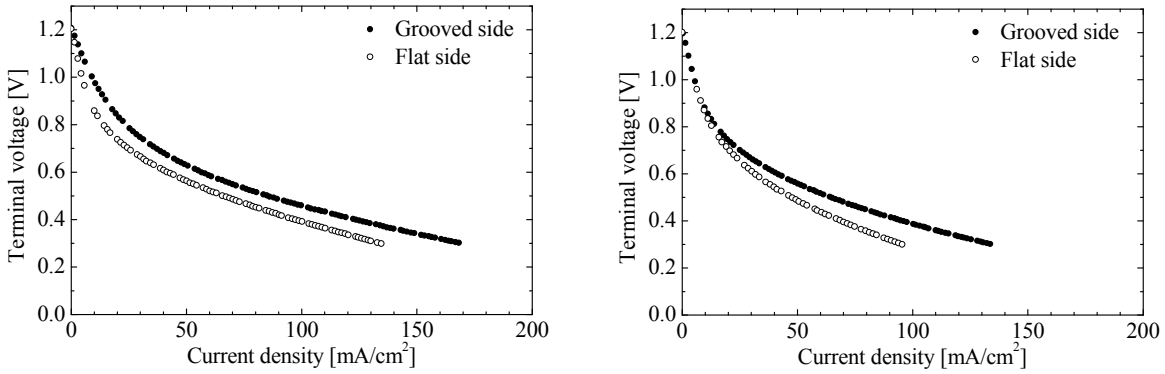
To collect the current from the electrodes, thin platinum mesh is physically contacted to the electrode surfaces as shown in Figure 6. As the cathode is divided into two parts in this study, two sets

of current collectors are carefully placed on each cathode so that there is no electrical contact between two electrodes. The segmented cathode electrodes are evaluated one by one to find if there is any difference between them. Platinum wire of 0.5mm in diameter is connected to each platinum mesh. For voltage measurement, thinner platinum wire of 0.2mm in diameter is also connected to each platinum mesh. An impedance meter (KIKUSUI KFM2150) and an electronic load (KIKUSUI PLZ164WA) is used for the power generation testing as shown in Figure 7 to obtain *i-V* characteristics. Current density is defined as a measured current divided by a projected electrode area. The projected area is measured by means of image processing. The experiments were conducted varying the operating temperature (800, 850 and 900°C). Three individual cells are tested for large (GL1, GL2 and GL3) and small grooves (GS1, GS2 and GS3), respectively.

RESULTS AND DISCUSSION

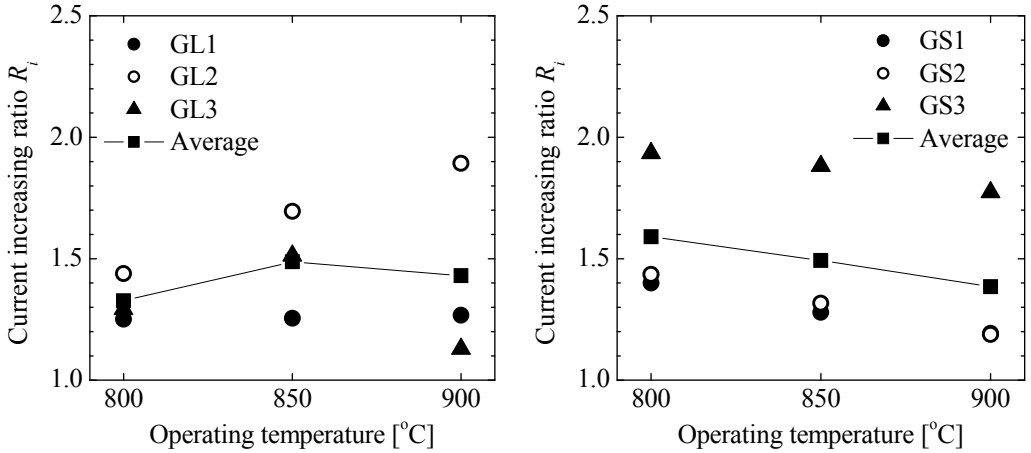
Fundamental characteristics

Fundamental power generation characteristics are examined for both large and small grooved cells. Figure 8 shows *i-V* characteristics of large grooves (a) and small grooves (b) at operating temperature of 800°C. Terminal voltage decreases as the current density increases. The current density of grooved side is always larger than that of the flat side at any terminal voltage. This is a common



(a) Large grooves (GL1) (b) Small grooves (GS1)

Figure 8. *i-V* characteristics at operating temperature 800°C and hydrogen concentration 100%



(a) Large grooves (b) Small grooves

Figure 9. Effect of operating temperature on current increasing ratio at hydrogen concentration 100%

tendency for all cells tested in this study. It shows that the cathode grooves improve the power generation performance of the cell.

Current density increasing ratio

To evaluate the effect of mesoscale grooves at different operating temperature, the current density increasing ratio R_i is defined as equation (4).

$$R_i = \frac{\text{Current density of grooved side}}{\text{Current density of flat side}} \tag{4}$$

The current density increasing ratio denotes enhancement of current density from a flat electrode to a grooved electrode at same terminal voltage. In the following discussion, the terminal voltage is fixed at 0.3V. Figure 9 shows the current density increasing ratio for both large grooves (a) and small grooves (b) at different operating temperature. In all cells, the current density increasing ratio is larger than unity. It shows that the mesoscale groove yields an enhancement of the power generation performance. In the case of the large grooves shown in Figure 9 (a), there seems no clear trend induced by the operating temperature. The average values of the current increasing ratio are 1.33, 1.49 and 1.43 at 800, 850 and 900^{o}C, respectively. In the case of the small grooves, the current density increasing ratio tends to decrease as the operating temperature is increased as seen in Figure 9 (b). The average values of the ratio are 1.59, 1.49 and 1.38 at 800, 850 and 900^{o}C, respectively. It is observed, however, that there are clear differences among the cells implying needs for more testing. The averaged current density increasing ratios take lower values than the averaged enlargement factors in both large and small groove cases. This is not surprising because the current density increasing ratio is affected by not only the enlargement of electrode-electrolyte interface area but also by the mean electrolyte thickness and the mean electrode thickness. Electrochemical reaction is enhanced near the groove bottom where the electrolyte is locally thin, while gas diffusion resistance is increased due to thicker electrode.

CONCLUSIONS

The effects of cathode mesoscale structure control on power generation performance are experimentally investigated. Scale analysis by characteristic lengths of the transport phenomena in the electrode was conducted to discuss the suitable size of mesoscale structure. The power generation experiments using cells with two different cathode grooves were conducted to evaluate the effect of cathode mesoscale grooves on the power generation performance.

(1) Preliminary scale analysis revealed that the ionic transport is the rate-limiting process among electron, oxide ion and gas phase transport in the electrodes under a standard cell condition.
(2) The power generation experiments showed that the cathode mesoscale grooves affect the cell performance. The current density is enhanced more than 30% compared with a standard flat electrode at terminal voltage of 0.3V.

[3] Tokyo Institute of Technology, Yokohama, Japan

ABSTRACT. A flow between two parallel disk shape plates at low Reynolds numbers (*Re*<100), which simulates a flow in the disk shape planar-type solid oxide fuel cell (SOFC), was experimentally investigated. Flow patterns at various flow rates were measured by using particle image velocimetry (PIV). In the channel installed flat plate current collectors, a velocity field indicated a stable radial flow pattern for a moderate Reynolds number, however, velocity gradient occurred along the radial direction. Since this result suggested the necessity of improvement of the channel shape, we designed a new channel with circle involute shape current collectors. In the new channel, a swirl flow occurred and maintained constant speed toward the channel exit. Furthermore, we confirmed that the velocity fields were remarkably improved and flow uniformity was achieved over the wide range of Reynolds numbers. This is because a flow passage consisting of two adjacent involute curves is equivalent to a constat-area channel due to the geometrical property of the involute curve.

Keywords: *Particle Image Velocimetry, Radial Flow, Swirl Flow, Solid Oxide Fuel Cell, Disk Shape Channel*

INTRODUCTION

Since solid oxide fuel cell (SOFC) using an oxygen-ion conducting electrolyte is operated at a high temperature, thermal management of the cell becomes an important issue. For instance, thermal stresses due to the temperature non-uniformity are unfavorable phenomena to cell's reliability. To solve this kind of problem, detailed information about the fluid dynamic phenomena occurring in the cell is required, because temperature distribution is strongly related to the velocity field. Furthermore, in order to achieve a homogeneous fuel supply to the electrode and to remove the heat generated in the cell, the uniformity of flow distribution is highly desirable.

Among several types of cell geometries, disk shape planar SOFC is prospective in a point that it can produce high electric power density [1]. Another advantage of disk shape SOFC is geometrical flexibility on flow passage. Therefore, it is expected to realize uniform fuel and air flows by optimizing a flow passage in the case of disk shape SOFC. However, it is difficult to confirm flow uniformity in practical operation.

In the present study, we investigated detailed flow structures between two parallel disk shape plates at low Reynolds numbers (*Re*<100) to simulate the practical operation in case of SOFC. The Reynolds number based on the fuel or air flow velocities was determined from electric current density, fuel utilization factor, and air utilization factor. In the experiment, airflow at room temperature was supplied to the model channel and flow patterns in the channel were measured by using particle image velocimetry (PIV) at various flow rates. In practical SOFC unit, a current

collector is an important component, because it can be used not only for conducting the electric current but also for determining the flow uniformity. Therefore, we installed current collectors with circle involute shape in the model channel, and tried to improve the flow uniformity by the optimization of flow passage.

EXPERIMENTAL SETUP

Figure 1(a) shows an experimental model of the disk shape SOFC channel employed in the present study. It has almost the same size as typical disk shape SOFC unit (outer diameter: D_O = 90 mm) and consists of a fuel channel and an air channel [2, 3, 4]. In the fuel channel, a working gas enters from the center hole (inner diameter: D_f = 24 mm) of the bottom disk, and then flows outward. Twelve air injection holes with a width of 4mm are drilled into the outer rim surface of the air channel at a regular interval. A working gas fed into the upper section of the air channel flows inward, changes its direction at the inner rim of a separation disk (inner rim diameter: D_i = 30 mm), and flows back through the lower section of the air channel. The fuel channel has a height of H_f = 5 mm or 2 mm, and both of the upper and lower air channels have heights of H_a = 2 mm, respectively. As shown in Fig. 1(a), the origin of coordinate system was chosen at the center of the bottom disk, and r and θ denote the radial and circumference directions, respectively.

Current collectors installed in the fuel channel and in the lower section of the air channel have a function of collecting the electric current. Furthermore, current collector acts as a guide for gas flow and determines the flow uniformity. Figure 2 shows two types of current collector examined in the present experiment. For one case, four flat plates are placed along the radial direction (hereafter referred to as "radial-type"). For the other case, eight curve plates having a circle involute surface geometry are regularly arranged (hereafter referred to as "involute-type"). The width of current collector is 2 mm for both cases. The height of the fuel channel is 2 mm when involute-type current collectors are installed. We adopt the curvilinear coordinate system (ξ,η) illustrated in Fig. 1(b), where ξ is measured along a circle involute and η is measured at right angles to it, respectively. The origin of ξ-axis is set on the circumference of the base circle, and ξ_0 is arc length between point O' and point P. A width between adjacent involute curve η_0 is given by $\eta_0 = r_i\alpha$.

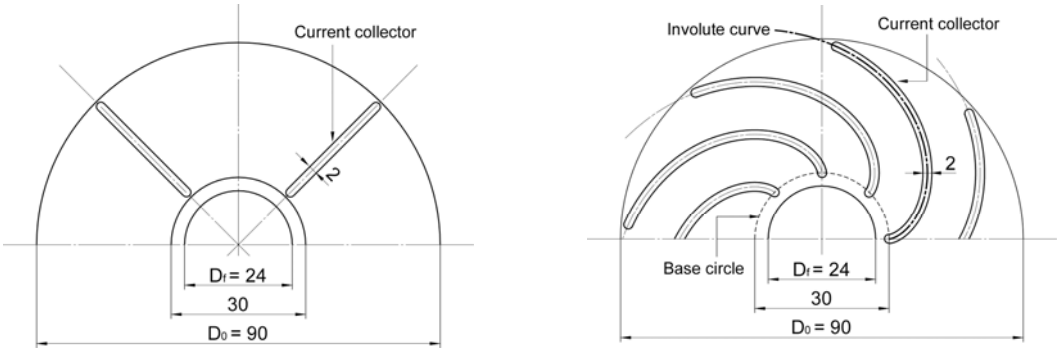

Figure 2. Arrangement of current collectors (Left: radial-type, Right: involute-type)

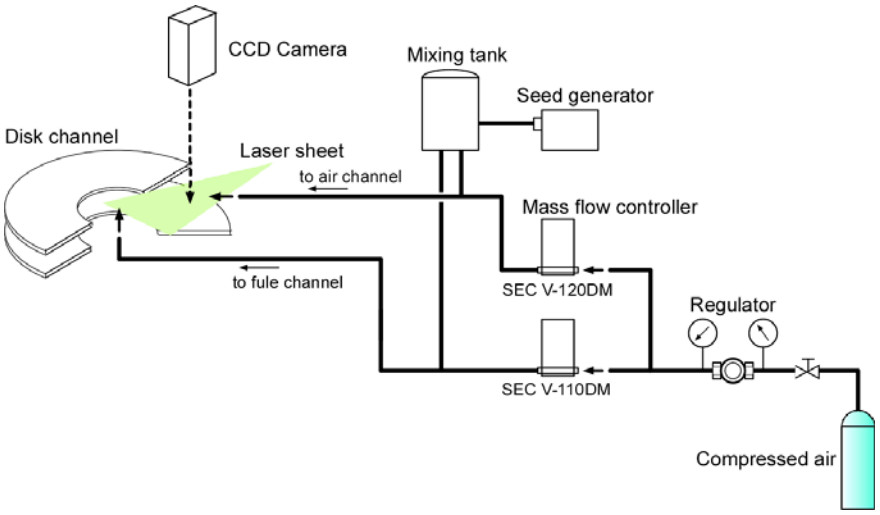

Figure 3. Schematic of the experimental setup

Figure 3 shows a schematic of the experimental setup. In order to give a detailed description of a flow field, instantaneous velocity vectors were measured by using PIV. The working gas is supplied from a compressed air cylinder at room temperature and seeded with tracer particles having about 10μm in diameter. Flow rates of the working gas in the fuel channel and in the air channel are controlled by mass flow controllers (HORIBA STEC, SEC-V110DM, SEC-V120DM). A light source of the PIV system is a double-pulsed Nd:YAG laser with an energy of 400 mJ per pulse (Spectra-Physics, PIV400). The pulsed laser beam is formed into light sheet having about 0.75 mm in thickness. This light sheet enters channel and illuminates the horizontal plane parallel to the disk plate. Light scattered from the particles in the field of view (60mm × 60mm) is captured by CCD camera (TSI, Model630046) settled above the channel and a series of particle images are recorded on PC. Instantaneous velocity vectors are deduced from successive particle images by using statistical correlation techniques with the aid of commercial software (Lavision, DaVis FlowMaster 7.1).

In order to simulate the practical operation in case of SOFC, experiments were performed at low Reynolds numbers of $1 \leq Re \leq 43$ in the fuel channel and $12 \leq Re \leq 92$ in the air channel, respectively. The Reynolds number is defined by $Re=U_f H_f / \nu$ or $Re=U_a H_a / \nu$. Here U_f and U_a denote respectively the velocities at the fuel channel inlet and air channel inlet, and are calculated from the operating condition of electric current density of 5000 A/m^2, fuel utilization factor of 0.5-0.8 and air utilization factor of 0.2-0.3. The above mentioned Reynolds numbers correspond to flow rates of 0.1 l/min $\leq Q_f \leq$ 3.0 l/min in the fuel channel and 1.0 l/min $\leq Q_a \leq$ 8.0 l/min in the air

channel. According to the method of ANSI/ASME PTC 19.1-1985 [5], uncertainty interval associated with the instantaneous velocity estimated at 95% coverage is evaluated as $0.04U_f$.

RESULTS AND DISCUSSION

Flow patterns in the disk channel with radial-type current collector

Fuel channel Figure 4 shows time-mean velocity vectors and contours in the horizontal plane at Q_f = 0.5 *l*/min. This flow rate corresponds to Reynolds number of 7. Time-mean values are calculated by ensemble averaging 50 instantaneous velocity fields. Although it is not shown here, the instantaneous velocity fields are almost identical to the time-mean flow representations. Therefore, we discuss overview of flow patterns on the basis of time-mean flow fields in the present paper. As seen in Fig. 4(a), in the middle horizontal plane (z=2.5 mm), the working gas flows radially and decelerates gradually toward the channel exit. However, a little higher velocities appear along the radial directions of θ = –26° and 28°. We can also see that low velocity regions are present near the current collectors owing to boundary layers developed on the current collector surfaces. Fig. 4(b) shows velocity field in the horizontal plane at z=4.5 mm which corresponds to the position of 0.5 mm apart from anode surface of the practical SOFC. Flow velocity decreases over the whole region of the channel by the effect of boundary layer on the disk plate. We found from a series of experiments that a relatively uniform radial flow was attained at Reynolds number of about 7 but occurrence of velocity gradient along the radial direction can not be avoided in the fuel channel.

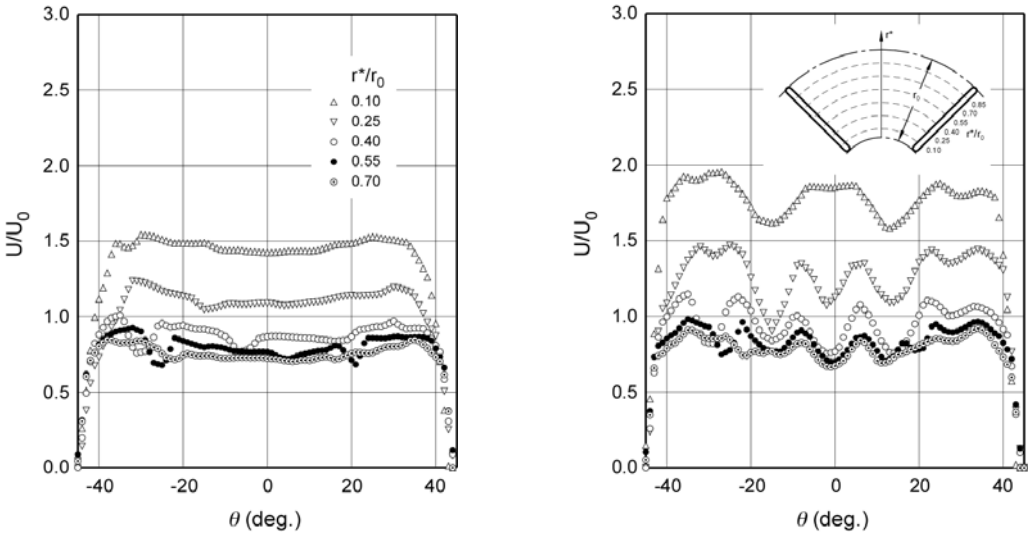
Figure 5. Velocity fields in the middle horizontal plane of the upper section of the air channel



(a) Q_a =2.0 *l*/min (b) Q_a =8.0 *l*/min

Figure 6. Velocity profiles along the circumference direction in the lower section of the air channel

<u>*Upper section of the air channel*</u> Figure 5 shows velocity vectors in the middle horizontal plane of the upper section of the air channel at Q_a=2.0 and 8.0 *l*/min. These flow rates correspond to *Re*=23 and 92, respectively. The air supplied from injection hole, which shows jet-like behavior, flows to inner rim of the separation disk and strikes inner cylindrical surface. After that, jet-like flow spreads over the inner cylindrical surface and strikes it uniformly for the case of Q_a=2.0 *l*/min. On the other hand, at Q_a=8.0*l*/min, jet-like flow strikes on narrow area of the inner cylindrical surface and returned flow gives rise to a large-scale vortex between adjacent jet-like flows. This flow pattern is similar to multiple impingement jet, and is induced by the interaction between jet-like flows from adjoining air injection holes.

<u>*Lower section of the air channel*</u> Figure 6 shows velocity profiles in the middle horizontal plane of the lower section of the air channel at Q_a=2.0 and 8.0 *l*/min. Here, *U* is calculated by $U = (u_x^2 + u_y^2)^{1/2}$ from PIV data, and U_0 is estimated by flow rates and channel cross-sectional area at *r* =15 mm. At Q_a=2.0 *l*/min, uniform radial flow is realized in the lower section of the air channel. However, at Q_a=8.0 *l*/min, it is found that high-speed regions exist along the radial directions of $\theta \approx 0°$ and ±27°. This is because a high-momentum fluid produced by the fluid impingement onto the inner cylindrical surface enters lower section of the air channel. Therefore, the optimum flow field in the air channel is obtained at lower flow rates that correspond to a range of *Re* of 12-46. These results suggest the necessity of improvement of the channel shape and injection method of air.

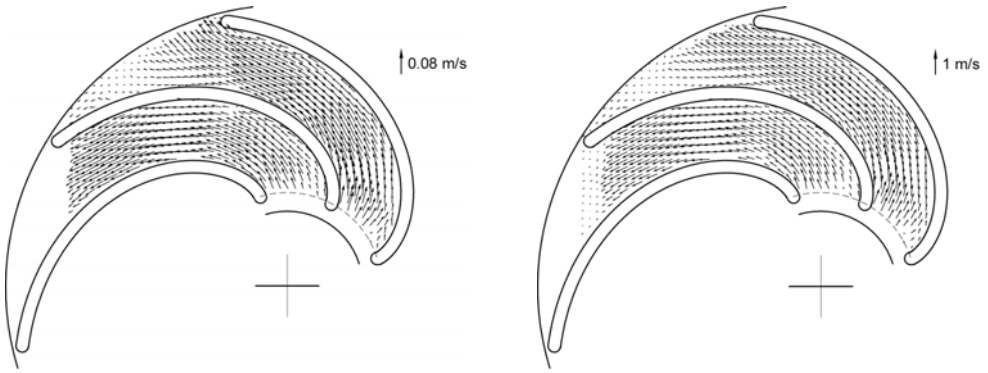
Flow patterns in the disk channel with involute-type current collector

As mentioned above, in the case of radial-type channel, velocity gradient occurs along the downstream direction. This is because a cross-sectional area of the disk channel increases along the radial direction. Accordingly, in order to improve flow uniformity in a disk channel, we designed a flow passage with circle involute shape current collectors (Fig. 2).

<u>*Fuel channel*</u> Figure 7 shows velocity vectors in the middle horizontal plane of the fuel channel at Q_f = 0.3 and 3.0 *l*/min. These flow rates correspond to *Re* = 4 and 43, respectively. We can see from Fig. 7(a) that a swirl flow occurs between adjacent current collectors and maintains nearly constant speed toward the channel exit. In addition, the flow pattern seen in Fig. 7(a) is still present at higher flow rate (higher Reynolds number) as seen in Fig. 7(b). It is clearly shown from these features that the velocity field is significantly improved and flow uniformity can be achieved over the wide range of Reynolds numbers by introducing the circle involute shape current collectors. This is because a

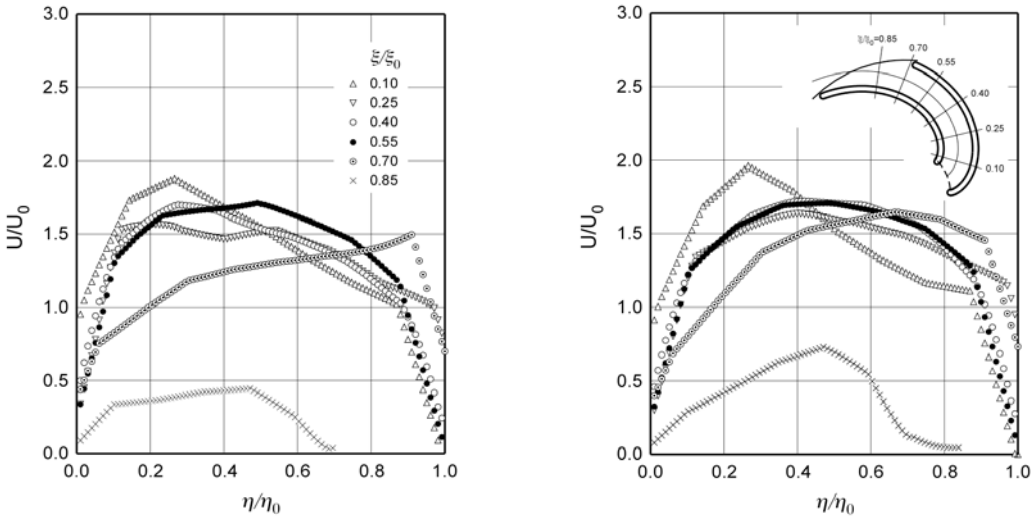
flow passage consisting of two adjacent circle involutes is equivalent to constat-area channel due to the geometrical property of circle involute.

In order to clarify flow uniformity, velocity profiles along the direction perpendicular to the current collector surface (i.e. η-direction) are shown in Fig. 8. Here, velocity profiles are plotted at dimensionless streamwise locations of ξ/ξ_0=0.1, 0.25, 0.4, 0.55, 0.7 and 0.85. As shown in Fig. 8(a), in the case of Q_f = 0.3 *l*/min, a maximum of U/U_0 =1.9 is reached near η/η_0=0.3 at ξ/ξ_0=0.1. In the region of 0.25 ≤ ξ/ξ_0≤ 0.55, U/U_0 is about 1.5 except near the current collectors where it falls rapidly to zero. However, in the downstream from a trailing edge of current collector (ξ/ξ_0> 0.7), the working gas is decelerated owing to the increase in channel cross-sectional area. From these characteristics, we can find that deceleration of the working gas is suppressed over a large part of the channel and the area of uniform velocity field in the involute-type channel extends wider than that in the radial-type channel. A peak of the velocity profile is observed close to η/η_0=0.3 at ξ/ξ_0=0.1 and close to η/η_0=0.5 at ξ/ξ_0=0.55, respectively. This flow feature indicates that the path of a working gas does not precisely follow the circle involute. As shown in Fig. 8(b), in the case of Q_f =3.0 *l*/min, velocity profiles show good similarity at ξ/ξ_0≤ 0.55, and the velocity at ξ/ξ_0=0.7 is higher than that for the case of Q_f =0.3 *l*/min. Comparing Fig. 8(b) with Fig. 8(a), the velocity field at higher flow rate of Q_f =3.0 *l*/min still exhibits the global features occurring at lower flow rate of Q_f =0.3 *l*/min, but flow uniformity is slightly enhanced with increase in flow rate.



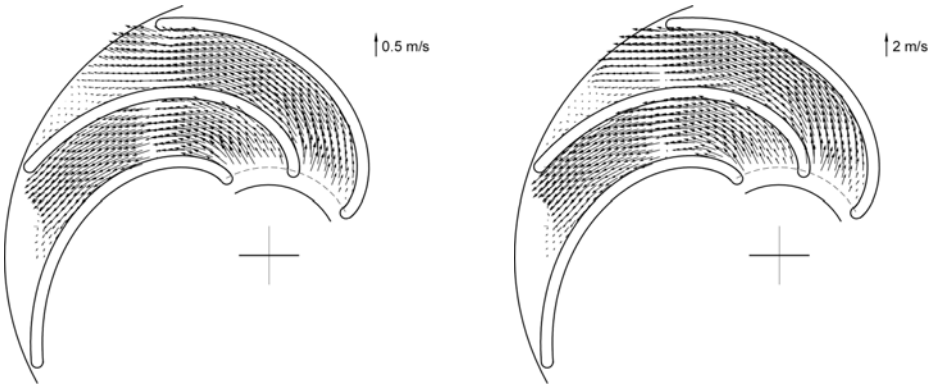
(a) Q_f =0.3 *l*/min (b) Q_f =3.0 *l*/min

Figure 7. Velocity fields in the middle horizontal plane of the fuel channel



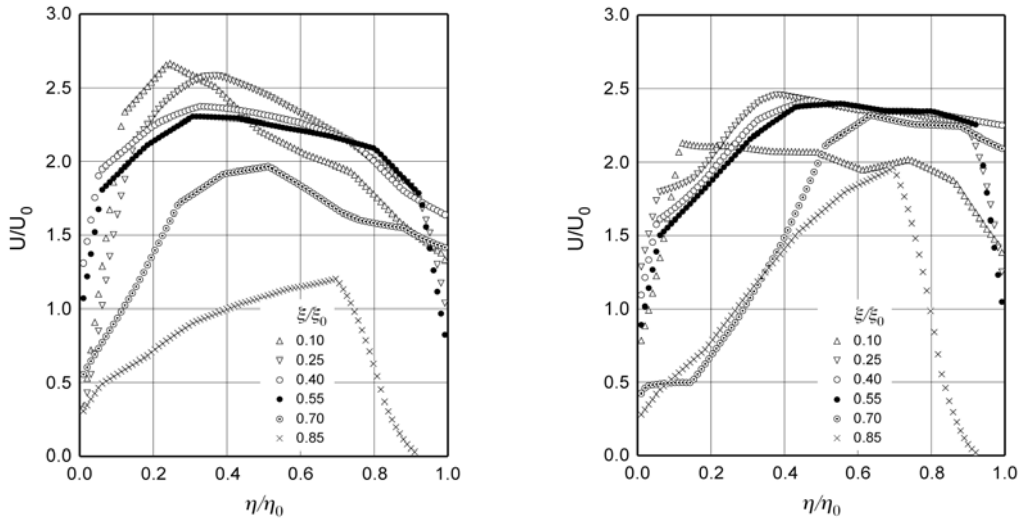
(a) Q_f =0.3 *l*/min (b) Q_f =3.0 *l*/min

Figure 8. Velocity profiles along the η-direction at several locations of ξ/ξ_0 in the fuel channel



(a) Q_a =2.0 *l*/min (b) Q_a =8.0 *l*/min

Figure 9. Velocity fields in the middle horizontal plane of the lower section of the air channel



(a) Q_a =2.0 *l*/min (b) Q_a =8.0 *l*/min

Figure 10. Velocity profiles along the η-direction at several locations of ξ/ξ_0 in the lower section of the air channel

Lower section of the air channel In the present experiment, velocity fields in the horizontal plane of the upper section of the air channel are not effectively affected by introducing the involute-type current collectors, and have similarity to velocity fields shown in Fig. 5. Hence, we focus on the velocity fields in the lower section of the air channel.

Velocity vectors in the middle horizontal plane of the lower section of the air channel at Q_a =2.0 and 8.0 *l*/min are compared in Fig. 9. These flow rates correspond to *Re*=23 and 92, respectively. Measured velocity fields are nearly identical regardless of flow rates and a strong resemblance can be observed between the velocity fields in Fig. 7 and those in Fig. 9.

Figure 10 shows velocity profiles along the η-direction at several dimensionless streamwise locations to investigate flow uniformity in more detail. In the case of Q_a =2.0 *l*/min, a maximum of U/U_0 exceeds 2.5 at ξ/ξ_0=0.1 and 0.25, and reaches about 2.3 at ξ/ξ_0=0.4 and 0.55. The position to achieve maximum velocity is around η/η_0=0.3 at $0.1 \leq \xi/\xi_0 \leq 0.55$. In the case of Q_a =8.0 *l*/min, U/U_0 is about 2.1 over the wide range of η/η_0 at ξ/ξ_0=0.1, whereas U/U_0 reaches up to 2.4 for $0.5 < \eta/\eta_0 < 0.9$ at $0.25 \leq \xi/\xi_0 \leq 0.55$. In addition, no apparent streamwise variation of U/U_0-profile is found in the region of $0.25 \leq \xi/\xi_0 \leq 0.55$. Comparing Fig. 10(a) and Fig. 10(b), flow uniformity is

enhanced at $0.25 \leq \xi/\xi_0 \leq 0.55$ and velocity increases at downstream part of the channel ($\xi/\xi_0 \geq 0.7$) with increase in flow rate. In addition, we can find that, in the case of higher flow rate, the η/η_0 location to achieve maximum velocity shifts toward positive η-direction and a gas flow deflects away from the involute curve. A fluid motion toward the η-direction is estimated by the η-component of the momentum equation. For simplicity, we consider the η-component of Euler's equation of motion [6]:

$$\frac{\partial U_\eta}{\partial t} + \frac{R}{R+\eta} U_\xi \frac{\partial U_\eta}{\partial \xi} + U_\eta \frac{\partial U_\eta}{\partial \eta} - \frac{U_\xi^{\,2}}{R+\eta} = -\frac{1}{\rho}\frac{\partial P}{\partial \eta} \tag{1}$$

where U_ξ and U_η are the velocity components in the ξ- and η-directions, P is the pressure, ρ is the density, and R is the curvature of circle involute at (ξ, 0), respectively. From equation (1) we see that, in the flow field where U_ξ is dominant compared with U_η, the pressure gradient along the negative η-direction plays primary role in a centripetal force to maintain a swirl motion. In case of higher flow rate, a momentum of fluid increases and the influence of pressure gradient on the fluid motion relatively weaken accordingly. Consequently, the gas flow strays from the involute curve.

CONCLUSIONS

A detailed flow structure between two parallel disk shape plates was investigated by using the particle image velocimetry. The experiment was performed at low Reynolds numbers (Re<100) to simulate the practical operation in SOFC. When we installed radial-type current collector in the disk channel, unfavorable flow deceleration occurred toward downstream direction. However, in the case of applying an involute-type current collector, a flow velocity was kept at nearly constant value toward the channel exit. This trend was observed regardless of flow rates, and hence flow uniformity was achieved over the wide range of Reynolds numbers by introducing the circle involute shape current collector. This is because a flow passage consisting of two adjacent involute curves functions as a constat-area channel due to the geometrical property of the involute curve.

MEASUREMENT AND MODELLING OF HEAT AND MASS TRANSPORT CHARACTERISTICS INSIDE PEMFC SYSTEMS

T. Araki*, So Manabe, Yuki Uemura, Kenji Ohora
Yokohama National University, Yokohama, Japan

ABSTRACT. To grasp and generalize effects of the local mass and energy transport on transient performance of PEMFC, we have measured voltage and membrane resistivity responses. Also, unsteady numerical model, which solved mass, electrical charge, and energy conservation equations had been developed. As necessary parameters for developing them, we measured properties of water content of MEA, MEA resistivity, the activation over-voltage, and mass transfer coefficients at boundaries etc. The measured and calculated transient responses were agreed well in many operating conditions. Especially complicated voltage responses with liquid water droplet evaporation could be numerically estimated.

Keywords: *PEMFC, Heat and mass transfer, unsteady power generating characteristics, water evaporation*

INTRODUCTION

Applications of PEMFC as good alternatives to conventional power generators are promising especially for vehicles and distributed stationary power generators. In PEMFCs, the water plays a significant role in proton conductivity of polymer electrolyte membrane (PEM) and reactant gas transport in channel and gas diffusion layers (GDL). However, mass, especially water, transport phenomena in each layers of PEMFC are so complicated as shown in Fig.1. For instance, the water is transported from the anode to cathode by electro-osmotic drag, and generated water at the cathode is diffused back toward the anode, and there are transport resistances at any boundaries between layers. Due to the importance of water transport factors, such as diffusion coefficient and electro-osmotic coefficient of water vapor through a membrane, have important effects on the performance of PEMFC, these factors have been measured in our previous reports.

Water transport phenomena in steady states have been cleared so far on some level, however, the water transport characteristic in transient state is still unclear, even transient state observed frequently during PEMFC operation such as start up and load change. The voltage, membrane resistivity and outlet gas humidity responses after supplying gas humidity stepwise change were measured. It is true that the supplying humidity change is not frequently occurred in actual PEMFC operation, however, the effect of water transport can be easily inspected by under these conditions.

To discuss more detail of effects of the local water transport on performance of PEMFC, we have developed unsteady numerical model, which solved mass conservation equations and

charge conservation equations in gas channel, GDL and MEA. As necessary parameters for developing them, we measured properties of Water content of MEA, MEA resistivity, the activation over-voltage, and overall mass transfer coefficient etc..

EXPERIMENTAL SETUP AND NUMERICAL MODEL

Experimental apparatus

Overview of experimental apparatus is shown in Fig. 2. Two sets of gas supplying systems (gas cylinders, mass flow controllers, humidifiers etc.) are placed on anode and cathode respectively, and supplied gaseous conditions could be changed quickly by use of four-way selector valves. The humidity change was mainly applied in present study for discussing water transport inside cell. Single cell was tested and it included membrane electrode assembly (MEA), gas diffusion layer (GDL), gas distributors (current collector), and end plates. The active area of MEA was 10cm^2, and its thickness was about 50μm. Carbon papers of 200μm thickness were used as GDL. The gas distributors were designed as single serpentine groove which length is 25cm with square cross section (1.0mm ×1.0mm). Supplied gaseous species are hydrogen and oxygen for decreasing effect of diffusion overpotential. Cell temperature was maintained at 70^{o}C by a constant temperature device. Dew point meters were used to measure relative humilities at inlet and outlet of anode and cathode. To control and measure accurate current/voltage polarization curves, the fuel cell was connected to a bipolar power supply. Membrane resistance were recorded by LCR meter connected with PC.

Numerical model

Investigating detailed transient of overvoltage distribution, it is needed to study not only experimentally but also numerically. Then, we have developed a transient two and three dimensional numerical model in PEMFC which includes equivalent circuit, conservation of mass and charge. Most of equations and algorithm of this model are as reported previously[1].

Electrical characteristics. As electrical parameters, activation overpotential, resistivities of membrane and GDL, and capacitance of electrical double layers have v\been measured. For example, measuring methods of activation overpotential are explained. Activation overpotential was measured with various supplied gaseous relative humidity (RH). Pure hydrogen and oxygen were used to eradicate the influence of concentration overvoltage, and relatively high flow rates of 1000 cc/min were supplied to even water content at MEA as far as possible. Current density was controlled at 0.1 A/cm^2. Fig.3 shows activation overpotential as a function of current density with

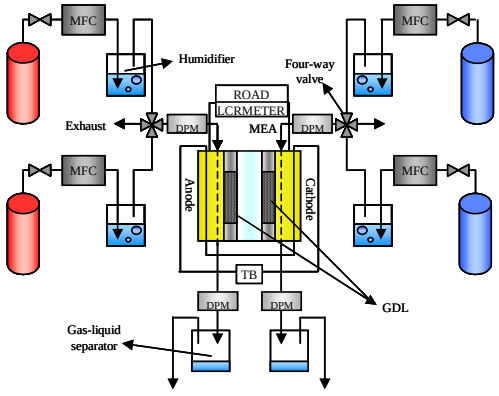

Fig. 1 Experimental apparatus

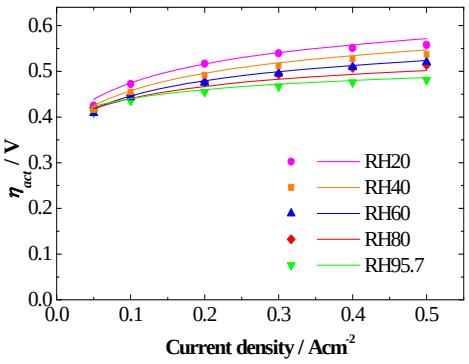

Fig.2 Effects of relative humidity on Activation overpotential

various supplied gaseous humidity. The activation overpotential increases as the supplied gaseous relative humidity decrease. The approximation, equation 1, was obtained by fitting results.

$$\eta_{act} = A + B \ln i \quad (1)$$

$$A = -1.4\times10^{-3}\,\mathrm{RH} + 0.6392\,,\ B = -3\times10^{-6}\mathrm{RH}^2 - 5\times10^{-5}\mathrm{RH}$$

Water transport characteristics. Overall mass transfer coefficient at the MEA/GDL interface, equation 2, was calculated from results of transient response MEA water content or resistivity after sudden supplied gas humidity change.

$$K_g = 1.0\times10^{-3}\ \mathrm{m/s},\ K_m = 1.19\times10^{-6}\ \mathrm{m/s} \quad (2)$$

Values of other properties such as the diffusion coefficients, electro osmotic drag coefficient, are used same as reported [2].

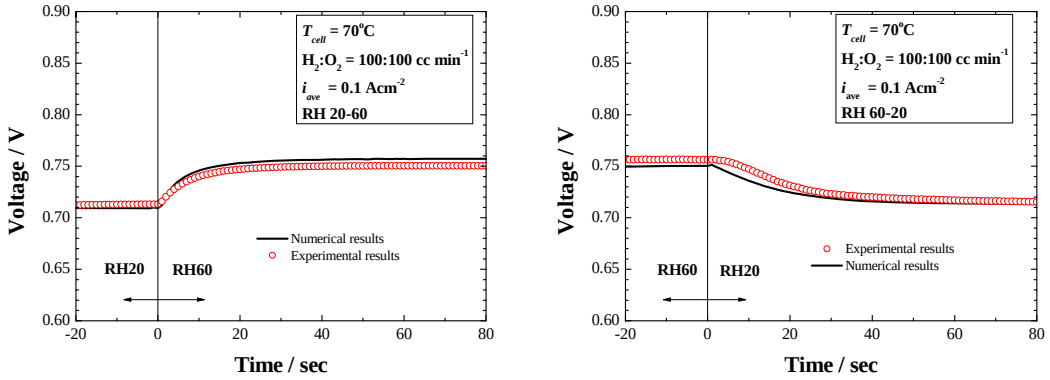
RESULTS AND DISCUSSIONS

Voltage responses after humidity change in dry condition

Transient cell voltage responses after sudden supplied gaseous humidity changes were measured Relatively low fuel and oxidant utilization ratio, in other words, high flow rates of supplied gases 100 cc/min, and low current density of 0.1 A/cm^2 were applied to keep test cell dry. Circle dots in Fig. 3 shows measured voltage response after supplied gaseous relative humidity (RH) change from 20% to 60% in (a) and from RH60% to RH20% in (b), respectively. Voltage increased after upward humidity change (a) due to decrease of resistivity and resistive overpotential. In figure (b) voltage decreased adversely. Downward change showed little bit slower response, however difference of time constants were not so big in these lower humidified conditions; no liquid water inside GDL.

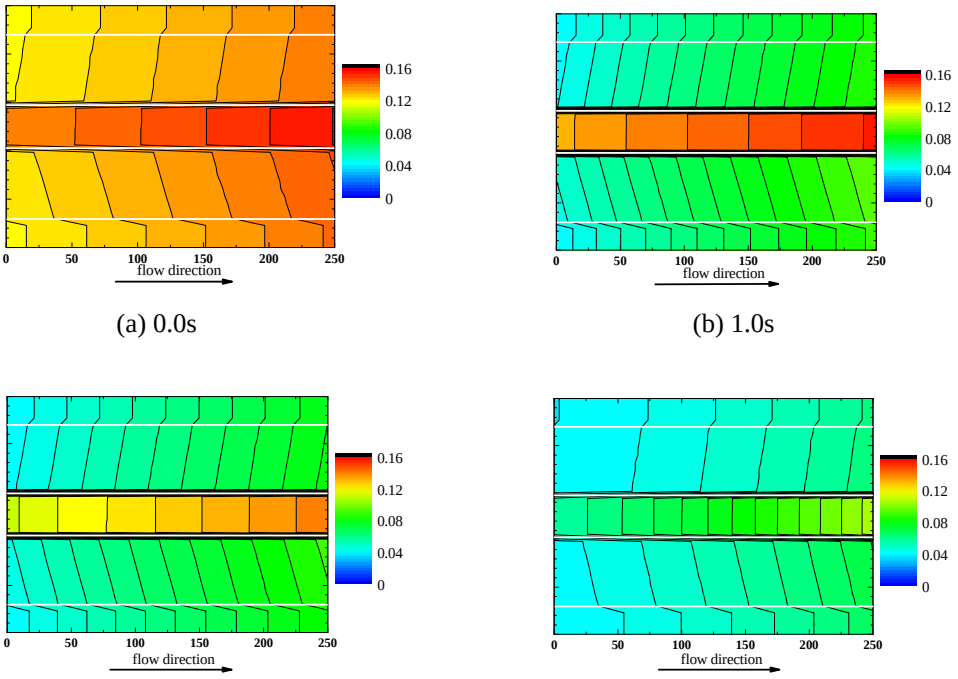
Numerical voltage responses in same conditions were also plotted in Fig. 3 with lines. Cell voltages at steady state and time constants agreed well. Differences of the amount of 10 mV is enough small compared with experimental errors and repeatability.

For investigating mass transport in detail, the water concentration contours at t=0.0s, 1.0s, 5.0s, and 30s after humidity change from RH60 to RH60 are shown in Fig.4. Because water concentration in MEA was much higher than that of vapor, they were converted to gaseous equilibrium value at cell temperature (70^{o}C). At t=1.0s, the concentration of water vapor in GDL and channel changed significantly, but the concentration in MEA hardly changes. This means large part of mass transport resistance exists at MEA/GDL interface consists of CL and MPL.



(a) upward change (RH20 to RH60) (b) downward change (RH60 to RH20)

Fig. 3 Voltage response after sudden supplied gas humidity change



(a) 0.0s (b) 1.0s

(c) 5.0s (d) 30s

Fig. 4 Water concentration contours after sudden supplied gas humidity change from RH60 to RH20

Consequently, time constants of cell voltage was mainly influenced by mass transport resistance at MEA/GDL under these conditions. This illation can be understood more easily from Fig. 5, which shows water concentration profiles in normal to PEM direction at 200mm from inlet.

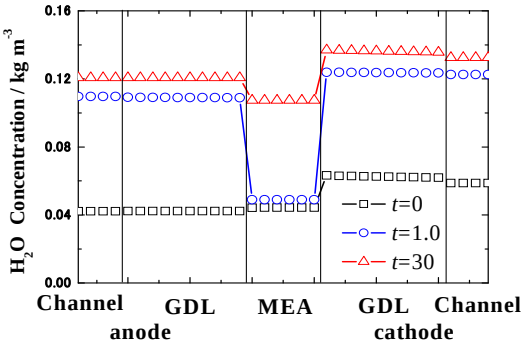


Fig.5 H_2O concentration profiles from anode to cathode at 200mm of the channel length

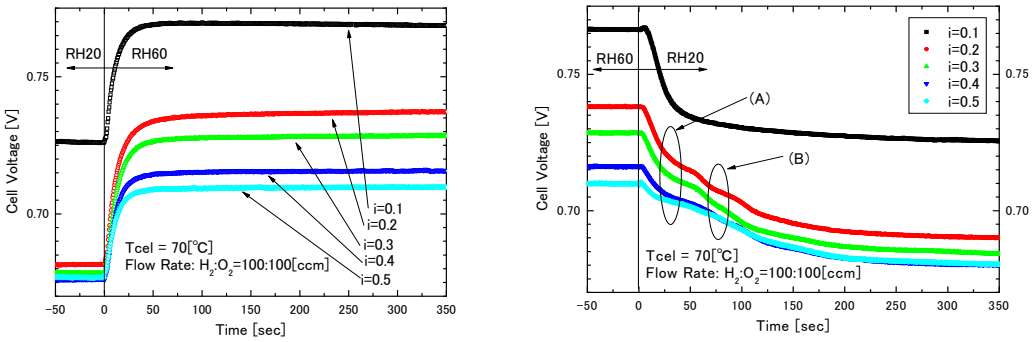
Voltage responses after humidity change with liquid water

The voltage responses in previous section were fast, because of a little amount of water in a cell. The responses could be extremely slowed if water droplets located in GDL or channel. Thus, experiments had been conducted in higher humidified conditions (or more current density, which means greater amount of generated water), to confirm and discuss effects of accumulated water. Fig. 6 shows voltage responses in various current densities ranging from 0.1 to 0.5A/cm^2. Responses after moisturize change and dryer change with low current density (0.1 A/cm^2) were fast and comparable with the dry conditions in previous section. On the contrary, it is clearly seen that the responses after desiccate change with higher current densities were very slow and completely unlike previous conditions. Please note that, the time axis is ten times extended compared with Fig. 3. These delays were subject to the accumulated water and its slow evaporation. Moreover, complicated voltage responses with inflexion points were observed. The inflection points could be accounted from the difference of evaporating speed at each layer or location. During water droplets exist in a cell, the membrane did not dried up and membrane resistivity did not change rapidly, however, after the instant of liquid water disappear from GDL or channel, the PEM dried up faster due to a thinness of PEM and low amount of water content.

We have also conducted numerical analysis considering amount of accumulated water in GDLs. The numerical responses are plotted in Fig. 7 with experimental responses. The numerical voltage response also showed some inflections and basically agreed with experiment. Thus, adequacy of our model was confirmed in those experimental conditions. Examining the results more minutely, experimental voltage drew away from numerical after 100s and reached steady state much slower than numerical voltage. These differences are probably owing to 3 dimensional effects. As shown blue arrow in Fig. 8, liquid water accumulated under rib is needed to transported long way to transport to channels and takes long time to completely evaporated. Then, the experimental responses need more time to reach steady state. Meanwhile, we constructed a 2 dimensional model in this study and did not considered such effects, then, .numerical response was estimated a little bit



(a) upward change (RH20% to 60%) (b) downward change (RH60% to 20%)

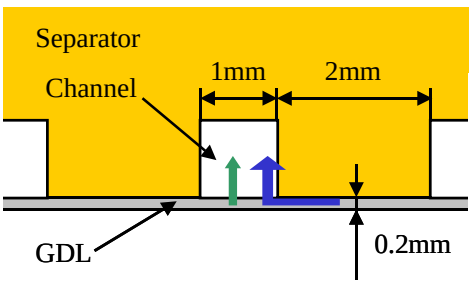

Figure 8 Effect of rib on water evaporation

quicker.

Energy transport

The temperature distributions in actual working cell have been also calculated and measured. The examples of calculated temperature distributions are shown in Fig. 9. The temperature at cathode catalyst layer seems to be highest in these results.

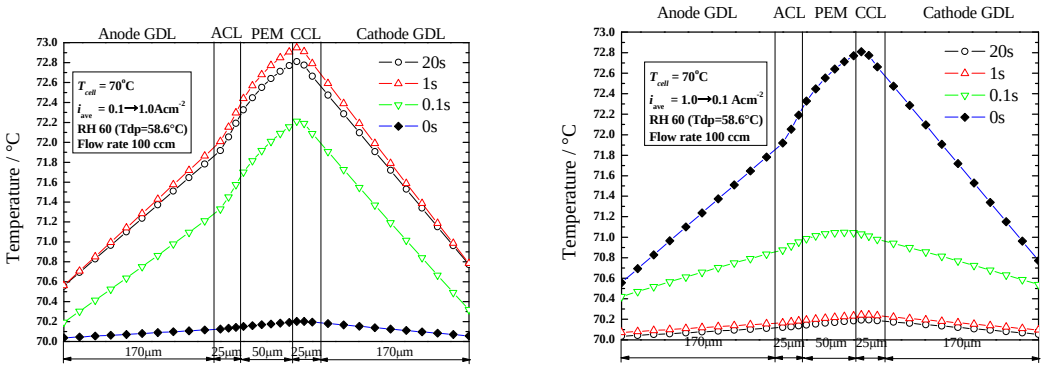

Figure 9 Temperature profile after load current density change
from 0.1 [A/cm^2] to 1.0 [A/cm^2](left side) and from 1.0 [A/cm^2] to 0.1 [A/cm^2](right side)

CONCLUSIONS

Voltage transient responses of PEMFC were investigated experimentally and numerically. In dry condition, the voltage responses were affected strongly by transport resistances at OEM-GDL, and they mainly dominate reaction time. The voltage responses with accumulated water droplets were extremely delayed and complicated. Some inflection points were observed, and they depend on locations of water accumulated position and its length of diffusion path.

STEAM REFORMING OF DIMETHYL ETHER WITH CATALYTIC COMBUSTION IN A SMALL ANNULAR TUBE

M. Saito[1, *], N. Kubo[1], Y. Kataoka[1], Y. Lee[1], K. Teramoto[1], H. Iwai[1], H. Yoshida[1]
[1]Kyoto University, Kyoto, Japan

ABSTRACT. Recently, hydrogen has attracted much attention as a fuel, particularly for fuel cells. If small equipment that can supply hydrogen is realized, its applications can be greatly extended. The steam reforming of dimethyl ether (DME) is expected to be used for the production of hydrogen. In this study, we fabricated a small DME reformer. Catalytic combustion is used as a heat source because the steam reforming of DME is an endothermic reaction. The reformer has the structure of a double tube, in which steam reforming of DME occurs in the outer channel, and the catalytic combustion occurs in the inner channel. At a sufficiently high temperature, DME was almost completely reformed. However, it is necessary to avoid an excessively high temperature because the formation of CO and CH_4 increases. Thus, temperature control is important for the steam reforming of DME.

Keywords: *fuel reforming, catalytic combustion, dimethyl ether*

INTRODUCTION

Hydrogen utilization is now recognized as a key technology for efficient energy conversion. The steam reforming of dimethyl ether (DME) is expected to be used for the production of hydrogen [1]. DME can be reformed at lower temperatures than hydrocarbons. Moreover, its portability is good because it is a liquid fuel and its toxicity and corrosivity are far less than those of methanol.

We designed a small DME reformer based on a self-sustaining reaction. The steam reforming of DME is an endothermic reaction. Therefore, catalytic combustion is used as a heat source. We fabricated a small reformer with an annular tube structure, and examined the conversion of DME for varying temperature profiles.

CONCEPT AND DESIGN

Steam reforming of DME

The overall reaction of DME steam reforming is expressed as follows:

$$CH_3OCH_3 + 3H_2O = 6H_2 + 2CO_2 - 123.84\ [\text{kJ/mol}] \quad (1)$$

In general, the steam reforming of DME progresses with in consecutive steps.

$$CH_3OCH_3 + H_2O = 2CH_3OH - 24.68\ [\text{kJ/mol}] \quad (2)$$

$$CH_3OH + H_2O = 3H_2 + CO_2 - 49.58\ [\text{kJ/mol}] \quad (3)$$

E-mail address: msaito@mech.kyoto-u.ac.jp

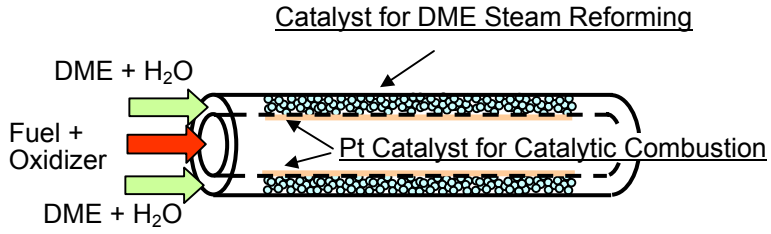

Figure 1. Conceptual figure of DME steam reformer

The first step is the hydrolysis of DME, which is well known to be enhanced by solid-acid catalysts [2]. The second step is the steam reforming of methanol, which proceeds in the presence of metal catalysts [3, 4], particularly Cu catalysts [2, 5]. As indicated in reactions (2) and (3), both reactions are endothermic.

When the temperature is high, a reverse water-gas shift reaction takes place.

$$H_2 + CO_2 = CO + H_2O - 41.17\ [\text{kJ/mol}] \tag{4}$$

This reaction is undesirable, because H_2 is consumed and CO is produced. Furthermore, the decomposition of DME is also expected to occur at higher temperatures.

$$CH_3OCH_3 = CH_4 + CO + H_2 \tag{5}$$

Thus, for the collection of H_2, temperature control is important to avoid excessive temperature rises.

Catalytic combustion

As described in the previous section, thermal energy must be added to enable the steam reforming of DME. We considered that catalytic combustion is a suitable heat source in a small reformer. In a small volume, it is difficult to sustain gas-phase combustion, because the heat loss is relatively large owing to the high specific surface area. On the other hand, the large specific surface area is an advantage for catalytic combustion [6]. Moreover, catalytic combustion can be maintained under a lean fuel condition and at a low temperature [7], so that it is possible to generate the heat to achieve the moderate temperature required for reforming DME.

Annular tube reformer

For our small DME reformer based catalytic combustion, we adopted the annular structure shown in Fig. 1. To reduce the heat loss, the channel used for catalytic combustion is installed on the inside of the reformer, and the released heat is recovered for the steam reforming of DME in the outer channel.

There are various choices for the fuel used in the catalytic combustion, for example, part of the unreformed DME, part of the reformed hydrogen or residual hydrogen from a fuel cell system. In the present experiment, we introduce hydrogen into the channel used for catalytic combustion independently of the reformed gas obtained by DME steam reforming.

EXPERIMENTS ON ANNULAR TUBE REFORMER

Apparatus

Figures 2 and 3 show schematic diagrams of the experimental apparatus. It has the structure of a double tube, in which the steam reforming of DME occurs in the outer channel, and the catalytic combustion occurs in the inner channel. The outer quartz tube has an inner diameter of 6.0 [mm] and an outer diameter of 8.0 [mm]. The inner stainless-steel tube, whose inner surface is coated with a Pt catalyst for catalytic combustion, has an inner diameter of 2.0 [mm] and an outer diameter of 4.0 [mm].

A mixture of DME, H_2O and balance N_2 is introduced into the outer channel, in which the reforming catalyst is packed. We fabricated the Cu-Fe spinel-type oxide catalyst referred to in the paper by Tanaka et al. [2]. The flow rate of H_2O in the liquid phase is controlled by a syringe pump, and the water vapor after heating is mixed with DME and N_2. To enable catalytic combustion, a mixture of H_2 and air flows into the inner channel and reacts on the inside surface coated with the Pt catalyst.

The gases for reforming and catalytic combustion are independently fed into each channel. The length of the Pt catalyst on the inner tube for catalytic combustion is 100 [mm]. To determine the amount of catalyst suitable for reforming DME, the length of catalyst packed in the outer channel was varied. We set it to 30, 50 and 100 [mm] in this experiment.

We set eight thermocouples at intervals of 10 [mm] in the catalyst for reforming DME. The thermocouple used to measure the temperature of catalytic combustion in the inside channel has a transverse mechanism that enable it to be moved to an arbitrary position.

The composition of reformed gas was analyzed by gas chromatography (Shimadzu, GC-8APT) with a thermal conductivity detector after the water trap. A Molecular Sieve 5A column was used to separate H_2, O_2, N_2, CH_4 and CO, and a Porapak Q column was used to separate CO_2 and DME. The exhaust gas after catalytic combustion was also analyzed by gas chromatography to confirm the completeness of the reaction.

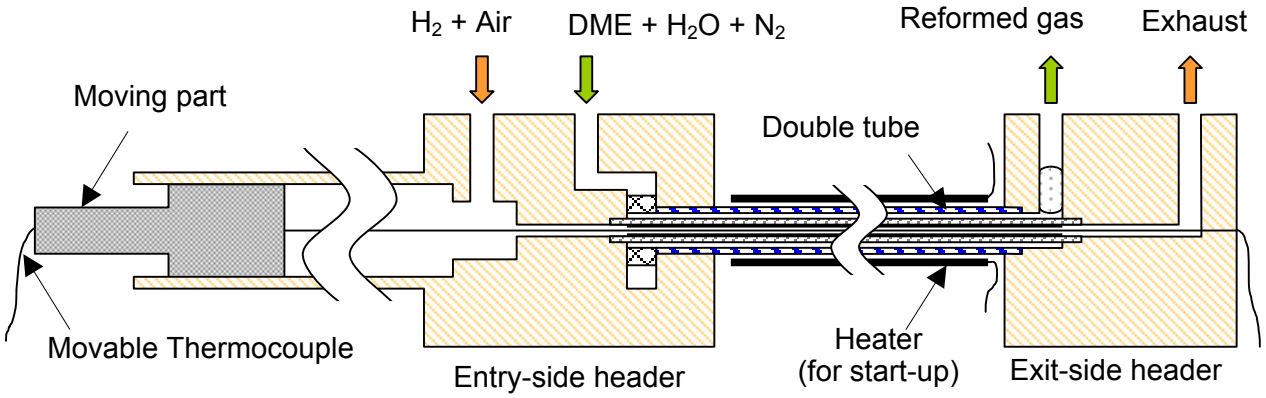

Figure 2. Schematic diagram of experimental apparatus

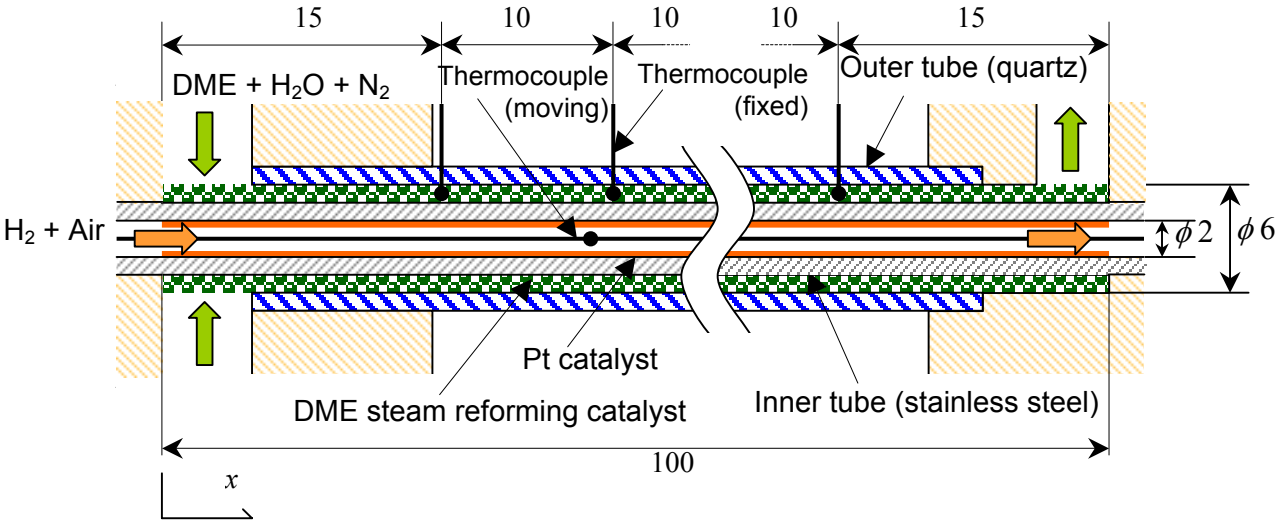

Figure 3. Test section

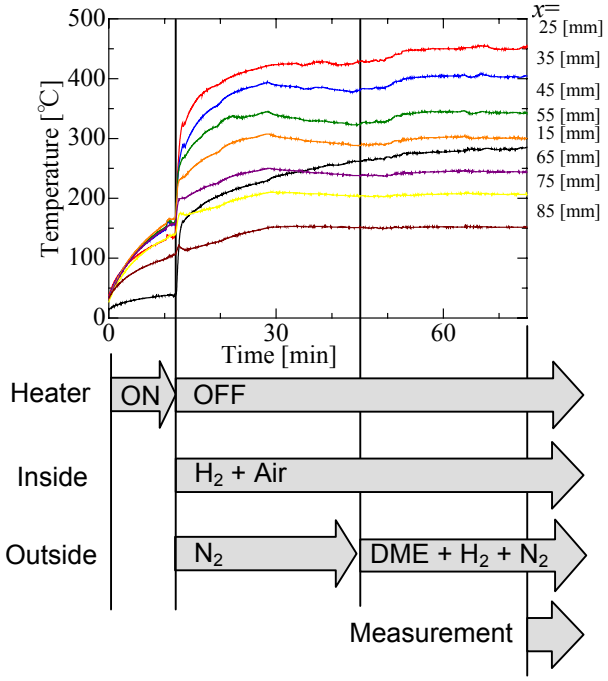

Figure 4. Experimental procedure

Procedure

Figure 4 shows the experimental procedure and the corresponding changes in temperature. The position of x is defined as the distance from the inlet as shown in Fig. 3.

This apparatus should be thermally self-sustaining during reforming. However, for start-up, the test section must be heated by using nichrome wire heater. When the heater was turned off, we introduced the mixture used for catalytic combustion into the inner channel. After the catalyst reached a sufficient temperature, the reformed gas was introduced. We measured the temperature and the concentration of the gases in the steady state, in which the amplitude of temperature variation had settled to within 0.5 [°C].

Results and discussion

Prior to discussing the experimental results, "space velocity", which is often used for the evaluation of catalysts, is defined as follows:

$$\text{Space velocity } [\text{h}^{-1}] = \frac{\text{Flow rate of reformed gas } [\text{m}^3/\text{h}]}{\text{Volume of catalyst } [\text{m}^3]} \quad . \tag{6}$$

Space velocity denotes the amount of reactants that can be treated per unit volume of catalyst. The larger this value, the better the performance of the catalyst.

Figure 5 shows an example of temperature profiles of the inner channel for catalytic combustion. The temperature was measured by moving the thermocouple in 5 [mm] steps. The temperature during reforming was lower than those before and after reforming. This temperature difference indicates that the heat released from catalytic combustion was used for the endothermic reaction of steam reforming of DME. We found that there is a region where the reaction does not take place. Because no residual hydrogen was detected by analysis with gas chromatography, it can be deduced that the catalytic combustion had been completed within the first 30 [mm], and the decline in temperature was caused by heat loss.

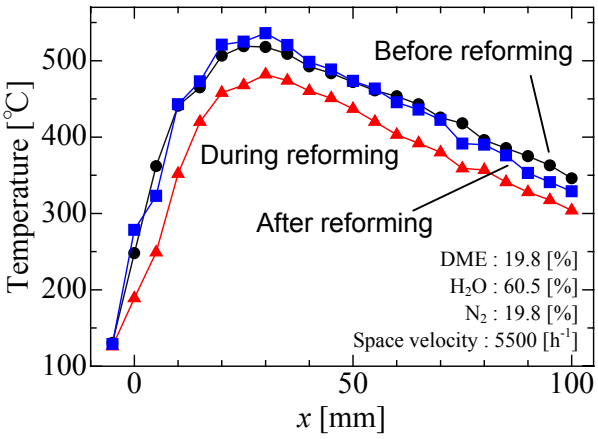

Figure 5. Temperatures of the inner channel

		Catalytic combustion		Steam reforming
		Equivalence ratio	Flow rate [l/min]	DME conversion [%]
(a)	▼	0.72	2.58	98.1
(b)	■	0.65	1.27	75.3
(c)	▲	0.56	1.22	65.0
(d)	●	0.46	1.17	0.0

Figure 6. Temperature profiles of the reforming catalyst and DME conversion for each temperature profile

The temperature profiles of the reforming catalyst are shown in Fig. 6, along with a table of the conditions of catalytic combustion and DME conversion. DME conversion is defined as follows:

$$\text{DME conversion}\,[\%] = 100 \cdot \frac{F_{\text{DME},\,in} - F_{\text{DME},\,out}}{F_{\text{DME},\,in}}\ , \tag{7}$$

where $F_{\text{DME},\,in}$ and $F_{\text{DME},\,out}$ are the volumetric flow rates of DME at the inlet and outlet of the reformer, respectively, which were calculated using the data obtained from gas chromatography.

The equivalence ratio and flow rate of the gas used for catalytic combustion in the inner channel had a strong effect on the temperature of the catalyst used for reforming DME in the outer channel.

Under condition (d), DME was not reformed, because the temperature was low throughout the channel. With increasing temperature, DME conversion increased, until it was almost completely reformed under condition (a) with a sufficiently high temperature. It was found that, for DME reforming, the temperature of the catalyst should be at least 250 [°C].

We changed the length of the DME catalyst to estimate a suitable amount of DME catalyst and size of the reformer. Figure 7 shows DME conversion and the concentrations of H_2, CO, CO_2 and CH_4 for DME catalyst of 30, 50 and 100 [mm] length. Only CO, CO_2 and CH_4 were detected by gas chromatography as single-carbon species.

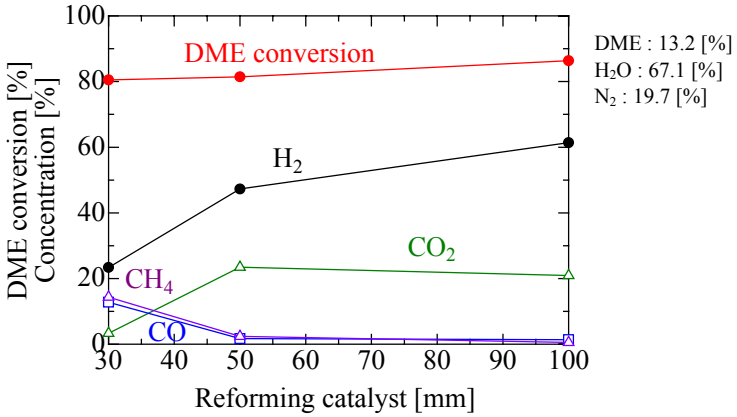

Figure 7. DME conversion and concentration of each species with varying catalyst length

There is little difference in DME conversion for different lengths of catalyst. However, when the catalyst length is 30 [mm], the concentrations of H_2 and CO_2 decreased markedly and those of CO and CH_4 increased. This indicates that 30 [mm] of catalyst is insufficient to complete the reaction of steam reforming and that the residual DME was decomposed into CO and CH_4 by reactions (4) and (5). As a result, we found that 50 [mm] is a suitable length of DME catalyst.

EXPERIMENTS ON A REFORMER INVOLVING TEMPERATURE CONTROL

Apparatus

In accordance with the results in the previous section, we designed and fabricated a new reformer with 50 [mm] length, as shown in Fig. 8. It has a pseudo-triple tube structure, which consists of an outer channel, an inner channel and an inner rod coated with the Pt catalyst for catalytic combustion.

To produce various temperature profiles, we can easily exchange the inner rod to one with a different coating distribution. We prepared four types of rods as also shown in Fig. 8. Although a heterogeneous reaction on a surface is generally a disadvantage in catalytic combustion, it is used as an advantage in this research to easily select the heat generation area.

Results and discussion

Figure 9(a) shows temperature profiles of the DME catalyst for each inner rod. The conditions except for the type of inner rods are fixed. It was found that a high temperature could be realized around the coated Pt catalyst and that Type B had a flatter temperature profile.

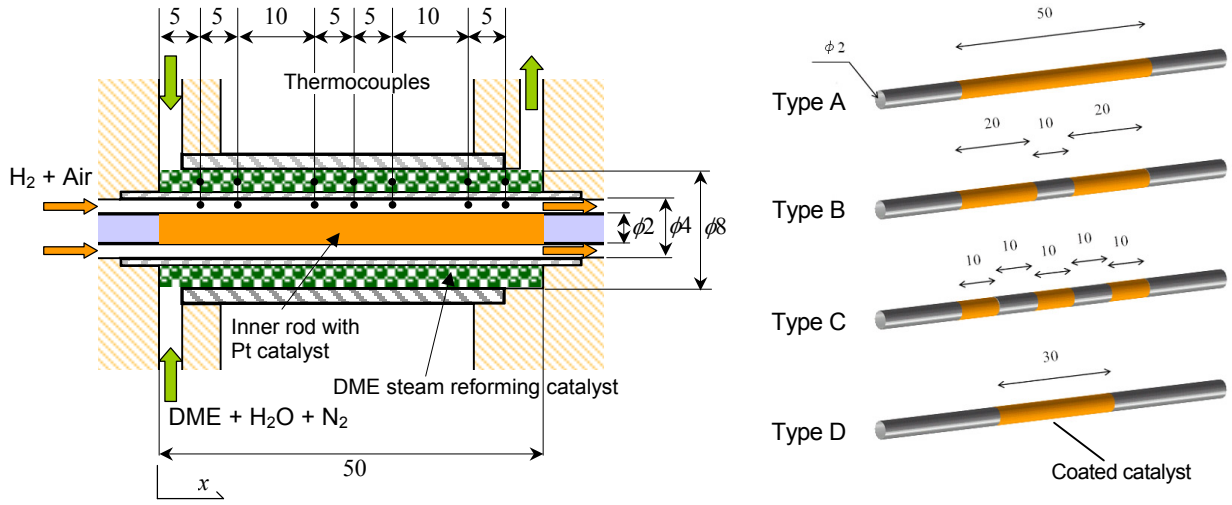

Figure 8. Schematic diagram of improved experimental apparatus

Figure 9(b) shows DME conversion for the four types of rods with varying temperature. While the temperature profile is different for each rod as shown in Fig. 9(a), the maximum temperature throughout the channel is adapted as a temperature in Fig. 9(b). DME conversion increases with the temperature. Note that Type B achieves the highest DME conversion in spite of the lowest temperature. This result agrees with the finding in Fig. 9(a) that Type B had the flattest temperature profile and maintained the largest region for effective reforming.

Figure 10 shows DME conversion and the concentration of each species for Type B. As expected, DME conversion and H_2 concentration increased with temperature because the reforming reaction was activated. Although CO and CH_4 concentrations also increased, it can be considered that their production is sufficiently small regardless of complete DME conversion. Thus, temperature control to achieve a flat profile is an effective method for ensuring the high production of H_2 and the suppression of undesirable species such as CO and CH_4.

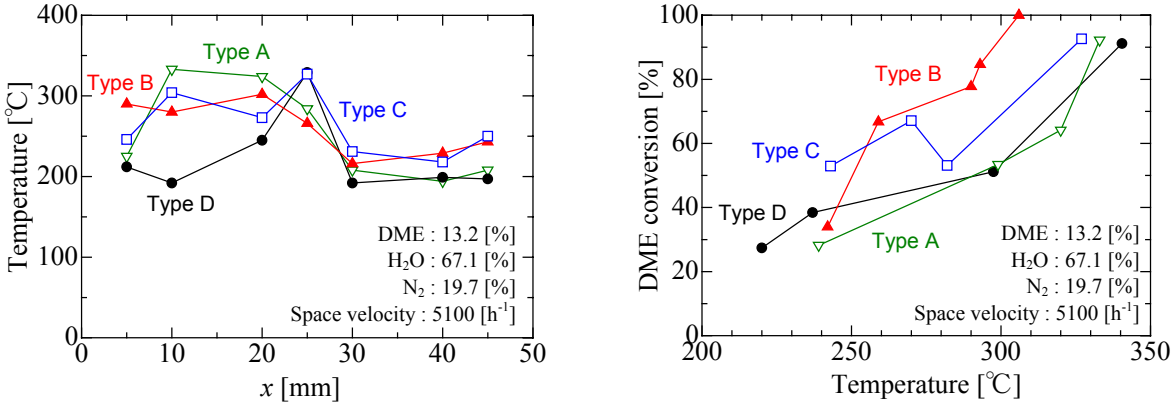

Figure 9. Temperature profiles and DME conversion for the four types of rods

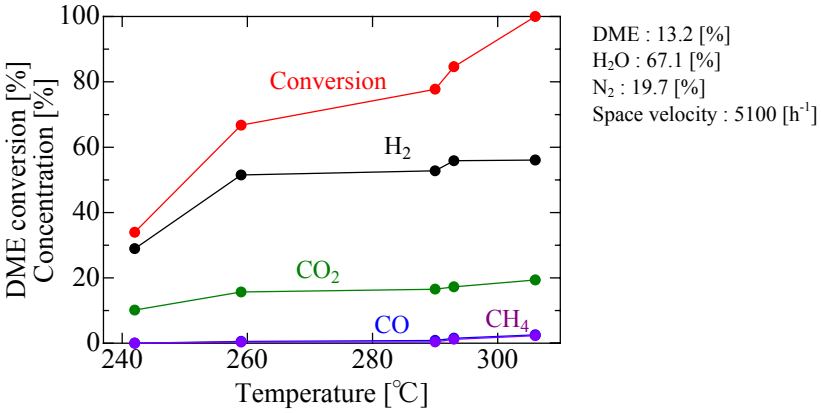

Figure 10. DME conversion and concentration of each species for Type B

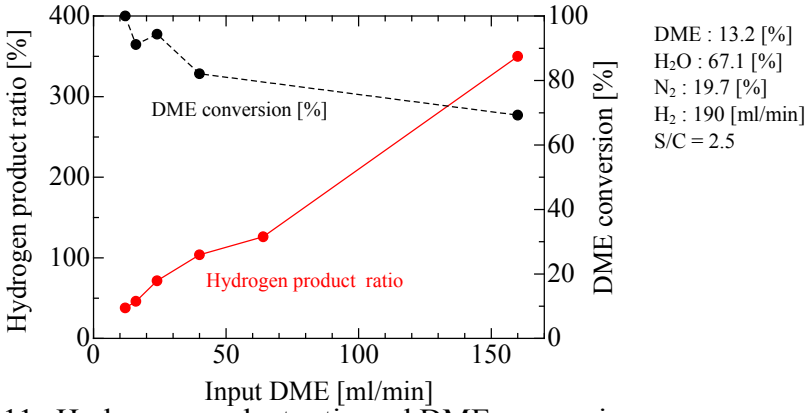

Figure 11. Hydrogen product ratio and DME conversion

Figure 11 shows the hydrogen product ratio and DME conversion for Type B. The hydrogen product ratio is defined as follows:

$$\text{Hydrogen product ratio}\,[\%] = 100 \cdot \frac{\text{Hydrogen produced from DME reforming}\,[\text{ml/min}]}{\text{Hydrogen used for catalytic combustion}\,[\text{ml/min}]} \quad (8)$$

This ratio indicates that how much hydrogen is produced from DME reforming in comparison with hydrogen used for catalytic combustion. If the hydrogen product ratio is smaller than 100 %, which occurs for a low flow rate of DME, this reforming system cannot be established because the hydrogen consumed in the catalytic combustion cannot be compensated by that produced during reforming. With increasing DME input, although DME conversion decreases owing to the short residence time, the hydrogen input ratio is improved. In the case of a DME input of 160 [ml/min], even if only 28.4 % of the hydrogen produced is used in the catalytic combustion, this reformer can maintain a self-sustaining reaction.

CONCLUSION

To produce hydrogen in a small device, we designed and fabricated a DME reformer, in which catalytic combustion is used as a heat source. The reformer has a structure of double tube, in which the steam reforming of DME occurs in the outer channel, and the catalytic combustion occurs in the inner channel. From experiments on the proposed reformer, the following findings were obtained: (1) The temperature of the reforming catalyst was controlled by the catalytic combustion in the inner channel. (2) At a sufficiently high temperature, DME was almost completely reformed. (3) To suppress the formation of CO and CH_4 while achieving high DME conversion, a flat temperature profile is desirable because the effective reforming region is large. (4) Under suitable conditions, the operation of the reformer is self-sustaining

ABSTRACT. Synthesis of supported Ni catalysts with a core/shell structure at the multibubble sonoluminescence (MBSL) condition and their catalytic tests for methane decomposition by partial oxidation were performed in this study. The catalysts prepared were analyzed by XRD, TEM and XPS. Without doping the third components, the supported catalyst of core/shell structure made with 10% Ni loading on Al_2O_3 yields 96% conversion efficiency of methane at reaction temperature of 800ºC and shows excellent thermal stability for the first 40 h. In addition, the uniform layer of Ni particles on the surface of support material hindered coke formation and sintering process, which enhances thermal stability for the catalysts.

Keywords: *Core/shell structure, Multibubble sonoluminescence, Partial oxidation of methane, Supported Ni catalysts*

INTRODUCTION

Methane is known to be an ideal source for hydrogen production due to its enormous reserves. Furthermore, it has the highest H/C ratio so that it reduces air pollutants while produces more hydrogen. Steam methane reforming (SMR) which produces 50% pure hydrogen consumption over the world is a conventional process for converting hydrocarbons into synthetic gas [1]. However this process is highly endothermic so that water must be heated to the reaction temperature of 1073K [2]. An alternative to SMR is the catalysts partial oxidation (CPO) of methane. This reaction shows mild exothermicity, high conversion and selectivity of hydrogen and H_2/CO ratio of 2.0, which is proper value for Fischer-Tropsch reaction. Furthermore, CPO process does not produce CO_2 emission. Detailed reaction involved in the process given was discussed by Otsuka et al. [3].
It is well known that supported Ni catalysts are effective for CPO except the noble metal-based catalysts whose high cost prevent from widespread industrial applications. However deactivation of the supported Ni catalysts occurs due to coke formation on Ni surface and sintering so that various

E-mail address: kwakhy@cau.ac.kr,

additives have been used to improve metal dispersion and minimize coke formation [4,5,6]. Usually the supported nickel catalysts were prepared by impregnation of supports with an aqueous solution or $Ni(NO_3)_2 \cdot 6H_2O$ followed by calcination of the impregnated materials at high temperature. A uniform dispersion of Ni particles on the surface of the supported materials is required for better performance for the catalysts.

Sonoluminescence (SL) is a light emission phenomenon associated with the catastrophic collapse of micro bubble oscillating under an ultrasonic field. The intense local heating and high pressure inside the bubble and liquid adjacent to the bubble wall from such collapse can give rise to unusual effects in chemical reactions and such sonochemical process has been proven to be a useful technique to create novel materials with unusual properties.

Sonochemistry is an application of sonoluminescence (SL), a light emission phenomenon associated with catastrophic collapse of a gas bubble oscillating under an ultrasonic field. The intense local heating and high pressure inside the bubbles and liquid adjacent the bubble wall form such a collapse that it can give rise to unusual effects in chemical reactions [7], and the sonochemical process has been proven to be a useful technique in making specialty nanomaterials. Recently observed results [8] of the peak temperature and pressure from the sonoluminescing gas bubble in sulfuric acid solutions were predicted [9] accurately by the hydrodynamic theory for sonoluminescence phenomena [10,11,12]. The estimated temperature and pressure in the liquid zone around the collapsing bubble with equilibrium radius 5 ㎛ (an average radius of bubbles generated in a sonochemical reactor at a driving frequency of 20 kHz and an input power of 179 W [13]) is about 1000º C and 500 atm, respectively[10]. A lot of transient bubbles which are generated and collapsed and synchronized with the applied ultrasound facilitate the transient supercritical state [14] in the liquid layer where rapid chemical reactions can take place. In fact, various core-shell structures of nanoparticles were prepared at the MBSL condition [15].

In this paper, we present a study on efficient synthesis of new nano materials of various kinds in MBSL conditions. In particular, the results of Ni-based nano catalysts for hydrogen production will be presented, as these catalysts have the potential to mass produce hydrogen which is touted as the driver of the future energy industry. The sonochemical method at MBSL condition can produce nanolayers of Ni particles that are uniformly formed on the supported material. Such nanolayers and structure of Ni particles on the supported particle may help enhance the activity and stability of the catalysts.

EXPERIMENTAL

Catalysts preparation

Figure 1 shows an experimental apparatus for an MBSL system consisting of a cylindrical quartz cell into which a 5 mm diameter titanium horn (Misonix XL2020, USA) is inserted. This system was operated at 20 kHz and 220 W. The solution in the test cell was kept at 1.4 atm with argon gas and the temperature of the solution inside the cell was kept to around 50º C by a circulating water bath, which is the optimal condition for the coating process [16].

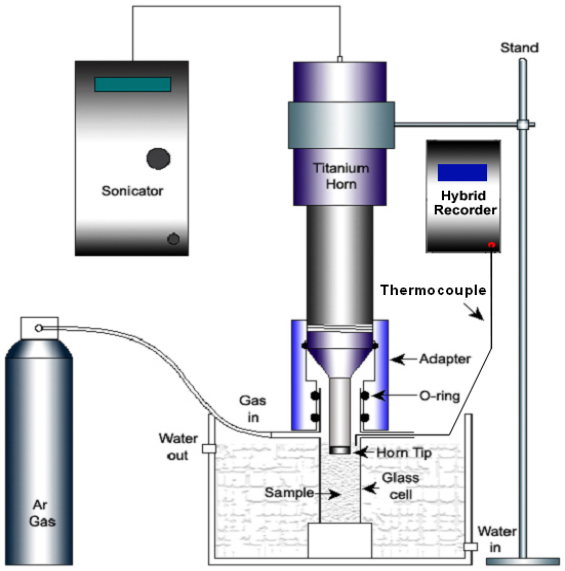

Figure 1. Experimental set up for multibubble sonoluminescence (MBSL)

For preparation of supported Ni catalysts, the supported material used is γ-Al_2O_3 (Aldrich) which has a large active surface area and thermal stability at high temperature [4]. Ni $(NO_3)_2 \cdot 6H_2O$ (Junsei, 0.7 mmol), NaOH (Aldrich,1.4 mmol) and γ-Al_2O_3 (2 mmol) in distilled water were sonicated for 20 minutes at the aforementioned MBSL condition to synthesize Ni/Al_2O_3, a catalyst with core/shell structure. The powders were separated by centrifuge and dried in an oven at 105ºC for 12 hr, subsequently calcined at 700~900ºC for 4h.

Characterization of catalysts

The supported Ni catalysts were characterized by various instruments, such as X-ray diffraction (Rigaku 12KW, Japan), high resolution transmission electron microscope (JEOL, TEM-3010, 300kV) and XPS(ESCA 2000).

Catalytic reaction

Partial oxidation of methane with air was performed in a fixed bed quartz reactor (8 mm ID, 500 mm height) at a reaction temperature of 700º C or 800ºC and atmospheric pressure and flow rate of 30 ml/min (GHSV= 17900/h). The weight of the catalyst employed is about 100 mg. Quartz wool was used as a distributor in the fixed bed reactor. The outlet gas products were analyzed on-line by a GC equipped with a thermal conductive detector (TCD). The conversion efficiency of methane is defined as

CH_4 conversion: $(F_{in,CH_4} - F_{out,CH_4}) / F_{in,CH_4}$ (1)

where F_i is the molar flow rate of i-species.

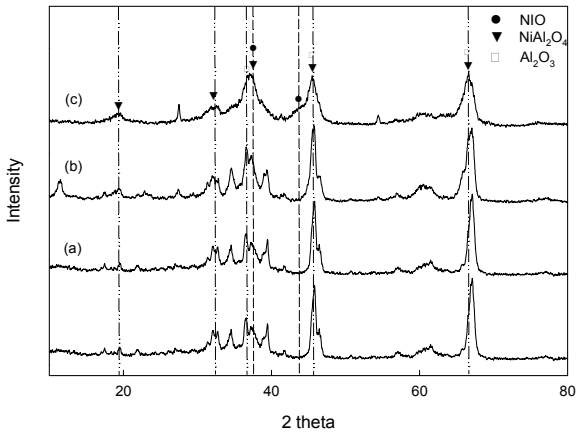

Figure 2. XRD patterns for Ni/Al_2O_3 nanopowder calcined at 700□ which depend on Ni-loading: 5 wt%, (b) 10 wt% and(c) 20 wt%. The XRD pattern at bottom is shown for Al_2O_3.

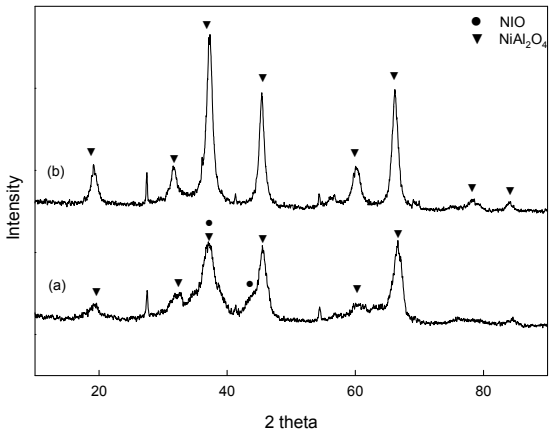

Fig.3. XRD patterns for 20 wt% Ni/Al_2O_3 nanopowder depending on calcination temperature: (a) 700□, (b) 900□.

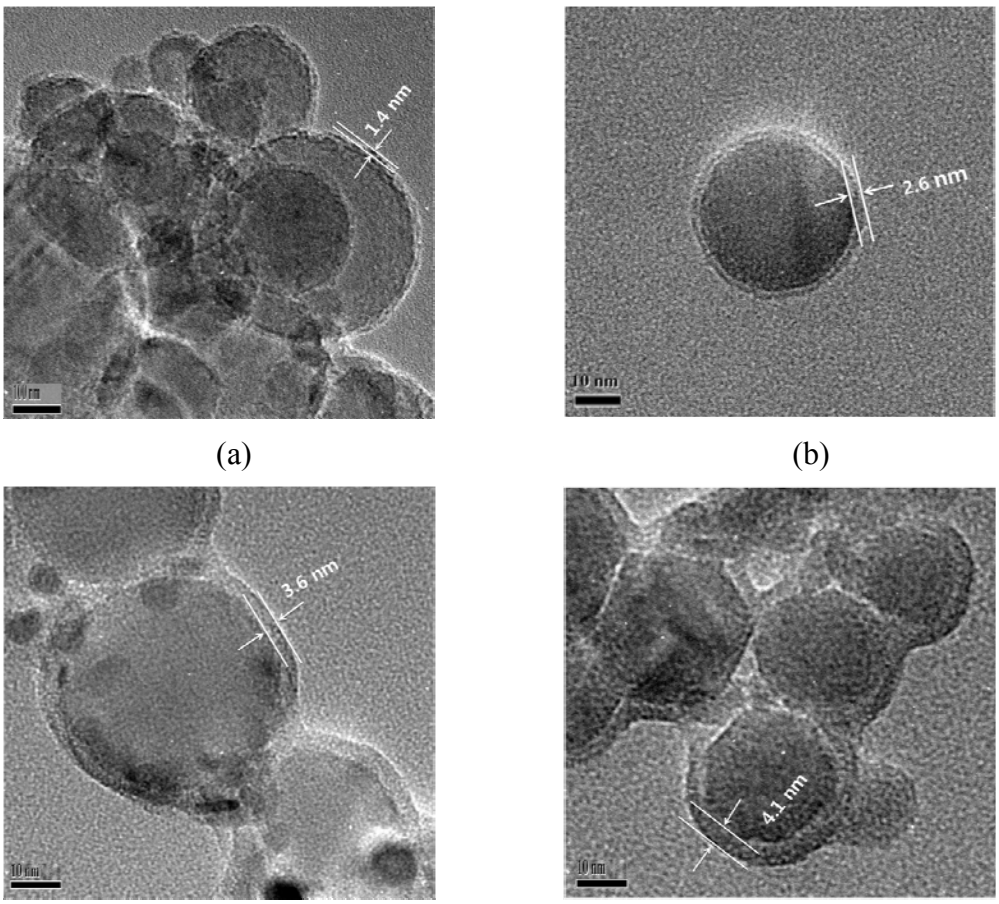
Figure 2 shows the XRD pattern for Ni/Al_2O_3 nanoparticles calcined at 700º C depending on their Ni loadings. For the supported Ni catalysts with Ni loading of 5% and 10%, the characteristic peak indentified as NiO at $2\theta = 37.04^o$ appears slightly and the Al_2O_3 peaks at $2\theta = 37.04^o$, and 67.37^o can be seen clearly. With 20% of Ni loading, the catalyst displays NiO characteristic peaks at $2\theta = 37.04^o$ and, 43.30^o corresponding to the (111) and (200) planes. Also the catalysts with 20% Ni loading show some peaks representing the spinel structure of $NiAl_2O_4$. With an increase of Ni loading, the characteristic peaks representing NiO and $NiAl_2O_4$ appear more clearly. As shown in Fig. 3, the catalysts with 20% Ni loading calcined at 900□ have characteristic peaks for the spinel structure of $NiAl_2O_4$ corresponding to the (111), (220), (311), (400), (511), (440), (553) and (444) planes.

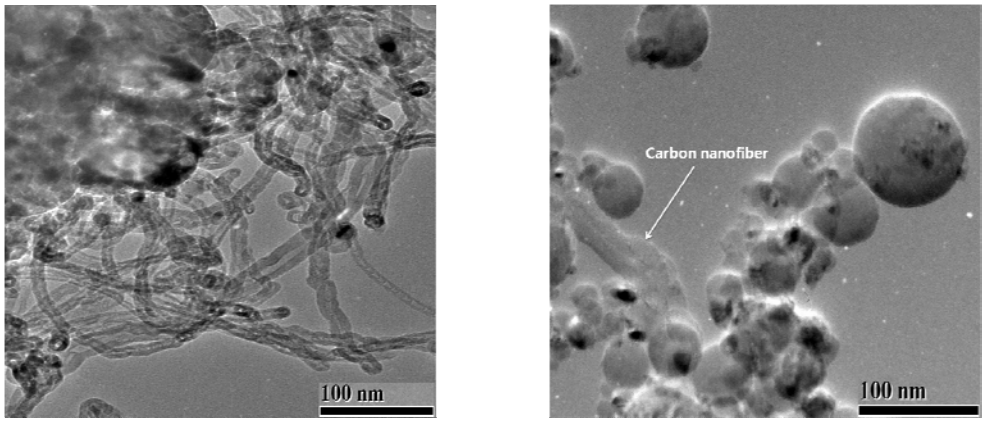
Figure 4 shows high resolution TEM images of Ni-based catalysts prepared by the sonochemical method at the MBSL condition, followed by calcination at 700□. With increase in Ni loading, the thickness of the Ni layer on Al_2O_3 also increases. The thickness of the Ni layer is about 1.4 nm for 5%, 2.6 nm for 10% and 3.6 nm for 20% Ni loadings. As shown in Fig. 4(d), the supported catalyst shows that Ni/Al_2O_3 transformed to the spinel structure, $NiAl_2O_4$, when it calcined at 900□. The conversion efficiency of methane increased at higher Ni loading. The CH_4 conversion efficiency of the catalyst with 20% Ni-loading, a spinel structure $NiAl_2O_4$ oxide at reaction temperature, 700□ is about 86 %, which is higher efficiency compare to the results obtained in previous works [17]. However, the catalysts show complete deactivation after 13 hours methane reforming, which is due to carbon nano-fiber formation on the surface of the supported material as shown in Fig. 5(a). A Ni particle is present at the tip of the carbon namo-fiber , which was observed



(a) (b)

(c) (d)

Figure 4. TEM image of Ni/Al_2O_3 nanopowder calcined at 700□ depending on Ni loading: (a) 5 wt% Ni/Al_2O_3, (b) 10 wt% Ni/Al_2O_3 and (c) 20 wt% Ni/Al_2O_3 and (d) $NiAl_2O_4$ spinel structure calcined at 900□.



(a) (b)

Figure 5. TEM image (a) of carbon nano-fiber formation on the surface of the catalyst $NiAl_2O_4$ with 20% Ni loading after 13 h run at reaction temperature of 700□ and TEM images of the supported Ni catalysts after 40 h run for (b) 10 wt%

in the previous works [18,19].

The conversion efficiency for the catalyst with 10% Ni loading at reaction temperature 800□ is about 96% as can be seen in Fig. 6. Furthermore, the supported Ni-based catalyst with core/shell structure shows good thermal stability in the first 40 h. This is because carbon nano-fiber did not form on the surface of the coated Ni-layer of the catalyst with 10% Ni content after 40 h run as can be seen in Fig. 5(b). Quite different pattern of carbon nano-fiber formed and grew at the site where NiO particles were present in the catalyst [17]. These are quite remarkable results among the results for the supported Ni-based catalysts prepared by other researchers [2,5]. For the magnesia supported nickel catalysts, the maximum methane conversion reached was about 94% [2]. Even for the Ni-based catalyst with doping of molybdenum (to prevent coke formation) the efficiency of methane conversion shows a maximum of 92% at the start, decreasing to 83% after 60 hours run [7]. From analyses by XRD, TEM and XPS, observed TPR pattern for the supported Ni catalyst with 5 and 10% Ni loadings we found that coexistence of NiO and NiOx species and the NiOx species which interact strongly with the supporting material play a very effective role in the partial oxidation of methane and they contribute to the thermal stability of the catalyst [17]. In fact, a similar TPR pattern was obtained for Ni/θ-Al_2O_3 catalyst by Roh et al. [20]. The maximum CH_4 conversion obtained in their study is 88% with a 12% Ni/θ-Al_2O_3 catalyst.

It is known that the sintering process occurs due to the microcrystalline nickel oxide particles which lead to aggregation of Ni particle at high temperature [4]. However, the drop in Ni/Al ratio due to the sintering process of Ni particles was not occurred for the supported Ni catalysts with the core/shell structure prepared in this study. The uniform coating layer of Ni particle on the catalysts with the core/shell structure prevents from the aggregation of Ni particles. Also it is noted that carbon deposition easily takes place on the surface of the supported Ni catalyst, Ni/ γ-Al2O3. The uniform dispersion of the Ni particles on the supported Ni catalyst with the core/shell structure prohibits the coke formation on the surface of the catalyst.

CONCLUSIONS

Supported Ni-based catalysts with a core/shell structure were prepared using a sonochemical method at the MBSL condition. Supported Ni-based catalyst of core/shell structure produced good conversion efficiency of CH4, at about 80% at reaction temperature of 700º C and 96% at reaction temperature of 800º C. The existence of NiO and NiOx on the surface of Ni/Al_2O_3 catalyts and the uniform layer of Ni particles on the Al_2O_3 support contribute to better conversion efficiency of methane and thermal stability of catalysts.

ABSTRACT. In the present paper, experimental and numerical studies on a methane/steam reforming process on Ru/Al_2O_3 catalyst have been conducted. The gas mixture composition and flow rate were measured at the outlet of the reformer to establish the methane/steam reforming rate and kinetics of the reforming reaction. Determining the reaction kinetics is of great significance in the design process of industrial reactors. To optimize reactor parameters such as diameters, catalyst density, catalyst distribution, steam/carbon ratio and intensity of fuel flow, detailed data about reaction kinetics is required. In the present paper, kinetics of methane/steam reforming on the Ru/Al_2O_3 catalyst was experimentally investigated. Measurements including different thermal boundary conditions, fuel flow rate and steam-to-methane ratios were performed. The reforming rate equation derived from experimental data was used in the numerical model to predict synthetic gas composition at the outlet of the reformer.

Keywords: *SOFC, Fuel Cells, methane/steam reforming, Ru/Al_2O_3 catalyst, reforming system*

INTRODUCTION

Industrial methane/steam reforming using Ni as the catalyst is preformed around 850 ^oC with a steam-to-carbon ratio of between 2 and 5 to prevent carbon deposition. Carbon formation is a major problem during methane/steam reforming reaction based on Ni catalysis. Carbon formation occurs between nickel and metal-support and creates fibers which damage the catalytic property of the reactor. It was found that by replacing Ni with a noble metal such as Rh, Ru, Pd, Ir and Pt, coke formation could be minimised [1]. From all noble metals suggested for the methane reformer, Ru seems to be the cheapest [1]. The price of catalyst material is an important consideration in industrial processes, where some materials can be rejected because of their relatively high cost. At the same time, Ru exhibits better catalytic properties for reforming reaction than do Pt, Pd, Ir, and it exhibits similar properties to Rh. The Ru/Al_2O_3 catalyst is also more durable than Ni when it comes to thermal shock and temperature fluctuations [1]. To this point, most publications on the topic have primarily investigated the kinetic properties of methane-steam reforming on Ni catalyst [1-5], which is the catalyst most often used for commercial reactors in hydrogen production. Different kinetics have been reported by the various research groups working on methane/steam reforming based on nickel catalyst [2-5]. The reaction order and kinetic parameters may be significantly different from one catalyst to another [1]. Experiments on Ni catalyst have been carried out by Achenbach and Riensche [2] to determine the kinetics of the methane/steam reforming process at anode materials of a solid oxide fuel cell. Their tests [2] showed that the partial pressure of H_2O has no catalytic effect on the reaction. Achenbach and Riensche [2] have proposed an equation for reforming kinetics in the form of the Arrhenius-type

E-mail address: brus@agh.edu.pl

independence of the partial pressure of H_2O, which is proportional to methane (CH_4) partial pressure. An alternative model of methane reforming reaction rate on a nickel-based catalyst was proposed by Odegard *et al*. [3]. Both of the proposed models assume reforming kinetic in Arrhenius type form and independence of the steam's partial pressure. An increasing number of papers have been devoted to methane/steam reforming on ruthenium catalyst. Kinetic analysis on low-temperature methane/steam reforming using a ruthenium-supported catalyst has been studied by Itoh *et al*. [6]. The reaction rate of methane/steam reforming at low temperature was measured to establish the rate of expression. A few models have also been proposed based on the Langmuir-Hinshelwood mechanism [6]. An equilibrium case of methane/steam reforming reaction based on Ru/Al_2O_3 catalyst has been studied by the Kimijima Group [7] and an equilibrium numerical model of the reforming reaction was developed. The numerical results have been compared with experimental data and good agreement found.
Determination of the reaction kinetics is significant in the design of industrial reactors. To optimize reactor parameters such as diameters, catalyst density, steam-to-carbon ratio and intensity of fuel flow, detailed data about reaction kinetics is required. In the present paper, experimental study on methane/steam reforming on Ru/Al_2O_3 catalysts was experimentally investigated. The gas mixture composition and flow rate were measured at the outlet of the reformer to establish the rate at which methane reforms and the kinetics of the reforming reaction.

EXPERIMANTAL INVESTIGATION

Experimental procedure

A schematic view of the experimental setup is shown in figure 1. A stainless steel reformer was located in an electrical furnace, which can be heated up to 1000^{o}C. The maximum working temperature of pre-heater and after-heater is 400^{o}C; however, for all experimental investigations presented in this paper, the temperature of pre- and post-heater was maintained at 200^{o}C. High purity methane was the fuel used in the experiment. It was supplied to the reformer via flow controller and an evaporator, which was also used as a pre-heater. Water was fed to the system with a pump. The gas composition after the reforming process was analysed by gas chromatography prior to which the steam had been separated by cooling down the gas mixture to 2 ^{o}C. The reforming reaction tube was partially filled with Ru/Al_2O_3 and partially with Al_2O_3 as will be precisely described in subsequent sections of this paper.
Ruthenium-supported alumina is a new type of catalyst material used for the methane/steam reforming reaction. Figure 2A shows a typical reaction tube, where a catalyst supported on metallic particles is located inside the reaction tube. The catalyst is spherical in shape and has a 3-mm diameter, and the Ru-Al density is 0,0025 g mm^{-3}. In the presented investigation the original spherically shaped particles were crushed into micro-particles roughly 300 μm in size and were located in the reaction tube as shown in figure 2B. To prevent large temperature gradients in the reformer, modifications of the reaction tube were applied. To avoid a cooling effect of the entering fluid, the reformer was partially filled with Al_2O_3, as shown in figure 2B. In this solution, a mixture of gases before getting to the reaction zone was pre-heated by electric furnace to the reaction temperature. To control thermal conditions of the experiment, four thermocouples were located in the experimental set-up, as shown in figure 1 (marked as "T"). To derive correct kinetics data, the reaction has to occur in a whole volume of catalyst. This can be accomplished by maintaining the reforming conversion rate at a low level. To achieve a low level of methane conversion, the fuel was additionally mixed with nitrogen (see figure 2B). Nitrogen does not have a direct influence on the reforming reaction but the partial pressure of the components changed, which results in a decrease in both the reaction and methane conversion rates.

Methodology

The methane/steam reforming process is widely considered the conventional process for producing hydrogen [4], [5]. In the reforming process of methane with steam, the dominant reactions are the following two [8]:

fuel reforming reaction

$$CH_4 + H_2O \rightarrow 3H_2 + CO \tag{1}$$

shift reaction

$$CO + H_2O \leftrightarrow H_2 + CO_2 \tag{2}$$

It follows from the stoichiometry of the steam/methane reforming reaction that the reaction rate expression can be approximated using the equation

$$r_{CH_4} = k\left(p_{CH_4}\right)^a \left(p_{H_2O}\right)^b, \tag{3}$$

where; $k = A \cdot \exp\left(-E / RT\right)$

where k is the reforming reaction constant, p_{CH4} and p_{H2O} are partial pressures [Pa] of methane and water, respectively, a and b are dimensionless coefficients responding to the reaction order, A is the pre-exponential factor, E the activation energy [J mol^{-1}], R the universal gas constant [J mol^{-1} K^{-1}] and T the reaction temperature [K].

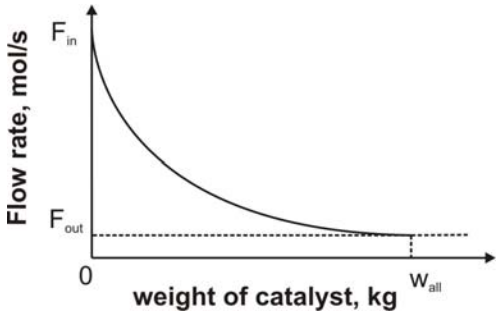

Figure 3. Methane flow rate as a function of catalyst weight

Equation (3) can be rewritten as the relationship between the molar flow rate of methane and the weight of the used catalyst. Figure 3 presents the relationship between the molar flow rate of methane and the weight of the catalyst used. As can be seen from figure 3, for given inlet flow rate of methane, increasing the amount of catalyst results in a decrease in the methane outlet flow rate as an effect of methane's higher conversion rate. However, for some amount of catalyst, marked on figure 3 as w_{all}, there is no more change in the conversion rate. The equilibrium occurs and outlet flow rate remains constant. Therefore, the non-equilibrium reaction rate can be described as a ratio between the change in the flow rate of methane and the change in the amount of catalyst. The mathematical form of this relation can be expressed as

$$r_{\text{CH}_4} = -dF_{\text{CH}_4} / dw_{cat}\,, \tag{4}$$

where $F_{\text{CH}_4} = F^{\text{in}}_{\text{CH}_4} \cdot (1-x)$,

where F_{CH_4} is the methane flow rate, [mol/s] x is a dimensionless amount of reacted methane in the reforming reaction, and w_{cat} is the weight of catalyst used, [kg].

By combining equations (3) and (4), the following equation was formulated:

$$k = \left(F^{\text{in}}_{\text{CH}_4} / w_{cat}\right) \cdot \int_0^{x_{out}} \left(1 / k\left(p_{\text{CH}_4}\right)^a \left(p_{\text{H}_2\text{O}}\right)^b\right) \cdot dx \tag{5}$$

From the stoichiometry of reaction (1) and (2) the partial pressures can be defined as

$$p_{\text{CH}_4} = \left(n_{\text{CH}_4} / n_{\text{all}}\right) \cdot P = \left[(1-x)/(1+SC+NC+2x)\right] \cdot P\,, \tag{6}$$

$$p_{\text{H}_2\text{O}} = \left(n_{\text{H}_2\text{O}} / n_{\text{all}}\right) \cdot P = \left[(SC-x-y)/(1+SC+NC+2x)\right] \cdot P\,, \tag{7}$$

where n_{all} is the total amount of product at the outlet of the reaction tube, P is total pressure [Pa], n_{CH4}, n_{H2O} are, respectively, the methane and water fractions at reformer output, x is a fraction of reacted methane, y is a fraction of reacted carbon monoxide, SC is the steam-to-carbon ratio and NC is the nitrogen-to-carbon ratio. n_{all} was derived from stoichiometry of reactions (1) and (2).

Introducing equations (6) and (7) into equation (5) yields the final form of the equation for the reaction constant:

$$k = \left(F^{\text{in}}_{\text{CH}_4} / w_{cat}\right) \cdot \int_0^{x_{out}} \left((1+SC+NC+2x)^{a+b} / P^{a+b} (1-x)^a (SC-x-y)^b\right) \cdot dx \tag{8}$$

where, a and b are coefficients related to the reaction order.

By following Itoh *et al*. [6] the methane conversion rate x is determined by the outlet quantity and can be calculated

$$x = \left(x_{CO} + x_{CO_2}\right) / \left(x_{CH_4} + x_{CO} + x_{CO_2}\right) \tag{9}$$

The shift reaction occurs very quickly, so the conversion rate can be estimated from the equilibrium equation

$$K_{shift}\left(x - y\right)\left(SC - x - y\right) = y \cdot \left(3x + y\right) \tag{10}$$

where: $K_{shift}=\exp[-\Delta G/(RT)]$
where ΔG is the change of standard Gibbs free energy of shift reaction, R is the universal gas constant [J mol^{-1} K^{-1}] and T is the reaction temperature [K].
Because the reaction constant does not depend on the *SC* and *NC* ratios, *a* and *b* can be found [9]. *K* is constant if *a* and *b* are set correctly. The real values of *a* and *b* are the ones which result in the smallest *k* derivation for different *SC* and *NC* ratios. Equation (8) was solved numerically for various values of *a* and *b* and for the different *SC* and *NC* ratios. The range from -1.0 to 2.0 has been chosen as a common range for reaction order according to already published data; figure 4 shows the results of computation. The smallest reaction constant deviation was found to be 0.3 and 0.1 for *a* and *b*, respectively.
To develop a fully kinetic model of the reforming reaction on the Ru catalyst, the relationship between the reaction temperature and reaction constant has been investigated. The effect of the temperature on the reaction was studied by increasing the temperature from 550°C to 725°C. Results of the experiment are presented in the form of Arrhenius plot, as shown in figure 5.

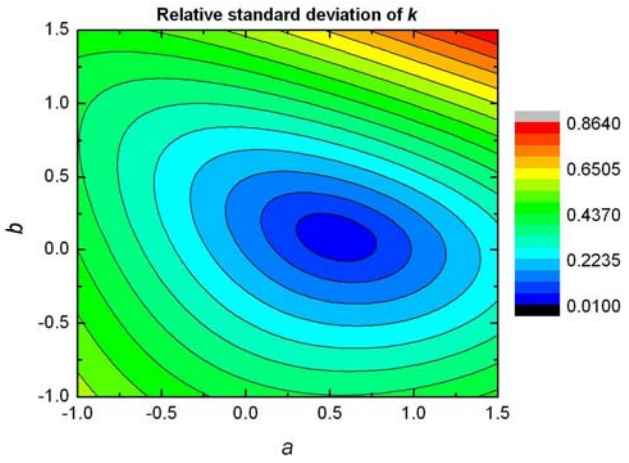

Figure 4. Relative standard deviation of *k*

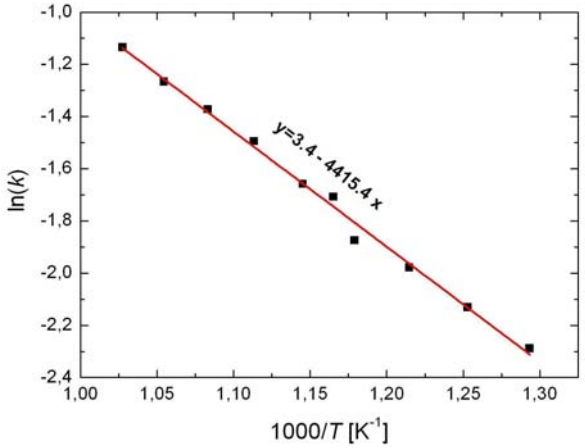

Figure 5. Arrhenius plot for Ru/Al_2O_3

To the experimental data a straight line was fitted as a result of approximation. The equation for the straight line for the experiment takes the form of Arrhenius equation and can be expressed

$$\ln k = \ln A - \left(E / R\right) \cdot \left(1 / T\right) \tag{11}$$

Where T [K] is the temperature of fuel conversion, R = 8.314472 [J mol^{-1} K^{-1}] is the universal gas constant, A is called the pre-exponential factor and corresponds to the intercept of line at 1/T=0 and E [J mol^{-1}] which is obtained from the slope of the line in the activation energy of the steam reforming reaction. Thus the kinetic of the methane/steam reforming reaction can be described by reforming rate [mol s^{-1} g^{-1}] based on the experimentally obtained data by following equation:

$$R_{st} = 29.96 \cdot \exp\left(-36711.89 / RT\right) \cdot p_{CH_4}^{0.3} \cdot p_{H_2O}^{0.1} \tag{12}$$

MATHEMATICAL MODEL FOR THE FUEL REFORMING PROCESS

The steam reforming reaction described by equation (1) is a slow and highly endothermic reaction; therefore a kinetic expression is required to calculate the reaction rate. Also, how methane is reformed inside the reformer is dependent on the local conditions including not only temperature but also the partial pressure of each chemical species and the density of the catalysis [10]. The water-gas shift reaction described by equation (2) is a fast and weak exothermic reaction and can be assumed to be in equilibrium at the reforming temperature [8].

In this paper, the reaction rates of the two main reactions (equations (1) and (2)) R_{st} and R_{sh} are calculated

$$R_{st} = w_{cat} \cdot 29.96 \cdot \exp\left(-36711.89 / RT\right) \cdot p_{CH_4}^{0.3} \cdot p_{H_2O}^{0.1} \tag{13}$$

$$R_{sh} = K_{sh}^{+} p_{CO} p_{H_2O} - K_{sh}^{-} p_{H_2} p_{CO_2} \tag{14}$$

Equation (13) is based on the experimentally obtained data and was described in the previous paragraph, where, w_{cat}, is catalyst weight [g], T [K] is temperature of fuel conversion, R = 8.314472 [J mol^{-1} K^{-1}] is the universal gas constant, p_{CH4} the partial pressure of methane [Pa] and p_{H2O} the partial pressure of steam [Pa]. The catalyst weight w_{cat} is an important parameter because control of its distribution can be used as a means to changing the distribution pattern of the reformer temperature.

K_{sh}^{+} and K_{sh}^{-} denote the rate constants of forward and backward water-gas shift reactions. The water shift reaction given by equation (2) reaches equilibrium rapidly; therefore CO_2, H_2, CO and H_2O must satisfy the equilibrium equation. Chemical equilibrium is represented by the equilibrium constant, which is a function of temperature and is equal to the ratio between the reactants' partial pressures and the products' partial pressures.

$$K_{sh} = K_{sh}^{+} / K_{sh}^{-} = (p_{CO_2} p_{H_2}) / (p_{CO} p_{H_2O}) = \exp(-\Delta G_{sh}^{0} / RT) \tag{15}$$

where ΔG_{sh}^{0} is the change of standard Gibbs free energy in the shift reaction.

This equilibrium constant given by equation (15) is introduced into equation (14) to calculate the rate of the shift reaction.

The change of each chemical species caused by the fuel reforming reaction (equation (11)) and shift reaction (equation (12)) are derived from the reactions' stoichiometry and are calculated as follows:

$$\Delta \dot{n}_{H_2} = 3x + y \tag{16}$$

$$\Delta \dot{n}_{CO} = x - y \tag{17}$$

$$\Delta \dot{n}_{CO_2} = y \tag{18}$$

$$\Delta \dot{n}_{CH_4} = -x \tag{19}$$

$$\Delta \dot{n}_{H_2O} = -x - y \tag{20}$$

RESULTS

Numerical simulation is a useful tool for designing SOFC reformer processes. In the numerical model presented in this paper, gas composition at the outlet of the reformer can be predicted based on the inlet conditions. Examples of numerical results and their comparison with the experimental data are shown in figures 7 and 8. In the present paper, the effect of the temperature on the steam reforming reaction was studied by increasing reaction temperature from 500 ^{o}C to 700 C. The data shows the outlet dry gas composition to be a function of reaction temperature. Predictably, the outlet molar fraction of

methane decreases with increasing reaction temperature and the opposite behavior can be observed for the molar fraction of hydrogen. As observed in figures 6 and 7, the amount of carbon monoxide increases as the reaction temperature increases. This observation is significant because in contrast to the low-temperature fuel cell, the carbon monoxide does no poison the high temperature solid oxide fuel cell anode but can be electrochemically converted as a fuel [2].

An important requirement for kinetic experiments is catalytic stability. In the presented investigation the condition of catalyst was periodically checked and no degradation was observed.

The quality of numerical computations can be presented by a correlation plot of the measurements against the numerical model. An example of such a comparison can be seen in figure 8 where the experimental results were set against calculated reforming conversion rates. The points situated on the line present a perfect fit between the experimental and numerical results. Most of the points are located on the line or in its vicinity. The presented correlation plot indicated that the quality of the numerical model is satisfactory and can be used to predict the outlet gas composition for the methane/steam reforming process.

CONCLUSIONS

In the presented paper experimental and numerical studies on the fuel reforming process on an Ru/Al_2O_3 catalyst have been investigated. The gas mixture composition and flow rate were measured at the outlet of the reformer to establish the methane reforming rate and kinetics of the reforming reaction. The experimental set-up was built to investigate results for different thermal boundary conditions, the fuel flow rate and the steam-to-methane ratios. The reforming rate equation derived from experimental data was used in the mathematical model to predict syngas composition at the outlet of the reformer for the isothermal fuel reforming process. It was shown that the results of numerical computations are a good fit to the experimental data. Obtained results indicate how important parallel, numerical and experimental studies are in designing SOFC reformers. It was also shown that successful predictions of the outlet gas composition for different modelling conditions can be made.

EFFECT OF SEPARATOR RIB ON WATER FORMATION IN POLYMER ELECTROLYTE FUEL CELL

H. Tanigawa[1,*], Y. Miyazaki[1], T. Tsuruta [1]
[1] Department of Mechanical and Control Engineering, Kyushu Institute of Technology, Kitakyushu, Japan

ABSTRACT. Water management is very important in the development of the Polymer Electrolyte Fuel Cells (PEFC) with high performance and high reliability. Three-dimensional numerical and experimental study has been done for the different type of flow passages. Two kinds of flow passages, that is, serpentine-type and straight type were selected. It is found that the separator rib plays as the covering to reduce water escaping from the GDL to the channel. The moisturizing effect in the straight-type channel is higher than that in the serpentine-type channels, but the draining effect in the serpentine-type channel is better than that in the straight-type channel.

Keywords: *Polymer Electrolyte Fuel Cell, Lattice Gas Automaton, Condensation*

INTRODUCTION

Polymer Electrolyte Fuel Cells (PEFCs) have attractive interest for portable, automotive and residential applications. Water management is important in the Polymer Electrolyte Fuel Cell (PEFC) operating at room temperature. The reaction between proton and oxygen produces water and condensation occurs in the cathode side of the PEFC. If the water droplets cover the gas diffusion layer (GDL) the supply of oxygen to the membrane would be limited, then the power generation rate of the PEFC decreases. On the other hand, in a dryout condition, the polymer electrolyte membrane (PEM) shows lower electrolytic conductivity. Many researches on the water management for the PEFCs have been conducted experimentally, theoretically and numerically. For example, in the experimental studies, the water distribution was measured by MRI imaging [1, 2], optical visualization [3~5] and neutron imaging [6~9]. The numerical works have been carried out on the transport characteristics in the cell and the effects of water distribution were discussed by using the finite element method [10], the control volume method [11,12] and the lattice boltzmann method [13]. The purpose of the present paper is to make clear these problems by using the Lattice Gas Automaton (LGA) method. First, we have developed a three-dimensional LGA simulation method for the analysis of the transport phenomena inside the cells. The flooding and the plugging phenomena are studied focusing on the effect of separator ribs. Secondly, the visualization experiments have been conducted to verify the simulation results. We use two kinds of flow passage, that is, the serpentine-type and the straight-type are selected and the performances are compared.

NUMERICAL METHOD

Figure 1 shows the numerical simulation system. Three-dimensional simulations are carried out by using the Lattice Gas Automaton (LGA) method. Simple and local rules are applied for

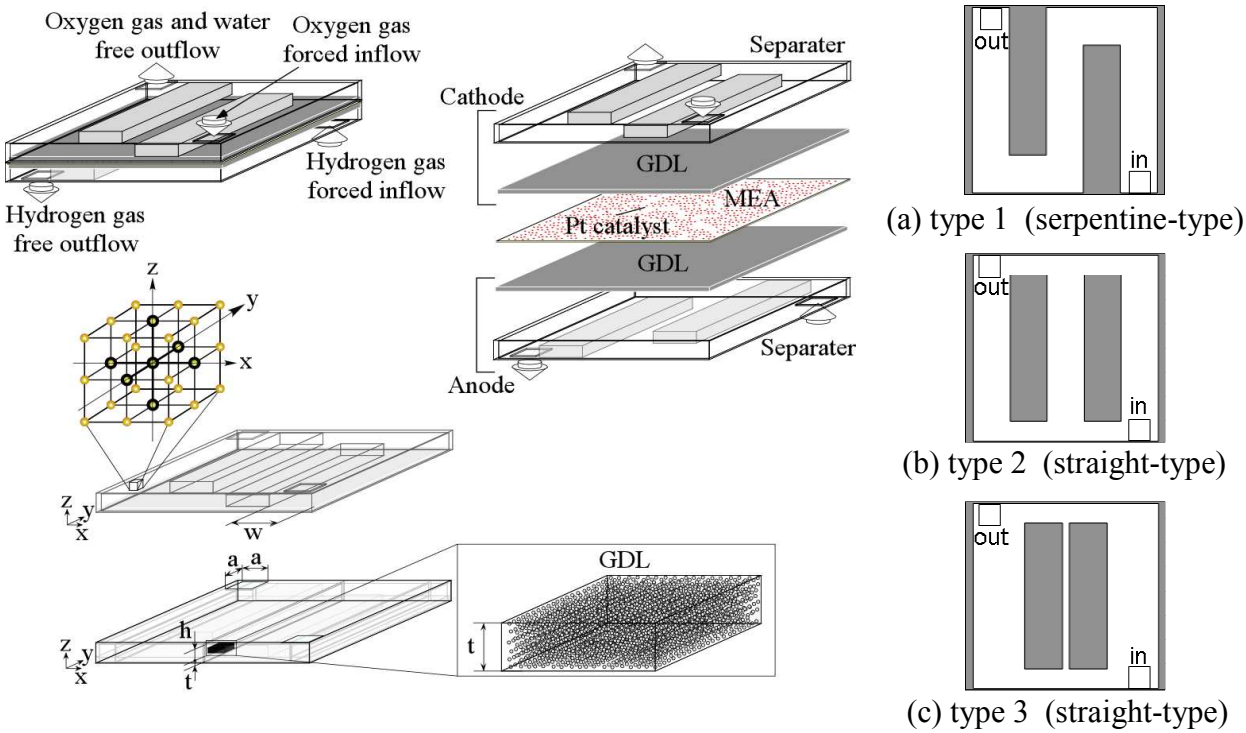

Figure 1. Analytical model

fluid particles and dominant flow pattern is calculated as self-organized macroscopic phenomenon. In this study, we use the HPP model [14] for the collision rule between particles. Also, the LG model [15] is used for the phase change by introducing an interaction length to consider the attractive force between the particles.

In the simulation on the cathode and anode side transport phenomena, we use four kinds of particles, i.e. oxygen, hydrogen, hot water and cold water for the serpentine-type and the straight-type flow passages. The oxygen and hydrogen particles are supplied to the entrance at each time-step. The GDL is modelled by porous layer made of solid particles arranged at random (porosity ε=0.8). The thickness of the MEA is assumed to be zero. In order to simulate the cell reaction at the MEA the catalyst particles are supplied randomly on the MEA surface. The number density of catalyst node to the total node number is set at α=0.2% in this study. The reaction occurs when the oxygen gas and the hydrogen gas encounter to the catalyst and they change to a hot water particle. In the LGA method, 6 particles can exist at one lattice point. We consider the effect of water vapor saturation by setting a saturation particle number Nsat at the lattice point. That is, if the number of the hot water particles exceeds Nsat, then excess particles change to the cold water particles. This scheme corresponds to the condensation. For a boundary condition at the electrode surface, an interaction length between the cold water particle and the solid surface is used in the similar way to the interaction length between the water particles [16]. The electrode surfaces are considered as hydrophilic and GDL is hydrophobic. The reaction rate is defined as a ratio of the number of reaction node to the catalyst node.

EXPERIMENTAL METHOD

Figure 2 shows the structure of the PEFC in this experiment. MEA is sandwiched between two carbon GDLs and two current collectors. The current collector has ϕ2.3 mm holes in an alternate arrangement. The active area of the cell is 16[cm^2]. As shown in Fig.2, we use two kinds of flow passage, that is, the serpentine-type and the straight-type are selected. The serpentine-type has an 8[mm] width channel and rib. In the straight-type, the width of the channel and rib are change to 12[mm], 4[mm] and 16[mm], respectively. The channel heights of both type are as same as 1[mm]. The both separators are made of polycarbonate for image measurements.

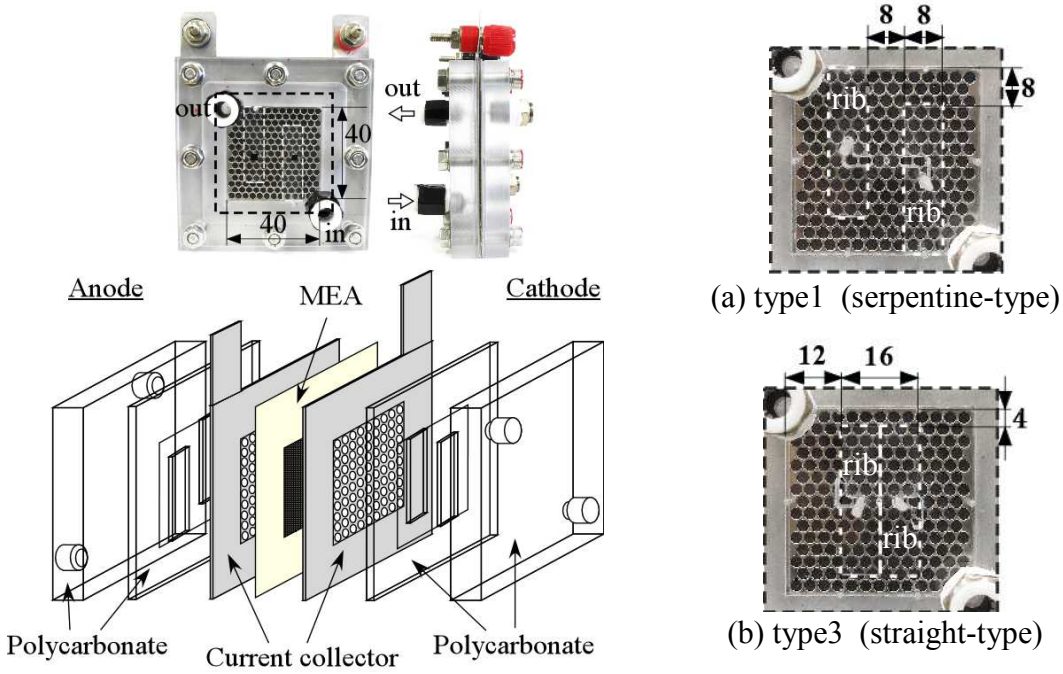

Figure 2. Polymer electrolyte Fuel cell

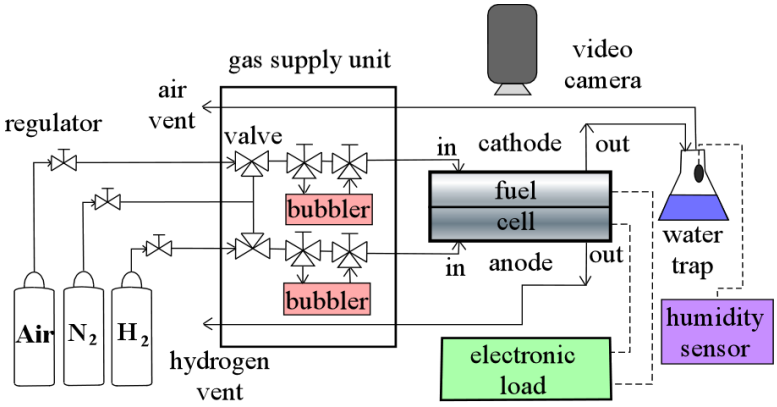

Figure 3. Experimental apparatus

Figure 3 shows the experimental apparatus. The PEFC is horizontally installed so that the cathode side might turn to a top. The experimental conditions are as follows; the current density 200 [mA/cm^2], the hydrogen gas flow rate 0.1 [l/min], the air flow rate 0.2 [l/min], and the room temperature 21 [^{o}C]. The outputs are measured with the fuel cell evaluation system. In the observation tests, distributions of the water at the cathode side are recorded with the digital video camera.

RESULT AND DISCUSSION

In Fig. 4, the numerical flow patterns are visualized. In the straight-type channel the gas selects a shortcut to the exit and flows into one side. The flow in the serpentine type channel the gas can not select the path and U-shape turning raises the flow resistance.

Figure 5 shows the time transients of the reaction rate. In the steady state condition, the reaction rate for the straight-type channel is lower than that for the serpentine-type. In the straight-type channel, the stagnation area is formed in the cell area as shown in Fig.4(b). These areas are not effective for the cell reaction. This is the reason why the straight-type channel shows the lower reaction rate.

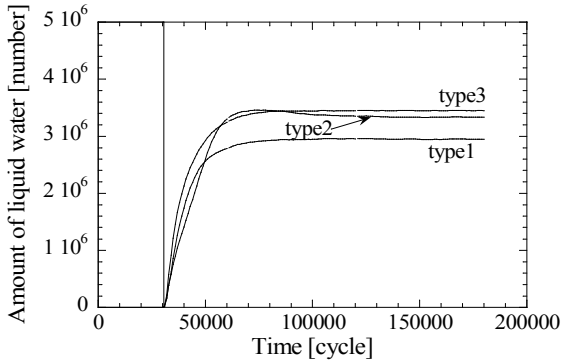

Figure 6. Time transients of the amount of liquid water in GDL (numerical)

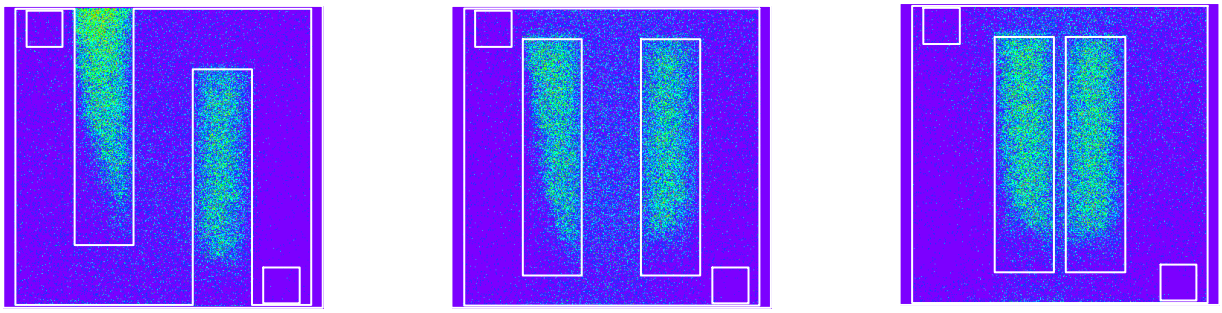

(a) type 1 (b) type 2 (c) type 3

Figure 7. Water distributions (cathode, numerical)

Figure 6 shows the time transients of the amount of liquid water in GDL. The both straight-type channels show larger water content than the serpentine-type channel. We can understand the reason from Fig. 7 which visualizes the water distributions for each channel type at the time t=180,000 cycle. The cold water is observed at the separator rib for each channel. We can see that the separator rib plays as the covering to reduce the escape of water from the GDL to the channel. Then, in the straight-type channel, the stagnation area is not effective for the drainage of the water droplets. On the other hand, in the serpentine flow channel, the gas-flow blows up the water droplets and the reaction area is kept uncovered. This is the reason why the straight-type channel shows larger water content than the serpentine-type.

Experimental images of the cathode side are presented in Fig.8. The condensed water is observed underneath the separator rib at the steady-state. We are sure that the separator rib plays as the covering shown by the numerical results.

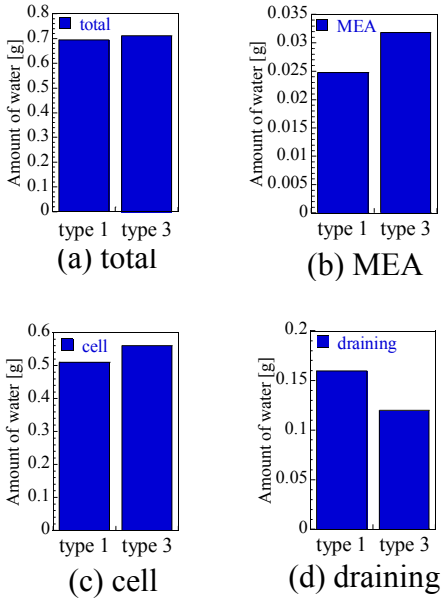
Figure 8. Water distributions (experimental, 992[min])



(a) total (b) MEA (c) cell (d) draining

Figure 9. The amount of produced water (experimental, 992[min])

Figure 9 shows the amount of produced water for each channel type at the time after 16 hour. The straight-type channel shows larger water content inside the cell than the serpentine-type channel, but the serpentine-type channel shows larger draining than the straight-type channel. The results show that the moisturizing effect in the straight-type channel is higher than that in the serpentine-type channels, but the draining effect in the serpentine-type channel is higher than that in the straight-type channel.

CONCLUSIONS

Experimental and three-dimensional numerical studies have been done for the different type of flow passages of the PEFC. It is found that the separator rib plays as the covering to reduce the escape of water from the GDL to the channel. The moisturizing effect in the straight-type channel is marked as compared with the serpentine-type channels, but the draining effect in the serpentine-type channel is better than that in the straight-type channel.

ABSTRACT. In this work we present an evaluation of ceria-based electrolyte-supported Intermediate Temperature Solid Oxide Fuel Cell (IT-SOFC) with composite, perovskite cathode possessing mixed ionic-electronic conductivity. A custom-made, testing unit is described and the operational parameters (OCV, current – voltage characteristics, cell power) measured in 600 – 675°C range are presented. Additionally, the measured impedance spectra of the cell allowed to determine the temperature dependence of the ohmic resistance, the charge transfer resistance and the diffusion resistance of the cell.

Keywords: *IT-SOFC, cell construction, ceria-based electrolyte, mixed ionic-electronic conductivity perovskite*

INTRODUCTION

One of a crucial issues of SOFC technology is to lower an operational temperature of the working cell. For a conventional cell, built using zirconia-based electrolyte, lanthanum strontium manganite cathode and nickel-zirconia cermet anode, the working temperature is around 900 – 1000°C. New materials, which are being developed nowadays, should allow to decrease the operational range down to 600 – 800°C. Among many gains arising from such a lowering, one should point out a slower chemical and thermal degradation of the cell components, a possibility of utilization of a cheaper and more environmentally friendly materials, especially for interconnectors, a shorter warm-up time, compatibility with internal fuel reforming and reduced problems with cell stack sealing and gas system [1, 2]. However, several important problems must be overcome, which are connected mainly to a lower catalytic activity of the electrode materials and a lower electrical conductivity of the solid electrolyte. This creates an urgent necessity of developing new materials with sufficient catalytic and transport properties in the lower temperature range.
In this work we show results of testing of a home-made, single cell, SOFC unit based on new, promising cathode and electrolyte materials. The influence of main operational parameters i.e. temperature and fuel flow on the performance of the cell are presented.

EXPERIMENTAL

Cathode and electrolyte materials were obtained using sol-gel and coprecipitation methods, details can be found elsewhere [3, 4]. In this work we focused on new and promising perovskite materials with $La_{0.4}Sr_{0.6}Co_{0.2}Fe_{0.8}O_3$ and $Sm_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ chemical composition and the electrolyte

material with $Ce_{0.85}Gd_{0.15}O_{1.925}$ composition [4-6]. These materials were found to be chemically inert to each other at high temperatures and seem to be promising in terms of a long-term stability of the cell [7]. The cell performance was studied using custom-made SOFC testing unit shown in Figure 1. The anode was fuelled with dry hydrogen, with flow changing in the range of 10 – 100 cm^3min^{-1}, whereas air was provided at the cathode side, with flow rate about 500 cm^3min^{-1}. The measurements of the electrochemical properties of the cell were carried out using Solartron SI 1287 electrochemical interface and Solartron 1252A frequency response analyzer. In order to evaluate the operational parameters of the cell, current – voltage and power density characteristics as well as impedance spectra were recorded.
The cell was constructed as:

- composite: 85wt.% $La_{0.4}Sr_{0.6}Co_{0.2}Fe_{0.8}O_3$, 15wt.% $Sm_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ as the cathode,
- $Ce_{0.85}Gd_{0.15}O_{1.925}$ gas-tight sinter as the electrolyte (about 0.8mm thick),
- 40:60 8YSZ-NiO reduced to 8YSZ-Ni cermet as the anode.

The sintering process of the cell was conducted with separate firings of the anode (1200°C) and the cathode (1100°C).

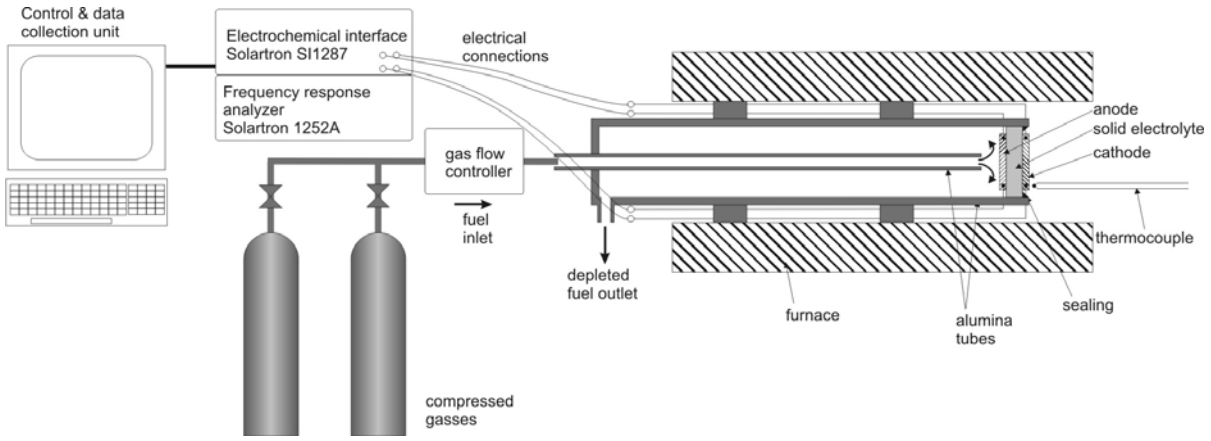

Figure 1. Schematics of the custom-made SOFC testing unit.

RESULTS AND DISCISSION

One of the most important features concerning materials used for SOFC technology is their electrical conductivity. In the case of the electrolyte it has to be purely ionic and should be as high as possible. In the case of the cathode material an utilization of mixed ionic-electronic conductivity was found to be beneficial, as it allows for the oxygen reduction reaction to take place all over the surface of the cathode, and therefore may allow for a better efficiency of the working cell [2]. The temperature dependence of the electrical conductivity of the cathode and electrolyte materials used for the cell construction are shown in Figure 2. Analyzing the data, two important issues may be noticed. Due to a relatively high activation energy of the ionic conductivity of the electrolyte material, its resistance increases rapidly with a decreasing temperature and therefore, the ohmic losses of the cell may become considerable. In the case of the cathode materials, the existence of a rather slightly pronounced maximum (or inflection) on the electrical conductivity dependence indicate an appearance of the oxygen vacancies at this temperature [2, 5]. The deviation from the oxygen stoichiometry increases with the increasing temperature, but the total conductivity decreases, due to the trapping of the created electrons on a high valence 3*d* metals [2]. The appearance of the oxygen vacancies indicate the existence of the mixed ionic-electronic conductivity in the perovskite material.

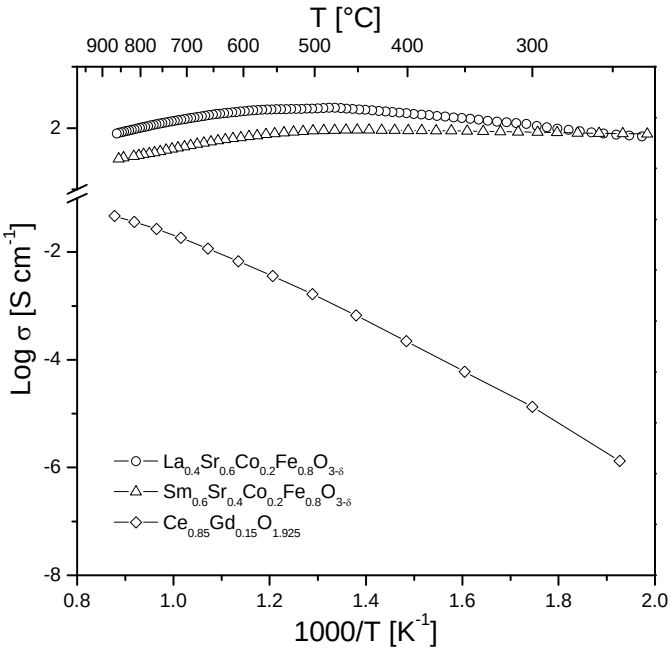

Figure 2. Electrical conductivity as a function of temperature for $La_{0.4}Sr_{0.6}Co_{0.2}Fe_{0.8}O_{3-\delta}$, $Sm_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ and $Ce_{0.85}Gd_{0.15}O_{1.925}$.

The impedance spectra recorded for the cell in 600 – 675°C temperature range are depicted in Figure 3. The obtained data were fitted using a typical equivalent circuit used for SOFC (Figure 4) [8]. The spectra consist of two depressed semi-circles shifted to the right from the origin. A clearly visible coil element is also present. R_{ohm} represents all of the ohmic resistances present in the cell, it can be however ascribed to the electrolyte resistance mainly. R_{ct} is related to the charge transfer resistance and R_d represents diffusion resistance [9]. Figure 5. presents the temperature dependence of the obtained R_{ohm}, R_{ct} and R_d values. The obtained results suggest that the cell performance is R_{ohm} limited in the whole temperature range. This in turn imply that the decrease of the electrolyte thickness should lead to a higher effectiveness of the working cell.

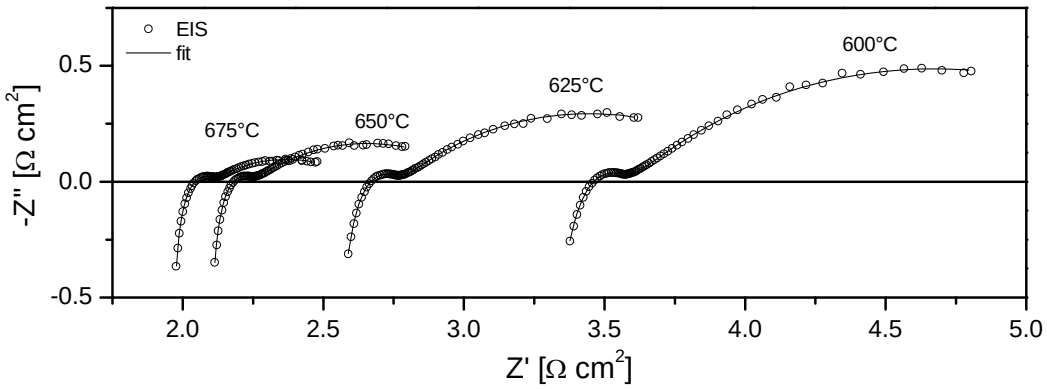

Figure 3. Impedance spectra of the measured cell.

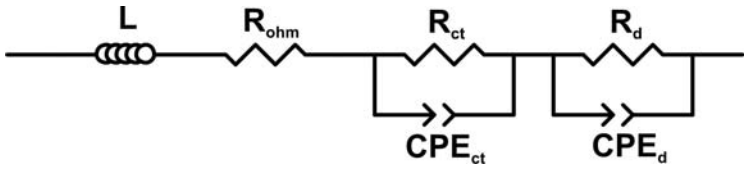

Figure 4. Equivalent circuit used for data analysis.

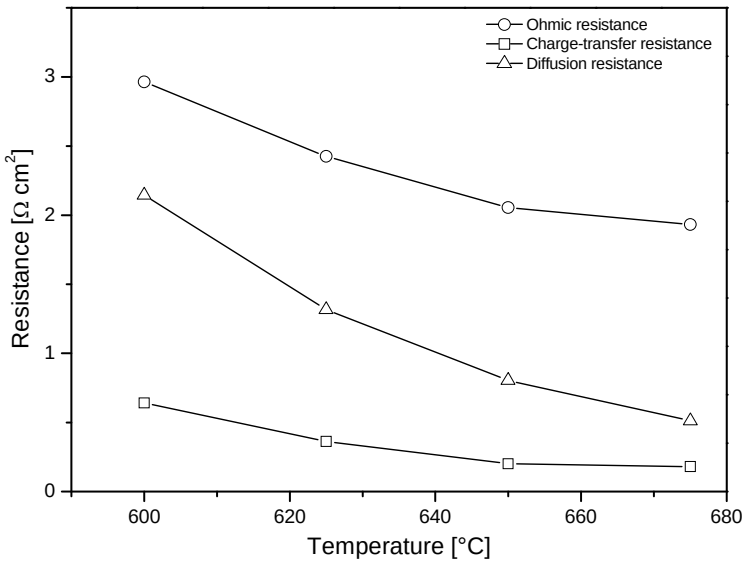

Figure 5. R_{ohm}, R_{ct} and R_d dependence on temperature.

The recorded OCV values (Figure 6) were relatively close to the theoretical ones, proving that the electrolyte layer was gas-tight and that the electronic component of the electrical conductivity of the electrolyte is rather marginal. A fairly weak dependence of OCV versus H_2 flow, for flow rates over 40 cm^3min^{-1}, was measured. However, low flow rates (especially 10 cm^3min^{-1}) seem to be not sufficient for our cell construction. The flow rate of 40 cm^3min^{-1} appears to be a good compromise between the cell voltage and the fuel utilization.

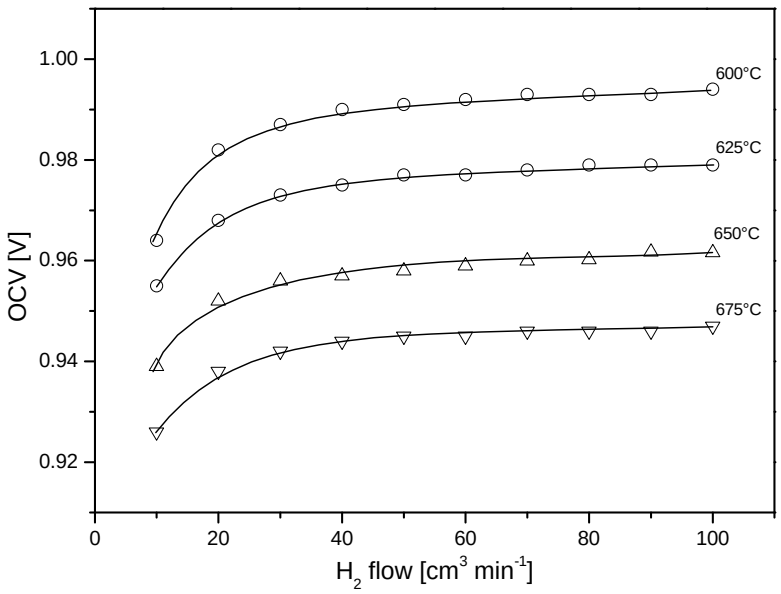

Figure 6. OCV values as a function of the H_2 flow recorded in 600 – 675°C temperature range.

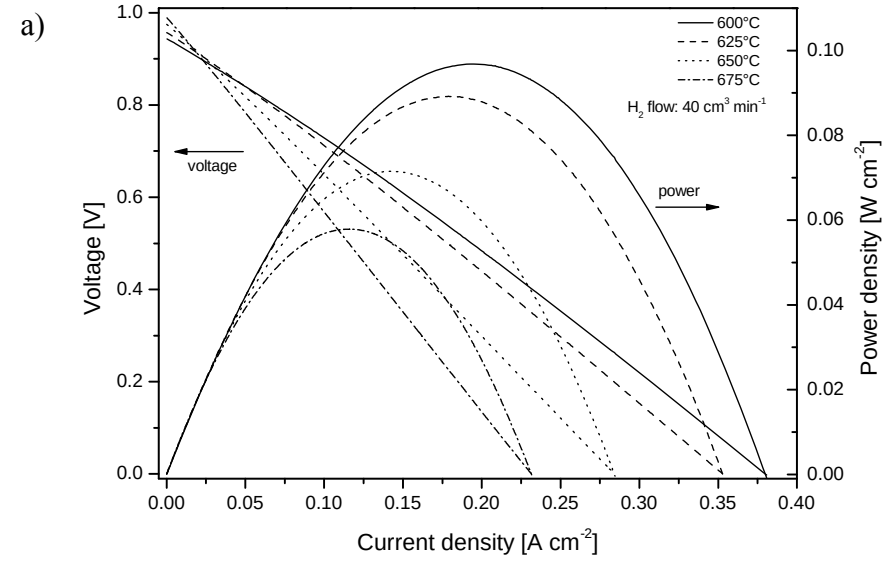
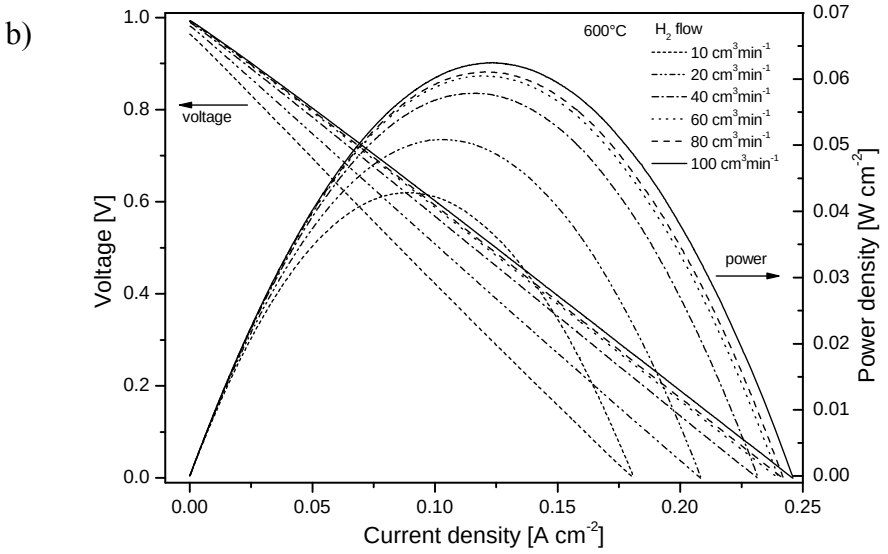
The measured in 600 – 675°C temperature range and for 40 cm^3min^{-1} fuel flow rate values of voltage and power density vs. current density are presented in Figure 7a. A typical increase of the maximum power of the cell with the increasing temperature was obtained. Figure 7b shows the evolution of voltage and power characteristics as a function of H_2 flow. The results additionally confirm that 40 cm^3min^{-1} fuel flow is optimal for the cell construction. The maximum values dependence vs. flow are shown in Figure 7c.





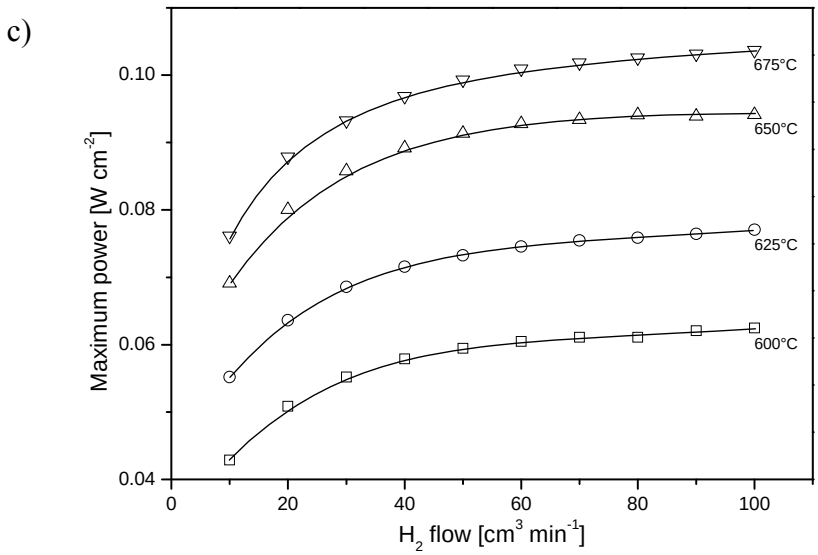


Figure 7. (a) Voltage and power density vs. current density recorded in 600 – 675°C temperature range for fuel flow rate of 40 cm^3min^{-1} and (b) at 600°C for fuel flow rate in the range 10 – 100 cm^3min^{-1}. (c) Maximum power as a function of H_2 flow for 600 – 675°C temperature range.

CONCLUSIONS

The presented results of the electrochemical characterization of the working, composite cathode 85wt.% $La_{0.4}Sr_{0.6}Co_{0.2}Fe_{0.8}O_3$, 15wt.% $Sm_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$, CGO15 electrolyte and 8YSZ-Ni anode, SOFC cell are encouraging and suggest that further improvements can be achieved. The used materials seem to be attractive in terms of their performance in the cell, especially, their electrical conductivity seems to be sufficient. The impedance spectra analysis indicate that the performance of the cell is limited by its ohmic resistance, which can be associated with the thickness of the electrolyte. A significant improvement of the working cell parameters, especially power density, may be expected when thinner electrolyte would be used. For our custom-made SOFC testing unit hydrogen fuel flow equal 40 cm^3min^{-1} seem to be the optimal one.

ABSTRACT. This paper presents experimental and numerical studies on the fuel reforming process on an Ni/YSZ catalyst. Nickel is widely known as a catalyst material for Solid Oxide Fuel Cells. Because of its prices and catalytic properties, Ni is used in both electrodes and internal reforming reactors. However, using Ni as a catalyst carries some disadvantages. Carbon formation is a major problem during a methane/steam reforming reaction based on Ni catalysis. Carbon formation occurs between nickel and metal-support, creating fibers which damage the catalytic property of the reactor. To prevent carbon deposition, the steam-to-carbon ratio is kept between 3 and 5 throughout the entire process. To optimize the reforming reactors, detailed data about the entire reforming process is required. In the present paper kinetics of methane/steam reforming on the Ni/YSZ catalyst was experimentally investigated. Measurements including different thermal boundary conditions, the fuel flow rate and the steam-to-methane ratios were performed. The reforming rate equation derived from experimental data was used in the numerical model to predict synthetic gas composition at the outlet of the reformer.

Keywords: *SOFC, fuel cells, methane/steam reforming, Ni/YSZ catalyst, reforming*

INTRODUCTION

The majority of commercial reactors in hydrogen production use methane/steam reforming on nickel catalyst. To design reforming reactors properly, detailed data about reaction kinetics are required. The kinetics of methane/steam reforming on Ni catalyst have been studied by many groups of researchers [1-6]. However, there is some disagreement as to the reported reaction order and activation energy of methane/steam reforming. Various researchers working on methane/steam reforming based on nickel catalyst [1-6] have reported different kinetics. The methane/steam reforming is an important part of the fuel conversion process for high temperature fuel cells such as Solid Oxide Fuel Cell. The high working temperature of an SOFC makes hydrocarbons the most suitable fuel in achieving high efficiency from natural resources [7]. For hydrocarbon-based fuel, three types of fuel conversion can be considered in reforming reactions: external, indirect internal and direct internal reforming systems. High-temperature SOFC eliminates the need for an expensive external reforming system. The possibility of using internal reforming is one of the advantages of high temperature fuel cells. Strong endothermic fuel reforming reactions can be thermally supported by the heat generated due to the sluggishness of electrochemical reactions, diffusion of participating chemical species and ionic and electric resistance. However, when operating at high temperatures, thermal management becomes an important issue. To carry out thermal management properly, detailed modelling and numerical analyses of the phenomena occurring inside the reformer are required. In the present paper, kinetics of methane/steam reforming on Ni/YSZ catalysts was

* Corresponding author: MSc Grzegorz Brus

E-mail address: brus@agh.edu.pl

experimentally investigated. The gas mixture composition and flow rate were measured at the outlet of the reformer to establish the methane reforming rate and kinetics of the reforming reaction. Based on experimental data, a mathematical and numerical model of the reforming reaction has been developed. The numerical model was compared to the experimental results and good agreement was found.

EXPERIMENTAL INVESTIGATION

Experimental procedure and facility

A schematic view of the experimental setup is shown in figure 1. A stainless steel reformer was located in an electrical furnace, which can be heated up to 1000°C. The maximum working temperature of pre-heater and after-heater is 400°C; however, for all experimental investigations presented in this paper, the temperature of pre- and post-heater was maintained at 200°C. High purity methane was the fuel used in the experiment. It was supplied to the reformer via a flow controller and evaporator, which was also used as a pre-heater. Water was fed to the system with a pump. The gas composition after the reforming process was analysed by gas chromatography prior to which the steam had been separated by cooling down the gas mixture to 2 °C. The reforming reaction tube was filled by nickel supported on yttria-stabilized zirconia. Figure 2A shows a typical reaction tube, where a catalyst supported on metallic particles is located in a reaction tube. For the presented investigation, a catalyst material was taken from an unused SOFC unit. The catalyst was a tubular-shape anode and consisted of 40% Ni and 60% YSZ. In the presented investigation the original tubular shape anodes were crushed into micro-particles roughly 300 μm in size and were located in the reaction tube as shown in figure 2B. To prevent large temperature gradients in the reformer, modifications of the reaction tube have been applied. To avoid a cooling effect of entering fluid, the reformer was partially filled with Al_2O_3 as shown in figure 2B. In this solution a mixture of gases before getting to the reaction zone was pre-heated by electric furnace to the reaction temperature. To control the thermal condition of the experiment, four thermocouples were placed in the experimental set-up as shown in figure 1 (marked as "T").

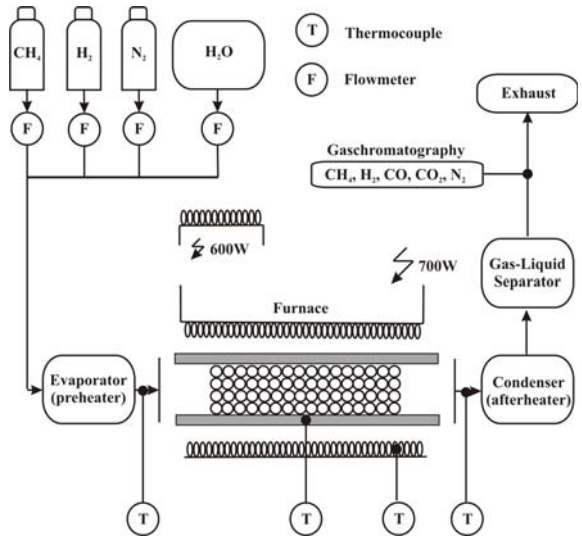

Figure 1. Schematic view of the experimental setup

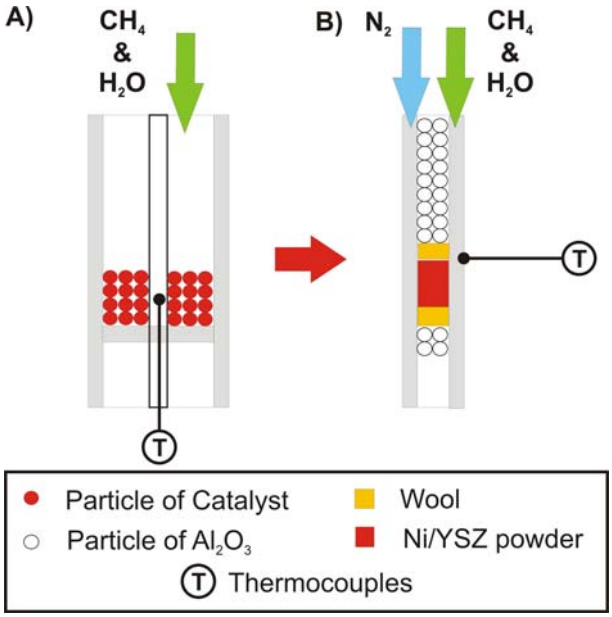

Figure 2. Schematic view of reaction tube. A) Typical reaction tube. B) Modified reaction tube.

To derive correct kinetics data, the reaction has to occur in a whole volume of catalyst. This can be accomplished by keeping the reforming conversion rate low. To achieve a low level of methane conversion, the fuel was additionally mixed with nitrogen (see figure 2B). Nitrogen does not directly influence the reforming reaction but the partial pressure of the components changed, which decreases both the reaction rate and methane conversion rate.

Methodology

The methane/steam reforming process is widely known as a conventional process for producing hydrogen [4], [5]. In the reforming process of methane with steam, the dominant reactions are the following two [8]
fuel reforming reaction

$$\mathrm{CH_4 + H_2O \rightarrow 3H_2 + CO}, \tag{1}$$

shift reaction

$$\mathrm{CO + H_2O \leftrightarrow H_2 + CO_2} \tag{2}$$

It follows from the stoichiometry of the steam/methane reforming reaction that the reaction rate expression can be approximated with this equation:

$$r_{\mathrm{CH_4}} = k\left(p_{\mathrm{CH_4}}\right)^a \left(p_{\mathrm{H_2O}}\right)^b, \tag{3}$$

where $k = A \cdot \exp\left(-E / RT\right)$

Where k is the reforming reaction constant, p_{CH4} and p_{H2O} are partial pressures of methane and water, respectively, [Pa], a and b are dimensionless coefficients responding to the reaction order, A is a pre-exponential factor, E is the activation energy, [J mol^{-1}], R the universal gas constant, [J mol^{-1} K^{-1}] and T the reaction temperature, [K]

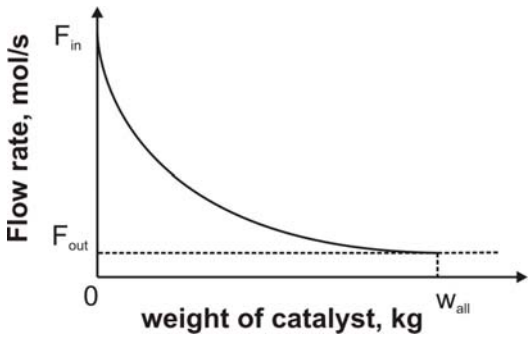

Figure 3. Methane flow rate as a function of catalyst weight

Figure 3 presents the relationship between the molar flow rate of methane and the weight of catalyst used. As can be seen for the given inlet flow rate of methane, increasing the amount of catalyst results in a decrease in the methane outlet flow rate as an effect of the higher conversion rate of methane. However, for some amount of catalyst, marked on figure 3 as w_{all}, there is no more change in the conversion rate. The equilibrium occurs while the outlet flow rate stays constant. Therefore the non-equilibrium reaction rate can be described as a ratio between the change in the flow rate of methane and the change in the amount of catalyst. Mathematically, this is written

$$r_{\mathrm{CH_4}} = -dF_{\mathrm{CH_4}} / dw_{cat}, \tag{4}$$

where

$F_{CH_4} = F^{in}_{CH_4} \cdot (1-x)$, where F_{CH_4} is the methane flow rate, [mol/s] and x is a dimensionless amount of reacted methane in the reforming reaction, w_{cat} is the weight of catalyst used, [kg].
By combining equations (3) and (4), the following equation was formulated:

$$k = \left(F^{in}_{CH_4} / w_{cat}\right) \cdot \int_0^{x_{out}} \left(1/k\left(p_{CH_4}\right)^a \left(p_{H_2O}\right)^b\right) \cdot dx \tag{5}$$

From the stoichiometry of reactions (1) and (2), the partial pressures can be defined as

$$p_{CH_4} = \left(n_{CH_4} / n_{all}\right) \cdot P = \left[(1-x)/(1+SC+NC+2x)\right] \cdot P\,, \tag{6}$$

$$p_{H_2O} = \left(n_{H_2O} / n_{all}\right) \cdot P = \left[(SC-x-y)/(1+SC+NC+2x)\right] \cdot P\,, \tag{7}$$

where n_{all} is the total amount of product at the outlet of the reaction tube, P is total pressure [Pa], n_{CH4}, n_{H2O} are, respectively, the methane and water fractions at the reformer output, x is a fraction of reacted methane, y is a fraction of reacted carbon monoxide, SC is the steam-to-carbon ratio and NC is the nitrogen-to-carbon ratio. n_{all} was derived from stoichiometry of reactions (1) and (2).
Introducing equations (6) and (7) into equation (5) yields the final form of the equation for the reaction constant:

$$k = \left(F^{in}_{CH_4} / w_{cat}\right) \cdot \int_0^{x_{out}} \left((1+SC+NC+2x)^{a+b} / P^{a+b} (1-x)^a (SC-x-y)^b\right) \cdot dx \tag{8}$$

where, a and b are coefficients related to the reaction order.
By following Itoh et al. [6] the methane conversion rate x is determined by the outlet quantity and can be calculated as

$$x = \left(x_{CO} + x_{CO_2}\right) / \left(x_{CH_4} + x_{CO} + x_{CO_2}\right) \tag{9}$$

The shift reaction occurs very fast and therefore the conversion rate can be estimated from the equilibrium equation

$$K_{shift}(x-y)(SC-x-y) = y \cdot (3x+y) \tag{10}$$

where:

$$K_{shift} = \exp\left[-\Delta G / (R \cdot T)\right], \tag{11}$$

where ΔG is the change of the standard Gibbs free energy of the shift reaction, R is the universal gas constant, [J mol^{-1} K^{-1}] and T is the reaction temperature, [K].
Because the reaction constant does not depend on the SC and NC ratios, a and b can be found [9]. K will be constant if a and b are set correctly. The real values of a and b are those that result in the smallest k derivation for different SC and NC ratios. Equation (8) was solved numerically for various values of a and b and for the different SC and NC ratios. The range from -1.0 to 2.0 has been chosen as a common range for reaction order according to already published data; figure 4 shows the results of computation. The smallest reaction constant deviation was found to be 0.3 and 0.1 for a and b, respectively.

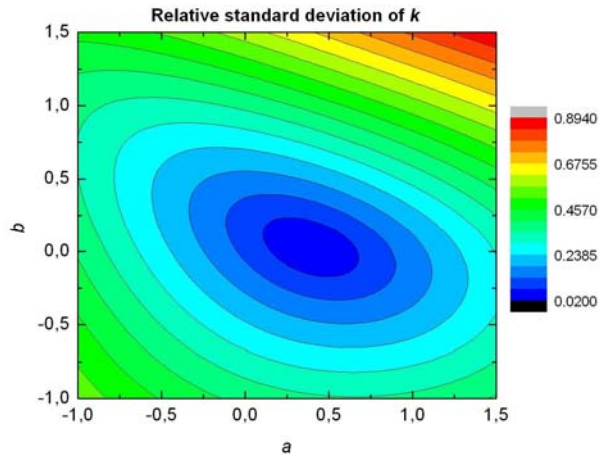

Figure 4. Relative standard deviation of *k*

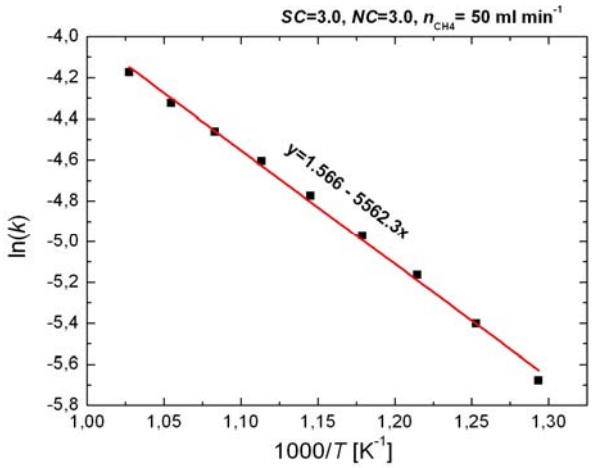

Figure 5. Arrhenius plot for Ni/YSZ

To develop a full kinetic model of the reforming reaction on the Ni/YSZ catalyst, the relationship between the reaction temperature and reaction constant has been investigated. The effect of the temperature on the reaction was studied by increasing the temperature from 500°C to 700°C. The results of the experiment are presented as an Arrhenius plot, as shown in figure 5.
A straight line was fitted to the experimental data as a result of approximation. The equation for the straight line for this experiment takes a form of Arrhenius equation and can be described

$$\ln k = \ln A - \frac{E}{R} \cdot \frac{1}{T} \tag{12}$$

Where T [K] is the temperature of fuel conversion, R = 8.314472 [J mol^{-1} K^{-1}] the universal gas constant, A is called the pre-exponential factor and corresponds to the intercept of line at 1/T=0 and E [J mol^{-1}], which is obtained from the slope of the line, is the activation energy of the steam reforming reaction.

Thus the kinetic of the methane/steam reforming reaction can be described by a reforming rate [mol s^{-1} g^{-1}] based on the experimentally obtained data by following this equation:

$$R_{st} = 4.79 \cdot \exp\left(-46223.11 / RT\right) \cdot p_{\mathrm{CH_4}}^{0.37} \cdot p_{\mathrm{H_2O}}^{0.05} \tag{13}$$

MATHEMATICAL MODEL FOR THE FUEL REFORMING PROCESS

The steam reforming reaction described by equation (1) is a slow and highly endothermic reaction; therefore a kinetic expression is required to calculate the reaction rate. How methane is reformed inside the reformer is dependent on the local conditions, including not only temperature but also the partial pressure of each chemical species and density of the catalysis [10]. The water-gas shift reaction described by equation (2) is a fast and weak exothermic reaction and can be assumed to be in equilibrium at the reforming temperature [8].
In the presented paper the reaction rates of the two main reactions (equations (1) and (2)) R_{st} and R_{sh} are calculated

$$R_{st} = 4.79 \cdot \exp\left(-46223.11 / RT\right) \cdot p_{\mathrm{CH_4}}^{0.37} \cdot p_{\mathrm{H_2O}}^{0.05} \tag{14}$$

$$R_{\mathrm{sh}} = K_{\mathrm{sh}}^{+} p_{\mathrm{CO}} p_{\mathrm{H_2O}} - K_{\mathrm{sh}}^{-} p_{\mathrm{H_2}} p_{\mathrm{CO_2}} \tag{15}$$

Equation (14) is based on the experimentally obtained data and was described in the previous paragraph, where, w_{cat}, is catalyst weight [g], T [K] the temperature of fuel conversion, R = 8.314472 [J mol^{-1} K^{-1}] the universal gas constant, p_{CH4} the partial pressure of methane [Pa] and p_{H2O} the partial

pressure of steam [Pa]. The catalyst weight w_{cat} is an important parameter because control of its distribution can be used as a means of changing the distribution pattern of the reformer temperature.

K_{sh}^{+} and K_{sh}^{-} denote the rate constants of forward and backward water-gas shift reactions. The water shift reaction given by equation (2) reaches equilibrium rapidly; therefore CO_2, H_2, CO and H_2O have to satisfy the equilibrium equation. Chemical equilibrium is represented by the equilibrium constant which is a function of temperature and is equal to the ratio of the reactants' to the products' partial pressures.

$$K_{sh} = K_{sh}^{+} / K_{sh}^{-} = (p_{CO_2} p_{H_2}) / (p_{CO} p_{H_2O}) = \exp(-\Delta G_{sh}^{0} / RT) \tag{16}$$

where ΔG_{sh}^{0} is the change of standard Gibbs free energy of shift reaction.

This equilibrium constant, given by equation (16), is introduced into equation (15) to calculate the rate of the shift reaction.

The change of each chemical species caused by the fuel reforming reaction (equation (11)) and shift reaction (equation (12)) are derived from the reactions' stoichiometry and are calculated as follows:

$$\Delta \dot{n}_{H_2} = 3x + y \tag{17}$$

$$\Delta \dot{n}_{CO} = x - y \tag{18}$$

$$\Delta \dot{n}_{CO_2} = y \tag{19}$$

$$\Delta \dot{n}_{CH_4} = -x \tag{20}$$

$$\Delta \dot{n}_{H_2O} = -x - y \tag{21}$$

RESULTS

This paper has presented experimental and numerical studies on the fuel reforming process on an Ni/YSZ catalyst. The gas mixture composition and the flow rate were measured at the outlet of the reformer to establish the methane-steam reforming rate and kinetics of the reforming reaction. Measurements including different thermal boundary conditions, the fuel flow rate and the steam-to-methane ratios were performed. The reforming rate equation derived from experimental data was used in the numerical model to predict synthetic gas composition at the outlet of the reformer. Figure 6 presents a mole fraction of fuel in the outlet of the reformer as a function of reaction temperature. As can be seen in the figure 6, numerical results, presented as a constant line, fit the experimental data well. Figure 6 indicates that the amount of carbon monoxide increases with the reaction temperature. This is significant because in contrast to the low temperature fuel cell, the carbon monoxide does not poison the high temperature solid oxide fuel cell anode but can be electrochemically converted as a fuel [2]. In figure 7 an effect of the methane flow rate on the steam reforming reaction was studied by increasing the inlet methane flow rate from 50 ml min^{-1} to 150 ml min^{-1}. As can be seen in figure 7, the inlet flow rate of methane has a small influence on the outlet mole fraction of CO and CO_2. The existing disagreement between the experimental and numerical data is a result of a high conversion rate. The relatively large amount of catalyst and low flow rate of methane results in a shift reaction (1) to the left side and cannot be precisely described by the numerical model used. The quality of the numerical computations can be presented by a correlation plot of the measurements against the numerical model. The example of numerical results and their comparisons with the experimental data are shown in figures 8, where the experimental results were set against the calculated reforming conversion rates. The points situated on the line present a perfect fit between

the experimental and numerical results. Most of the points are located on the line or in its vicinity. Good agreement between the experimental and numerical results was obtained.

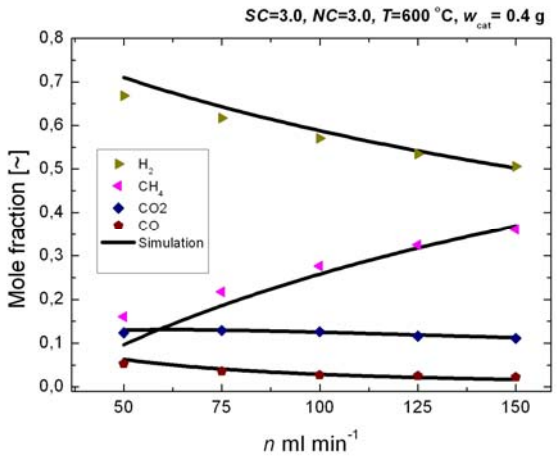

Figure 7. Experimental results in comparison with numerical simulation. Mole fraction of fuel in the outlet of the reformer as a function of inlet methane flow rate.

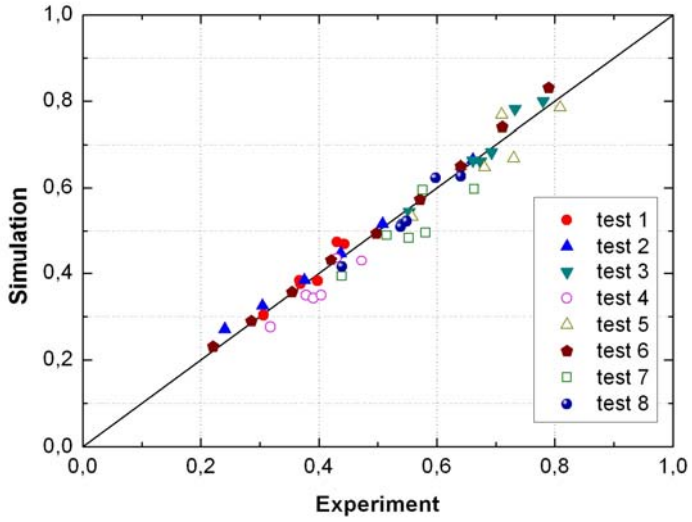

Figure 8. Experimental results in comparison to calculated reforming conversion rates.

CONCLUSIONS

This paper has presented experimental and numerical studies on the fuel reforming process on an Ni/YSZ catalyst. The gas mixture composition and the flow rate were measured at the outlet of the reformer to establish the methane reforming rate and kinetics of the reforming reaction. The experimental setup was built to investigate results for different thermal boundary conditions, the fuel flow rate and the steam-to-methane ratios. The reforming rate equation derived from experimental data was used in the mathematical model to predict the synthetic gas composition at the outlet of the reformer for the isothermal fuel reforming process. It was shown that the results of numerical computations fit the experimental data well. The obtained results show how important parallel, numerical and experimental studies are in the process design of SOFC reformers. It was also shown that applying a combined approach leads to the successful prediction of the outlet gas composition for different modelling conditions.

SURFACE TENSION DOMINATED CONDENSATION IN MICROCHANNELS

H. S. Wang, J. W. Rose *
Queen Mary, University of London, Mile End Road, London E1 4NS, UK

ABSTRACT. A wholly theoretical model for condensation in rectangular and triangular cross section microchannels has been developed by the authors (Wang and Rose [5]). This takes account of the effects of gravity, streamwise shear stress on the condensate surface and, most importantly, the transverse pressure gradient due to surface tension in the presence of change in condensate surface curvature. Numerical results have been generated for various channel shapes, sizes, fluids, vapour-to-surface temperature differences and vapour mass fluxes. It is found that, over a certain length of channel, the local mean (around the channel perimeter) heat-transfer coefficient is essentially independent of gravity (including inclination of the channel) and surface shear stress and depends only on surface tension. Dimensional analysis for the surface tension dominated region leads a relation between the Nusselt number and a single dimensionless group analogous to that occurring in the simple Nusselt theory except that the gravity is replaced by surface tension. Data for 7 fluids, 5 temperature differences, 7 channel geometries and 5 channel inclinations are well correlated by a Nusselt-like equation with Nusselt number dependant on one dimensionless group involving surface tension and vapour-to-surface temperature difference. This is a step towards the objective of summarising the results of numerical solutions for the whole channel, including those positions along the channel where gravity and shear stress also play important roles, by algebraic equations.

INTRODUCTION

Refrigeration and air conditioning, account for a significant proportion of electricity usage, and consequently for fuel consumption and associated CO_2 emissions. Improvement in design and performance of refrigeration plant can make a significant contribution to mitigation of these problems. Condensers employing microchannel tubes such as those shown in Fig. 1 have been used successfully in automotive air conditioners for around 20 years and have proved both compact and effective.

Fig. 1 Multi-port extruded tube, Koyama et al. [1]. Typical channel dimension around 1 mm.

Available experimental heat-transfer data for condensation in microchannels are relatively few and widely scattered. Vapour-side, heat-transfer coefficients have, with a few exceptions (Koyama et al. [1], Cavallini et al. [2] generally been inferred from overall measurements by subtraction of thermal resistances and/or using "Wilson plot" techniques; such data have high uncertainty.

Four correlations based on data for R134a (Wang et al. [3], Koyama et al. [1], Cavallini et al. [2], Bandhauer et al. [4] and one theoretical solution (Wang and Rose [5]) have been proposed. For R134a the correlations have been shown (Su [6], Su et al. [7-8]) to be broadly in agreement with each other and with the theoretical solution (see Fig. 2). Wide differences are seen when the correlations and theory are used for other fluids as (see Fig. 3).

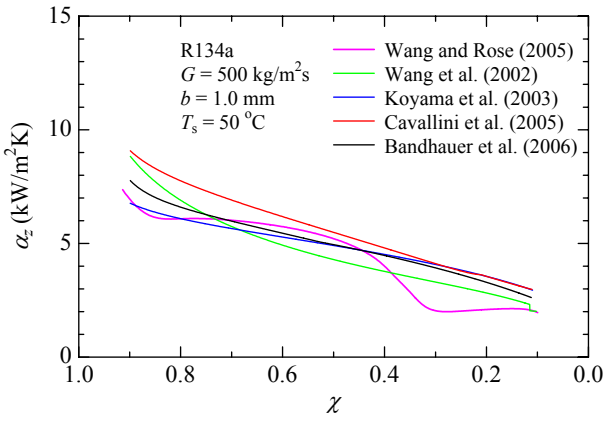

Fig. 2 Comparison of correlations and theory for R134a

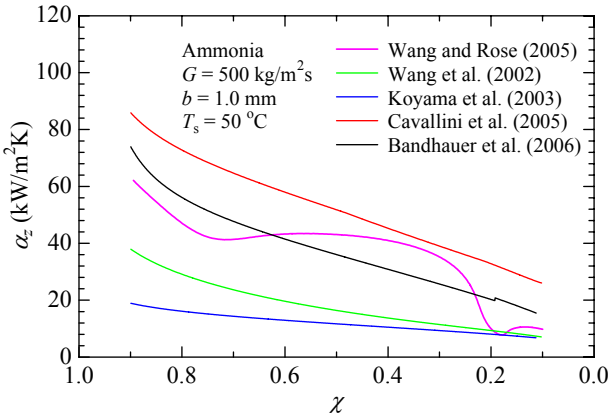

Fig. 3 Comparison of theory and correlations for ammonia

The theory has no empirical input and numerical solutions can readily be obtained for any fluid and any channel cross section with a vertical axis of symmetry. Solutions have been obtained for a range of channel geometries, fluids, mass fluxes, vapour-to-surface temperature differences and channel inclinations (Wang and Rose ([5, 9-11], Wang et al. [12], Su et al. [7-8]). The theory requires numerical solution of the differential equation for the condensate film thickness and consequently is not so convenient for use in design and optimisation as algebraic equations. The present paper describes an approach towards summarising theoretical results by approximate algebraic equations.

THEORY

The co-ordinate scheme for rectangular and triangular channels are shown in Fig. 4.

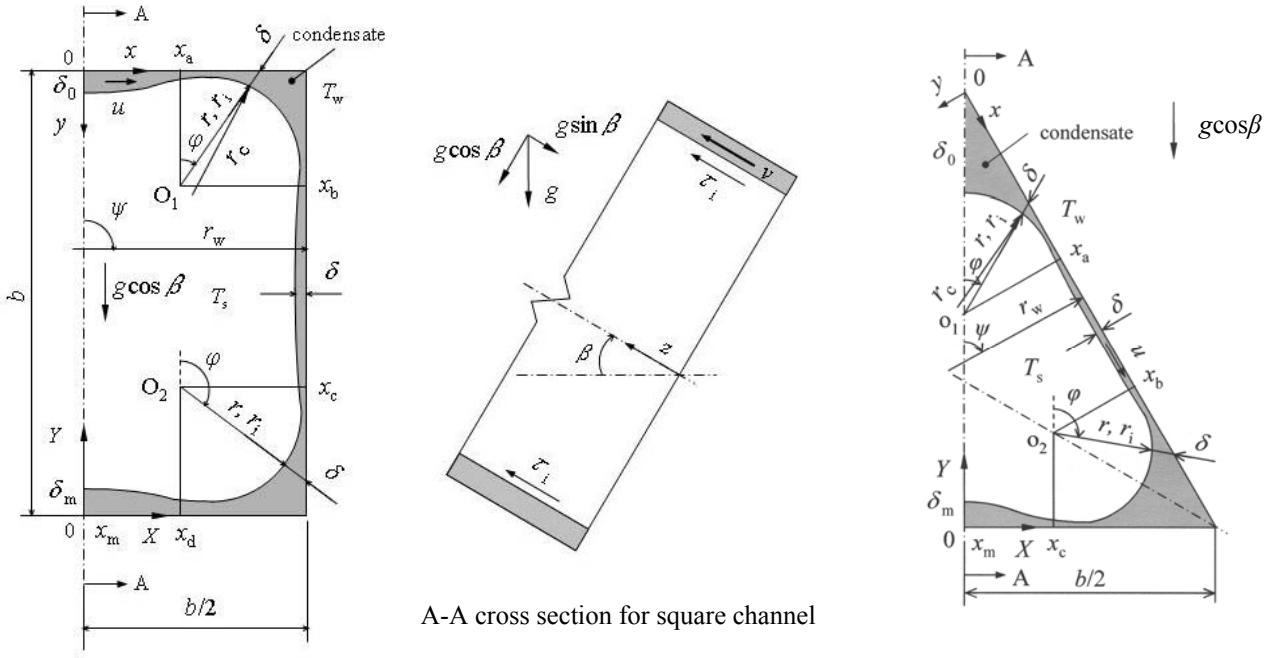

Fig. 4 Co-ordinate scam in the theory of Wang and Rose [5, 9]

When the transverse pressure gradient due to surface tension, and the streamwise shear stress on the condensate surface are included in an otherwise Nusselt treatment of the condensate film on the channel surface (see Wang and Rose [5, 9]) the differential equation for the condensate film thickness, δ, on the channel wall is found to be:

$$\frac{(\rho_l - \rho_v)g\cos\beta}{3\nu_l}\frac{\partial}{\partial x}(\delta^3\sin\psi) + \frac{\sigma}{3\nu_l}\frac{\partial}{\partial x}\left\{\delta^3\frac{\partial}{\partial x}\left(\frac{1}{r_c}\right)\right\} + \frac{1}{2\nu_l}\frac{\partial\left(\tau_i\delta^2\right)}{\partial z} - \frac{(\rho_l - \rho_v)g\sin\beta}{3\nu_l}\frac{\partial}{\partial z}\left(\delta^3\right)$$

$$-\frac{1}{3\nu_l}\frac{\partial}{\partial z}(\delta^3\frac{\mathrm{d}P_v}{\mathrm{d}z}) = \frac{1}{(1+\zeta\lambda_l/\delta)}\frac{\lambda_l(T_s - T_w)}{h_{fg}\delta} \qquad (1)$$

where

$$\frac{1}{r_c} = \frac{\partial^2\delta/\partial x^2}{\left\{1+\left(\partial\delta/\partial x\right)^2\right\}^{3/2}} \qquad (2)$$

z and x are the streamwise and transverse co-ordinates, T_s and T_w are the vapour and wall temperatures, τ_i is the streamwise surface shear stress on the condensate surface, P_v is the vapour pressure, ν_l and λ_l are the condensate kinematic viscosity and thermal conductivity, h_{fg} is the specific latent heat of evaporation, ζ is a minor correction term for the interface temperature discontinuity (see Wang and Rose [5]) and r_c is the radius of curvature of the condensate surface in the transverse plane.

Equation (1) is valid (to the same degree as the classical Nusselt theory) for the annular or annular/stratified flow regime. An equivalent equation in polar co-ordinates, used to treat corners and for a circular channel, is given by Wang and Rose [5]. Modified polar coordinate equations to include channel inclination are given by Wang and Rose [9]. Solution of Eq. (1) requires an estimate of the streamwise surface shear stress distribution on the condensate surface. In the solutions obtained to date this has been obtained using standard approximate methods (see Cavallini et al. [13]) which take account surface transpiration (condensation). The model has been used to predict a wide range of results for typical conditions. Results are found to be only marginally affected by moderate arbitrary changes in the streamwise shear stress so that the accuracy of the streamwise shear stress estimate is of secondary importance.

SURFACE TENSION DOMINATED REGIME

A particularly important finding is the fact that the solutions show the transverse (to the flow direction) pressure gradient due to surface tension dominates over both gravity and streamwise shear stress in certain circumstances. In this regime the mean (around the channel perimeter) heat-transfer coefficient remains virtually constant for some distance along the channel. When gravity is set to zero the heat-transfer coefficient in this regime is essentially unaffected. When the vapour flow rate is increased so as to increase the streamwise shear stress on the condensate surface, the heat-transfer coefficient is not increased, rather the length of channel over which the coefficient remains high is increased.

Figure 5 shows, for a triangular channel and for the conditions indicated, that the heat-transfer coefficient is essentially independent of gravity for distances from the channel inlet between about 80 mm and 210 mm. Figures 6a and 6b give solutions for different vapour mass fluxes for triangular and square channels. These indicate that, while the heat-transfer coefficient near the

channel inlet is affected by vapour mass flux (surface shear stress), there exist ranges of mass flux where the heat-transfer coefficient is essentially constant (independent of both vapour shear stress and gravity); the distances along the channel where this is so increases with increasing vapour mass flux. Fig. 7 demonstrates, for the case of the square channel, that the condensate film profiles are closely similar at z = 95 mm when G =300 kg/m^2 s and at z = 489 mm when G = 1000 kg/m^2 s. This is due to the fact that the vapour shear stress has appreciable effect on the liquid film near the corners while having little effect along the channel walls where the film flow is dominated by transverse surface tension generated pressure gradient.

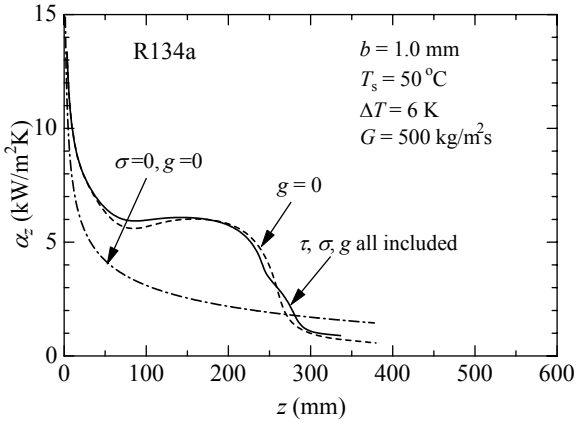

Fig. 5 Mean heat-transfer coefficient along upright triangular channel (Wang and Rose [5])

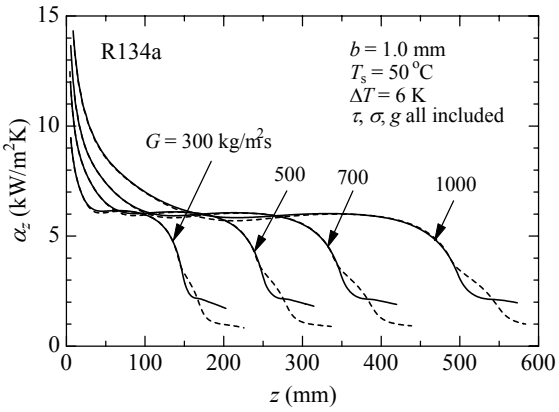

Fig. 6a Mean heat-transfer coefficient along triangular channel for different vapour mass fluxes (dashed line vertex up, solid line vertex down; Wang and Rose [5])

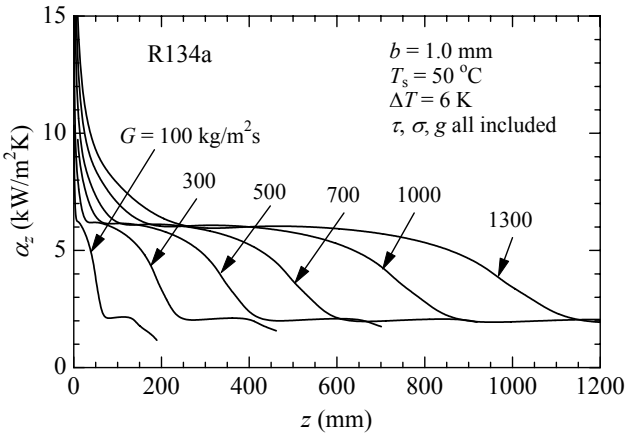

Fig. 6b Mean heat-transfer coefficient along square channel for different vapour mass fluxes (Wang and Rose [5])

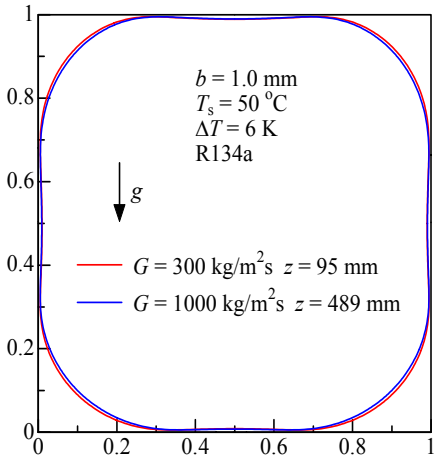

Fig. 7 Condensate film profiles at two vapour flow rates and two distances along thew channel

Figure 8 shows results for different vapour-to-surface temperature differences for a square channel. It is seen, that the heat-transfer coefficient is higher at low ΔT as expected owing to lower condensation rates and consequently thinner condensate films. It is also seen that the range of distance from the channel inlet over which the heat-transfer coefficient is essentially independent of z is larger at lower ΔT. Figure 9 gives results for square channels of different dimensions. Regions where the heat-transfer coefficient is essentially independent of gravity are identifiable for channels with side 2 mm or smaller. For larger channels it appears that the transverse surface tension effect is small. The heat-transfer coefficient where surface tension dominates increases strongly with decrease in channel dimension while the distance over which the coefficient remains high decreases with decreasing size due to flooding of the channel.

Figure 10 shows results for different channel inclinations. Again, a range of inclinations can be seen where the heat-transfer coefficient is independent of inclination for some distance along the channel. Figure 11 gives results for various fluids showing in all cases a range of distance where the heat-transfer coefficient is almost constant. This is least evident for the case of carbon dioxide.

DIMENSIONAL ANALYSIS FOR THE SURFACE TENSION DOMINATED PART OF THE CHANNEL

Here, as in the Nusselt problem, inertia and convective effects in the film are neglected together with gravity so that the mean condensate film thickness is governed by surface tension, viscosity and the rate at which liquid condenses on unit area of the surface V. Thus the effective mean thickness of the condensate may be written

$$\delta = \xi(\sigma, \mu, x, V) \tag{3}$$

where x is the relevant linear dimension.

Dimensional analysis then gives

$$\frac{\delta}{x} = f\left(\frac{\sigma}{\mu V}\right) \tag{4}$$

We now suppose, as is often done when correlating heat-transfer data, that this function takes the form

$$\frac{\delta}{x} = A\left(\frac{\sigma}{\mu V}\right)^{p} \tag{5}$$

where A and p are constants.

Then, as in Nusselt, we neglect convection in the condensate film and write

$$V = \frac{m}{\rho} = \frac{q}{\rho h_{fg}} = \frac{\lambda \Delta T}{\delta \rho h_{fg}} \tag{6}$$

Substituting volume condensation rate per area V in Eq. (5) and rearranging gives

$$Nu = C\left(\frac{\rho\, h_{fg} \sigma\, x}{\mu\, \lambda\, \Delta T}\right)^{n} \tag{7}$$

where $C = A^{1/(p-1)}$ (8)

and $n = p/(p-1)$ (9)

For the case of the triangular and square channel the relevant linear dimension is the side of the channel b so we have

$$Nu = C\left(\frac{\rho\, h_{fg} \sigma\, b}{\mu\, \lambda\, \Delta T}\right)^{n} \tag{10}$$

Values of the heat-transfer for the surface tension controlled region have been identified as closely as possible from all of the results obtained to date and plotted as shown in Fig. 12. (For rectangular channels the geometric mean of the lengths of the two sides has been used for b). It may be seen that the data for all cases (7 fluids, 7 channel geometries, 5 values of ΔT in the range 2-10 K) are satisfactorily fitted by

$$Nu = 1.43\left(\frac{\rho\, h_{fg} \sigma\, b}{\mu\, \lambda\, \Delta T}\right)^{1/4} \tag{11}$$

which may be compared with the Nusselt equation for gravity controlled condensation on a vertical flat plate

$$Nu = 0.943\left(\frac{g \Delta \rho\, h_{fg} L^{3}}{\mu\, \lambda\, \Delta T}\right)^{1/4} \tag{12}$$

where L is the height of a vertical condensing surface.

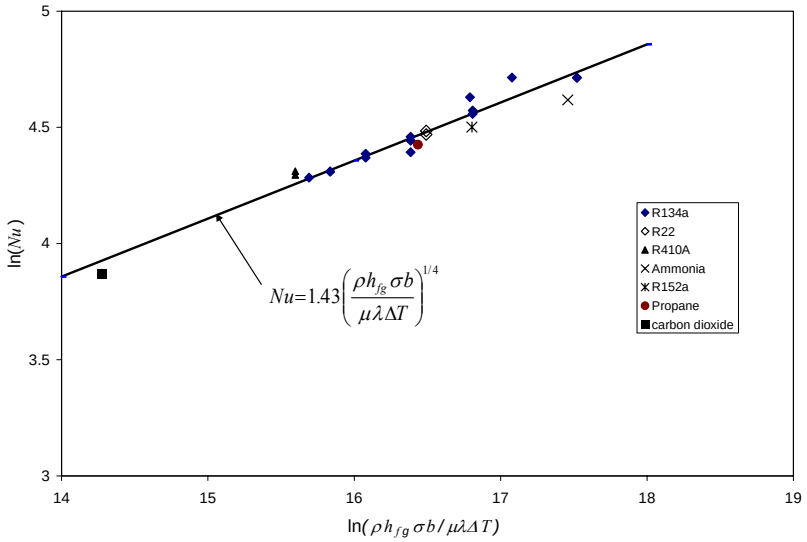

Fig. 12 Correlation of results for surface tension dominated region

CONCLUSION

For condensation in sufficiently small channels, solutions of the differential equation for the annular flow regime indicate ranges of the relevant variables where the transverse flow, due to the pressure gradient resulting for surface tension in the presence of surface curvature, dominates. For these circumstances, where gravity and streamwise shear stress on the condensate film due to vapour flow have negligible effect on the heat-transfer coefficient, a simple Nusselt-like correlation has been obtained. The same result has been found in an approximate analysis which does not invoke dimensional analysis (Wang and Rose [11]). This is a first step towards the objective of summarizing the theoretical results in the form of simple equations for ready use in design and optimization.

TURBULENCE IN MICRO-CHANNELS

T. A. Kowalewski*, S. Blonski
IPPT PAN, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT. Fluid mechanics in small channels, i.e. channels of micrometer size, is dominated by surface effects and often exhibits striking differences of flow characteristics when compared with macro scale. One of important microfluidic problems is flow destabilization and occurrence laminar-turbulent transition. In this paper we describe our experimental and numerical attempts to understand growth of flow instabilities and development of turbulent structures in small channels. In the first configuration flow of water through 1mm long and 0.4mm high microchannel formed between two planes is investigated varying Reynolds number from 1000 to 6770. Fluorescent traces are used for flow visualization and microPIV acquisition of temporary velocity fields. The microPIV data are used to evaluate turbulent flow characteristics. Our experimental study shows that destabilization of flow in such a micro-channel does not necessarily occurs when it is usually expected. Nearly laminar flow structure is present within the channel even for the highest investigated flow Reynolds number. These findings are confirmed by numerical simulation performed using finite volume code.
On the other hand it appears possible to achieve unstable flow pattern even for quite low Reynolds number flow regime by proper modification of the channel walls. In the second experimental and numerical study we demonstrate that appropriately chosen wall waviness of the micro-channel may lead to flow destabilization already at quite low flow Reynolds number (~100).

Keywords: *microchannels, microPIV, turbulence, flow instability*

INTRODUCTION

The advances of microfluidics allow for the manufacturing micro-reactors, micro-scaled cooling devices or small liquid atomisers. These devices are characterised by a large surface-to-volume ratio, hence provide possibility for larger heat fluxes or offer large catalytic surface for reactions. In most of these applications flow unsteadiness or turbulence is desirable, however not easy to achieve in small scales. The design and optimisation of microfluidic devices is usually based on our knowledge gained for macro scale hydrodynamics. However, it can be expected that small channel hydrodynamics has to be reconsidered in different contexts: relative large surface area can be responsible for delayed (or accelerated) laminar-turbulent transition [1-8]; wall roughness becomes elevated relative to small channel size and may influence laminar-turbulent transition [9]; appropriate wall corrugation can be used to activate flow instability and effectively diminish critical Reynolds number [10].
In spite of the existence of numerous experimental and theoretical investigations, a number of principal problems related to laminar-turbulent transition in micro scales are not fully resolved. There are contradictory data on transition from laminar to turbulent flow. Some studies indicate that the transition from the laminar to the turbulent flow in micro-scale passages takes place at critical Reynolds numbers, ranging from 300 to 2000. The reported values are lower than those known from the conventional theory for large-size tubes. In particular, Wu and Little [1,2] experimentally observed that in glass and silicon microchannels having hydraulic diameters between 45.5 μm and

* Corresponding author: Prof. T.A. Kowalewski

E-mail address: tkowale@ippt.gov.pl

83.1 μm, the flow was laminar for Re < 1000 and became fully turbulent for Re > 3000. Choi et al. [3], analysing microtubes with a hydraulic diameter of 53 μm and 81.2 μm, indicated that the transition to turbulent flow occurs at Re = 2000. However, they found that this value decreases for smaller microchannels (Re = 500 for D_h = 9.7 μm and 6.9 μm). These and following measurements were performed by employing "classical" experimental methodology, i.e. detecting global effects like pressure drop, heat fluxes or mixing effectiveness. In small channels entrance effects and probe size may largely modify measurements, as indicated by Celata et al. [4]. Only quite recently it appeared possible to acquire detailed information on the temporary velocity flow fields within micro channel. Time-dependent measurements of the velocity field within microchannels by means of the microPIV technique have been performed to access the laminar/turbulent transition range [5-8]. These measurements, in principle, are able to resolve not only the integral information on the laminar/turbulent transition, they can, moreover, provide local information on both mean and fluctuating velocity contributions. Hence, information on the developing flow, on the spatial distribution of the mean flow, on the spatial distribution of turbulent fluctuations and stresses, and on the intermittent flow is accessible. Li et al. [5] measured time-dependent velocity fields in a rectangular microchannel of 320 x 330 μm^2 cross section. They discuss profiles of the mean axial velocity, of the axial and transversal velocity fluctuations, and reported good agreement with findings known for macroscopic channels. Quite recently Wibel and Ehrhard [6] in their very careful microPIV study of velocity fluctuations confirmed that the laminar/turbulent transition in 133μm channels occurs in the range $1900 \leq Re \leq 2220$, in reasonable agreement with macroscopic findings. Moreover, the profiles of the turbulent quantities are reported in good agreement with findings within macroscopic channels. All reported investigations deal with well developed flow in a long channel. However, due to high pressure drop only very short micro channels can be used in practical realization. In our micro-PIV study of high Reynolds number flow in very short micro channel [7,8] delayed occurrence of turbulence was reported. This finding is subject of the present paper as well.

The occurrence of laminar/turbulent transition can be strongly modified by wall roughness, which becomes an issue for small channels [9]. On the other hand it was predicted by Szumbarski [10,11] that controlled wall waviness may lead to flow destabilization already at Reynolds number close to 100. The outcome of our numerical and experimental study of this remarkable feature is reported in the second part of the present paper.

EXPERIMENTAL

Apparatus

The main part of the experimental set-up consists of a microscope, a laser light source and a digital camera. The flow is observed using 10x (NA 0.3 / WD 17.30 mm) microscope lens and area covered by the camera is *854 μm x 683 μm.* Short illumination time is achieved by using a pulsed light of Nd:YAG laser, delivering 30 mJ energy at 532 nm wavelength (New Wave Research, Inc.). The flow is illuminated and observed through the upper window of the channel. By traversing the field of observation in the horizontal and vertical direction, the position of the interrogated flow plane was selected. For the recording of images a high-resolution (1280 x 1024 pixels) 12bit *PCO SensiCam* camera was used. When coupled with the double pulse laser the system permits acquisition of two images at the minimum time interval of 200 ns, exposition time of 5 ns, and about 3.75 Hz repetition rate. The micro-PIV measurements were performed for pure water seeded with fluorescent tracers, polystyrene spheres of 2 μm in diameter (Duke Scientific Inc.). The particle volumetric concentration was very low (<0.0001%wt), hence they did not affect the flow structure. Unlike typical PIV methods, microPIV does not utilize a thin laser sheet to illuminate the seeding particles [12]. The whole investigated volume is flooded with the laser light using beam expander and the microscope objective. Two low pass filters, mounted between the objective and the camera, permit only the fluorescent red light to pass, while preventing the green laser light to be detected by the camera. The micro-PIV images present well detectable bright spots of the seeding

particles. The accuracy of the velocity measurement depends on several experimental factors (quality of the images, seeding concentration, particle displacement), as well as on the vector evaluation procedure. Using in house developed software and by evaluating uniform, predefined flow of water through the micro-channel, the error of velocity measurement was estimated to be below 5%.
In most cases the flow was driven by the micro pump (Cole-Palmer Inst.) permitting flow rate variation from $Q_V = 0.02$ cm^3/s to 70 cm^3/s. For the highest measured flow rates (200 cm^3/s) pressurized supplying system was used [7].

Short channel turbulence
The flow of pure water was studied using in a flat model of an emulsifier, described already in details [7,8]. It consists of a small channel formed between two glass plates and a triangular processing element creating the rapid flow contractions (Fig. 1). Dimension of the two gaps created between glass plates and processing element (triangular obstacle) are 0.4mm in height, 1mm in length and 15mm in width. The flat geometry and two glass windows permit application of optical methods for measuring flow velocity fields (microPIV method) within the gap (P_1,$P_{1\text{-}2}$,P_2) as well as nearly 4 mm upstream (P_0) and 3mm, 5mm, and 8mm downstream (P_3,P_4,P_5). The flow rate used varied from *16 to 204 cm^3/s*, and the corresponding Reynolds number based on the microchannel height varied from *1000 - 6770*. For the highest flow rate the both symmetrical microchannels (upper and lower gap) were supplied, whereas in other cases only interrogated upper gap was open for the flow.

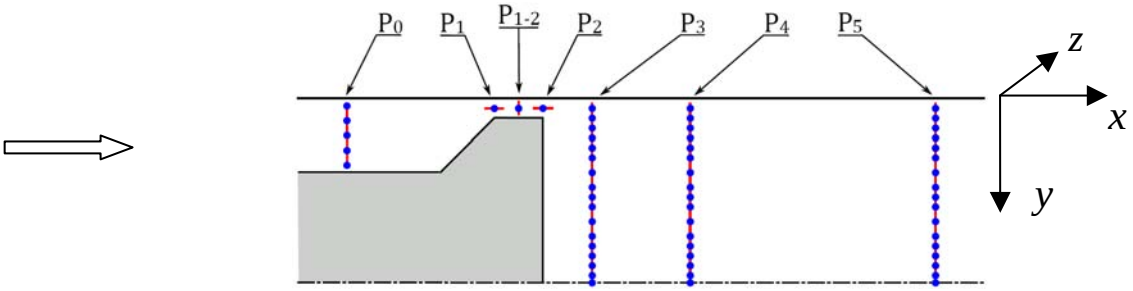

Figure 1. Schematic drawing of the channel and locations P_0 - P_5 interrogated by the PIV method. The flow is driven from left to right. Distances are measured from the gap exit (*x = 0*) and the top wall (*y=0*). At location P_0 (*x = -4 mm*) PIV covers 5 planes between top and bottom wall; at P_1 and P_2 PIV interrogation planes are in the mid-height of the gap (*y = -0.2 mm*), covering partly gap inlet and outlet, respectively; at $P_{1\text{-}2}$ measurements are located in the middle of the length of the microchannel (*x = -0.5 mm*) and cover three vertical positions *y = -0.1 mm*, *y = -0.2 mm* and *y = -0.3mm*. P_3 - P_5 indicate location of PIV interrogation planes used to measure velocity distribution from the top wall to the flow axis (*y = 0 : -3.75 mm*). They are located at distances *x = 1 mm* (P_3), *x = 3 mm* (P_4), and *x = 8 mm* (P_5) from the gap exit.

Corrugated wall
A simple model of the wavy channel formed between two plates has been machined in polycarbonate using micro-machining technique. The average channel height is *793 µm*, its width is *33.6 mm*, and the length *75 mm*. Surface of the bottom wall is modulated by 20 rows (comp. Fig. 2). They create spanwise periodic structure with channel depth varying from *0.4mm* to *1mm*. The upper wall of the channel is flat to permit optical measurements. An average flow velocity in the corrugated channel varied from about *0.76 mm/s* to *2.6 m/s*, which corresponds to Reynolds number based on the average channel height *Re=0.6* and *Re=2100*, respectively. The channel length is probably too short to allow for fully developed flow instabilities to occur spontaneously. However, it is assumed that initial spanwise flow disturbances generated by the strongly divergent flow inlet may become amplified by the wall waviness, if the theoretical prediction [10,11] is correct. The

microPIV velocity measurements and the flow visualisation of single florescent traces are done. These experiments aim identification of the critical Reynolds number. The microPIV measurements provide quantitative data about development of flow field disturbances. Long time exposure of single florescent traces are used to indicate possible spatial fluctuations of observed streaklines.

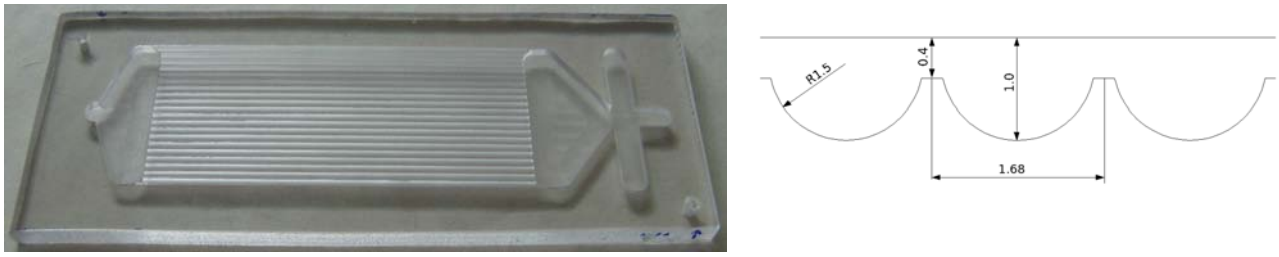

Figure 2. Left: experimental channel with 20 spanwise wall corrugations. The top wall is flat for better optical access; right: cross section of the channel with dimensions of the corrugations (in mm).

NUMERICAL

Finite–volume package Fluent 6.3 (Ansys Inc.) is used to generate the computational grid and to perform stability analysis using unmodified three-dimensional set of Navier-Stokes equations (DNS). The DNS model allows obtaining accurate, unsteady solution of unmodified Navier-Stokes equations by resolving the whole range of spatial and temporal scales of the turbulence. In our case the main aim of the simulation is to identify presence of instability modes and the critical Reynolds number for their amplification. All the spatial scales of the turbulence must be resolved in the computational mesh. Hence, very fine mesh and small time steps are used (typical 10^{-7}s). The direct numerical simulation (DNS) performed with the classical finite volume code implemented in *Fluent* is time consuming and vulnerable. Nevertheless, it appeared that for both investigated geometries it was possible to obtain reasonable solutions reproducing typical for the turbulence flow characteristics.

Short microchannel. The numerical domain used in the simulations of flow in the short microchannel describes full 3D geometry of the whole device, including 97.5 mm long inlet and 78.5 mm long outlet. Preliminary estimation of the Kolmogorov scales shows that smallest flow structures should be about 1μm in size with time scale below 1μs. According to this estimation structural hexahedron mesh with boundary layer was generated in the gap and in the vicinity of the processing element. The tetrahedron mesh was used in the remaining parts of the computational domain. It was found that sufficient accuracy of the numerical model was obtained for the gap mesh of 50x60x50 nodes (smallest distance between gap mesh nodes was about 3μm), fine enough to resolve expected Kolmogorov microscale. The total number of computational cells for the whole domain was over 1.7 mln. Detailed parameters used for modeling flow in the short microchannel are those collected in [8]. Simulations performed covered four flow rates, corresponding to the microchannel Reynolds number 1000, 1800, 3300 and 6770.

Corrugated wall. Numerical simulation of instabilities growth in the channel must assume long enough (theoretically infinite) channel length. Hence, computational domain used for simulating flow in the corrugated channel assumed periodic boundary conditions for the inlet and outlet. For the spanwise direction two sets of performed computations included either periodic boundary conditions or two side walls limiting computational domain [11]. For the first case (fully periodic boundary conditions) total number of elements was about 0.4mln. Inclusion of side walls increased this number from 0.7mln for five corrugation periods to 23.4mln elements for full 20 periods of wall corrugation. The last configuration reproduces the experimental geometry. However, due to

prohibitive computational time most of the numerical solutions are obtained for fully periodic computational domain or domain with five periods of corrugation limited by two side walls.

RESULTS

Short microchannel

In order to quantify the turbulence in the channel, the ensemble-averaged velocity fields are calculated at each of seven selected location before, within, and behind the microchannel (Fig. 1). Measurements were repeated up to hundred times at the same position to obtain sufficient statistics [8]. With 5 flow rates, 70 areas interrogated by microPIV measurements, and in average 50-100 measurements taken for each position, the total number of evaluated flow fields exceeds 50,000.

Velocity measurements performed at two positions P_1 and P_2 within the gap indicate that the flow through the gap is practically laminar, even for the highest applied flow rate no large temporal flow field fluctuations could be found. The streamwise velocity of the flow rapidly increases in the vicinity of the entrance to the gap, but turbulent fluctuations remain low despite high flow Reynolds number (6770). Velocity measurements at the gap exit (P_2) show development of the first instabilities (Fig. 3a). Behind the gap streamwise flow velocity decreases and strong recirculation zone with the reversal of flow can be found in the region behind the processing element [7,8]. The turbulent fluctuations of the velocity field and break-up of the flow symmetry, observed in this region, indicate that probably transition from laminar to turbulent flow regime occurs there.

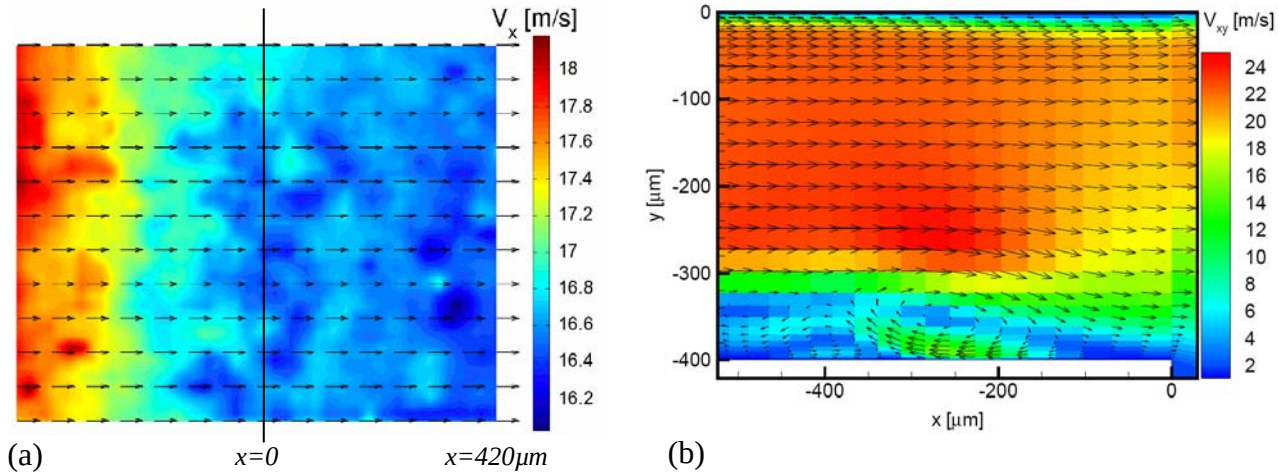

Figure 3. (a) - flow structure measured by micro-PIV at the *x-z* horizontal plane located in the mid-height (*y=-0.2 mm*) of the outlet region of microchannel (half of the field covers region in the microchannel and half behind it). (b) - temporary flow structure at the vertical symmetry plane of outlet region of the microchannel obtained form DNS simulation. Contours colored by the velocity magnitude.

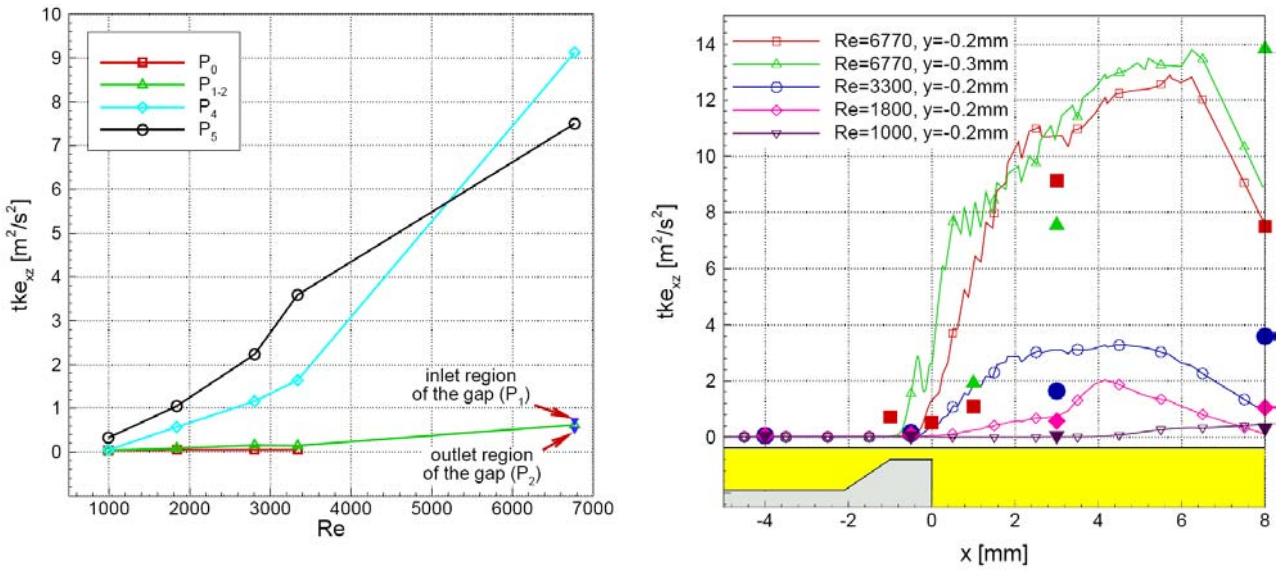
Numerical modeling confirms main details of the velocity flow field measured by the micro-PIV method. For the highest flow rate a small vortex in the bottom part of microchannel outlet region (Fig. 3b) could be found. It indicates place where flow destabilization is initiated, propagating downstream to the outer region. Both experimental data (Fig. 4a) and DNS simulations (Fig. 4b) indicate that intensity of turbulence (turbulence energy tke_{xz}) remains relatively low before and in the microchannel, rapidly increasing downstream from the gap. However, the turbulent kinetic energy values estimated form the numerical model and from the PIV measurement are only in a qualitative agreement (Fig.4b). Visible quantitative differences are believed to be mainly due to limited accuracy of the micro-PIV measurements and missing data for the third velocity component (comp. [7,8]).

The numerical data are used to reevaluate Kolmogorov microscales within the microchannel. It appears that even for the highest Reynolds number Kolmogorov length and time scales amount within the gap about 1mm and 1s, respectively. It confirms experimental findings that in spite of relatively high Reynolds number the velocity fluctuations are very small and flow within the microchannel seems to be laminar.



(a) (b)

Figure 4. (a) - turbulent kinetic energy tke_{xz} as a function of Reynolds number evaluated from the PIV data *0.2 mm* below the top wall (*y = -0.2 mm*) at 4 different locations along the experimental model ($P_0 – P_5$); (b) – variation of turbulent kinetic energy tke_{xz} evaluated from DNS results along the computational domain, given for two vertical positions: *y=-0.2 mm* (red line) and *y=-0.3 mm* (green line) below the top wall. Filled symbols indicate corresponding experimental data.

Corrugated wall

The transversal flow disturbances are generated across the whole channel width, interacting in a complex way with all 20 corrugations (Fig. 2). Flow pattern in the corrugated channel was visualized using long time exposure (120 ms) of single florescent traces. These experiments allow for fast identification of the critical Reynolds number. At low flow rates the particle tracks exhibit straight lines. Increasing flow rate the wavy character of particle tracks reveals emerging transversal flow disturbances. Our preliminary experimental study [11] shows that transversal velocity fluctuations can be visualized by particle tracking at least for the flow Reynolds number *Re = 120* (Fig. 5). The wavy motion of the tracer implies presence of the transversal velocity component.

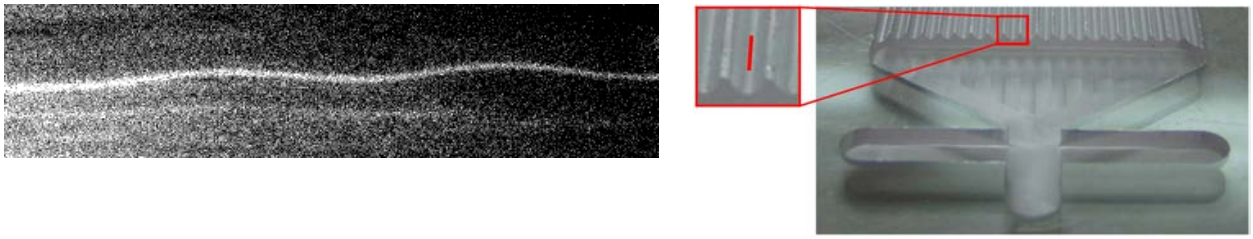


Figure 5: Left: trace of the fluorescent particle recorded in the corrugated channel (Fig. 2). The image width corresponds to 0.3mm, illumination time is *0.12s*, flow Reynolds number *Re = 120*. Right: position in the channel, where particle trace was recorded.

Micro-PIV measurements performed within the channel were used to obtain the flow disturbances. Proper understanding of the full structure of the analysed flow needs recombination of several sets of single flow fields obtained at different locations across the channel, and at its different depths. The typical disturbed velocity field structure obtained by means of micro-PIV is given in Fig. 6a. The mean flow is subtracted to reveal transversal velocity components. Due to the small interrogated flow area (0.85 mm x 0.68 mm) only flow in the vicinity of a single corrugation can be shown. Nevertheless, one may find that local spanwise flow disturbances are present, indicating emerging flow instabilities.

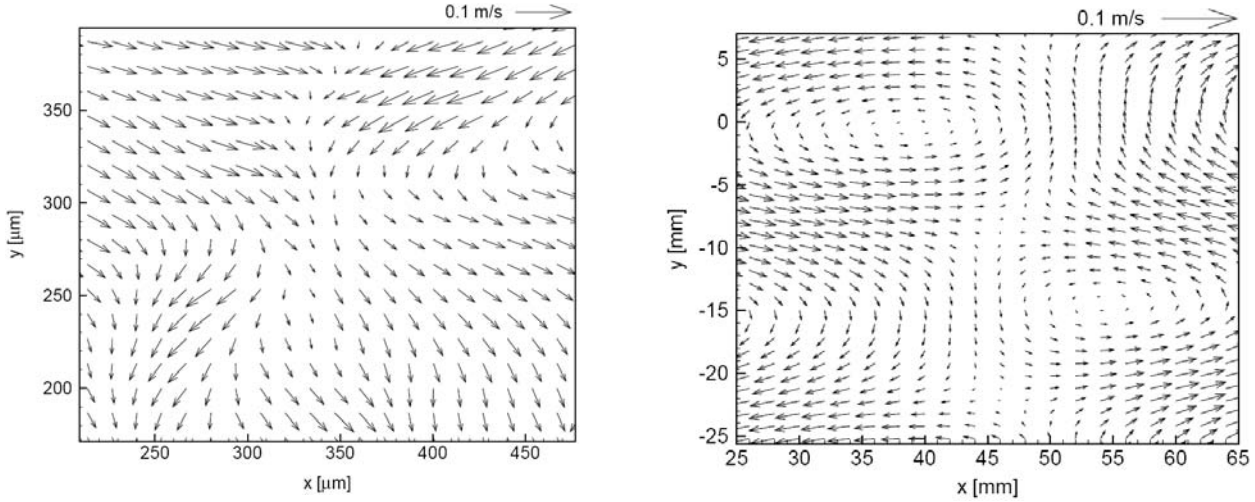

Figure 6. (a) Velocity field fluctuations measured in the corrugated channel *0.2 mm* below the upper wall, Reynolds number *Re = 200*; (b) - flow fluctuation predicted by the numerical simulations for the symmetry plane, flow Reynolds number *Re = 100*.

Numerical simulations performed for the corrugated channel confirmed generation of transversal instability modes for flow Reynolds number as low as *100*. It was found that for the flow with Reynolds number *Re = 100* small initial flow disturbances are quickly amplified and after about 200 s fully developed unsteady flow is observed [11]. The flow velocity field extracted from the numerical solution for the channel central cross-section (Fig. 6b) well reproduces predicted by the linear stability analysis space periodic counter-rotating vortices [10] travelling in the streamwise direction. It seems evident that the introduced wall waviness generates spanwise instabilities propagating along the channel and disturbing the flow structure. The new unstable flow pattern, which emerges form the unstable mode have complex three-dimensional structure promoting mixing properties of the channel flow. It is interesting to note that numerical model indicates that presence of the side walls (confined channel) does not significantly change this picture.

CONCLUSIONS

Experimental and numerical investigations demonstrated that flow pattern within the short, nearly two-dimensional microchannel remains laminar even for Reynolds number well above 6000. Obviously small channel dimensions are responsible for damping the development of classical cascade of turbulent vortices. This fact may have an important impact on design of emulsifiers [8], or microchannel heat exchangers. On the other hand it is shown that proper modification of the micro-channel walls may lead to flow destabilization already at Reynolds numbers about 100. This effect predicted by the theoretical study [10] is confirmed both numerically and experimentally.

ABSTRACT. The pressure-sensitive paint (PSP) has potential as a diagnostic tool for pressure measurement in the high Knudsen number regime, because it works as a so-called "molecular sensor". However, there are few reports concerning application of the PSP to micro-flows, because the conventional PSP is too thick owing to polymer binder. In our previous work, we have adopted Langmuir-Blodgett (LB) technique to fabricate a pressure sensitive molecular film (PSMF). In this study, we constructed four samples of PSMFs whose luminophore was Pt(II) Mesoporphyrin IX (PtMP), Pt(II) Mesoporphyrin IX dimethylester (PtMPDME), Pt(II) Protoporphyrin IX (PtPP) and Cu(II) Mesoporphyrin IX dimethylester (CuMPDME), respectively. The pressure sensitivity of those PSMFs were tested, and it is clarified that the PSMF composed of PtMP has the highest pressure sensitivity among the four and has equivalent pressure sensitivity of conventional polymer PSPs (e.g. PtOEP/GP-197). Moreover, we have applied PSMF to pressure measurement of a gas flow through the 170μm width micro-channel, and the pressure distribution on the surface along the channel was successfully obtained.

INTRODUCTION

For the development of micro- and nano-technology with small characteristic length and semiconductor process technology under high vacuum environments, it has been strongly desired to understand thermo-fluid phenomena around a device such as magnetic head slider of hard disk drive, micro thruster for micro satellite, and semiconductor thin film fabrication system and so on. Optical measurement techniques based on emission and absorption of photons by molecules are useful tools for the experimental analyses of high Knudsen number flows. However, the experimental techniques are behind in development compared with numerical simulation techniques. In particular, there are no appropriate techniques for measurement of gas pressure on a solid surface inside micro-systems. To measure pressure distribution in high Knudsen number regimes, we have adopted a pressure sensitive paint (PSP) technique [1]-[2]. Because the PSP works as a so-called "molecular sensor", it seems suitable for analyses of high Knudsen number flows, which require diagnostic tools in the molecular level. However, application of the PSP to micro-devices is very difficult, because the conventional PSPs are very thick compared to the dimension of micro-devices owing to the use of polymer binders. Moreover, they do not have sufficient spatial resolution for pressure measurement of micro-flows because of the aggregation of luminescent molecules in polymer binders [3].

In the previous study, we have developed pressure sensitive molecular films (PSMFs) by using Langmuir-Blodgett (LB) technique [4] to construct ordered molecular assemblies, and have tested

the PSMF to clarify the feasibility of the pressure measurement around micro-devices [5]. PSMF with nanometer order thickness and high spatial resolution is suitable for analyses of micro-flows. The PSMF based on Pd(II) Mesoporphyrin IX (PdMP), which is used as luminescent molecules, has been fabricated and it is clarified that the pressure sensitivity of PSMF of PdMP is sufficiently high [5]. However, the PSMF composed of PdMP cannot be applicable to the pressure range higher than 130 Pa due to saturation of oxygen quenching of PdMP; this is caused by the long life time of PdMP, which is so long (1.0msec [6]) that most of luminescent molecules are quenched. It is desired for PSMF to work around the atmospheric pressure, because the most micro-devices are used in the atmospheric pressure. In order to fabricate a useful PSMF for atmospheric pressure range, we constructed four samples of PSMFs composed of Pt(II) Mesoporphyrin IX (PtMP), Pt(II) Mesoporphyrin IX dimethylester (PtMPDME), Pt(II) Protoporphyrin IX (PtPP) and Cu(II) Mesoporphyrin IX dimethylester (CuMPDME), respectively. Those luminescent molecules have shorter life time compared with PdMP (e.g. the life time of PtMPDME and CuMPDME are 0.14msec and 0.1msec, respectively [6]).

RELATION BETWEEN PRESSURE AND LUMINESCENT INTENSITY

The pressure measurement technique using PSP is based on oxygen quenching of luminescent molecules. PSP is composed of luminescent molecules and a binder material to fix the luminescent molecules to a solid surface. When the PSP layer applied to the surface is illuminated by UV light, the luminescent molecules are excited by absorption of photon energy, and then the molecules emit phosphorescence. On the other hand, oxygen molecule with triplet ground state acts as a quencher of the luminescence. As a result, the phosphorescence intensity decreases as an increase in partial pressure of oxygen. Pressure on the solid surface can be deduced from the relationship between pressure and the luminescence intensity (Stern-Volmer plot [1]).

$$\frac{I_{ref}}{I} = \sum_{n=0}^{N} A_n \left(\frac{P}{P_{ref}} \right)^n , \tag{1}$$

where I is the luminescence intensity and P is the oxygen pressure. I_{ref} is the luminescence intensity at the known reference pressure P_{ref}. The coefficients A_n are the constants called as Stern-Volmer coefficients determined by calibration tests. The luminescence intensity I of the ideal PSP (N = 1) depends inversely on P following to Eq. (1), but the actual PSPs have nonlinear dependence of I^{-1} on P. In practice, a second-order polynomial (N = 2) is commonly used. In the PSMF, however, the relation of the luminescence intensity I and P is different from that of PSP, because the quenching rate of PSMF is dominated by adsorbed oxygen molecules on the surface of PSMF. The adsorption quantity is determined by Langmuir adsorption isotherm. Then, the relationship between pressure P and the luminescence intensity I can be written as following equation.

$$\frac{I_{ref}}{I} = B_0 + B_1 \frac{P / P_{ref}}{P / P_{ref} + \alpha} , \tag{2}$$

where B_n are the Stern-Volmer coefficients.

EXPERIMENTAL METHODS

Fabrication of pressure sensitive molecular film

In this study, we have adopted Langmuir-Blodgett (LB) method to fabricate a pressure sensitive molecular film (PSMF) with ordered molecular structure applicable to pressure measurement around micro-devices. The LB method provides us with capability to construct ordered molecular assemblies. LB films are fabricated according to the following procedure. At first, a drop of a dilute solution of amphiphilic molecules in a volatile solvent is spread on the interface between air and subphase. After the solvent is evaporated, a monolayer of the molecules remains on the interface. The monolayer is transferred to a substrate with compressing the monolayer so as to control the order of the molecules (see Fig. 1).

Experimental apparatus

Figure 2 shows the experimental apparatus composed for this study. The PSMF samples were applied to glass plates, and the specimens were set inside a vacuum chamber evacuated by a scroll pump (ULVAC DVS-631) and a turbo molecular pump (ULVAC UTM-1500). Pure oxygen gas was supplied into the chamber, and the pressure in the chamber is monitored by a capacitance manometer and an ionization vacuum gauge. A xenon-arc lamp (USHIO UXL-500SX) with a band-pass filter (400±20 nm) was used as an excitation light source illuminating the specimen via an optical fiber. The luminescence was filtered by a long-pass filter (600 nm) to eliminate the light from the xenon-arc lamp, and was detected by an EM-CCD camera (Andor Technology DV887AC-UV, 512×512 pixels, 14 bit). The image of the luminescence was processed by a personal computer.

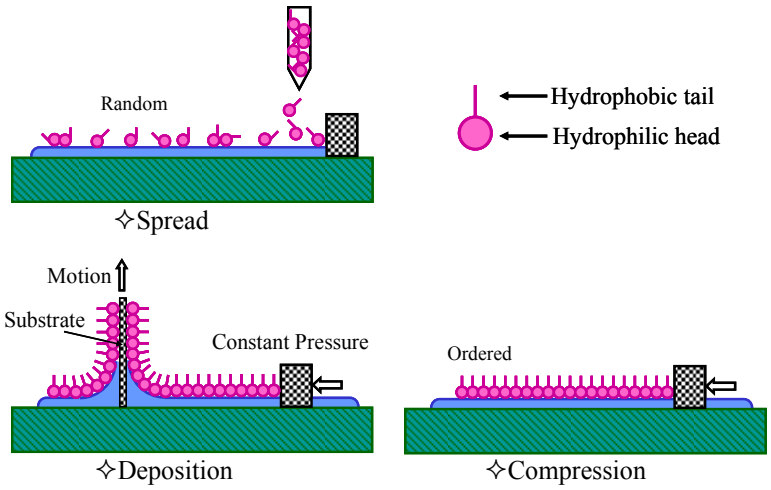

Figure 1. A schematic process of LB method.

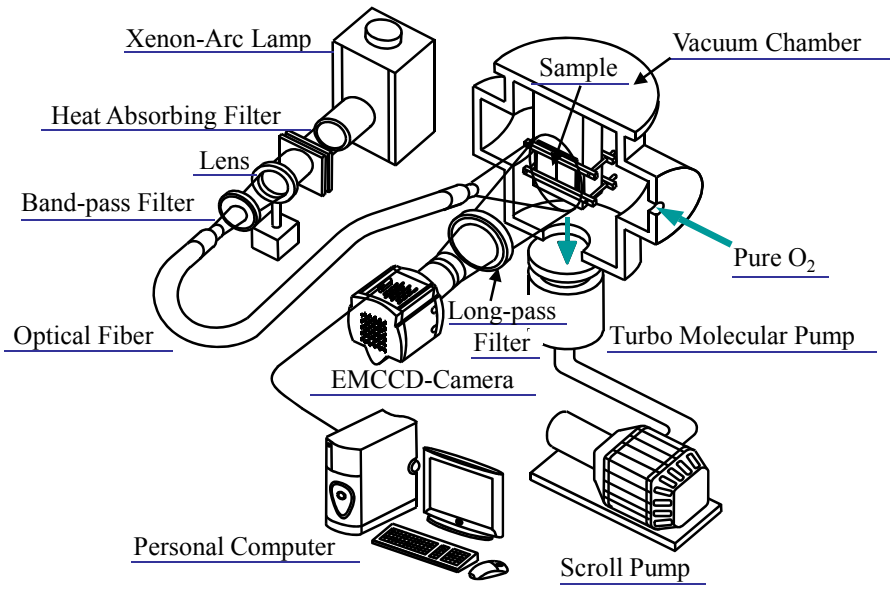

Figure 2. Experimental apparatus.

RESULTS AND DICUSSIONS

Pressure sensitivity of pressure sensitive molecular film

Figure 3 shows the pressure sensitivities of the PSMFs composed of PtMP, PtMPDME, PtPP and CuMPDME below 21kPa (equal to the partial pressure of oxygen in atmospheric pressure). The horizontal axis of the Stern-Volmer plot is the normalized pressure p/p_{ref} and the vertical axis is the inverse luminescent intensity ratio I_{ref}/I, where I_{ref} is the reference luminescent intensity at the reference pressure p_{ref}=1.0x10^{-2} Pa. It is clarified that the pressure sensitivity of PSMF-PtMP is highest among the four tested PSMFs and is comparable to that of conventional PSPs (e.g. PtOEP/GP-197[1]). In contrast, PSMF-PtPP and PSMF-CuMPDME have little pressure sensitivity. These results indicate that both PtPP and CuMPDME are nearly insensitive to oxygen molecule.

Pressure measurement in micro-channel gas flow

As an application of our PSMF to pressure measurement of micro-scale gas flows, we measured the pressure distribution of the micro-channel. The high pressure camber of the micro-channel is connected to the supply port of mixed gas (N_2: 79%, O_2: 21%) and the low pressure camber is connected to the outer port evacuated by vacuum pump. The channel width is 170μm and the length is 270μm. The stagnation and the downstream pressure were set at 11.5kPa and 1.4kPa, respectively. Since both the inlet port and outlet port are attached far from the micro-channel, the effect of inlet and outlet condition can be negligible. The luminescent of PSMF is detected by a fluorescence microscope.
Figure 4(b) shows the pressure fields of micro-channel obtained by the measurement using the PSMF-PtMP and by Direct Simulation Monte Carlo (DSMC) method [7]. Both results obtained by PSMF and DSMC are in agreement with each other. These results show the usefulness of our PSMF for measurement of micro-scale gas flows, although PSMF result contains noticeable noise, because the amount of luminescent molecules of PSMF is smaller than that of conventional PSP.

Figure 4. Pressure fields of micro-channel obtained by PSMF-PtMP.

CONCLUSIONS

In this study, the following results are obtained:

1. We fabricated PSMF composed of Pt(II) Mesoporphyrin IX (PtMP). It is shown that PSMF of PtMP has higher pressure sensitivity compared with PSMF of Pd(II) Mesoporphyrin IX (PdMP) below 11kPa, and PSMF of PtMP has enough pressure sensitivity in the range from 0kPa to 21kPa of oxygen pressure.
2. The pressure distribution of micro-scale gas flow was measured using PSMF, showing the usefulness of our PSMF for measurement of micro-scale gas flow.

MICROLAYER CONFIGURATION IN NUCLEATE POOL BOILING FOR WATER

Y.Utaka[1,*], K.Nakamura[2], Y.Kashiwabara[1]
[1]Yokohama National University, Yokohama, Japan
[2]Hitachi Appliances, Hitachi, Japan

ABSTRACT**.** The objective of the study is to clarify the configuration of a microlayer formed between the vapor bubble and the heat transfer surface in nucleate pool boiling of an isolated bubble region. The microlayer thickness was measured using specially devised measurement system by applying the laser extinction method. A thin optic fiber in a thin stainless tube was inserted into the liquid pool with the gas blowing both for preventing the getting wet of fiber made of fluorinated glass and removing the liquid in the path of laser light. The process of bubble growth was recorded with the two high speed cameras. It was elucidated that the thickness of the initially formed microlayer was decided uniquely. The thickness was between 1 μm and 8 μm and was increased with the increase of distance between incipient bubble site and measuring position regardless of heat flux in this experiment.
Keywords: *pool boiling, phase change, microlayer, isolated bubble region, laser extinction method*

INTRODUCTION

Nucleate boiling is a widely used in industry due to its good heat transfer characteristics. However, there are unknown factors about the heat transfer mechanisms of nucleate boiling due to the physicochemical factors, such as in the process of the bubble nucleation, bubble growth, bubble behavior, phase changes at the liquid-vapor interface.

As the mechanisms of heat transfer in nucleate boiling, the convective heat transfer and the latent heat transfer have been proposed. The mechanism of the convective heat transfer is based on the diffusion of thermal boundary layer by bubble behavior and sensible heat transport. The mechanism of the latent heat transfer is based on the conversion of sensible heat stored in superheated liquid layer to bubble growth and vaporization of the microlayer formed between the growing bubble and heat transfer surface. Although the mechanisms of heat transfer in nucleate boiling were examined from viewpoint of the above, the quantitative discussions were insufficient. Especially, the heat transfer characteristics of microlayer evaporation, in which a large amount of heat transport occurs by latent heat of evaporation, are thought to be important. Therefore, clarification of the configuration of the microlayer is of fundamental importance.

Concerning the thickness of the microlayer in nucleate boiling, the presence of the microlayer was clarified, and its thickness of 4.2 μm for water in the gap between the heat transfer surface and the window parallel to the surface by the interferometric method was measured by Sharp [1]. Jawurek [2] measured the microlayer thickness of 0.5 μm for ethanol on a glass surface. Furthermore, Voutsinos and Judd [3] measured the thickness of dichloromethane to be 1 μm to 6 μm, and the thickness increased with the increase of distance from the bubble incipient site. Also, the theoretical

model was proposed by Cooper and Lloyd [4] for the prediction of microlayer thickness, experimental validation of the prediction does not show sufficient correspondence.

In this study, the laser extinction method was used with a specially device to make non-contact measurements using a thin optic fiber in a thin stainless tube with a gas blowing. By applying this method, the objective of this study is to clarify the characteristics of the microlayer configuration by direct measurement of the thickness of the microlayer formed underneath the vapor bubble and by observation and measurement of vapor bubble behaviors using two high-speed cameras.

NOMENCLATURE

h : height from the heat transfer surface to the optic fiber front edge [m]

I : laser intensity through microlayer [-]

I_0 : reference laser intensity [-]

q : heat flux [W/m^2]

r_L : distance between bubble site and measurement position [m]

R_M : radius of microlayer on heat transfer surface [m]

R_{Mmax} : maximum radius of microlayer [m]

t : elapsed time from generation of bubble [s]

t_g : elapsed time before formation of initial microlayer [s]

δ : microlayer thickness [m]

δ_0 : initial microlayer thickness [m]

EXPERIMENTAL APPARATUS AND METHOD

Figure 1 shows the experimental apparatus used in the present study. The apparatus is composed of a boiling system for water at atmospheric pressure and a measurement system for the transmission ratio of laser light. As the heat transfer plate, a 2-mm-thick quartz glass plate with high transparency for laser light was attached to the bottom of the boiling chamber. The test water in the boiling chamber was maintained at the saturation temperature by heating with surrounding electric heater. The rear side of the cavity on the heat transfer surface was heated by impinging a jet of hot nitrogen gas from a nozzle having an inner diameter of 2 mm at an angle of 60° for bubble generation from the fixed point. The mechanism for the adjustment of the position of fiber optic equipment was placed on top of boiling container. The velocity of the nitrogen jet was approximately 180 m/s, and the temperature of the jet was changed from 513 to 673 K for adjustment of the heat flux. Heat flux was determined by iteration for the overall heat transfer system using the heating-side heat transfer coefficient obtained from the flow rate and the temperature of the nitrogen jet, and the boiling heat transfer coefficient from the boiling characteristic curve [5].

A helium-neon laser light with a wavelength of 3.39 μm and a detector made of Pb-Se were used in the laser light transmission ratio measurement system. Fig.2 shows the principle of the laser extinction method used to measure the thickness of the microlayer. The intensity of the laser light is

reduced by scattering and adsorption in the microlayer formed under the bubble on the heat transfer surface, and the intensity ratio of transmitted light to incident light can be determined. Laser light from an oscillator was concentrated and directed through a 94 μm diameter optical fiber with high transmission for infrared light. The intensity of transmitted light, I_0, was determined by detecting the intensity through the air and a dry heat transfer plate. The thickness of the microlayer could then be determined by application of Lambert's law, as shown in equation (1):

$$e^{-A\delta} = \frac{I}{I_0} \tag{1}$$

where A is the extinction coefficient of water, which is 5.42×10^4, as measured by Utaka-Nishikawa [6].

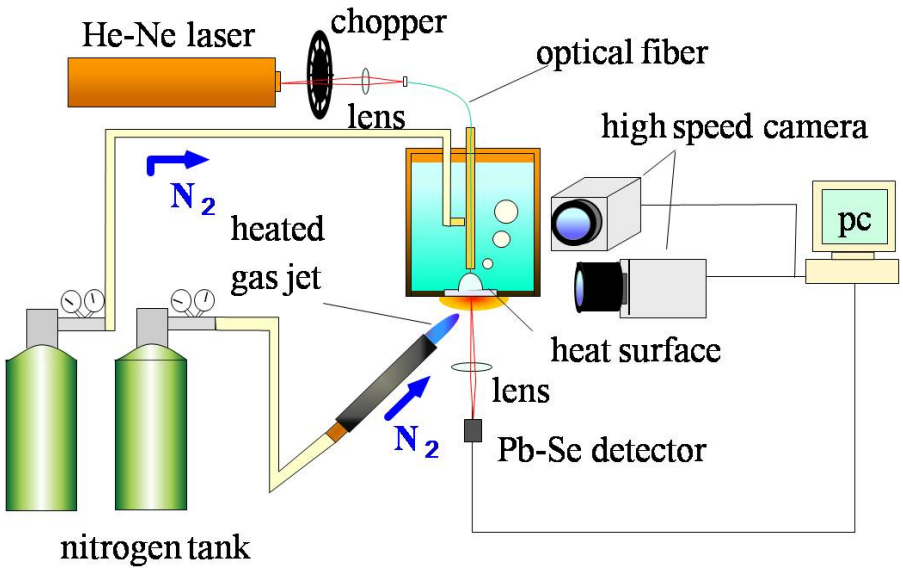

Figure 1. Schematic diagram of experimental apparatus

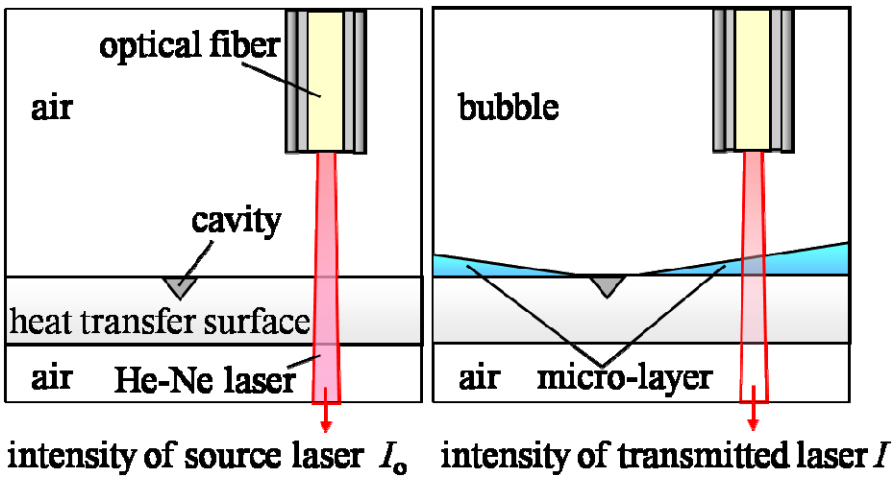

Figure 2. Principle of the laser extinction method

The laser extinction method used in the present study is based on the nature of extinction of infrared light in the test liquid, so that the bulk liquid must be removed from the pathway of the laser in the pool and optical fiber made of fluorinated glass must be prevented the getting wet. Therefore, a thin stainless steel tube having a diameter of 0.4 mm was used to cover the optical fiber and confine the nitrogen gas blowing in the apparatus, as shown in Figure 3. The detailed structure of the laser light emitting apparatus is shown in Figure 4, in which the optical fiber is installed inside the thin stainless steel tube and located at the position of bubble generation. The gas blown through this tube coalesced with the vapor bubble, so that the effect of the bulk liquid could be removed. Furthermore, there was a possibility that a thin liquid film could form between the nitrogen gas bubble and the vapor bubble. Therefore, fine wires having diameters of 70 μm were attached to the tip of the stainless steel tube in order to break the film.

The aspect of boiling was simultaneously recorded with laser signal by using two high-speed digital cameras with a maximum frame rate of 5,000 fps at two orthogonally oriented directions from the plane of the heat transfer surface, and this data was used to develop the distance measurement from the incipient bubble point.

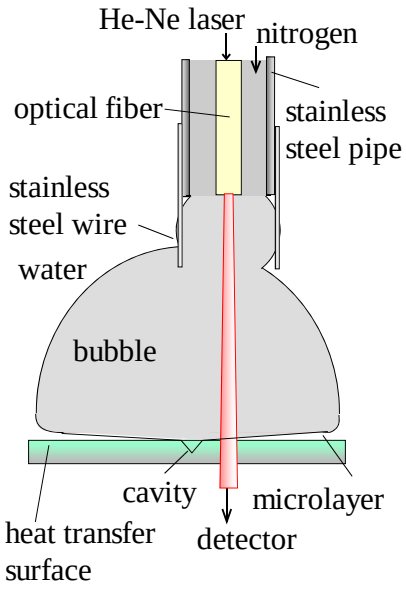

Figure 3. Method for measurement of the microlayer thickness

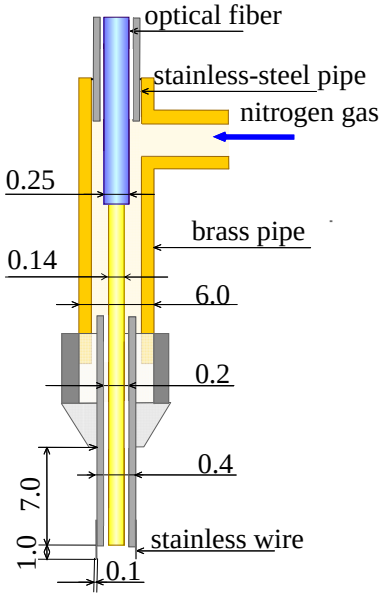

Figure 4. Details of the fiber equipment (dimensions are in mm)

EXPERIMENTAL RESULT AND DISUCUSSION

Effect of the height from the heat transfer surface to the optical fiber front edge

Measurements were performed for three heat flux conditions by varying the distance from the incipient bubble site to the light axis on the surface r_L , and the distance between the tip of the optical fiber and the heat transfer surface *h*, as shown in Figure 5. In general, since there is a spread angle from the fiber exit, it is possible to minimize the irradiation area by shortening the distance from the heat transfer surface. However, in the range of smaller *h*, that is, when the tip of the fiber is near the heat transfer surface, the fiber apparatus prevents nucleation of the bubble due to the disturbance of the superheated layer near the surface. Therefore, the experiment was carried out with a distance *h* of greater than 2.3 mm. Next, measurement of the laser irradiation area and intensity distribution on the surface was performed in order to determine the measurement area for the microlayer thickness. Figure 6 shows the intensity distribution on the surface, which confirms the straight nature of the laser light in this system. This indicates that the effect of changing *h* is not significant in the range *h* > 2.3 mm. The irradiation area was 0.3 mm in diameter for the case of *h* = 3.3 mm, which was a typical distance used in the present study.

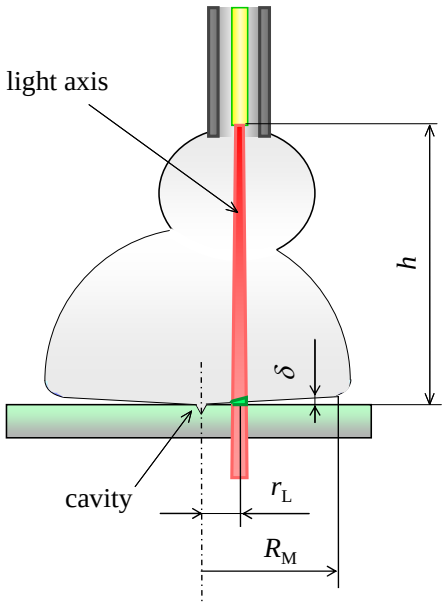

Figure 5. Parameter notation

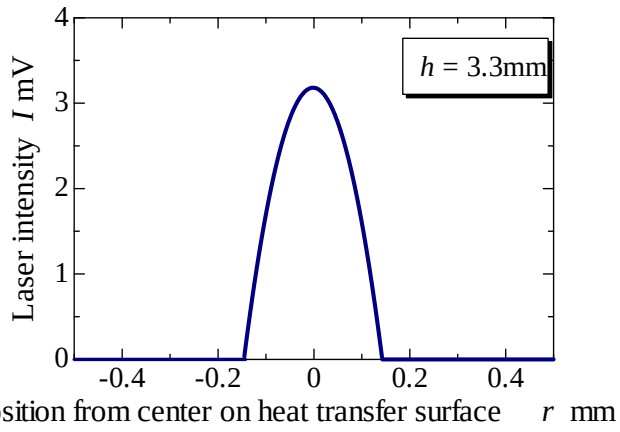

Figure 6. Distribution of laser intensity

Variation of microlayer thickness

Figure 7 shows a typical example of variation in microlayer thickness when the height of the fiber h = 3.3 mm the distance from the incipient site r_L = 0.39 mm and the heat flux q = 50 kW/m^2. It is impossible to measure the thickness of the microlayer, because there is bulk liquid present between the bubbles of gas and vapor, and most of the laser light fraction is absorbed and scattered by the bulk liquid immediately after bubble generation. After just a few moments, the effect of the bulk liquid disappears, with partial extinction of the laser light by the microlayer, so that measurement of the microlayer thickness becomes possible when the vapor bubble reaches the thin stainless steel tube in which the optical fiber is installed. The initial microlayer thickness was approximately 1.5 μm, and the thickness was reduced by the effect of evaporation over time. Since the film thickness was zero at approximately t = 20 ms, a dryout area appeared.

As shown in Figure 8, the initial microlayer thickness δ_0 can be defined as the thickness appearing at the time just after the microlayer forefront moves past the measurement point and the microlayer is formed. In most cases, it is not possible to measure the thickness of the initial microlayer. Therefore, the initial microlayer thickness is determined by extrapolation of the linear line fitted using the least squares method to the domain of the straight change. The average value of correction used for the microlayer thickness was approximately 0.5 μm.

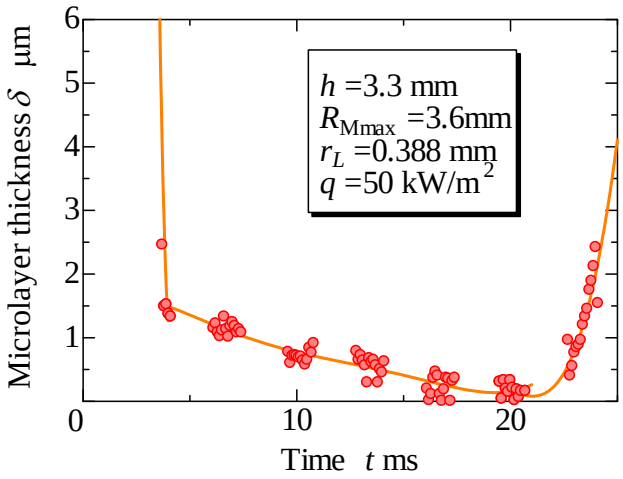

Figure 7. Variation of microlayer thickness

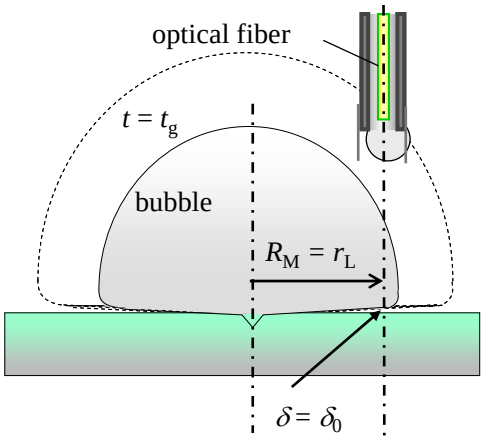

Figure 8. Definition of the initial microlayer thickness measurement

Distribution of microlayer thickness

Figure 9 shows the variation of initial microlayer thickness δ_0 as a function of the measurement position r_L. The microlayer grew to a radius of around 2-4 mm on the heat transfer surface. The radius of microlayer was approximately 80% of the vapor bubble radius in the horizontal direction. The initial microlayer thickness δ_0 was increased with the increase of the distance from the bubble initiation site, and its thickness was approximately 1-8 μm. Furthermore, since the effect of heat flux on the microlayer thickness was slight, the linear curve shown in Figure 9 was fitted to all data by the least squares method under the assumption of zero film thickness $\delta_0 = 0$ at the incipient bubble site $r_L = 0$. The relationship between the distance from the incipient bubble site and the microlayer thickness is expressed by equation (2):

$$\delta_0 = 3.14 \times 10^{-3} \times r_L \tag{2}$$

Investigation of the precision of measurement

The variation of the extinction rate of the laser due to the change in microlayer thickness was determined in this measurement. The small irradiation area of the heat transfer surface was achieved by investigation of the relationship between the height of the laser exit from the optical fiber and the area of irradiation of the laser. Therefore, the dominant factor concerning the measurement accuracy was the fluctuation of the laser intensity and the characteristics of the detector. The variation of the detected laser intensity was measured by irradiating the laser to the detector under conditions to similar the experimental conditions. As a result, the maximum fluctuation of the detected intensity was 8.6%, as shown in Figure 10. This fluctuation value converted to a microlayer thickness of ±1.7 μm calculated from equation (1), as shown by the broken line in Figure 9. The microlayer thickness distribution expressed by equation (2) is thought to be reliable, because the error investigated above was relatively large compared to other error factors, and more than 90% of measured data were in the area between the two broken lines in Figure 9.

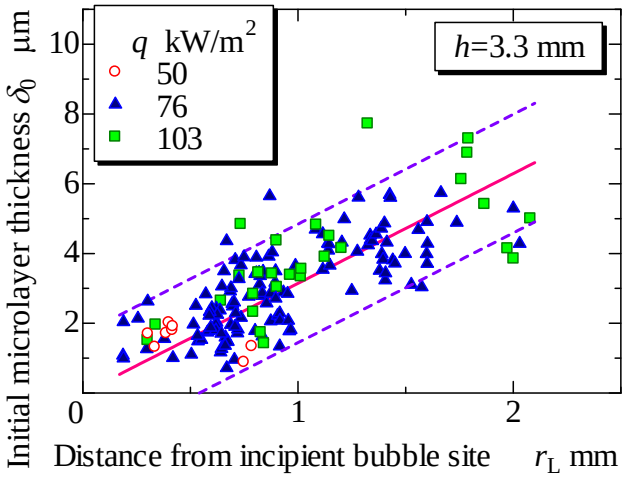

Figure 9. Variation of initial microlayer thickness with respect to the distance from the incipient bubble site

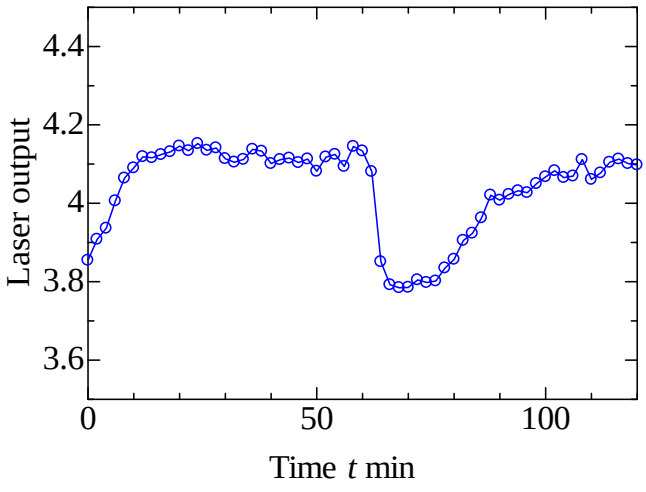

Figure 10. Variation of laser output with respect to time

CONCLUSIONS

The laser extinction method was used to elucidate the characteristics of the microlayer configuration in nucleate pool boiling by direct measurement of the microlayer thickness formed underneath the vapor bubble. The special device used both a thin optic fiber and a gas blowing system. The results are summarized as follows:

(1) The initial microlayer thickness was approximately 1-8 μm.
(2) The heat flux appeared to have little effect on the initial microlayer thickness.
(3) The initial microlayer thickness was increased with the increase of the distance from bubble initiation site. The relationship between the distance from the incipient bubble site and the microlayer thickness was expressed by the following equation:

$$\delta_0 = 3.14 \times 10^{-3} \times r_L .$$

(4) The microlayer thickness was reduced by the effect of evaporation.

ACKNOWLEDGMENTS

The authors would like to thank Mr.Akinori.Sakurai, Mr.Kunitoshi Itagaki and Mr.Hideyuki Sonoda, who were graduate students of Yokohama National University, for helping the experiment. A NOVEL PARTICLE MIXING METHOD WITH FREQUENCY SELECTION BASED ON AC ELECTROKINETICS

D. Akutsu*, M. Motosuke and S. Honami
Tokyo University of Science, Tokyo, Japan

ABSTRACT. In a microfluidic device, the utilization of electrokinetics is effective for fluid or particle control. Under high frequency alternating-current (AC) electric field over kilohertz, the effect of polarization emerges and the electric charge of particle can be neglected. The control of particles can be achieved in the condition with low voltage. In this frequency range, two kinds of phenomena involving dielectrophoresis and electrothermal effect exist. The purpose of this study is to investigate the potential of particle mixing technique based on the frequency-dependent AC electrokinetics. The behavior of polystyrene submicron particles suspended in water under the AC electric field with high frequency (1 ~ 300 kHz) was evaluated by means of micron-resolution particle image velocimetry. As a result, particle movement indicates drastic change with applied frequency. In addition, the quantitative assessment of mixing effect was conducted.

Keywords: *Microfluidics, AC electrokinetics, Particle mixing, Joule heating*

INTRODUCTION

The microfluidic devices have attracted considerable attention and have broadened their application fields in biology, chemistry, medical and mechanical engineering. However, there is a problem that a stable laminar flow in the channel inhibits the sorting and mixing of suspended particles. Therefore, efficient and versatile technique for microparticle control is strongly required. Many studies on particle control in the microfluidic device have been suggested and researched. For instance, a mixing promotion using the microchannel with a certain three-dimensional shape fabricated by MEMS (Micro Elecro-Mechanical Systems) technology has been studied [1]; however, the mixing method with complicated structure is lack of durability and tends to generate undesired pressure loss in the area for mixing. Also, there are other particle manipulation techniques with direct-current (DC) electrokinetics which include electrophoresis and electroosmosis [2]. In these methods, the influence of temperature rise in solution cannot be negligible because high voltage applied is needed in a minute area [3]. In the present study, we have focused on the high-frequency alternating-current (AC) electrokinetics. In the operation method using the AC electric field over kilohertz, charge of particle is cancelled and the effect of polarization becomes dominant. So, electrically neutral particle can be used in this frequency range. Phenomena under the AC electric field for particle manipulation focused in this study are dielectrophoresis (DEP) and electrothermal effect (ET). These phenomena are induced by low voltage with a simple electrode pattern. These phenomena occur simultaneously when an appropriate frequency is selected. The intensity and direction of these effects are determined by applied frequency and electrical properties of fluid and particle. Therefore, an appropriate selection of the frequency at each solution is essential for the particle mixing in the microfluidic device. In order to establish a novel mixing technique based on AC electrokinetics, it is necessary to understand the behavior of particles both under DEP and ET force. The evaluation of the mixing

effect including the frequency dependence is also needed. The objective of this study is the investigation of particle movement in detail and the evaluation of the mixing effect under the frequency dependent AC electrokinetics.

AC ELECTROKINETICS

Dielectrophoresis (DEP)

Dielectrophoresis is a phenomenon in which a force is exerted on a dielectric particle under nonuniform electric field. Since the polarization of the particle generates DEP force [4], the particle does not have to be charged. DEP force acting on a sphere particle suspended in a medium is given as follows.

$$\mathbf{F}_{\mathrm{DEP}} = \frac{1}{4}\pi\varepsilon_m d^3 \,\mathrm{Re}\left[\frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*}\right]\nabla|\mathbf{E}|^2 \tag{1}$$

$$\varepsilon^* = \varepsilon - \frac{\sigma}{\omega} j \tag{2}$$

Subscript *m* and *p* means medium and particle, respectively. The fractional factor in brackets is known as Clausius-Mossotti factor $K(\omega)$. Positive DEP occurs when $\mathrm{Re}[K(\omega)] > 0$, the particle is attracted to the area of high electric field. The converse of this is negative DEP which occurs when $\mathrm{Re}[K(\omega)] < 0$, the particle is toward the area of low electric field. The polarity of electric field does not have an effect on DEP force. The intensity and direction of the force strongly depend on the applied frequency and the electrical properties of fluid and particle.

Electrothermal effect (ET)

Electrothermal effect is a convection flow driven by electric field. This phenomenon is caused by gradient in electrical properties due to a nonuniform temperature field by the Joule heating [5]. The ET force acting on fluid becomes,

$$\mathbf{F}_{\mathrm{ET}} = -\frac{1}{2}\left\{\left(\frac{\nabla\sigma_m}{\sigma_m} - \frac{\nabla\varepsilon_m}{\varepsilon_m}\right)\cdot\mathbf{E}\frac{\varepsilon_m\mathbf{E}}{1+(\omega\tau)^2} + \frac{1}{2}|\mathbf{E}|^2\nabla\varepsilon_m\right\} \tag{3}$$

The first and second term in equation (3) represents the Coulomb force and the dielectric force, respectively. The intensity and direction of ET flow are also controlled by the frequency; positive- and negative- ET can be generated. In the positive ET, a body force exerts the fluid to flow from higher temperature area to lower one along the applied electric field gradient, and negative ET induces reversely-directed flow with positive ET.

Combination of DEP and ET

The two phenomena of DEP and ET occur simultaneously in a practical microfluidic device under AC electric field with nonuniformity. Four pattern of combination can be considered; p-/n- DEP and p-/n- ET. The contribution of each effect can be determined by the balance of electrical properties in particle and fluid associated with a frequency selection.

EXPERIMENTAL SETUP

Microfluidic device

A microfluidic device used in this study is fabricated with photo- and soft-lithography (see Figure 1). The microchannel structure made of PDMS (polydimethylsiloxane) is placed on a flat glass substrate with electrodes. The scale of the microchannel is 200 μm in width, 40 or 50 μm in height and 40 mm in length. The PDMS channel has a thin wall in one side. The substrate has an electrode pattern made of ITO (indium tin oxide). The electrode pattern is comb-shaped with the space of 25 μm. Two kinds of electrode patterns are fabricated, and the line of electrodes is 25 μm (narrow type) and 2 mm (wide type). PMMA (polymethylmethacrylate) reservoirs with inner diameter of 8 mm are served as the inlet and outlet. A difference in the liquid surface level at each reservoir causes stable pressure-driven flow in the microchannel. A fully developed laminar channel flow can be obtained in a measurement section because Reynolds number is 3×10^{-3}. The applied voltage and frequency were controlled by a function generator (FG) with the voltage of 1 ~ 3 $V_{p\text{-}p}$ at the frequency of 1 ~ 300 kHz.

Working fluid

Distilled water is used as the working fluid. Fluorescent polystyrene particles (PS) with the diameter of 720 nm are seeded to observe the particle behavior. Volume fraction of particles in the working fluid was approximately 0.048 %. Table 1 indicates the electrical properties of the working fluid and particle. Electrical conductivity of the fluid is measured and other properties are reference values [6].

Table 1
Electrical properties of working fluid

Conductivity (mS/m)		Relative permittivity	
Fluid	Particle	Fluid	Particle
1.4	10	67	2.25

Micro-PIV setup

As the measurement method, micro-PIV (particle image velocimetry) technique was employed in this study. This technique is based on the volume illumination and the detection of the movement of fluorescent particles in the focal plane of an objective lens. Figure 2 shows a schematic of the experimental system. This system has been developed around an inverted microscope. A continuous mercury lamp is used as an illumination source. The microscope consists of an objective lens (Obj; 20×, *NA* 0.4), a filter cube, and a zoom lens (ZL; 2.5×). The filter cube has an exciter filter (ExF), an emitter filter (EmF) and a dichroic mirror. We have developed a lateral observation arrangement by

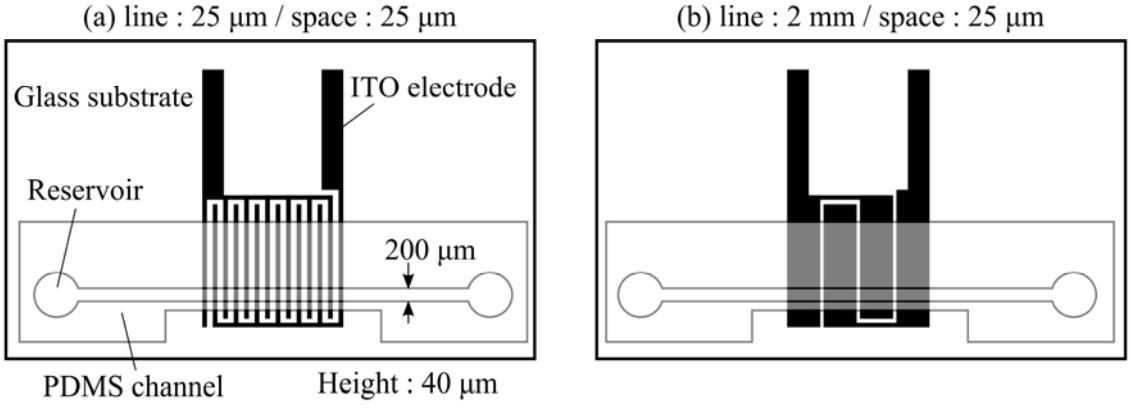

Figure 1. Microfluidic device (a) Narrow type (b) Wide type

using a minute reflection prism to obtain the particles movement in the cross-section normal to the electrode substrate. In this setup, the particle behavior is observed through the side PDMS wall (See Figure 3). The fluorescent image of PS is collected by Obj via the prism, and then coupled to a CCD camera (640×480 pixels, 12 bit). The excitation and emission wavelength of the fluorescent particles is 468 and 508 nm, respectively. Time interval between two images in a pair was 35 ms. In order to reduce the effect of diffusion due to the Brownian motion of the particles, time-average processing between 200 image pair is performed.

RESULTS AND DISCUSSIONS

Observation of frequency-dependent particle position

In order to observe the frequency-dependent AC electrokinetics in the fabricated microfluidic device, distributions of the particles were observed from the lower side of the microchannel. Each particle image was acquired immediately above 30 second after the voltage application. Figure 4 shows the distributions of fluorescent intensity in streamwise direction of the channel and the CCD images with the voltage of 1 $V_{p\text{-}p}$. The flow velocity at the center of the channel was about 50 μm/s. Here, the narrow electrode pattern with line of 25 μm is used. From Figure 4, it is obvious that the particle position is strongly influenced by the frequency. At 1 kHz, the peak fluorescent intensity

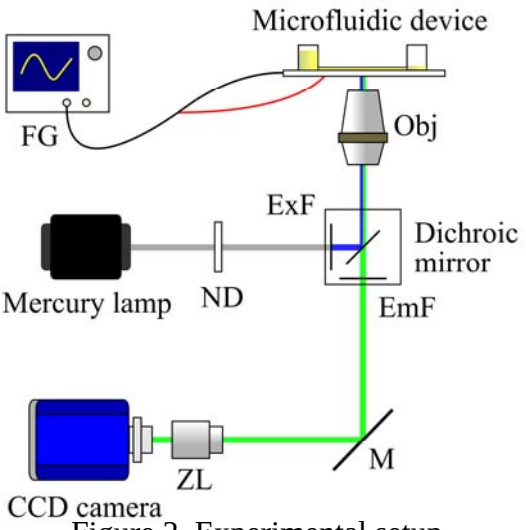

Figure 2. Experimental setup

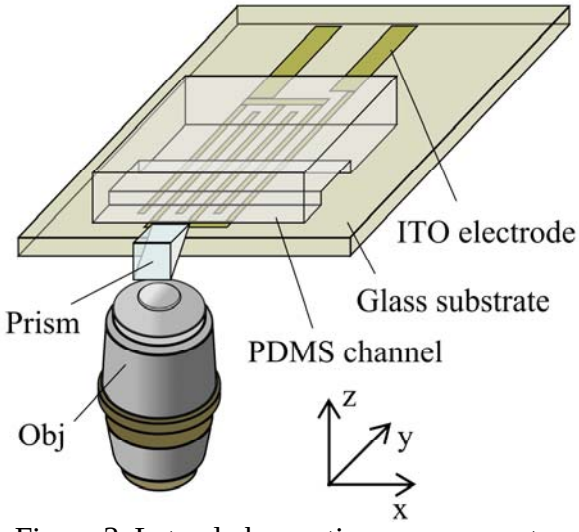

Figure 3. Lateral observation arrangement

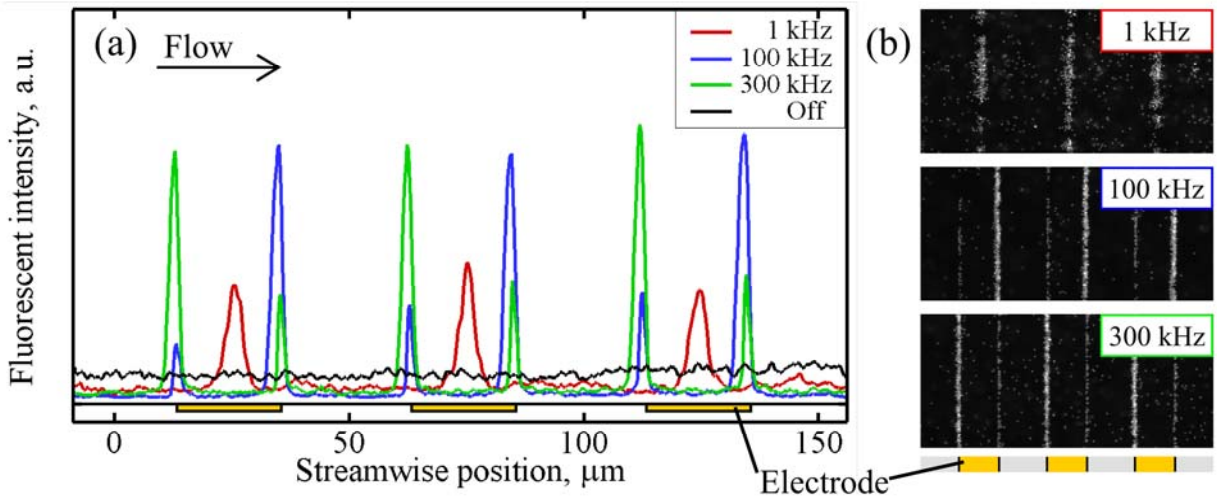

Figure 4. Particle distribution with different applied frequency
(a) Fluorescent intensity distribution (b) CCD image

was located on the center of each electrode. On the other hand, at 100 and 300 kHz, the peak was at the electrode edge. This frequency-dependence is due to the difference in the contribution of DEP and ET on the particle behavior. At 1 kHz, the particle motion along the electrode surface is recognized before the collection on the center of electrode; this is considered as the positive ET convection. At 100 and 300 kHz, particles gather around the electrode edge as if they experience the attraction force toward the edges. The origin of the attraction force and counterflow is DEP and ET, respectively. At 100 kHz, the particles move to the electrode gap due to the positive ET convection as well as the positive DEP. Therefore, the fluorescent intensity is higher at the upstream edge of the electrode gap because the relative velocity of particle becomes lower around the upstream edge. At 300 kHz, since the negative ET convection force acts on the particle, the fluorescent intensity is higher at the downstream edge of the electrode gap. These results indicate the two phenomena of DEP and ET have different features.

Validity of lateral observation arrangement

The microfluidic device used in this study consists of the different materials PDMS and glass. Therefore, in the case of using the lateral observation arrangement, it can be considered that difference of the refraction indices might distort the image in heightwise direction. As a preliminary step for the measurement of particle velocity from the side wall of the channel, the validity of measurement with the lateral observation setup was investigated. The thickness of the side PDMS wall around center of the microchannel was made to 125 μm. Figure 5 shows a velocity profile in the microchannel measured from the side wall. The measured velocity distribution indicates a good agreement with Poiseuille flow without distortion in heightwise direction.

Behavior of particle subjected to AC electric field

ET convection. The micro-PIV measurement with the lateral observation was carried out to confirm the detail of the particle behavior. In this experiment, the particle images without the flow were acquired. Figure 6 indicates the velocity field of the particles with 1 $V_{p\text{-}p}$ at 1 kHz. The counter-rotating behavior with strong tangential flow on the electrode surface is observed. This flow pattern agrees with the characteristics of the flow induced by ET effect. X-component velocity distributions in heightwise cross-section at the center of the rotation (x = ± 19 μm) are shown in Figure 7. Figure 8 depicts the z-component velocity distribution in the cross-section passing the rotational center (z = 7.3 μm). The particle velocity in x-component around the electrode plane is about 60 μm/s, and this is higher than the z-component one. In the vicinity of the edge, it is confirmed that the particles approach the electrode edges as shown in two valleys of the heightwise velocity in Figure 8. Therefore, these results indicate that the particle is subjected to the resultant force of the body force

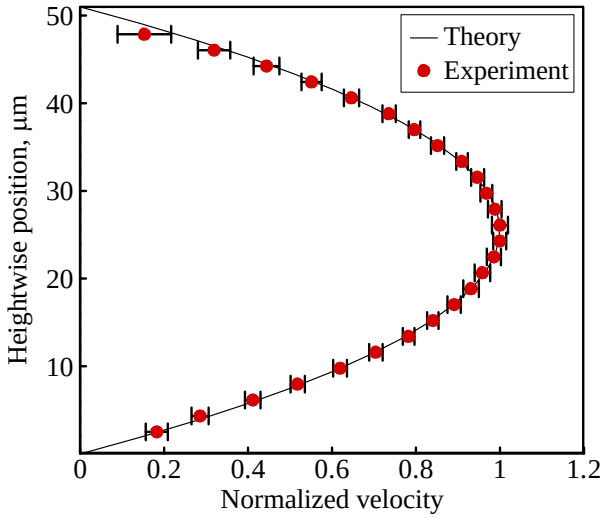

Figure 5 Channel flow measured from side wall

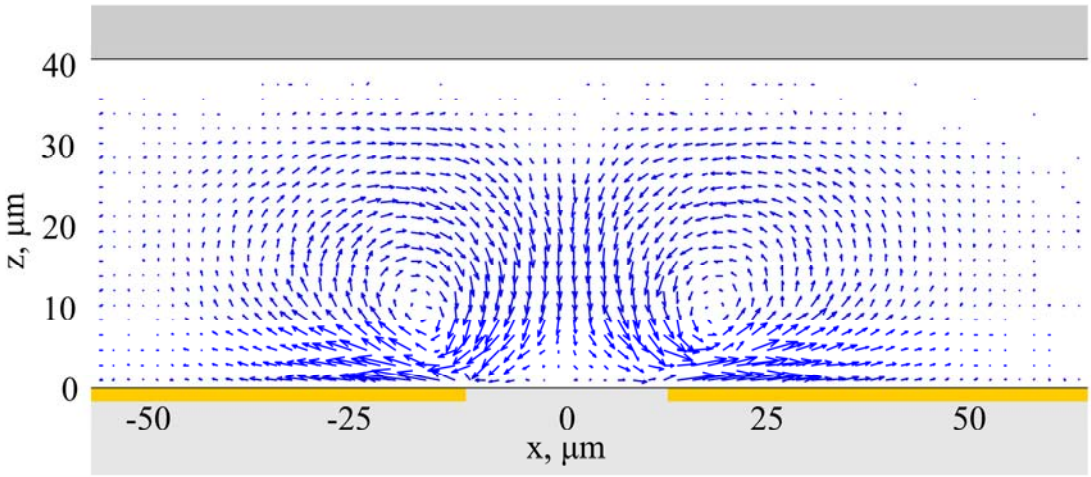

Figure 6. Particle velocity field at 1 kHz with 1 V_{p-p}

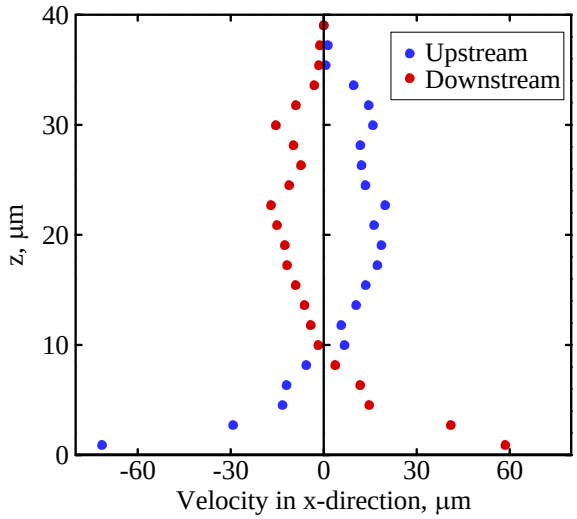

Figure 7. Heightwise distributions of particle velocity at the rotational center

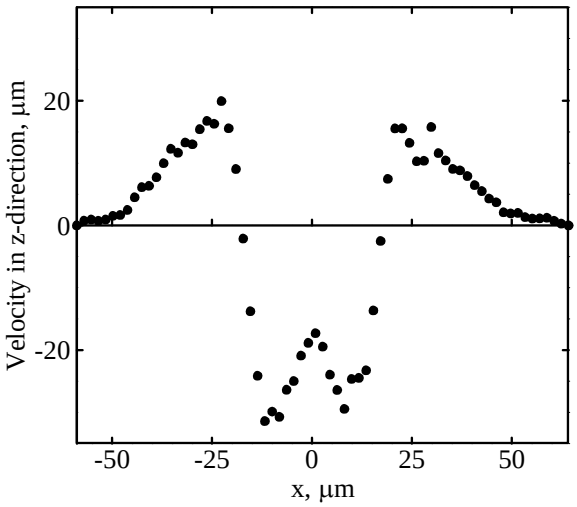

Figure 8. Streamwise distribution of particle velocity at the rotational center

by ET convection and the dielectrophoretic force by DEP attraction. It can be said that the measurement field is dominated by positive ET under the applied frequency of 1 kHz.

Evaluation of particle mixing. In order to evaluate the effect of the particle mixing, comparison with the spontaneous diffusion by Brownian motion was performed. The root mean square displacement of the particle due to Brownian motion is given by,

$$\Delta l = \sqrt{\frac{2k_B T}{3\pi d\eta}\Delta t} \tag{4}$$

In this study, for the quantitative assessment of the particle mixing, we define the mixing coefficient as a ratio of the particle migration distance under electric field to the Brownian displacement,

$$\phi = \frac{v\Delta t}{\Delta l} \tag{5}$$

Here, the mixing coefficient per unit time was evaluated. Figure 9 shows the contour of streamwise- and heightwise- component of mixing coefficient at 1 kHz. In x-component, there are two local peaks with high mixing coefficient around the electrode surface. The similar experiments in the frequency range of 1 ~ 100 kHz are carried out. The spatial-averaged mixing coefficient in all the measurement area and the electrode gap region was calculated. The relation between the averaged mixing coefficient and the applied frequency is shown in Figure 10. In this range, the mixing coefficient is increased as the frequency is decreased. The high heightwise mixing effect can be obtained at the gap area under 30 kHz. It is confirmed that the mixing with the low voltage of 1 V_{p-p} is possible.

DEP attraction. Next, the applied frequency was switched to 300 kHz. Since the significant behavior of the particles was not confirmed, the applied voltage was elevated to 3 V_{p-p}. In this condition, the particle behavior differs much from the that at 1 kHz. Figure 11 shows the particle velocity field with 3 V_{p-p} at 300 kHz. The particles migrate toward the electrode edges, and weak upward flow at the center of the electrode gap is recognized. The nearer the electrode edge, the stronger the DEP force acting on the particle is. The particle velocity around the electrode edges is about 9 μm/s. It is considered that the particle is exerted by the negative ET and the positive DEP.

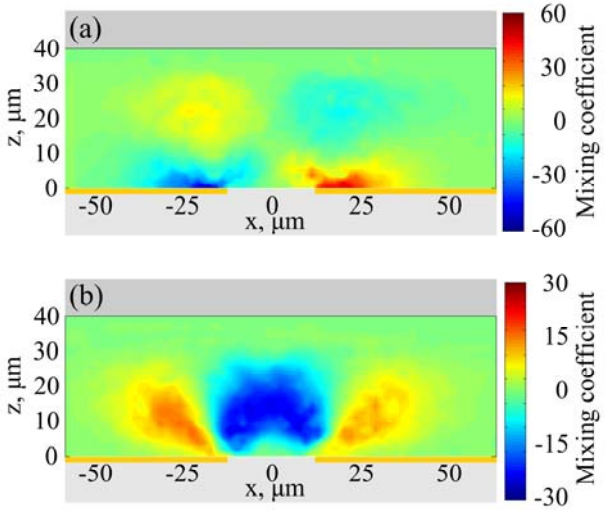

Figure 9. Spatial distribution of mixing coefficient
(a) Streamwise component
(b) Heightwise component

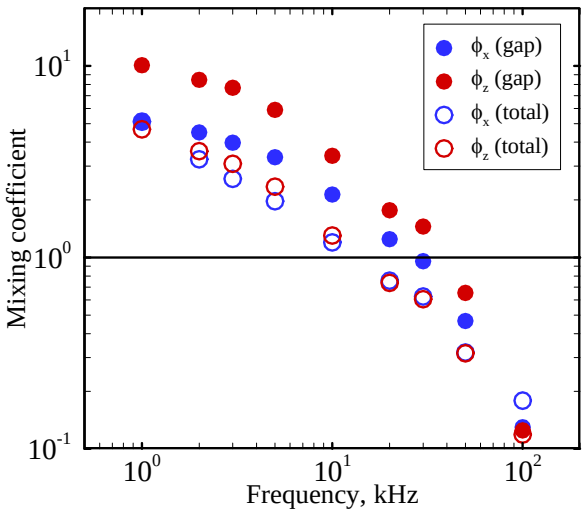

Figure 10. Frequency dependence of average mixing coefficient at 1 ~ 100 kHz with 1 V_{p-p}

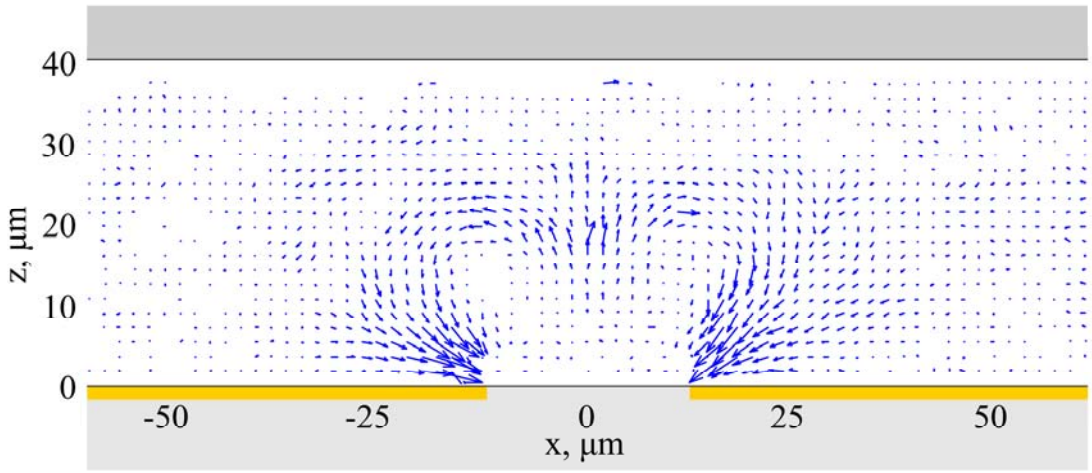

Figure 11. Particle velocity field at 300 kHz with 3 V_{p-p}

The particles are convected by the negative ET and finally attracted to the electrode edges. Therefore, it can be said that this behavior is efficient movement as mixing rather than collection.

CONCLUSIONS

In this study, the particle mixing based on AC electrokinetics is investigated. It is confirmed that the difference of the particle behavior depending on the applied frequency is caused by the frequency-dependent contribution of dielectrophoresis and electrothermal effect. The distributions of the fluorescent intensity indicate that the positive DEP is dominant in the range of 100 ~ 300 kHz and the cross frequency which changes the ET direction exists between 100 and 300 kHz. The measurement result of the particle velocity field indicates that these two forces act on the particle simultaneously. The efficient particle operation for mixing is evaluated by the mixing coefficient, and it is confirmed that the coefficient increases as the frequency decreases. Finally, our results imply the validity of the innovative mixing control with frequency selection.

EXPERIMENTAL MEASUREMENT OF ENERGY ACCOMMODATION COEFFICENT FOR METAL SURFACE BY LOW-PRESSURE METHOD

H. Yamaguchi[1, *], Y. Aoki[1], Y. Matsuda[1], T. Niimi[1]
[1]Nagoya University, Nagoya, Japan

ABSTRACT. The energy accommodation coefficients for metal surface have been measured by the Low-Pressure method. The energy accommodation coefficient was deduced from the pressure dependence of the heat flux between concentric cylinders. Experimental results are reported for argon and oxygen in contact with a platinum surface. The surface temperature dependence of the energy accommodation coefficients is also studied, and discussed in comparison with previous results.

Keywords: *Energy accommodation coefficient, Low-Pressure method, Gas-surface interaction, Heat flux, High Knudsen number flow*

INTRODUCTION

Heat transfer to and from surfaces in micro flow fields has been an important research field because of problems in removal of heat generated in micro-devices along with the progress in micro- and nano-technology. In micro gas flows, the molecular mean free path, λ, becomes comparable to the characteristic length of the system, L. Knudsen number, Kn, which is defined as a ratio of the molecular mean free path to the characteristic length of the system, is large in these so-called "high Knudsen number flows". Noncontiuum effects appear in high Knudsen number flows, and gas-surface interaction becomes dominant over the flow field compared to interactions between gas molecules.

Gas-surface interaction phenomena have been investigated for a long time. Detailed information about the interaction has been investigated using molecular beam scattering experiments and molecular dynamics simulations. However, for a simple thermal design of a system, the accommodation coefficient, which illustrates overall gas-surface interaction without any detailed processes, is the most widely used empirical parameter. The energy accommodation coefficient, α, is defined as

$$\alpha = \frac{E_i - E_r}{E_i - E_s}, \tag{1}$$

where E_i is the averaged incident energy, E_r is the averaged reflected energy, and E_s is the averaged energy when the reflected molecules are in equilibrium at the surface temperature.

The energy accommodation coefficient has been experimentally measured with several methods in a variety of gas-surface combinations. However, there are few reports on the energy accommodation coefficient of non-metallic surfaces, which are important materials for micro- and nano-technology. Therefore, we set our final goal as the measurement of the energy accommodation

E-mail address: hiroki@nagoya-u.jp

coefficients on non-metallic surfaces. To establish a measurement scheme, the energy accommodation coefficient was measured experimentally for a metal surface in this research.

LOW PRESSURE METHOD

The energy accommodation coefficient was measured following the Low-Pressure method [1]. In this method, the energy accommodation coefficient is obtained from the temperature dependence of the heat flux between two surfaces with a certain temperature difference in the free-molecular flow regime. Experimental setup was designed as the geometry of two concentric cylinders with a gas filled gap. In the free-molecular flow regime, theoretical heat flux between two cylinders, q, as in Figure 1 depends on gas-surface interaction, i.e. the energy accommodation coefficient.

The radii of the inner cylinder and the outer cylinder are defined as r and R, respectively. The temperature of the inner cylinder, T_H, is higher than that of the outer cylinder, T_C. The gas between the cylinders is quiescent, thus conduction is dominant in the heat transfer between the cylinders: convection is negligible.

The heat flux between concentric cylinders is described depending on the gas phase flow regime. In the free-molecular limit, q_{FM}, where $Kn \gg 1$ and in the continuum limit, q_C, $Kn \ll 1$, the description is exactly shown [1,2]:

$$q_{FM} = \frac{1}{2}\alpha\left(1+\frac{\zeta}{4}\right)\frac{\bar{c}}{T}p\left(T_H - T_C\right), \tag{2}$$

$$q_C = \frac{k}{r\ln\left(R/r\right)}\left(T_H - T_C\right), \tag{3}$$

where ζ is the number of internal degrees of freedom of gas molecules, $\bar{c}$ is the mean speed of the gas molecules, T is the average temperature of the gas, and k is the gas thermal conductivity. q_{FM} is proportional to the pressure, p, whereas q_C is independent of p.

In the transitional regime between the two limits, the heat flux, q, is often approximated as [2],

$$\frac{1}{q} = \frac{1}{q_{FM}} + \frac{1}{q_C}. \tag{4}$$

Since the condition for a free-molecular flow is quite severe in our experimental measurements, the analytical form extended to the transitional regime, eq. (4), was employed to derive the energy accommodation coefficient in this research.

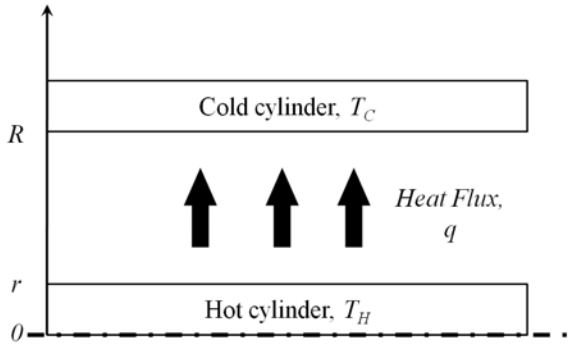

Figure 1. Schematic image of the geometry of concentric cylinders.

EXPERIMENTAL SETUP

The concentric cylinders were realized with a non-treated thin platinum wire and a Pyrex cylinder in this research. The radii of the wire and the cylinder were 25 μm and 6 mm, respectively. Argon and oxygen were chosen as a test gas. The pressure was ranged from the free-molecular to the transitional regime, and was measured with MKS 627B Baratron pressure transducer. The temperature of the Pyrex cylinder was uncontrolled and was measured by K-type thermocouple. The temperature of the thin platinum wire was controlled by an analog bridge circuit, which was similar to that used in the hot-wire airflow meter or the Pirani gauge, and the heat transfer was calculated from the electrical power consumption of the wire. The temperature was deduced theoretically from the resistance of the wire using the temperature dependence of the specific electric resistance of platinum.

RESULTS AND DISCUSSIONS

Heat Flux between Cylinders

The heat flux between the thin platinum wire and the Pyrex cylinder is proportional to the pressure in the low pressure range, and asymptotically increase to a constant value. The measured heat flux and the fitted analytical curve by eq. (4) to determine the energy accommodation coefficient for argon at the surface temperature of about 450 K are plotted in Figure 2 with red circles and blue solid line, respectively. From these results, the energy accommodation coefficient was obtained to be 0.822 in this case, which is smaller than unity.

Temperature Dependence of Energy Accommodation Coefficient

The energy accommodation coefficient is known to be affected by surface conditions, such as temperature, roughness, and so on. To investigate the temperature dependence, the temperature of the thin platinum wire was changed from about 300K up to about 600K. The obtained energy accommodation coefficients are plotted in Figure 3 with the results given in the previous report [3]. They show quite similar with previous reported results, and the energy accommodation coefficients decrease as the surface temperature increases. The results for oxygen shows smaller value compared with that for argon.

Energy Accommodation Coefficient of Platinum Surface

For metal engineering surfaces, the energy accommodation coefficient is often assumed to be unity, i.e. the scattering process is modeled by the diffuse reflection. However, it must be inappropriate from these results. The energy accommodation coefficient varies according to the gas species and the surface temperature, and the temperature dependence is also different from one to one.

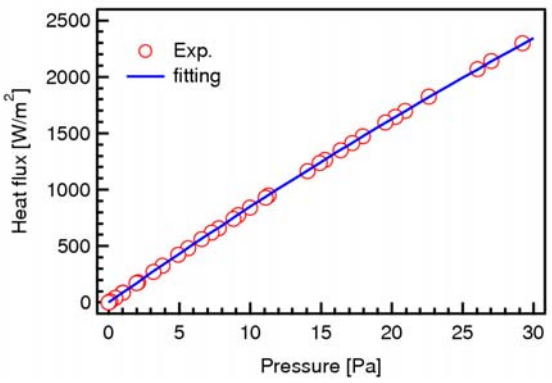

Figure 2. Pressure dependence of heat flux between cylinders for argon at the surface temperature of about 450 K.

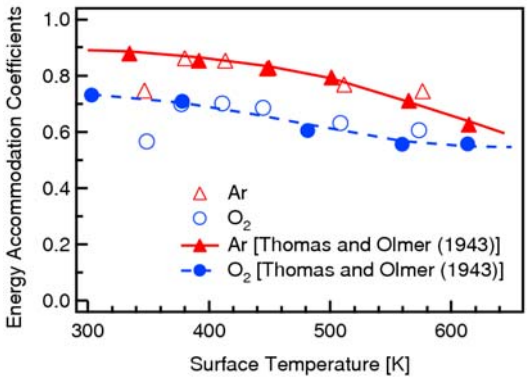

Figure 3. Temperature dependence of energy accommodation coefficients.

Since the gas-surface interaction significantly influences the micro-flow field, the energy accommodation coefficient for various pairs of gas and surface should be experimentally investigated in detail further.

CONCLUSIONS

The energy accommodation coefficients for non-treated platinum surface have been measured by the Low-Pressure method with the simple concentric cylinder geometry. The energy accommodation coefficient was obtained from the pressure dependence of the heat flux between the cylinders. The energy accommodation coefficients are reported for argon and oxygen for wide range of surface temperature, which show good agreement with previously reported results. The energy accommodation coefficients show decreasing against the surface temperature increase, and the tendency is deferent for argon and oxygen.

NONCONTAT MANIPULATION OF MICROFLOW BY PHOTOTHERMAL CONTROL OF VISCOUS FORCE

M. Motosuke[1, *], J. Shimakawa[1], D. Akutsu[1], S. Honami[1]
[1]Tokyo University of Science, Tokyo, Japan

ABSTRACT. This paper describes the experimental validation of a novel noncontact microflow manipulation by the local control of the viscous force. This technique relies on the photothermal technique to induce a local viscosity distribution in microflow. The absorption of focused laser beam generates the change in the viscosity of the fluid corresponding to the temperature rise. The temperature and velocity was measured by the micron-resolution particle image velocimetry and laser-induced fluorescence, respectively. Measurement results indicate that the local variation of the viscosity due to the temperature rise can cause the change in flow structure. At the high temperature area, the streamwise velocity was increased. In addition, the agreement between the experimental results and numerical simulation clarifies that the primary factor for the change of the microflow structure is the locally controlled viscous force.

Keywords: *microfluidics, viscosity, photothermal effect, local property control*

INTRODUCTION

Microfluidic system has recently emerged owing to the development of micro- / nano- fabrication technology, and attracted considerable attention from biological, medical, chemical and engineering fields [1]. The miniaturized system offers several advantages over conventionally sized one, including small sample volume, short reaction time, portability and potential for parallel operation. In microscale, the effect of properties on transport phenomena becomes dominant; heat conduction, mass diffusion, interfacial tension and viscous force often dominate the system [2]. An appropriate control on the property can be an effective thermal and fluid handling method especially for the microfluidic device. In this study, we have focused on the local control of the viscosity, because the viscous force is dominant in low Reynolds number flow in the microdevice. A local spot with different viscosity can yield a spontaneous shear force, and then it may cause the change in flow structure. In order to induce the local viscosity distribution in a liquid flow, the photothermal effect which is a property variation due to the light-induced temperature change [3], is utilized. The viscosity of liquid is known as the temperature-sensitive property, and the method using the viscosity change by the temperature variation can be applied in various liquids. In addition, an optical based technique has attractive features such as non-intrusive and high temporal- / spatial-resolution, and also has a possibility for a flexible flow control. In the present paper, we discuss a potential of the noncontact control of the flow behavior in a microfluidic device by changing the viscosity in the liquid by means of photothermal effect. The temperature field of a liquid flow in a microfluidic device was measured, and the corresponding velocity measurement in the field with the local viscosity change was performed. Furthermore, the temperature and velocity profiles were compared with those from the numerical simulation.

EXPERIMENTAL SYSTEM

Microfluidic device

In this study, a microchannel structure made of PDMS (polydimethylsiloxane) elastomer was fabricated by soft lithography [4]. PDMS has highly transparent in visible wavelength [5] so that an optical access for heating or measurement is possible. Figures 1 and 2 show the fabrication process and a schematic of the microchannel. A master mold is fabricated by the standard photolithography process with SU-8 photoresist on a silicon wafer. Then the PDMS mold with the negative relief structure is prepared by casting over the master mold. The PDMS mold is placed on the glass substrate and sealed. The difference in liquid surface levels between inlet and outlet reservoirs causes the stable pressure-driven flow in the microchannel. The microchannel has rectangular cross section with 50 μm in height, 200 or 500 μm in width, and the length is 40 mm. The Reynolds number in the present experimental condition was less than 0.1.

Heating optical setup

Figure 3 (a) indicates the overview of heating optical system. In the experimental system, a compact diode laser (LD) with the wavelength of 635 nm is used as the heating source. The LD beam is focused by an objective lens (Obj 1) and irradiated into the microchannel. The irradiation timing and power of LD beam can be controlled by a function generator (FG). The use of low magnification lens with long focal length enables the suitably constant beam waist within the microchannel. Therefore, the temperature rise of the fluid around the center in heightwise direction is assumed to be uniform.

Temperature and velocity measurement system

A schematic of the measurement system for temperature and velocity is shown in Figure 3 (b); measurement is conducted from the lower part of the microchannel. The temperature measurement is performed by micro-LIF (laser-induced fluorescence), which uses a temperature-sensitive fluorophore dissolved in the liquid [6]. The temperature of fluid can be determined by utilizing the inverse function of the calibration function f_c which relates the fluorescent intensity to the temperature of the solution, as presented in equation (1).

$$T = f_c^{-1}\left\{\frac{I(T) - I_d}{I_{ref} - I_d}\right\} \tag{1}$$

Here, the fluorescent intensity for the calibration was normalized by that at a reference temperature after subtracting the background intensity. Although rhodamine B is a popular fluorescent dye with strong temperature dependence in the fluorescent intensity [7], slight absorption in the wavelength of the heating laser in this study (635 nm) might affect the emission intensity distribution. Thus, fluorescein (FL) which does not absorb the LD wavelength was used as the temperature sensitive

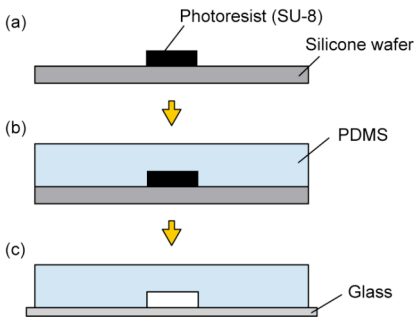

Figure 1. Fabrication process of soft lithography (a) Relief structure (b) Casting (c) Sealing

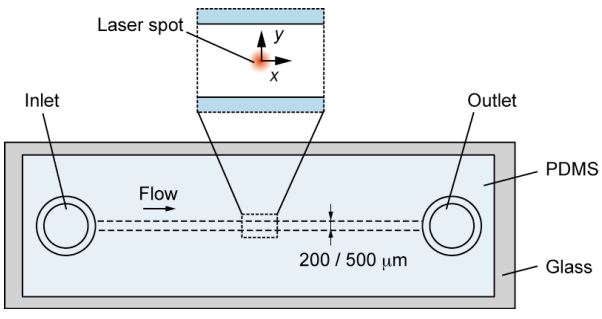

Figure 2. Schematic of PDMS microchannel

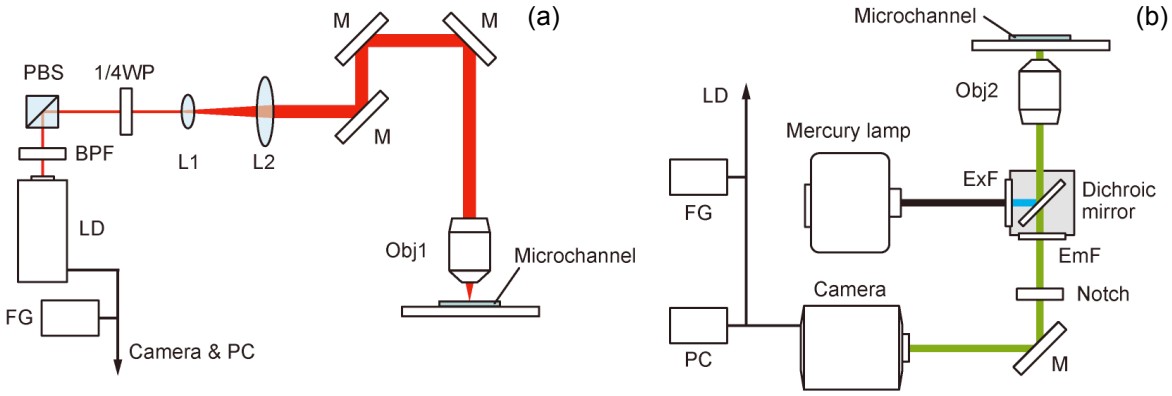

Figure 3. Schematic of experimental setup (a) Heating system (b) Measurement system

fluorescent dye. In addition, fast lifetime of fluorescence in FL of 3-4 ns is suitable to apply the dynamic flow field. The velocity field is measured by micro-PIV (particle image velocimetry), in which the velocity can be obtained by the image processing for the motion of fluorescent tracer particles in the focal plane of an objective lens [8]. Fluorescent polystyrene particles with the nominal diameter of 700 nm are used as tracer. Considering the specification of the objective lens for velocity measurement having a magnification of 40 and NA of 0.95 (air immersion), the measurement depth defined by following equation (2) [9] results in 3.0 μm.

$$\Delta z = \frac{3n\lambda}{\mathrm{NA}^2} + \frac{2.16 d_p}{tan\theta} + d_p \qquad (2)$$

Time-averaging procedure is used in the image processing to reduce the random Brownian motion of tracer particles. By adopting this, RMS value in a measured velocity field can be reduced from 5.5 (instantaneous) to 0.4 % (100 pairs averaged). Both in micro- PIV/LIF system, a mercury lamp is used as the illumination source, and an excitation filter extracts the wavelength for the excitation of fluorescent dye or particle. Fluorescent image is obtained by a Peltier-cooled CCD camera or a CMOS camera with an image intensifier. A notch filter inserted in front of the camera is designed to eliminate only the LD wavelength. The excitation and emission peak wavelengths of the fluorescent dye for temperature measurement and the particle for velocity measurement are indicated in Table 1. Because of the similar bands for the temperature and velocity measurement, the same optical system including filters can be used in this study. The measurement section in heightwise direction was set at the center of the microchannel, $z = 25$ μm.

Emission wavelength (nm)	521	508

Working fluid

The working fluid is buffer solution, hydrodynamically regarded as water. In order to absorb the wavelength of the heating beam, non-fluorescent absorption dye of Brilliant Blue FCF (BB) is added. BB has strong absorption band in the wavelength range over 600 nm. Thus, BB aqueous solution can be heated by the irradiation of LD in the present setup without an interference with the wavelength for excitation and emission to measure the temperature or velocity. Since fluorescein

has strong pH dependence on the fluorescent intensity, it is necessary to prevent pH variation according to the temperature change. In this study, tetra-borate buffer solution (pH 9.18) was employed; the effect of the variation in the fluorescent intensity due to pH variation corresponding to the temperature change on the measurement value of the fluid temperature was estimated to be less than 1 K.

RESULTS AND DISCUSSION

Temperature calibration experiment

As a preliminary step to measure the temperature of the working fluid from the fluorescent intensity, the calibration experiment was conducted with a constant temperature plate connected to the circular water bath. The temperature range for the calibration was 283 to 343 K. Figure 4 presents the temperature dependence of fluorescent intensity in several concentration of absorption dye, BB. The concentration of FL is fixed to 0.1 mM. The higher temperature dependence in higher BB concentration implies a little overlap in the distributions between the absorption of BB and the emission of FL. This is recognized as a slight decay at high wavelength in the fluorescent spectrum obtained by a spectroscope. There is no shift around the peak wavelength of FL emission in the present temperature range. There are two ways to deal with this issue; one is to use another emission filter (EmF) transmitting narrowly around the peak emission wavelength, and the other is to obtain the calibration function at each BB concentration. In this study, the calibration curve for each BB concentration is approximated by the third-order polynomial fit to determine the relationship between temperature and the fluorescent intensity normalized by the value at 298 K.

Change in microflow structure with local temperature distribution

Figure 5 shows the temperature field measured by micro-LIF and the relative velocity field where the relative velocity between the velocity with and without the laser heating is indicated. The reference velocity at the center span, u_{ref}, was approximately 1800 μm/s and the concentration of BB was 0.5 mM. The focused beam diameter was 7 μm, and the laser power at immediately above the microchannel was 4 mW. It is clear that the flow velocity is increased at around the high temperature area. In this result, the increment in the streamwise velocity was about 7 % of u_{ref}, and the temperature rise at the position was around 30 K. This change in the flow behavior is induced by adding the local temperature rise in microflow. Figure 6 depicts the laser-induced velocity variation in streamwise and spanwise velocities at x = 0 and ± 40 μm. The streamwise velocity variation upstream of the heated area was higher than the downstream one, as shown in Figure 6 (a). This is attributed to the difference of the temperature rise in the streamwise direction due to the convection toward downstream. Moreover, there was the decrease in the velocity away from the heating spot in spanwise direction. The spanwise velocity profiles in Figure 6 (b) means a

(a) Streamwise component (b) Spanwise component

convergence flow into the center span at upstream region and an outflow at downstream area. In addition, it is found that the flow field in spanwise direction has a symmetric structure. This behavior can be explained as the nature of continuum. Since the area with high temperature has low viscosity, fluid tends to flow into the region with a low flow resistance. After passing the low viscous area, then, the spreading flow occurs. For further investigation, the effect of the focused laser irradiation near the sidewall of the cannel was investigated. Figure 7 depicts the velocity field including the dependence of the laser power. Here, PDMS microchannel with 500 μm in width was used. For the measurement without change in the measurement depth, Δz, a relay lens with magnification of 0.7 was set in light path between the objective lens and the camera. The heating beam diameter and u_{ref} was 50 μm and 1300 μm/s, respectively. The velocity variation similar to that shown in Figure 4 (b) can be observed, and the maximum velocity at the region of the laser heating is increased with the increase of the irradiating laser power. Accordingly, the reduction of the velocity is increased. Furthermore, the position where the streamwise velocity does not change is independent of the laser power. In order to examine the influence of u_{ref} on the change in flow structure, the velocity measurements with different u_{ref} was performed. For an appropriate evaluation, the same microchannel was used under the same heating condition, and u_{ref} set here was 1420 and 3200 μm/s. As a result, there is no variation in the induced velocity profile by the laser heating against u_{ref}. In a preliminary experiment, the similar changes of the velocity profiles were observed with u_{ref} of 10, 50 or 100 μm/s. Given the same viscosity distribution in the fluid, this u_{ref}

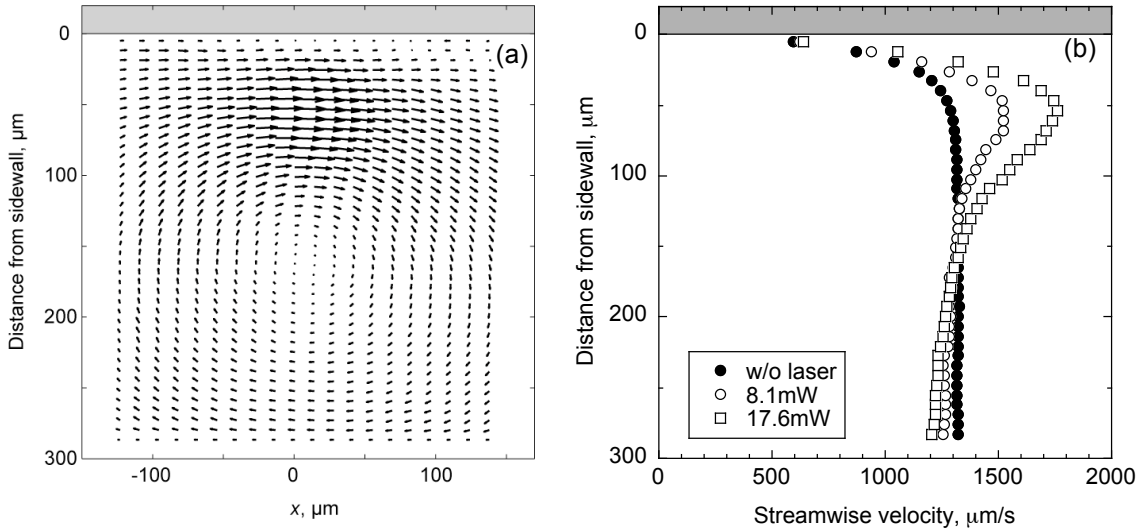

Figure 7. Microflow behavior with local temperature distribution near sidewall (a) Relative velocity field (b) Comparison of streamwise velocity at $y = 0$ without laser and with different irradiation power

independence is reasonable under the literalized Stokes equation which is valid in low Reynolds number flow [10]. From these experimental results, it is confirmed that the generation of local temperature distribution causes the change in microflow structure.

Comparison between experimental and numerical results

The main factor which causes the velocity variation under the local temperature rise is assumed to be the distribution of the viscous force. However, above-mentioned results are not sufficient to uniquely characterize the origin of the change in microflow structure, because the temperature change can provoke the variation in other properties. In this study, a comparison with the numerical simulation was performed. The geometry of the microchannel model was a three-dimensional straight channel with the same cross-sectional area as the PDMS channel of 200 μm in width and 50 μm in height. The Navier-Stokes, continuity and energy conservation equations were coupled. The heat source considered here has the Gaussian intensity distribution as in the TEM_{00} mode of the laser beam. The beam diameter was set at 7 μm, which was the same as the experimental condition. In this calculation, the heat generation density was adjusted to fit the temperature data measured by

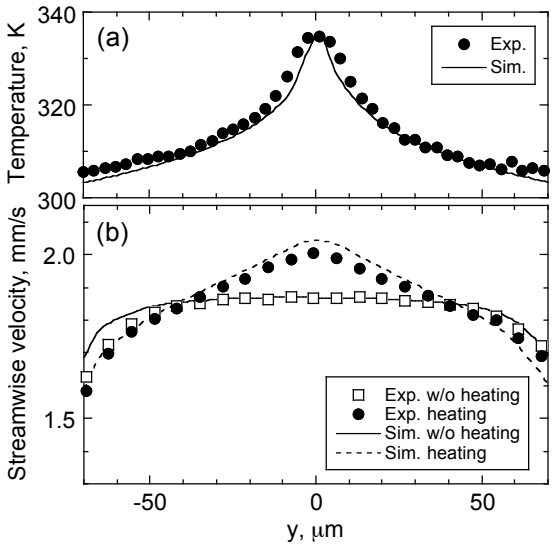

Figure 8. Comparison of temperature and velocity profiles between experiment and simulation (a) Temperature (b) Streamwise velocity

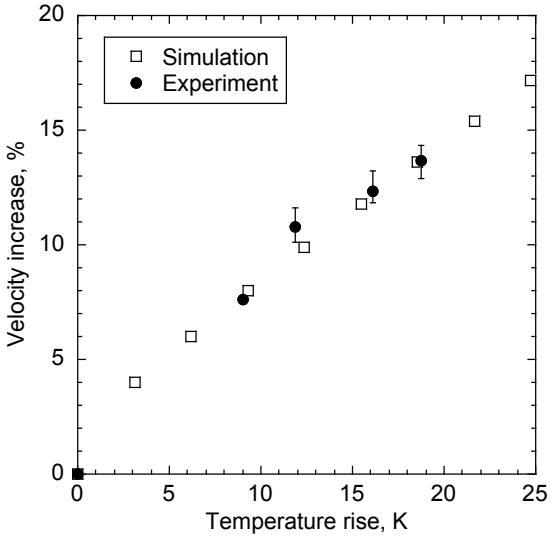

Figure 9. Dependence of temperature rise by laser heating and the induced velocity increase at beam spot

micro-LIF, because this parameter strongly depended on the optical transmitting or scattering characteristics of PDMS microchannel. Working fluid was water, and only the temperature dependence of the viscosity was considered. Numerical analysis was conducted with the finite element simulation software *COMSOL Multiphysics*. Figure 8 shows experimental and simulated results of the temperature and streamwise velocity profiles at $x = 0$ (beam spot position). Both simulated velocity profiles with and without heating indicate good agreement with those in the experimental results. This agreement means that the primary factor to induce the velocity change is the local variation of the liquid viscosity. The relationship between the maximum temperature rise at the beam spot and the corresponding velocity increase is depicted in Figure 9. The tendency of the positive dependence of the temperature rise which is controlled by the beam intensity on the velocity increment can be obtained in both results. A slight departure from the linear relationship is attributed to the nonlinearity in the temperature dependence of the viscosity. These numerical investigations elucidate the role of the local change in viscosity on the flow structure in the microfluidic device.

CONCLUSIONS

An investigation of a potential of the photothermally-induced distribution of the viscosity for the manipulation of the liquid flow in a microfluidic device was conducted. Micro- PIV and LIF was utilized for the velocity and temperature measurement of the microflow undergoing the local heating. At the heated area where the working fluid has low viscosity, the velocity was increased due to the local reduction of the flow resistance. The distribution of the viscosity also yields an accompanying flow both upstream and downstream of the high temperature region. It was found that the primary factor causing the change in flow structure was the distribution of temperature-dependent viscosity. The velocity fields obtained by the present experiment agree well with those from the numerical simulation considering the temperature dependence of the viscosity. This flow behavior owing to the local temperature change can be controlled by the irradiation condition including the beam parameter or the impinging location.

MODELLING PRESSURE FLUCTUATIONS DURING FLOW BOILING IN MICROCHANNELS WITH INLET COMPRESSIBILITY AND RESISTANCE

S. Gedupudi, T. G. Karayiannis, D. B. R. Kenning*
School of Engineering and Design, Brunel University, Uxbridge, Middlesex, UB8 3PH, U.K.

ABSTRACT. Confined bubble growth during flow boiling at low pressures in microchannels generates pressure fluctuations that may cause transient flow reversals that disturb the flow distribution in heat sinks formed of parallel channels joined by plena. A simple model is developed for the effects of upstream compressibility and flow resistance at the channel inlet on the magnitude of the pressure transient during the growth of one bubble in a single channel. Preliminary results are presented.

Keywords: *flow boiling, microchannel, heat sink, pressure fluctuations*

INTRODUCTION

Flow boiling at near atmospheric pressure in assemblies of closely-spaced, parallel micro-channels connected by inlet and outlet plena is a promising method of cooling micro-electronic devices at high heat fluxes. The growth of long confined bubbles causes local fluctuations in pressure that may cause temporary reversals of the inlet flow, triggering transient dryout and driving liquid and/or vapour through the plenum towards other channels. The flow reversals may be suppressed by a large frictional resistance at the entry to each channel, e.g. [1-4]. The design guidance is that the time-averaged pressure drop across this resistance should be similar to the pressure drop along the channels. Elimination of flow reversal does not eliminate the pressure fluctuations within channels, which may still influence heat transfer and in extreme cases cause structural damage. Pressure fluctuations have been measured at different axial locations in studies of single channels [5-10] dependent on the compressibility in the upstream boundary conditions, which may result from the pump characteristics or trapped bubbles of vapour or gas. The pressure variations were also measured and simulated by a 1-D model for the special case of bubble growth in an initially uniformly superheated channel with one sealed end (no inlet compressibility, no inlet flow) [11]. 1-D models with different approximations have been developed for oscillatory heat pipes [12].

It is of practical importance to improve the understanding of the effects of bubble-driven pressure fluctuations in assemblies of parallel channels. Parametric studies with 1-D models with simplified physics are less demanding computationally than fully 3-D simulations. A 1-D model for the pressure variations during the growth of a single vapour bubble in a single channel for the special conditions of constant inlet flow (i.e. no inlet compressibility) and constant exit pressure, with features suggested by experimental observations of bubble growth and supported by some 3-D numerical simulations, was presented in [13,14]. The new features of the model, specific to channels of rectangular cross-section of high aspect ratio, are: (i) confinement in two stages, first "partial confinement" by the minor dimension, then "full confinement" by the major dimension of the cross-section, (ii) growth driven by a constant heat flux only to the area of the bubble surface pressed against the heated wall of the channel. Viscous forces are assumed negligible compared to

inertial forces. The vapour density is assumed (a) constant, or (b) equal to the saturated vapour density for the instantaneous pressure in the bubble. Variable vapour density is more realistic for the large pressure changes at high heat fluxes and reduces the predicted amplitude of the pressure variations. However, it introduces some modelling problems for a smooth transition to full confinement, discussed in [11] and not yet fully resolved. Using the model with constant vapour density, it was shown that the amplitude of the pressure variation increased with the length of the liquid slug downstream of the bubble nucleation site and with the wall heat flux driving exponential bubble growth.

In this paper, the model for constant density is extended by the addition of sub-models for upstream compressibility in the plenum and a flow resistance at the inlet to the channel. Figure 1 illustrates the sensitivity of bubble motion to apparently minor changes in the rig design that introduced upstream compressibility during experiments on rigorously degassed water boiling at 1.1 bar pressure in a test channel of rectangular section 1.6 mm wide, 0.38 mm deep and 40 mm long, machined in an electrically heated copper block, with a glass window on one side. Reduction in the heat transfer area of the preheater in the external circuit some distance before the test section created compressible vapour due to local subcooled boiling. Further particulars are given in [13].

Examples of bubble growth are shown in Figure 1, (a) with the larger preheater, no upstream compressibility and (b) with subcooled boiling in the smaller preheater creating upstream compressibility despite the same rigorous degassing procedure. In both cases, partial confinement occurred within 2 ms of detectable nucleation but growth to full confinement took 7 - 9 ms. In (a), the growing bubble was pushed downstream by the incoming liquid immediately. Rapid axial

growth only in the downstream direction occurred after full confinement. Nucleation of succeeding bubbles occurred at intervals of about 13 ms, corresponding approximately with the estimated time for the bubble to reach the channel exit. In (b), growth of the partially confined bubble occurred nearly symmetrically in the upstream and downstream directions. Rapid upstream growth occurred after full confinement. The upstream end of the bubble moved out of view at 19 ms and did not return for a further 30 ms. The downstream end of the bubble rapidly moved out of view. The period between nucleation events at the same site was not regular. Recordings at lower magnification showed that more than one nucleation site was active in the channel for both conditions (a) and (b). For the images shown in cases (a) and (b), nucleation sites were located at about 17 mm and 20 mm from the inlet respectively.

1-D MODEL FOR CONFINED GROWTH, WITH UPSTREAM COMPRESSIBILITY

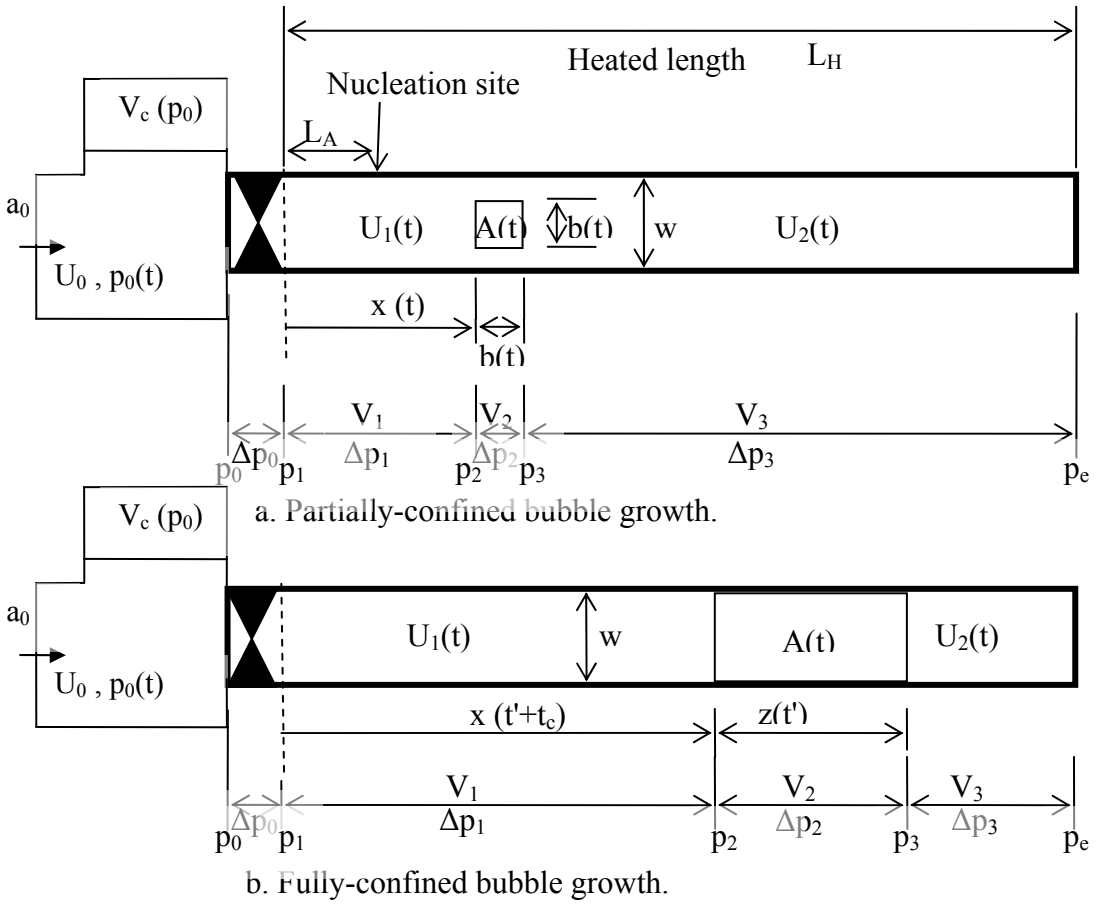

Figure 2. Bubble growth models.

The two-stage model for partially and fully confined growth is summarised in Figure 2. The channel is of rectangular section, width w, depth h << w and heated length L_H. Heat input is on one of the sides w, with an adiabatic window on the opposite side and negligible heat input on sides h. A single nucleation site is located at L_A from the inlet. A constant volumetric flow rate U_0 a_0 is delivered by the pump to the upstream plenum of cross-sectional area a_0 >> wh so that $p_0(t)$ is the stagnation pressure. A restriction at the channel inlet imposes a frictional resistance with constant loss coefficient F based on the velocity U_1 in the channel so that, depending on the direction of U_1,

$$p_0 - p_1 = [1 + FS(\rho_f/\rho_l)]\, \rho_l\, U_1^2\, /2, \quad \text{where } S = |U_1| / U_1 \qquad (1)$$

ρ_f depends on whether liquid or vapour phase is passing through the constriction. In the present model, it is assumed that only liquid enters or leaves the upstream end of the channel. Models for flow reversal with vapour passing through the inlet will be developed later.
The plenum is connected to a compressible volume $V_C(t)$ defined by a sub-model, so that

$$(U_0 a_0) + dV_C/dt = whU_1 \quad (2)$$

Sources of compressibility include presence of vapour or noncondensable gas, connections to parallel channels, pump characteristics, and sub-cooled boiling in the preheater upstream of the channel. In the present model, the only source is assumed to be due to non-condensable gas with initial volume V_{Ci} , as in the Brutin et al. experiments [8]. Assuming an isothermal process,

$$p_0 V_C = p_{0i} V_{Ci}, \; dV_C/dt = -C\, dp_0/dt, \quad C = p_{0i} V_{Ci}/p_0^2 \approx V_{Ci}/p_e \text{ for small changes} \quad (3)$$

$$\text{From (1) – (3),} \quad \frac{dp_1}{dt} = \left(\frac{U_0 a_0 - whU_1}{C} \right) - (1+FS)\rho_l U_1 \frac{dU_1}{dt} \quad (4)$$

Partially-confined growth (PC)

The earliest stage of unconfined growth from a nucleus with dimensions << h is neglected. When the bubble is confined fully along the depth h, except for very thin liquid films between the bubble and the surfaces w, it is assumed that the bubble length and width b(t) are equal. Neglecting the volume of the thin liquid films on sides w, the volume of the bubble V(t) is hb^2. Assuming constant heat flux q through the single contact area b^2 and neglecting the change of ρ_v and h_{lv} with pressure,

$$b = he^{t/(2\tau)}, \quad \tau = \rho_v h_{lv} h/q \quad (5)$$

$$\text{From continuity,} \quad U_2 = U_1 + \left(h^2/w\tau\right)e^{t/\tau} \quad (6)$$

From conservation of momentum, neglecting friction and assuming that the upstream end of the bubble moves at U_1 and the average velocities of the bubble and the liquid alongside are $(U_1+U_2)/2$, the pressure differences over the control volumes V_1, V_2 and V_3, are given by

$$\Delta p_1 = \rho_l \left(U_1 \frac{dx}{dt} + x \frac{dU_1}{dt} \right) + \left(0 - \rho_l U_1^2\right) = \rho_l \left(x \frac{dU_1}{dt} \right) \quad (7)$$

$$\Delta p_2 = \left\{ \left[\left(\rho_l \frac{db}{dt} \right) - (\rho_l - \rho_v) \frac{2b}{w} \frac{db}{dt} \right] \frac{(U_1 + U_2)}{2} + \left[(\rho_l b) - (\rho_l - \rho_v) \frac{b^2}{w} \right] \frac{1}{2} \left(\frac{dU_1}{dt} + \frac{dU_2}{dt} \right) \right\} \quad (8)$$

$$\Delta p_3 = \rho_l \left[U_2 \left(-U_1 - \frac{db}{dt} \right) + (L_H - x - b) \frac{dU_2}{dt} \right] + \left[\rho_l U_2^2 - 0 \right] \quad (9)$$

From the above equations, with r as the ratio of vapour density to liquid density, ρ_v / ρ_l ,

$$\frac{dU_1}{dt} = \frac{\left(\frac{p_1(t) - p_e}{\rho_l} - U_1 \left[r \frac{h^2}{w\tau} e^{t/\tau} \right] - e^{t/\tau} \frac{h^2}{w\tau^2} (L_H - x) + e^{3t/2\tau} \frac{3h^3}{4w\tau^2} - e^{2t/\tau} \frac{h^4}{w^2\tau^2} r \right)}{\left[L_H - (1-r) \frac{h^2}{w} e^{t/\tau} \right]} \quad (10)$$

Fully-confined growth (FC)

Fully-confined bubble growth commences from the time t_c at which b = w. Let $t' = t - t_c$. The contact area A = w z (t'), where z is the length of the bubble, and from the bubble growth equation

$$z = we^{t'/\tau} \quad (11)$$

$$\text{From continuity,} \quad U_2 = U_1 + \frac{dz}{dt'} = U_1 + \left(\frac{w}{\tau} \right) e^{t'/\tau} \quad (12)$$

From the momentum equation, assuming that the ends of the bubble move at U_1 and U_2 and its average velocity is $(U_1+U_2)/2$, the pressure differences over the control volumes V_1, V_2 and V_3 are

$$\Delta p_1 = \rho_l\left(U_1\frac{dx}{dt} + x\frac{dU_1}{dt}\right) + \left(0 - \rho_l U_1^2\right) = \rho_l\left(x\frac{dU_1}{dt}\right) \quad (13)$$

$$\Delta p_2 = \left\{\left[\left(\rho_v\frac{dz}{dt}\right)\frac{(U_1+U_2)}{2}\right] + \left[(\rho_v z)\frac{1}{2}\left(\frac{dU_1}{dt}+\frac{dU_2}{dt}\right)\right]\right\} + \{0-0\} \quad (14)$$

$$\Delta p_3 = \rho_l\left[U_2\left(-\frac{dx}{dt}-\frac{dz}{dt}\right) + (L_H - x - z)\frac{dU_2}{dt}\right] + \left[\rho_l U_2^2 - 0\right] = \rho_l\left[(L_H - x - z)\frac{dU_2}{dt}\right] \quad (15)$$

$$\frac{dU_1}{dt'} = \frac{\left(\frac{p_1(t)-p_e}{\rho_l} - U_1\frac{rw}{\tau}e^{t'/\tau} - (L_H - x)\frac{w}{\tau^2}e^{t'/\tau} + (1-r)\frac{w^2}{\tau^2}e^{2t'/\tau}\right)}{\left[L_H - (1-r)we^{t'/\tau}\right]} \quad (16)$$

The equations are solved by a finite difference method. The incoming flow a_0U_0 and the exit pressure p_e are assumed to be constant. The initial conditions are assumed to be $p_1 = p_e$, $U_1 = a_0U_0 / wh$, neglecting any impulsive changes associated with the initial unconfined growth of the bubble.

SIMULATIONS FOR WATER AT 1 BAR

Conditions

The simulations in this paper correspond to the flow conditions of the visualizations in Figure 1 : water in a channel 0.38 x 1.5 x 40 mm, constant exit pressure of 1 bar, constant inlet flow to the plenum equivalent to a liquid velocity U_1 = 0.7 m/s in the channel. The vapour density is assumed constant and viscous forces are neglected. The nucleation site is placed at the mid-point of the channel, unless otherwise mentioned. At present, the simulation is terminated when either end of a bubble reaches the end of the channel. Simulations for multiple bubbles are under development.

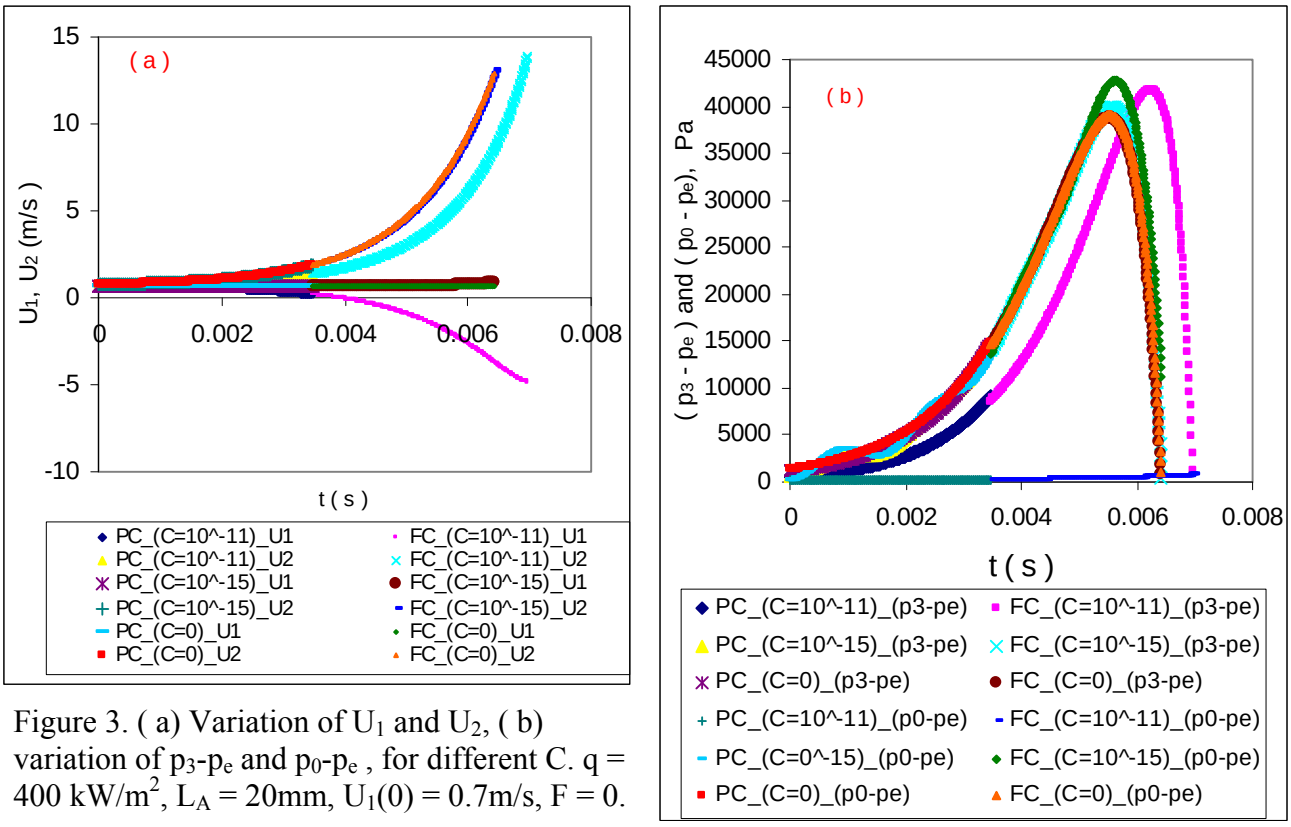

Figure 3. (a) Variation of U_1 and U_2, (b) variation of p_3-p_e and p_0-p_e , for different C. q = 400 kW/m^2, L_A = 20mm, $U_1(0)$ = 0.7m/s, F = 0.

Simulations of the liquid velocities U_1, U_2 on each side of the bubble, the bubble pressure p_3 and the pressure in the inlet plenum p_0 at a heat flux of 400 kW/m^2 are shown in Figure 3 for C = 0, 10^{-11} and 10^{-15}, corresponding respectively to trapped gas volumes in the inlet plenum of 0 (original model in [14]), 1000 mm^3 and 0.1 mm^3 (from Eq.(3)). For comparison, the volume of liquid displaced from the channel to the plenum by movement of one end of the bubble through 20 mm is 11.4 mm^3.

The simulations for C = 10^{-15} are very similar to those for C = 0, except for a small oscillatory component at a frequency of approximately 660 Hz, of the same order as the estimate of 850 Hz for the natural frequency of a spring – mass system using the mass of the upstream liquid column in the channel. The plenum pressure (p_0) is nearly equal to the bubble pressure (p_3). For relatively large upstream compressibility, C = 10^{-11}, the upstream velocity U_1 reverses after about 4 ms , after which growth is nearly symmetrical in the upstream and downstream directions. The bubble pressure rise is reduced and the plenum pressure remains nearly constant. In all the figures, only the total pressure drop ($p_0 - p_e$) and pressure drop at the downstream end of the bubble ($p_3 - p_e$) are shown, and the pressure drop at the upstream end of the bubble ($p_0 - p_3$) can be obtained from it. The pressure drop across the bubble ($p_2 - p_3$) is negligible, at least for the constant vapour property considered in the present model. The simulations show that in the presence of upstream (or inlet) compressibility, the pressure drop at the upstream end will be of the same order of magnitude as that at the downstream end, though they may differ in signs, which makes the total pressure drop between the inlet and outlet much smaller than that for without inlet compressibility. This also shows that for upstream (or inlet) compressibility, the local pressure fluctuations within the channel will be much higher than that between the two channel ends. The amplitude of these pressure fluctuations may be grossly underestimated by experimental measurements of the pressure difference between the inlet and outlet plena.

Additional simulations (not shown here) confirm that the initial asymmetry in growth and the associated delay in flow reversal are modified by changes in the initial incoming flow rate. The amplitude of the bubble pressure within the channel depends strongly on the heat flux, being much smaller at 100 kW/m^2, Figure 4. Also there is no flow reversal for 100 kW/m^2. The simulations performed so far do not exhibit the eventual return of liquid observed in Figure 1(b). Further investigation is required over a wider range of parameters. It may be necessary to use the non-linear version of the compressibility model in Eq.(3), so that the compressibility decreases as reverse flow proceeds, or a different sub-model that is more representative of the subcooled boiling that is the source of compressibility in these particular experiments.

For relatively large compressibility C = 10^{-11}, which maintains the pressure in the inlet plenum nearly constant, a large inlet resistance factor F = 40 reduces the reverse flow into the inlet

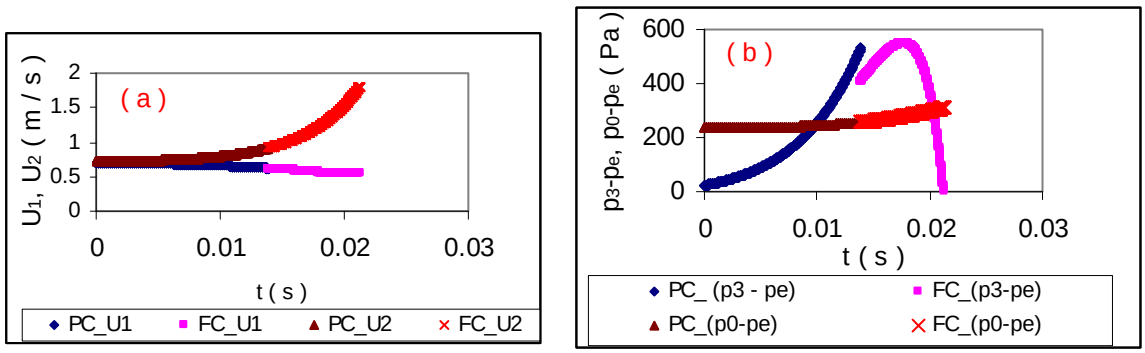

Figure 4. (a) Variation of U_1 and U_2, (b) variation of p_3-p_e and p_0-p_e , for q = 100 kW/m^2, L_A = 20mm, $U_1(0)$ = 0.7m/s and C=10^{-11}, F = 0. Compare with q = 400 kW/m^2 and C=10^{-11} in Figure 3.

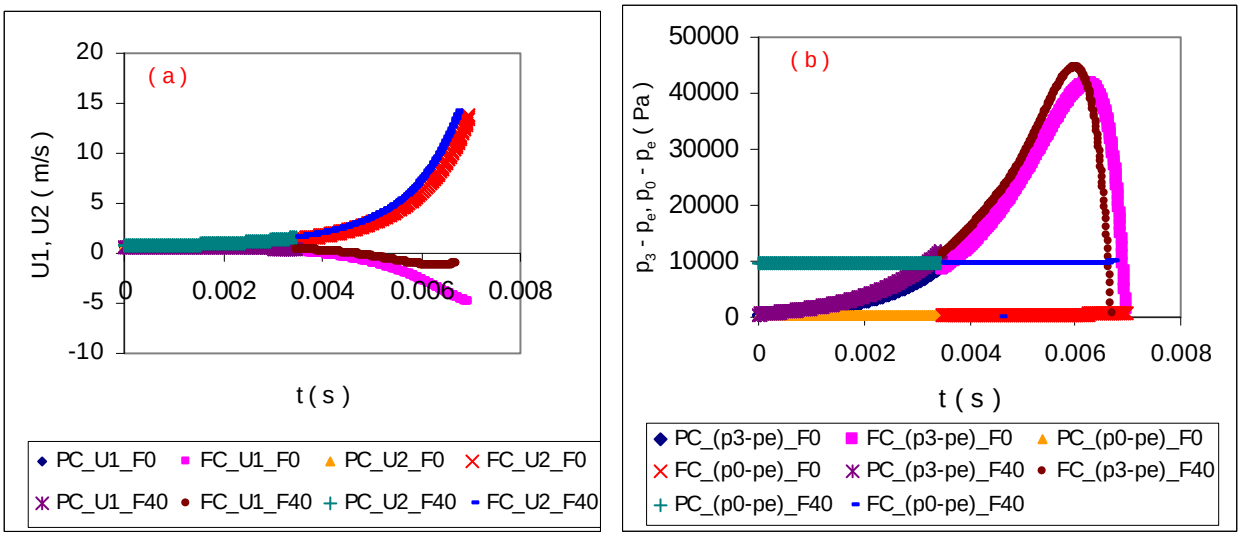

Figure 5. (a) Variation of U_1 and U_2, (b) variation of p_3-p_e and p_0-p_e , for F = 0, 40. q = 400 kW/m^2, L_A = 20mm, $U_1(0)$ = 0.7m/s and C = 10^{-11}.

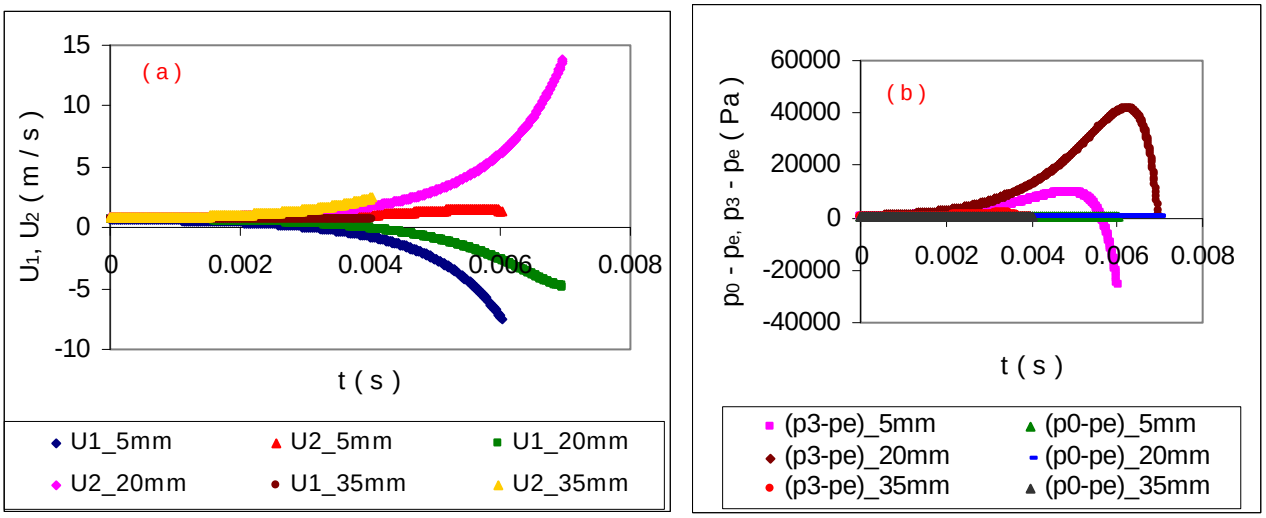

Figure 6. (a)Variation of U_1 and U_2, (b) variation of p_3-p_e and p_0-p_e, for different L_A (5, 20, 35 mm) . q = 400 kW/m^2, U_1 (0) = 0.7 m/s, C = 10^{-11}, F = 0.

plenum but increases slightly the maximum pressure within the channel, Figure 5. Figure 6 shows that the position of the nucleation site influences the reverse flow, with the nucleation site close to inlet showing more flow reversal (negative U_1) than the one at the middle, while the one close to the outlet hardly shows any flow reversal. In the experiments with inlet compressibility, it was observed that the bubbles near the channel inlet and middle grew in both upstream and downstream directions, with irregular periods between nucleation events, whereas those near the outlet only grew in downstream direction with more regular nucleation. The pressure fluctuation ($p_3 - p_e$) caused by the bubble near the outlet is very small compared to that caused by the bubbles near the inlet and middle. However, ($p_0 - p_e$) is very small and similar for all three cases, Figure 6b. The present model considers only single bubble. But in reality, there will be multiple bubbles and their interactions can also influence flow reversal. As the amplitude of pressure fluctuations and their frequencies increase with the heat flux, it will becomes necessary to consider the variation of vapour density and saturation temperature with pressure, not considered in the present bubble growth model.

CONCLUSIONS

A simple model has been developed for the pressure fluctuations and flow reversal caused by the growth of a single vapour bubble in a single micro-channel of rectangular cross-section with upstream compressibility and inlet flow resistance. Preliminary simulations have revealed the interactions between these external influences and conditions within the channel such as the heat flux and the position of the nucleation site. Further development of the model is required to include viscous forces, pressure-dependent vapour properties, different models for compressibility and multiple bubbles that may eventually guide the design of the plena for multichannel heat sinks.

μ– SCALE LIF AND PIV INVESTIGATION OF MIXING IN A RIBBED MICROMIXER

Mohammed Asfer, P. K. Panigrahi *
Mechanical Engineering Dept,
IIT Kanpur, U.P. 208016 (INDIA)

ABSTRACT. Mixing of binary or multi component fluid streams is an essential feature of many microfluidic systems i.e. DNA purifications, polymerase chain reaction (PCR), protein folding etc. However, mixing rates are governed by molecular diffusion for low Reynolds number micro flows and in the absence of enhanced mixing techniques, mixing lengths and residence times can be much longer than the requirement of most applications. The present study presents a passive mixing strategy for mixing between acetone-water and glycerol-water injected into the Y-shaped inlet of the micromixer. The mixing-channel of the micromixer is a PDMS microchannel of 30μm (depth) × 220μm (width) cross section with micro-ribs located on both the sidewalls of the mixing-channel. The width and height of ribs on the mixing-channel walls are equal to 30μm and 20μm respectively. The mixing performance between two fluid streams has been visualized and quantified by the μ-LIF (Laser Induced Fluorescence) technique. It has been observed that mixing index increases due to the presence of micro ribs and the mixing index at the outlet of the micromixer is 17.36% and 33.98% more than that without ribs (smooth micromixer) for acetone-water and glycerol-water respectively. The mixing index for glycerol-water flow is lower than that of the acetone-water solution. The μ-PIV (particle image velocimetry) results provide detailed flow field near the micro-ribs responsible for the mixing enhancement between the fluid streams. Overall, the present study demonstrates the influence of micro-ribs, fluid properties (viscosity ratio) and flow condition i.e. velocity ratio on mixing performance between two fluid streams.

Keywords: *μ-LIF, μ-PIV, micromixer, micro ribs, two-fluid mixing*

INTRODUCTION

Mixing in microscale is primarily driven by diffusion and therefore is slower compared to that in the macroscopic length scales. Therefore, many high performance passive and active mixing schemes have been investigated in literature to overcome the limitations imposed by the laminarity of micro flows. It is not always feasible to use mechanical agitation at the microscopic scale. The fabrication of passive structures through micro fabrication techniques has its own limitations. Two common arrangements for introducing the two fluid streams are T-shaped and L-shaped micromixer. The mixing is not so significant except at higher Reynolds numbers in T-shaped mixer. In L-shaped conduits, the bend induced vortices at low values of Reynolds number decay before they have an opportunity to significantly stir the fluid. In the experiments of Johnson *et al*. (2002) and Stroock *et al*. (2002), a series of micro ridges were fabricated on the bottom of a polydimethylsiloxane (PDMS) channel at an oblique angle to the flow direction. The mixing enhancement between two-fluids was attributed to the helical secondary flow generated along the ridges on the surface of the channel. The increase in the depth or frequency of micro ridges

increases the strength of the helical flow and the rate of mixing in the mixing channel**.** Ou *et al*. (2007) experimentally studied a series of ultra hydrophobic surfaces with diagonal microridges fabricated on the bottom wall of a Y-shaped channel and observed a reduction in the mixing length as much as ten times compared to a smooth hydrophobic surface. They demonstrated maximization in mixing by changing the geometry of the surface structure due to the generation of most favorable slip velocity along the shear-free air-water interface aligned obliquely to the flow direction. They observed the mixing to be less sensitive to the area ratio of the shear-free air-water interface compared to the angle of the microridges. Also the mixing mechanism suggests that fluorescent tagged and untagged fluids stacked vertically leads to enhanced mixing even for micro ridges aligned at 90^o to the flow direction compared to the horizontal stacking. Hu *et al*. (2006) investigated the mixing of pure water and acetone solution under different Reynolds numbers and acetone solution concentration. The mixing efficiency decreases with increase of acetone solution concentration and mixing efficiency equal to 98% was observed for the proposed micro mixer. Liu *et al*. (2004) carried out numerical study of mixing between pure water and a solution of glycerol in different micromixers. They observed that at Re=1, the mixing performance for both herringbone and serpentine mixer varies inversely with mass fraction of glycerol due to the dominance of molecular diffusion. However, at Re=10, opposite trend was observed for serpentine mixer which was attributed to the enhancement of flow advection at large mass fraction. Hoffmann *et al*. (2006) used both μ-LIF and μ-PIV techniques for investigating liquid-liquid mixing in T-shaped micromixers. Lindken *et al*. (2005) used a stereoscopic μ-PIV technique to investigate the three dimensional nature of flow in a T-shaped micromixer. Asfer *et al*. (2008) used μ-PIV technique for investigating the effect of repeated transverse micro-ribs on laminar flows in PDMS microchannel. The above literature survey demonstrates the role played by concentration field (two dimensional or three dimensional), the velocity field (two dimensional or three dimensional) and the surface geometry modification as the source for enhanced mixing between the fluid streams. However, no systematic study is available on the influence of relative physical property of the two fluid streams i.e. viscosity ratio and the flow properties i.e. velocity ratio on mixing enhancement between two fluid streams.

The preset study investigates the influence of fluid properties of the two mixing streams on the mixing behavior in a passive ribbed micro mixer with Y-type inlet. A series of micro ribs are oriented at an angle of 90^o to the flow direction on both sidewalls of the mixing-channel. The mixing of two miscible fluids (1) DI water and a solution of acetone in water, and (2) DI water and a solution of glycerol in water has been studied experimentally. The mass fraction (φ) of acetone and glycerol in water has been set equal to 0.2. The mixing performance of the micromixer has been visualized and quantified using the Laser induced Fluorescence (μ-LIF) technique. The Particle Image Velocimetry (μ-PIV) has been used to study the role played by the flow field on mixing of the micromixer.

EXPERIMENTS

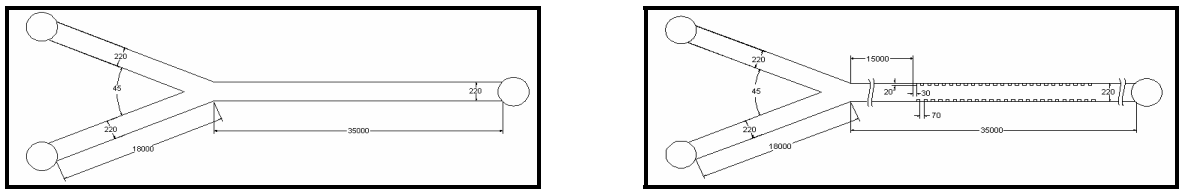
Fabrication of micromixer

Micromixers used in the present experiments were fabricated by using PDMS replica moulding technique at Stanford Microfluidics Foundry (Dept. of Bio-engineering, Stanford University). Two types of micromixers were used: (1) smooth micromixer and (2) micromixer with rectangular ribs on the sidewalls of the mixing-channel. Both the ribbed and smooth micromixer has Y-type inlet and mixing-channel cross-section is equal to 220 μm (width) ×30 μm (depth). Ribs are 20 microns in height and 30 microns in width with a spacing of 70 microns between each rib. The schematic drawing of the micro channel and the microscope image of the ribbed section of the micromixers used in the present study are shown in figure 1 (a) and (b) respectively.

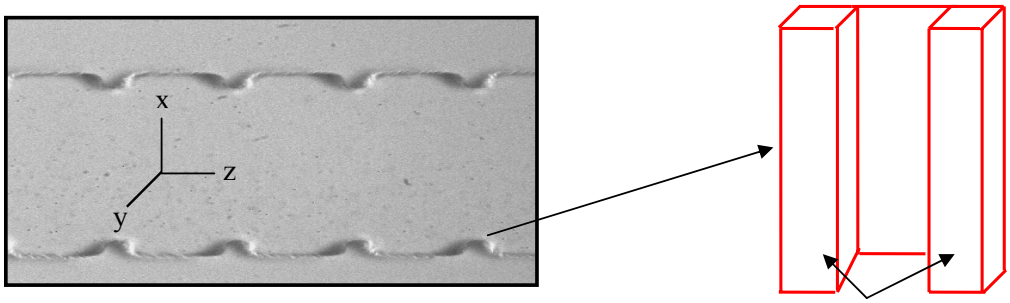
Experimental set up and conditions

The experimental apparatus shown in figure 2 consists of two parts: (a) the flow delivery system and (b) the micro-LIF/PIV system. A double-syringe pump (Injectomate 216, Vital Bio-systems

co.) was used to supply the fluids to the two inlets of the micromixer. The range of flow rates that can be obtained from this pump is 0.1-99 ml/hr with an accuracy of ≤ 2 %. The micromixer was



(a)



(b)

Figure 1. Micromixer geometry (a) smooth and ribbed micromixer (b) Microscope image of the ribbed section of the mixing-channel

kept over the stage of the inverted microscope (Leica Microsystems; DMI 5000M) and connected to the flow delivery system with flexible tubing. In order to prevent building up of any contaminants in the system, pure water was first pumped through the micromixer to expel stagnant contaminants. For μ-LIF measurements, one inlet stream was marked with the fluorescent dye (Rhodamine 6G). The excitation and emission wavelengths of the fluorescent dye are between 460-560 nm and 540-640 nm respectively. Illumination of the flow is achieved by using the light source (halogen lamp 12 V, 100W) with the epifluorescent filters and microscope objective. The concentration images of flow are recorded using a 12-bit 1344×1024 pixels digital CCD camera (HiSense Mk II) and then acquired in the PC for subsequent mixing analysis. For quantitative estimation of mixing, the grey values of the recorded concentration images at different positions (in relation to length of the mixing channel) are investigated by using the DynamicStudio analysis software (Dantec dynamics Inc.). For μ-PIV study, deionized water is used as the working fluid, seeded with a dilution of 1:20 fluorescent carboxylate-modified microspheres (diameter ≈ 1μm, Molecular probes, Inc). This particle concentration is selected as it is the maximum seeding load for acceptably low noise levels under the current illumination conditions. Tracer particles are visualized under bright field illumination mode with a high-power LED serving as light source. The light source and camera are synchronized by a timer box (Dantec dynamics Inc.) The timing between two consecutive LED pulses is set such that the tracer particles moved approximately 1/4th of an interrogation window between the pulses. A standard adaptive cross correlation technique is used to obtain the instantaneous flow field in the mixing channel. The Reynolds number in the respective leg of the Y-inlet is calculated using $\mathrm{Re} = \frac{u_{avg} D_H}{\nu}$ where u_{avg} is the average fluid velocity in the channel, D_H hydraulic diameter and ν kinematic viscosity of fluid. For the solutions of Acetone and Glycerol with a mass fraction φ=0.2 the kinematic viscosity ν is calculated as 0.7962×10^{-6} and 1.8296×10^{-6} m^2/s respectively.

Mixing performance evaluation

Evaluation criterion for the performance of two-fluid mixing inside micromixer has been based on the uniformity of the concentration inside the micro channel. Liu *et al*. (2004) assessed two-fluid mixing in micromixers through measurements of the deviation of the pixel intensity I_i values in a given image from average intensity value I_{mean}, i.e.

$$C_{dev} = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N}(I_i - I_{mean})^2}}{2^n - 1} \quad (1)$$

where N is the total number of pixels and n' the grey bit number of the image under analysis. To compare the mixing performance of the mixers under a range of conditions C_{dev} is further normalized as follows to give the mixing index,

$$C_{mix} = \frac{(C_{dev\_inlet} - C_{dev})}{C_{dev\_inlet}} \quad (2)$$

Where C_{dev_inlet} and C_{dev} are the values at the inlet and at the position of interest (in relation to mixing-channel length) respectively. If two fluids are fully mixed in the mixing-channel, the intensity I_i in equation (1) is the same for every pixel, and consequently C_{mix} is equal to 1 and for no mixing it is zero. The concentration field is calculated based on the calibration between dye concentration and intensity values (grey values) of pixels. Figure 3 shows a linear relationship between the intensity of the fluorescent image and the dye concentration for both acetone and glycerol solution in the concentration range of 0-29.2 μmol/lit.

RESULTS AND DISCUSSION

LIF Results

The mixing performance of ribbed micromixer for acetone-water and glycerol-water solution under different flow conditions has been investigated using LIF technique. The positions of interface between the two fluid streams with respect to one of the sidewalls for different flow conditions are presented in Table 1. The Reynolds number is calculated based on the flow rate in respective leg of the Y-channel. The position of the interface with respect to the ribbed surface is expected to play an important role as there is a possibility of cross flow generation near the interface. Table 1 shows the interface to be located at about 24.36 and 26.66 μm for the acetone-water flow at $Re_{acetone}$ = 2.8 and 4.0, and Re_{water} = 20.8 and 29.5 respectively. For the glycerol-water flow, the interface is located at about 31.4 and 34.96 μm at $Re_{glycerol}$ = 1.2 and 1.7, and Re_{water} = 20.8 and 29.5 respectively. For the same velocity ratio (VR = 9.17), the interface of glycerol-water is located farther (31.4 μm) from the side wall compared to that of acetone-water (24. 36 μm). It should be remembered that the rib

height is equal to 20 μm and therefore the acetone-water interface is located closer to the rib compared to that of glycerol-water.

For the velocity ratio, VR=9.17, the mixing index results have been reported in Figure 4 (a) and (b) for acetone-water and glycerol-water respectively. The mixing index variation along the mixing-channel of a smooth micromixer under the same experimental conditions is also shown for comparison with that of ribbed micromixer. The mixing index at the end of the mixing-channel increases in streamwise direction for both acetone-water and glycerol–water flow. The mixing index in the ribbed section is higher than that of the smooth channel for acetone-water flow. The mixing index at the exit of the channel is also largest for the higher Reynolds number case. The corresponding fluorescence images of concentration field at different streamwise locations of the mixing-channel are shown in figure 5**.** The interface between the two fluids is sharper in the entrance region of the Y-channel clearly showing the two-fluid region. In the ribbed and post-rib region, the interface region is comparatively blurred due the mixing between the two-fluids. The water flow side in the ribbed region of acetone-water flow shows higher light intensity compared to that in the pre-rib region and also the ribbed-region of glycerol-water flow due to superior mixing. Overall observation from the visualization images of figure 5 corresponds well to that of mixing index in Figure 4.

The PIV measurements show parabolic velocity profile indicating higher mean fluid velocity at the center of the channel compared to that in the near the wall region. The interface in the present flow is located closer to the wall resulting in lower velocity at the interface. Hence, the mixing is expected to be influenced by both convection and diffusion. The residence time for diffusion near the wall is high because of low velocity as compared to the center region of the mixing channel. The numerical predictions for smooth T-mixer shows increase in the mixing length requirement for complete mixing between two fluid streams with increase in Re. The present study shows more mixing for the same mixing-channel length with increase in Re due to the presence of ribs. This can be attributed to larger effect of ribbed structures on the interface of the two fluid streams at higher Re compared to the lower Re case due to more stretching and thinning of fluids occurring in the near ribbed wall region. The stretching and thinning of fluids near the ribbed wall produces stronger transverse velocity component as compared to the smooth micromixer contributing to higher mixing between the two fluid streams. The mixing index at the outlet of the mixing-channel is about 17.36% and 33.98% more compared to the smooth micromixer for acetone- water and glycerol- water flow respectively. Thus, the influence of ribbed region is also a function of the nature of the fluid.

Table 1 Interface locations (δ) between the two fluid streams (acetone- water and glycerol- water) as a function of Reynolds number.

Velocity ratio (VR)	Reynolds no. (Acetone- water)	Interface location (μm)	Reynolds no. (Glycerol- water)	Interface location (μm)
9.17	$Re_{acetone}$ =2.8 Re_{water} =20.8	26.66	$Re_{glycerol}$ =1.2 Re_{water} =20.8	34.96
9.17	$Re_{acetone}$ = 4.0 Re_{water} =29.5	24.36	$Re_{glycerol}$ =1.7 Re_{water} =29.5	31.40

PIV Results

The velocity field from PIV measurements is useful for understanding the role played by convection on mixing between the two streams. The flow in the smooth region of the mixing-channel is fully developed due to long length of the channel prior to the ribbed region. Figure 6 shows the normalized u and v velocity field in the inter-rib region between 3rd and 4th ribs for both acetone-water and glycerol-water flow. The normalization has been carried out using the maximum u-velocity. The centerline velocity (u_{max}) is equal to 0.0223 ms^{-1} and 0.019 ms^{-1} for acetone-water

and glycerol-water flow respectively. The measurements are reported in the half-width region of the channel i.e. from mixing-channel centerline to the lower ribbed wall at different streamwise locations (z/h) in the inter-rib regions. The streamwise velocity profile shows a gradual decrease in magnitude from the channel centerline towards the lower ribbed wall, however there is no significant variation along the streamwise directions. The nature of the u-velocity profile is not exactly parabolic as in the smooth region of the mixing-channel, which can be attributed to the presence of micro ribs on the sidewalls of the mixing-channel. The transverse v-velocity changes its sign from negative to positive along the streamwise directions in the inter-rib region. The v-velocity magnitude is stronger between z/h= 0.6 to 1.2 compared to that between z/h=0 to 0.3 in the inter-rib region which can attributed to the different flow behavior in the upstream and downstream portion of the inter-rib region. The average v-velocity magnitude for the acetone-water flow is more than that of glycerol-water flow. There is also a general increase in the v-velocity magnitude in ribbed micromixer compared to that of the smooth micromixer. The higher v-velocity is attributed towards better mixing enhancement between the two fluid streams. This observation from velocity field correlates well with the observation from LIF measurements. The u-velocity vector field and v-velocity magnitude contours in the inter-rib region for acetone-water and glycerol-water flow are shown in figure 7. There is in general higher magnitude of both u and v-velocity for the acetone-water flow case compared to that of the glycerol-water. There is no significant difference in u-velocity between the acetone-water and glycerol-water flow case. The gradient in u-velocity is observed for both the flow. However, the overall v-velocity magnitude is higher for the former case compared to the later. Therefore, the higher v-velocity fields due to the rib near the interface between two-fluid is attributed to higher mixing.

SUMMARY

The present study reports the effect of surface modification, i.e. micro ribs on mixing between two different fluids (acetone-water and glycerol-water solution) by using the "micro-laser induced fluorescence'' (μ-LIF) and "micro particle image velocimetry'' (μ-PIV) techniques. The ribs on the side walls of the microchannel aligned at an angle of 90^o to the flow direction lead to stretching and thinning of fluid elements, which efficiently reduces the mixing length requirement for complete mixing compared to that of smooth micromixer. The mixing between the two streams is higher at higher Reynolds number for both acetone-water and glycerol-water flow case. The mixing is lower for glycerol-water case compared to that of the acetone-water at same velocity ratio between the two streams. The μ-PIV results demonstrates a strong transverse velocity component as compared to smooth micromixer leading to higher stretching and thinning of liquid elements near the interface and hence mixing enhancement between the two fluid streams.

HEAT TRANSFER PROPERTIES OF NANODIAMOND-ENGINE OIL NANOFLUID FLOWING IN A MICROFIN TUBE

M.Ghazvini*, M.A.Akhavan-Behabadi, M.Raisee, E.Rasouli
Faculty of Mechanical Engineering, University College of Engineering, University of Tehran, Iran

ABSTRACT. Heat transfer enhancement of engine oil-nanodiamond nanofluid with different particle concentration under constant heat flux is investigated, experimentally. The test section is a horizontal microfin tube of 8.92 mm I.D., 9.52 mm O.D. and 1025 mm length. The nanofluid flowing inside the tube is heated by an electrical coil heater wrapped around it. Experiments are carried out under three different constant heat fluxes of 3, 8 and 13.5 kW/m^2 and Reynolds numbers up to 100. Experimental results clearly indicate a heat transfer enhancement of up to 55% due to the presence of nanoparticles in the base fluid. This heat transfer augmentation increases with an increase in Reynolds number and heat flux. The performance analysis of adding nanodiamond to engine oil flowing inside a microfin tube shows that, by increasing the Reynolds number, the performance index is increased; it means that the use of nanoparticles as additives to enhance heat transfer coefficients, is recommended specially at high Reynolds numbers.

INTRODUCTION

Ultrahigh-performance cooling is one of the most vital needs of many industrial technologies. However, to develop an energy-efficient heat transfer fluid that is required for ultrahigh-performance cooling, the low thermal conductivity is a primary limitation. The produce of metallic or nonmetallic particles of nanometer dimensions can be achieved by modern nanotechnology. Nanomaterials have unique mechanical, optical, electrical, magnetic, and thermal properties. Nanofluids are made by suspending nanoparticles with average sizes below 100 nm in traditional heat transfer fluids such as water, oil, and ethylene glycol. Fluids with suspended solid particles are expected to have better heat transfer properties compared to conventional heat transfer fluids. These special properties make nanofluid a revolutionary coolant for future devices.

In addition, another way of enhancing heat transfer is extending the heat transfer surfaces; it provides a better contact between the fluid and the carrier. The microfin tubes are widely used in different heat exchangers because of their good enhancement capability and relatively low pressure drop in comparison with the other conventional extended surfaces.

Nanofluids found to possess long time stability and large efficient thermal conductivity [1]. Lee [2] reported that suspension of 4% volume fraction of CuO 35 nm particles in ethylene glycol shows 20% increase in thermal conductivity. Since the theoretical models such as Maxwell correlation [3] cannot determine exactly the thermal conductivity of nanofluids, therefore it is necessary to study about thermal conductivity enhancement mechanisms of this kind of fluids. Chopkar et al [4] prepared nanofluids by dispersing about 0.2–1.5% volume fraction of Al_2Cu and Ag_2Al nanoparticles in water

and ethylene glycol. They characterized the size/microstructure of nanoparticles by X-ray diffraction and transmission electron microscopy, and measured the thermal conductivity of nanofluid using a modified thermal comparator. Moreover, Nie et al. [5] in a paper discussed several proposed mechanisms of thermal conductivity enhancement in nanofluids using a mathematical and analytical approach.

There are relatively few studies involved in describing fluid flow and convective heat transfer performance of the nanofluids. Li and Xuan [6] studied convective heat transfer of 35 nm Cu/ water nanofluid and showed that the suspended nanoparticles remarkably enhance heat transfer process with smaller volume fraction of Cu nanoparticles.

Some other experimental or theoretical investigations indicated that the Nusselt number of the nanofluids increases with increasing volume fraction of the nanoparticles [7, 8]. However Pak and Cho [9] expressed that the convective heat transfer coefficient of Al_2O_3 /water and TiO_2 / water nanofluids with concentration of 3.0% volume was 12.0% smaller than that of pure water. Putra [10] reported suppression of natural convection heat transfer by nanofluid of Al_2O_3 / water and CuO/ water and concluded that this could be due to nanoparticles settling and velocity difference between nanoparticles and main fluid. Nanofluid boiling process was investigated experimentally by several researchers. Das et al. [11] observed nanofluids boiling performance deterioration.

As far as the numerical predictions for forced convection of nanofluids is concerned, only recently a few papers have been published. Maiga et al. [12] presented numerical results for laminar and turbulent nanofluid flow through a uniformly heated tube using the Fluent code; however, no comparison between their numerical and experimental data was reported. Akbarinia and Behzadmehr [13] have numerically studied laminar mixed convection of a nanofluid consisting of water and Al_2O_3 in a curved tube. No comparison with experimental data was reported in their work. Recently, Raisee and Moghaddami [14] numerically studied laminar forced convection of nanofluids through circular pipes using two different models. Comparisons of numerical results with experimental data showed that it is necessary to include the effects of Brownian motion in modeling of viscosity and thermal conductivity to achieve reliable predictions.

Al-Fahed and Chamra [15] experimentally investigated the heat transfer and pressure drop of oil flow in plain tubes, microfin tubes and in tubes with twisted tape inserts. They reported that heat transfer enhancement and pressure drop of microfin tube flow were more than those of plain tube. Also, Afroz and Miyara [16] tested water flow in microfin tubes and found similar results.

The objective of the present work is to study the convective heat transfer characteristics of nanodiamond / engine oil nanofluid flowing inside a microfin tube.

EXPERIMENTAL FACILITY AND PROCEDURE

Figure 1 shows the schematic diagram of experimental set-up. The flow loop is consists of test section, cooler, receiver, gear pump, flow measuring apparatus, various thermocouples and flow controlling system. In order to control the fluid flow rate a reflux line with a valve is used. The test section is a horizontal microfin tube of 8.92 mm I.D., 9.52 mm O.D. and 1025 mm length. The microfin tube is a copper tube having internal microfins with triangular fin cross-sections. The geometrical parameters of microfin tube are shown in Figure 2.

The nanofluid flowing inside the tube is heated by an electrical heating coil wrapped around it. The test section (tube and heater) is completely insulated with glass wool pads. Two K-type thermocouples are used to measure the bulk temperatures of nanofluid flow at inlet and outlet of test section. Also, six

pairs of K-type thermocouples are mounted with uniform distances of 125 mm on the external surface of the test tube to measure the wall temperatures.

Pipe length	L= 1200 mm	Area enhancement	$\varepsilon_a = 1.63$

Figure 2. Geometrical parameters of microfin tube.

In the present work, nanodiamond-engine oil nanofluid is used as the working fluid. Nanofluids with different diamond nanoparticles concentrations of 0.2%, 0.5%, 1.0%, and 2.0% weight fractions in 20W50 engine oil are used. The nanofluid is prepared and dispersed using mechanical (ultrasonic vibrator) and chemical (adding dispersant) treatments. Flow measuring section is consisted of a 500 cm^3 glass vessel with a valve at its bottom. The flow rate is directly computed by measuring the time required to fill the glass vessel. The constant exerted heat fluxes are 3, 8 and 13.5 kW/m^2 with

Reynolds numbers varying from 2 to 100. Furthermore, the thermal conductivity and specific heat of nanofluids are measured using KD2 and DSC F3 Maia apparatuses, respectively.

RESULTS AND DISCUSSION

Specific heat

A differential scanning calorimeter was used to measure the heat capacity of different nanofluids and the pure engine oil. Based on the collected data, different correlations were developed to predict the specific heat of pure engine oil and nanofluids. Table 1 demonstrates the correlations for pure engine oil and 1% weight fraction nanofluid.

Table 1
Specific heat as a function of Temperature

Fluid	Correlation
Pure Engine Oil	$Cp = 1.77 + 1.18\times10^{-2}T - 2.02\times10^{-4}T^2$
1% Nanofluid	$Cp = 2.07 - 2.30\times10^{-3}T + 1.19\times10^{-4}T^2$

Thermal conductivity

The thermal conductivity of nanofluids were measured at several temperatures. Using the present data, the following correlation was developed to estimate the thermal conductivity of nanofluids:

$$k_{nf} = 0.126 + 0.074\varphi - 0.056\varphi^2 + 0.015\varphi^3 \quad (1)$$

where φ is the weight fraction of nanoparticles.

Convection heat transfer

During all the test runs, the Reynolds number is small enough so that the flow can be considered as fully-developed; however, the Prandtl number of engine oil is about 1500 and the temperature field is in thermally developing condition.

Equation (2) is used to calculate the local convection heat transfer coefficient.

$$h(x) = \frac{\dot{m}c_p}{\dot{m}c_p (T_s - T_i)/q'' - Px} \quad (2)$$

Where, T_s and q" are taken from experimental data.

To calculate the mean heat transfer coefficient, the following expression is used.

$$\bar{h} = \frac{1}{L}\int_0^L h(x)\,dx \quad (3)$$

The variation of local convection heat transfer coefficient along the tube for pure engine oil and different nanofluids is presented in Figure 3. The results are for Peclet number of 10000 and heat flux of 8 kW/m^2. A significant enhancement is seen as a result of utilizing nanofluid instead of pure

engine oil. This enhancement is about 41% for the nanofluid with 2% weight fraction in comparison with pure engine oil at x=0.2 m.

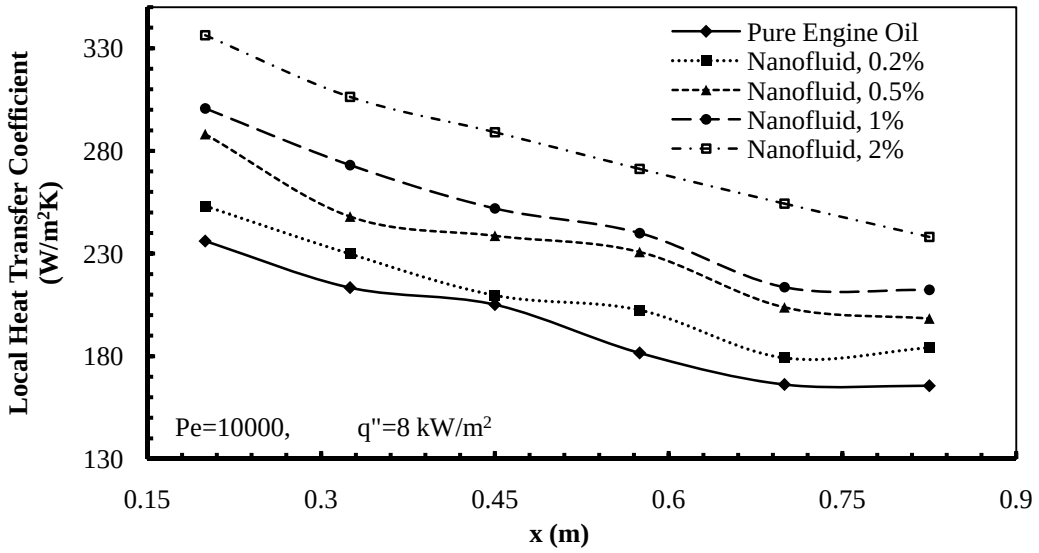

Figure 3. Local heat transfer coefficient as a function of *x* for different nanofluids

Figure 4 shows the variation of mean heat transfer coefficient as a function of weight fraction in two Peclet numbers of *Pe*=10000 and *Pe*=15000, and two heat fluxes of 3 and 13.5 kW/m^2. The effect of nanoparticles in enhancing heat transfer can be easily seen in this figure. In addition, one can note the effect of heat flux changes on the heat transfer coefficient. For microfin tube, the highest heat transfer enhancement is about 55% which is belonged to 2% nanofluid at heat flux of 3 kW/m^2. Moreover, higher Peclet number leads to a higher heat transfer coefficient.

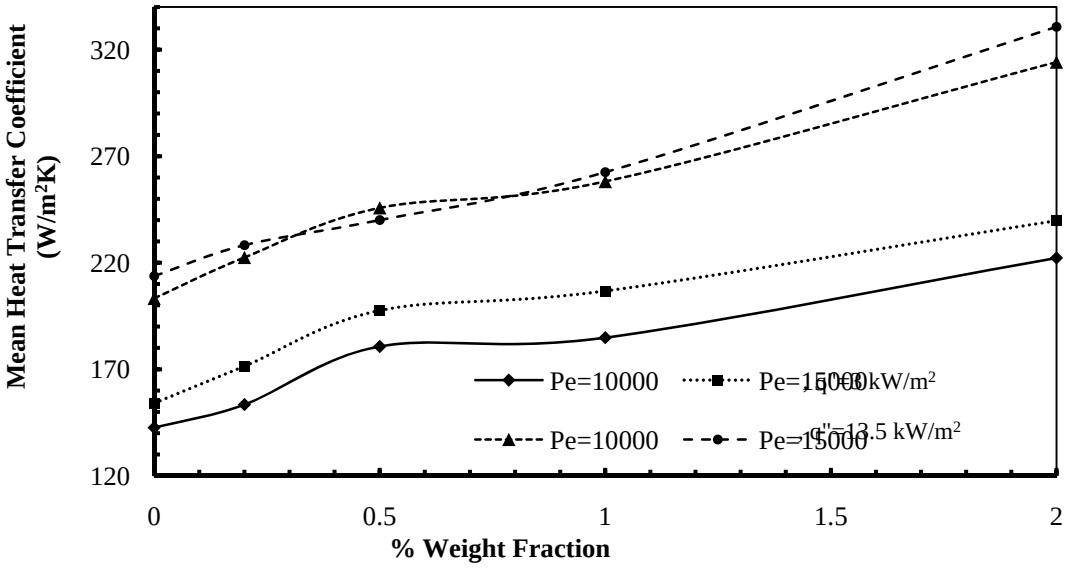

Figure 4. Variation of mean heat transfer coefficient with weight fraction

Performance analysis

In order to analyse the performance of a system using microfin tube and nanofluid together, the increase of pressure drop as a result of adding nanoparticle should also be considered. Utilizing the experimental data of pressure drop exists for the same set-up and flow conditions, the performance index (η) is calculated using Equation (4).

$$\eta = \frac{\left(\frac{h_{nf}}{h_f}\right)}{\left(\frac{\Delta P_{nf}}{\Delta P_f}\right)} = \frac{R_h}{R_{\Delta P}} \tag{4}$$

According to the above correlation, if the index is more than one, using nanofluid is efficient. Figure 5 shows the performance index for different working conditions. As it is seen, by increasing the Reynolds number, the performance index increases. Therefore, using both of nanofluid and microfin tube to enhance heat transfer coefficient is recommended specially at Reynolds Numbers more than 10.

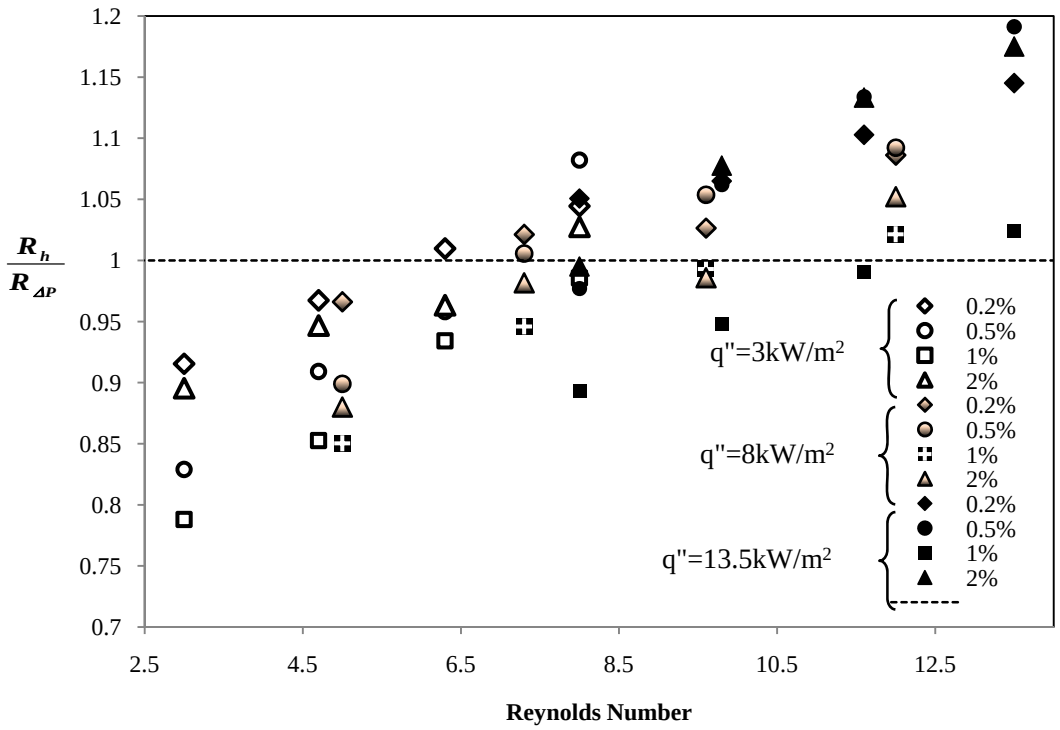

Figure 5. Performance index as a function of Reynolds number

CONCLUSION

The following conclusions are achieved from the present experimental work:

1) The use of nanofluid instead of pure fluid and microfin tube instead of smooth tube, enhances the heat transfer coefficients significantly. The rate of enhancement is more in lower heat fluxes.
2) Higher Reynolds (Peclet) numbers and higher heat fluxes lead to higher heat transfer coefficients.

3) The maximum heat transfer enhancement is about 55% which is belonged to nanofluid of 2% weight fraction at heat flux of 3 kW/m^2.
4) The performance analysis of adding nanodiamond to engine oil flowing inside a microfin tube shows that, by increasing the Reynolds number, the performance index is increased; it means that the use of nanoparticles as additives to enhance heat transfer coefficients, is recommended specially at high Reynolds numbers.

INVESTIGATIONS ON THE DELIVERING BEHAVIOUR OF MULTIPHASE SCREW PUMPS

A. Scharf[1], G. Aleksieva[1], J. Lewerenz[2], D. Mewes[1]*
[1]Institute of Multiphase Processes, Leibniz University Hannover, Germany
[2]Bornemann Pumps, Obernkirchen, Germany

ABSTRACT. Multiphase screw pumps are used for the delivery of gas-liquid-flows even at high gas rates. In order to estimate their delivering behaviour a model is derived, which is based on mass and energy balances for single closed chambers formed by the intermeshing and counter-rotating screws. Thereby the pressure profiles inside the pumps are predicted, which determine the mechanical loads to the rotating and static components as well as the delivered volume flows. In order to verify the calculated results, the pressure profiles are measured along the inside of the cylindrical casing in dependence of several characteristic operating modes of multiphase screw pumps.

Keywords: *multiphase pump, screw pump, multiphase flow*

INTRODUCTION

Multiphase pumping is applied in the oil and natural gas exploring and conveying industry especially in offshore applications. By means of multiphase transport cost-intensive separation units on offshore platforms can be avoided, because the gas-liquid-mixtures can be conveyed directly to central separation units located onshore. As a consequence the number of platforms is reduced, which leads to a saver and more efficient offshore oil production.

Multiphase screw pumps can handle gas-liquid-flows with gas volume fractions up to 0.95 and withstand even temporary dry runs. Furthermore, screw pumps are suitable for the delivery of high-viscous fluids since they operate without valves.

In Figure 1 the design of a screw pump is presented.

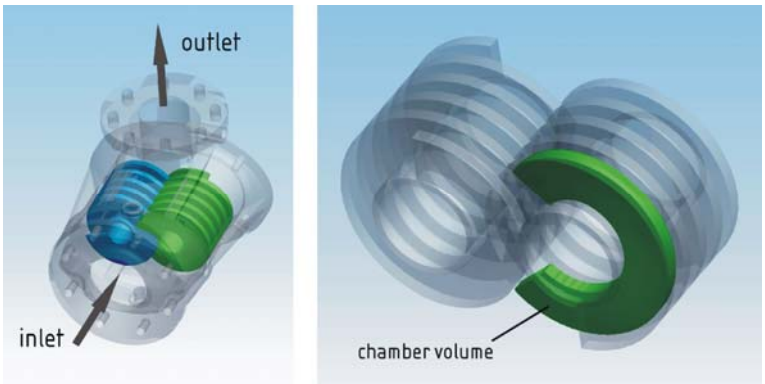

Figure 1. Twin screw pump and position and shape of a chamber

* Corresponding author: Prof. Dr.-Ing. Dr. h.c. Dieter Mewes

E-mail address: mewes@ifv.uni-hannover.de

The multiphase mixture entering the pump gets into the chambers formed by the intermeshing screws and the enclosing housing (cp. Figure 1). Due to the rotation of the screws, the chambers are closed at the suction side of the pump and move along the screw axis towards the outlet. At the discharge side, the chambers open and the gas-liquid-mixtures are released through the outlet.

Since the rotation of the screws is contactless, several gaps are located between the intermeshing screws and between the screws and the housing. Three different types of gaps occur and are shown schematically in Figure 2.

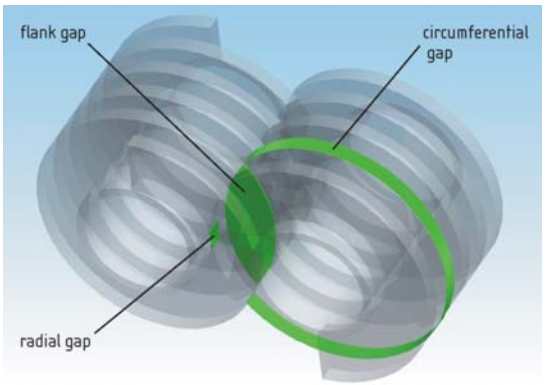

Figure 2. Gap types in a screw pump

The circumferential gap is an annular gap between the tip circle of a screw and the inner wall of the housing. The radial gap is placed between the tip circle of one screw and the root circle of the opposed screw. The flank gap is a lenticular gap, which is placed between the flanks of adjacent intermeshing screws.

During the movement of a chamber along the axis of the intermeshing screws, the chamber pressure increases. This leads to pressure differences between adjacent chambers and thus to internal backflows of the gas-liquid-mixture through the different types of gaps. The gap flows determine the shape of the resulting pressure profiles along the screw axis.

The pressure profiles are highly affecting the delivery flows as well as the mechanical loads to the pump's components. In order to estimate the delivering behaviour of screw pumps the calculation of the pressure profiles are done by mass and energy balances for closed chambers. In order to verify the calculated pressure profiles the pressure build-up is measured in a multiphase screw pump for different operational conditions and compared to the calculated results.

There are several attempts to describe the delivering behaviour of multiphase screw pumps by the transport equations for momentum, mass and energy. Etzold [1] calculates the change of pressure in closed chambers inside the pump and the loss flows by setting up boundary conditions for continuous pressure raise in the closed chambers while moving from the inlet to the outlet. Furthermore, Etzold [1] reduces the boundary value problem to an initial value problem, which he solves iteratively. Körner [2] and Wincek [3] use similar approaches but calculate two separate cases with an integer number of stages, which are below and above the real number of stages. Weighting these two cases according to the real number of stages leads to an approximate solution. Feng, Yueyuan, Ziwen and Pengcheng [4] present a model, by which the backflow within the screw pump depending on the rotational angle is determined. There is two-phase flow in the radial and flank gaps and pure liquid flow in the circumferential gaps. The effect of acceleration pressure drop on the gap flows is neglected. Nakashima [5] chooses a different approach by deviding the multiphase pumping operation into an arrangement of fundamental processes like separation, pumping, compression and mixing. Nakashima applies the process simulator HYSYS for solution.

Naujoks [6] applies a chamber model to calculate the delivering behaviour of screw compressors, which considers the reduction of the chamber volume. Neumann [7] calculates the delivering behaviour of screw compressors by means of mass and energy balances, including heat transfer across the chamber boundaries.

MATHEMATICAL FORMULATION

The volume flow of the multiphase mixture at inlet conditions

$$\dot{V} = \dot{V}_{theo} - \dot{V}_{loss} - \dot{V}_{rec} \tag{1}$$

is determined by the difference between the theoretical displacement volume flow $\dot{V}_{theo}$ and the loss flow

$$\dot{V}_{loss} = \dot{V}_{l,loss} + \dot{V}_{g,loss} \tag{2}$$

and the recirculation flow $\dot{V}_{rec}$. The theoretical displacement volume flow is a function of the shape and the rotational frequency of a twin screw pump. In order to estimate the performance of a pump the volumetric efficiency

$$\eta_{vol} = \frac{\dot{V}_{theo}}{\dot{V}} \tag{3}$$

is defined as the ratio of the theoretical displacement volume flow $\dot{V}_{theo}$ and the actual displacement volume flow of the pump $\dot{V}$. Within some special designed pumps, separated liquid is recirculated from the outlet to the inlet. This flow is defined as recirculation flow. This design helps to enhance the sealing of the gaps inside the pump for high gas volume fractions. The loss flow is directed across the closed chambers inside the pump via different gaps back to the inlet of the pump. It can be of multiphase type and caused by two components. One is pressure driven and the other component is due to the rotation of the screws a shear flow induced one [8].

Time intervalls model the movement of the chambers along the rotating screws. For each time intervall mass and energy balances are set up for each closed chamber. Those are considered as open systems (Figure 3). The differential equation for the change of liquid mass inside a closed chamber gives

$$\frac{dM_{l_i}}{dt} = \sum_{in} \dot{M}_{l_i} - \sum_{out} \dot{M}_{l_i} \tag{4}$$

and for the mass change of gas

$$\frac{dM_{g_i}}{dt} = \sum_{in} \dot{M}_{g_i} - \sum_{out} \dot{M}_{g_i} \tag{5}$$

i has the meaning of the chamber index. Eq. 4 and Eq. 5 mean that the amount of each phase in a closed chamber is only changed by the incoming and the outgoing mass flows crossing the gaps.

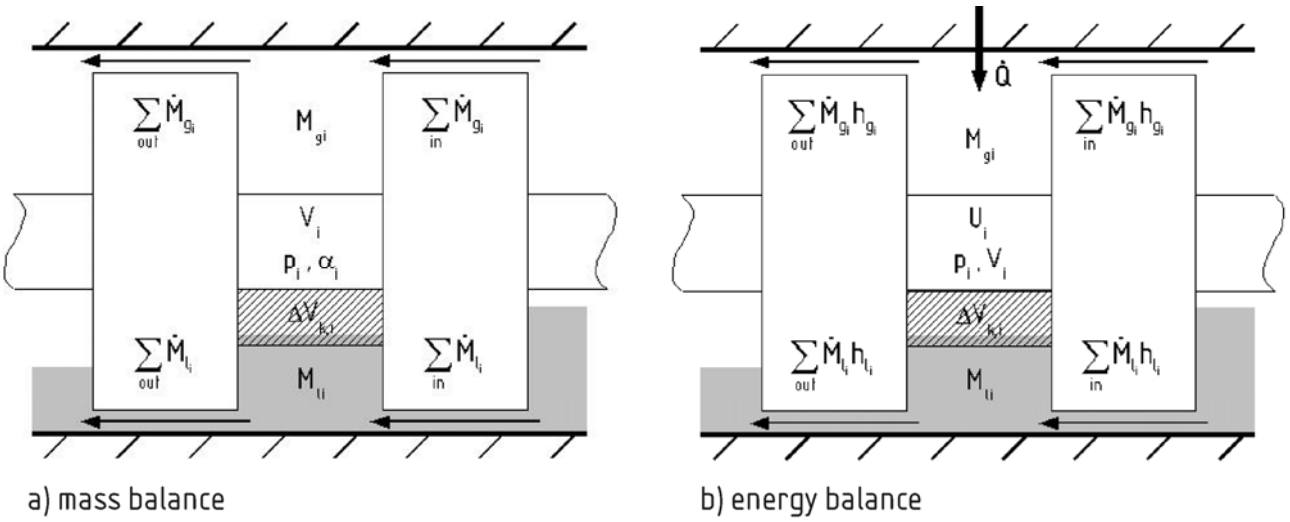

Figure 3. Closed chamber as an open mass system (a) and a transient thermodynamic system (b)

Since enthalpy is transferred between adjacent chambers via the gap streams, a closed chamber is considered as a transient open thermodynamic system (Figure 3 (b)).

The energy blance for a closed chamber is

$$\frac{dU_i}{dt} = \sum_{in}\left(\dot{M}_{l_i} h_{l_i} + \dot{M}_{g_i} h_{g_i}\right) - \sum_{out}\left(\dot{M}_{l_i} h_{l_i} + \dot{M}_{g_i} h_{g_i}\right) + \dot{Q} + \dot{W}_v \qquad (6)$$

the change of the internal energy U_i by time is determined by the sum of incoming and outgoing enthalphy flows. The heat flow $\dot{Q}$ is crossing the chamber boundary and W_v is the requested power for compressing the gas phase. The heat flow $\dot{Q}$ is caused by the friction in bearings and sealings. It is measured in dependence on the rotational frequency. The additional power of compression is caused by the reduction of the chamber volume while moving along a screw with declining pitch.

The algorithms for calculating the delivering behaviour are taken from an existing numerical program called SiMuS (simulation of multiphase screw pumps) and published in [9]. As input data geometrical and operational parameters have to be provided. Output values are for example volume flow, volumetric as well as thermodynamic efficiency and pressure distribution within the pump.

The internal backflows between adjacent chambers through the different gaps affect the shape of the resulting pressure profile along the screw axis. Thus it is important to calculate the different gap flows precisely [10]. In the current applied equations all gap flows are assumed to be pure liquid according to a hypothesis mentioned by many authors [1], [2], [3]. A gap flow consists of two components. One is pressure driven and the other component is due to the rotation of the screws a shear flow induced one.

EXPERIMENTAL SETUP

In order to verify the calculated pressure profiles the pressure build-up along the screw axis is measured by means of a test rig. The corresponding flow chart is shown in Figure 4.

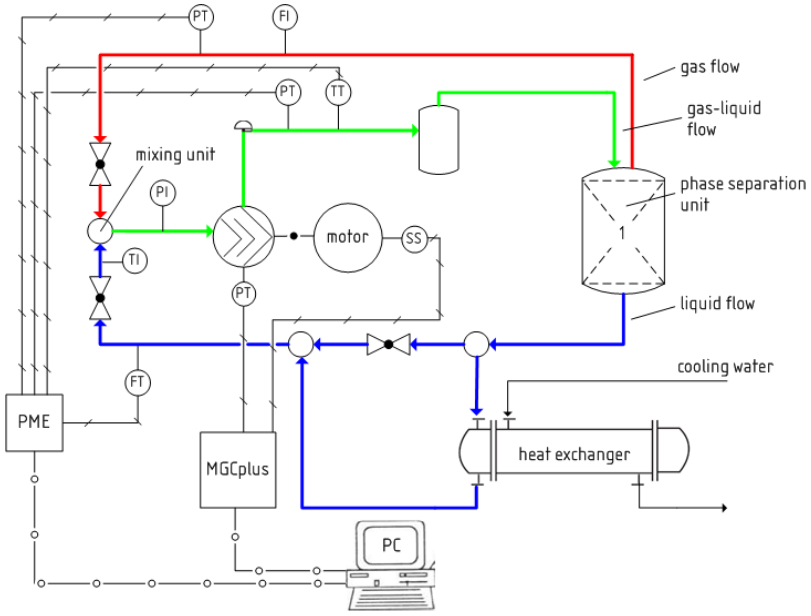

Figure 4. Flow chart of the test facility

The gas and liquid flows are mixed in a Y-mixing unit, downstream of which the gas-liquid-mixture enters the pump. After leaving the pump, the pressurised fluid flows into a small vessel, in which liquid accumulates at the bottom for external recirculation. Downstream the phases are separated in a separation unit by means of a structured packing and further internals, which extend the hold-up time of the liquid phase in the vessel. The temperature of the liquid phase is determined by a tube heat exchanger. Valves in the gas and liquid stream determine the pressure build-up in the pump. The rotational frequency of the motor and thus of the screws is determined by a frequency converter.

The signals of temperature, flow rate and pressure metering points are processed by means of the software Catman Professional 5.0.

The used pump is a SL 125 Twin Screw Pump, produced by Bornemann Pumps GmbH (Figure 5).

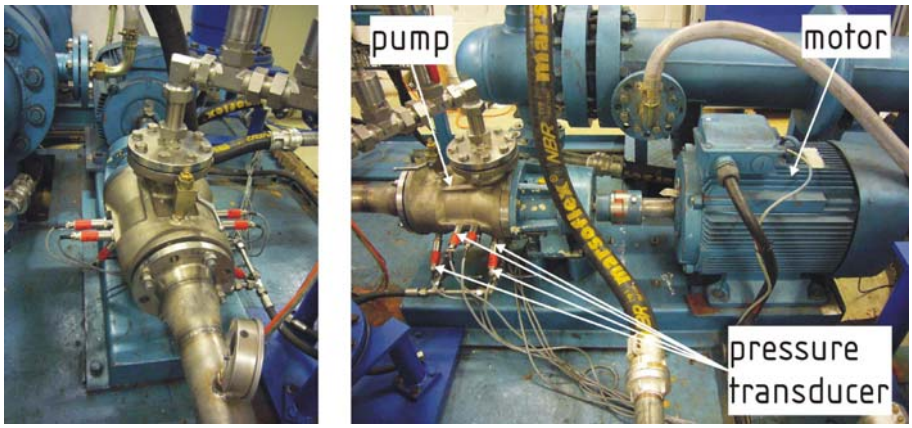

Figure 5: Used screw pump with installed pressure transmitters

The red labelled instruments are seven pressure transducers. In dependence on the rotation angle of the screws a pressure profile is obtained by combining and synchronising the time-dependent signals of all seven pressure transducers.

RESULTS

In context of the experimental investigation the influence of the

- rotational frequency of the screws
- pressure difference over the pump
- gas volume fraction of the mixture
- the design of the screws (degressive/constant pitch)

on the pressure profile along the screw axis are observed. Thereby the gas volume fraction turns out to influence on the pressure profile. In Figure 6 measured pressure profiles along the screw axis are presented as a function of the gas volume fraction. The measured pressure profiles are not measured over the whole length of the screw. For increasing gas volume fractions the pressure profile becomes more progressive ($0.00 \leq \alpha \leq 0.74$), which leads to less loss flow due to the lower pressure build-up close to the suction side ($0 \text{ mm} \leq z \leq 23 \text{ mm}$). Over a certain gas volume fraction of the mixture ($\alpha > 0.74$) the pressure profile becomes linear again.

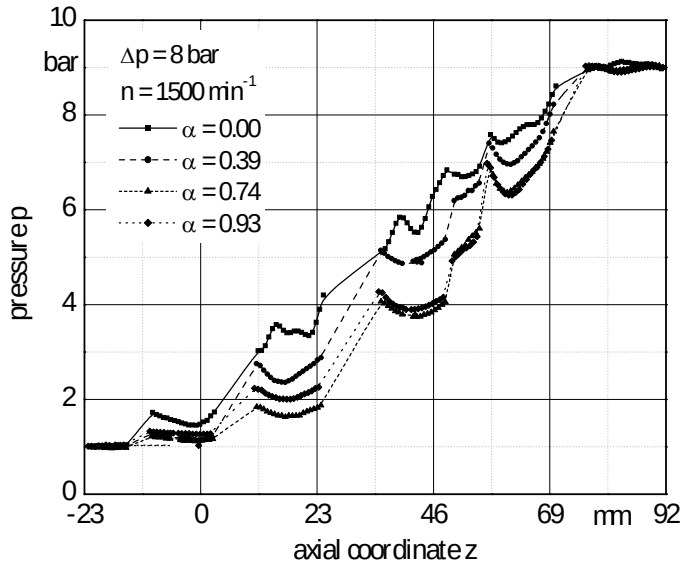

Figure 6. Measured pressure profiles as a function of the gas volume fraction

The corresponding volumetric efficiencies are presented in Figure 7 as functions of the gas volume fractions and the rotational frequencies of the screws. Since the screw pump does operate without recirculation the amount of liquid conveyed in the chambers does not seal the gaps properly with liquid. This leads to higher gaseous gap flows and thus to a higher loss flow for very high gas volume fractions.

In Figure 8 measured and calculated pressure profiles are shown for a medium gas volume fraction ($\alpha = 0.39$) and for a high gas volume fraction ($\alpha = 0.93$). Since the calculations are conducted for screws with the constant pitch of 23 mm the vertical lines are separating the adjacent chambers from each other. After 3.28 rotations (3.28 chambers) a chamber is opened to the discharge side and the pressure increases rapidly to the discharge pressure. The calculations are conducted with and without considering the flow through the flank gaps.

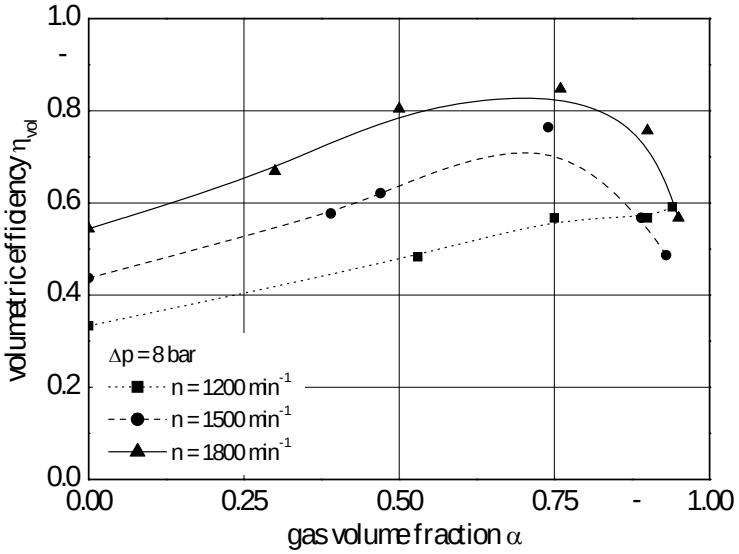

Figure 7. Measured volumetric efficiency as a function of the gas volume fraction

The differences between measured and calculated pressure profiles are smaller, if the flow through the flank gaps is taken into account. The consideration of the flank gaps leads to an interaction between the pressure profiles of both screws. This is why besides the opening of the last chamber the opening of the opposed screw's last chamber also leads to pressure increases in all chambers at a certain rotation angle. Without considering the flank gaps the received pressure profiles are too progressive, which leads to an underestimation of the pump's loss flow and thus to an overestimation of the pump performance. Since the pressure profiles become more linear by considering the flank gaps the difference of the calculated results with and without the flank gaps becomes bigger for increasing gas volume fractions (cp. $\alpha = 0.93$).

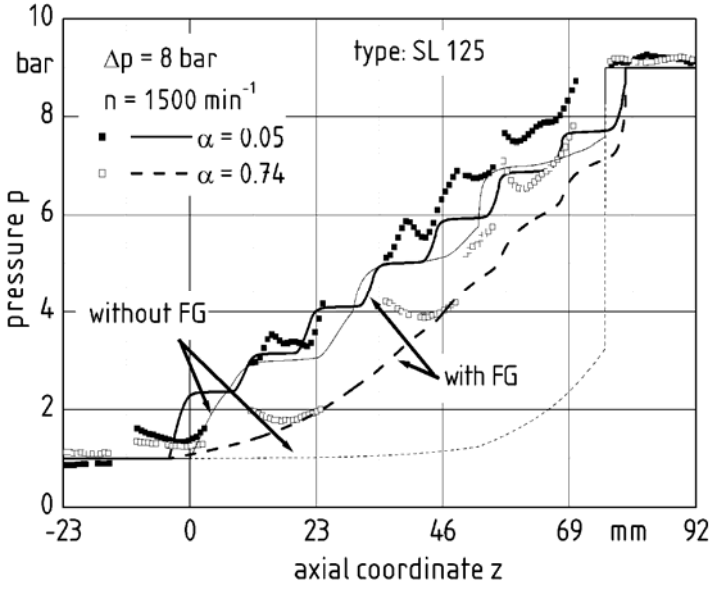

Figure 8. Measured and calculated pressure profiles

CONCLUSIONS

The calculation model allows to obtain the pressure build-up and the delivery flow of a multiphase screw pump in dependence on the screw design and the operating conditions. By means a new

designed experimental setup the pressure build-up and the delivery flow are measured and compared to the calculated results. The comparison is done with and without considering the flow through the flank gaps in the calculation model. The measured pressure profiles indicate that the flow through the flank gaps affects the delivering behaviour of a screw pump significantly. By considering the flow through flank gaps, the obtained pressure profiles match the experimental data. Furthermore the experimental investigation shows the necessity for a recirculation system. Without any recirculation flow, the different gaps are not sufficiently sealed with liquid over a certain gas volume fraction. This leads to an increasing loss flow. Consequently the volumetric efficiency of a screw pump without a recirculation system decreases for very high gas volume fractions.

ACKNOWLEDGEMENTS

The authors would like to thank the Bornemann Pumps GmbH for the close cooperation and technical support for the experimental investigations and the German Federal Ministry of Economics and Technology for the financial support of this project.

HEAT RECOVERY FROM A 1 MW CLASS GAS ENGINE CHP SYSTEM: 1/5 SCALE MODEL TEST

J. Ahn[1,*], H. J. Kim[1], K. S. Choi[1], D. S. Song[1]
[1]Korea Institute of Energy Research, Daejeon, Korea

ABSTRACT. The present study has been conducted to develop a heat recovery system for a 1 MW class gas engine based cogeneration system. In the cogeneration system, heat is recovered from two parts of the engine, which are jacket water and exhaust gas. The heat from the jacket water is recovered by a plate type heat exchanger and used for the room heating and/or hot water supply. The heat from the exhaust gas is used to generate steam. For both of the heat recovery devices, 1/5 scaled experiments are performed and the results are compared to the conventional correlations for the design.

Keywords: *Combined Heat and Power (CHP), Heat Recovery Steam Generator (HRSG), Heat Transfer*

INTRODUCTION

With the pursuit of high quality and reliability of electricity, the distributed energy system is proposed to be constructed in place of the conventional centralized system. Many kinds of energy sources including renewable ones have been considered for the distributed system and the combined heat and power (CHP) system based on the reciprocating engine has appeared to be one of the most feasible solutions within the current state of the art. Among the fuels for the engines for power generation, LNG has big merits not only for its economic feasibility but also for the environmental issues, since the exhaust gas contains less pollutants and carbon dioxide (CO_2).

In the CHP system, the heat is obtained by recovering the thermal energy from the cooling water and the exhaust gas of the engine, while it generates the electricity. The engine is rather fixed for its capacity and maker. The heat recovery system, however, has some room for engineering to be adjusted to the characteristics of the site such as its seasonal variation of energy demand. The energy demand of the site should be well analysed to decide a proper core engine and system configuration. After the decision, the heat recovery system is supposed to be engineered to maximize the economic feasibility.

The gas engine is mostly used for the site, whose electricity demand is less than 5 MW. A relatively small system of several hundreds kW class is mostly installed at a site with the thermal energy demand as a form of hot water. However, sites for MW class system, which is the scope of the present study, often have some demand for steam, e.g. a hospital with steam based sterilizers. Since the temperature from the cooling water of the engine is not high enough to boil the water, the steam is generated by recovering the thermal energy from the exhaust gas as illustrated in Fig. 1.

The core engine of the present CHP system has been chosen as 1 MW class Waukesha 15V150LTD [1]. Based on its engineering data, the energy balance has been analysed and depicted in Fig. 1(b). The heat recovered from the cooling water and the exhaust gas of the engine is 487 and 621 kW, respectively. Prior to the design of the full scale system, 1/5 scaled model experiments have been conducted for each heat exchanger in the present study. The design and off-design performance for

each heat exchanger have been obtained and compared with the conventional correlations, which have been used for the thermal design of the system.

EXPERIMENTAL SETUP

Heat Recovery from Engine Jacket Coolant

Since water is used as coolant for the engine jacket for the present study, its thermal energy is recovered as a form of hot water through a heat exchanger. The working fluid at both sides of the heat exchanger is water, so that a plate type heat exchanger (Figure 2(b)) is mostly adopted. The heated water from the recovery system is supplied directly to the household demand or used for the room heating as shown in Figure 2(a). For both of the cases, the low temperature part is supposed to have more flow rate and less temperature difference between inlet and outlet compared to the high temperature part, i.e. the engine coolant side. The difference should affect the heat transfer characteristics and they need to be considered in designing the heat recovery system.

To study the performance of a plate type heat exchanger at an operating condition similar to a CHP system, the test rig is devised to form closed circuits for hot and cold side as depicted in Figure 3(a). The coolant from the gas engine is supplied at the flow rate of 10 t/h and temperature of 98^{o}C. The flow rate at the hot side is 2 t/h in the present experiment, which corresponds 1/5 scale of the real application. The water from the hot side is supplied from a boiler, whose control system has been modified to achieve the temperature over 90^{o}C. The cold side, which corresponds to the energy demand site in the CHP system, has temperature controlled drains to investigate the effects of energy demand of the site. An extra valve has been installed at the inlet of the burner of the boiler to simulate the partial load condition of the engine.

The temperature at the exit and inlet of the heat exchanger has been measured by RTD (Resistance Temperature Detect) to evaluate its design and off-design performance. The flow rate at each side has been measured by an electro magnetic flow sensor. A gas analyser has been installed at the exhaust gas exit of the boiler to check its combustion characteristics (Figure 3(a)).

Model Heat Recovery Boiler

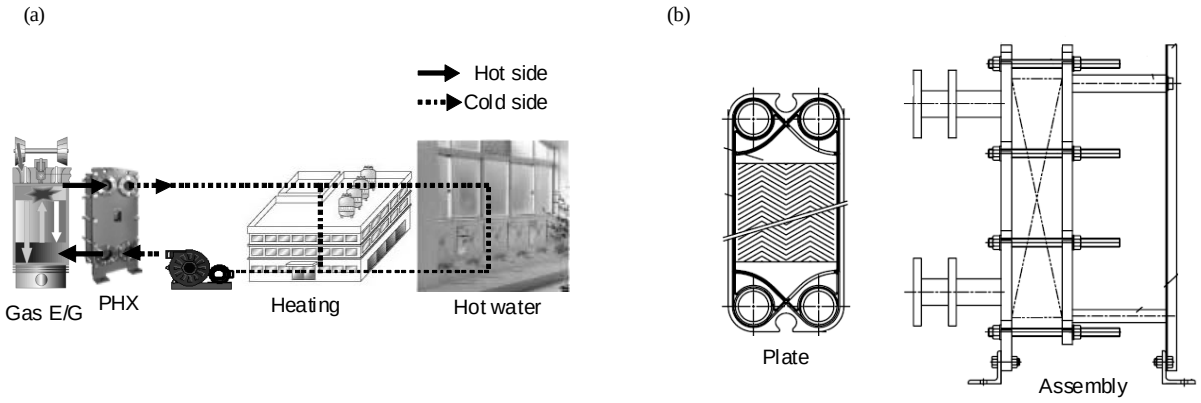

Figure 2 Heat recovery from the jacket water; (a) system configuration; (b) heat exchanger

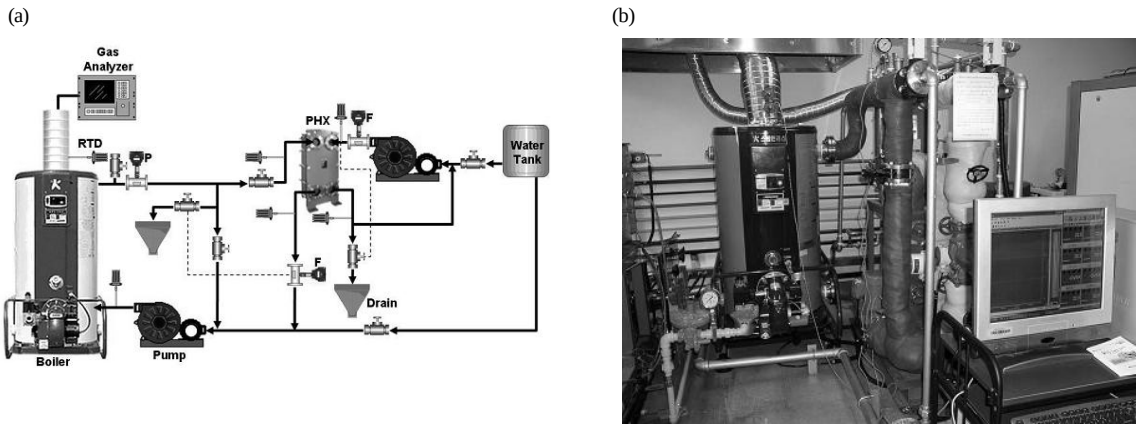

Figure 3 Test rig for the jacket water heat recovery; (a) schematics; (b) photograph

In the present CHP system, the thermal energy from the exhaust gas of the engine is recovered in the form of steam by a water tube type boiler, where fins can be installed at the evaporator section to efficiently recover heat from the exhaust gas with low temperature compared to the combustion gas directly from a burner for a conventional boiler. The evaporator section is a bundle of finned tube as shown in Figure 4(a). The bulk temperature of exhaust gas should decrease as it flows downstream. By considering the temperature change, finned tubes in the downstream have two times larger fin density as shown in Figure 4(b). The bundles with two types of finned tubes are composed into two separate modules as shown in Figure 4(a) to achieve more sophisticated design data from each module.

The exhaust gas to supply the model waste heat boiler is obtained from combustion gas of LNG, which is the fuel for the present gas engine. The burner is placed in a combustion chamber, surrounded by a furnace type boiler (Figure 5). The combustion gas is firstly cooled by the water outside and then diluted by additional air with the flow rate of 330 kg/h, which is supplied by a blower at the exit of the combustion chamber. Finally, the combustion gas is cooled through a heat exchanger until 430^{o}C, which is prescribed as the temperature of exhaust gas of the engine.

The water is supplied to each module separately to keep the water level at the steam separator, so that its flow rate indicates the amount of evaporation. The evaporation is also calculated from the change of enthalpy of the exhaust gas, which is measured by the thermocouples installed among the riser tubes.

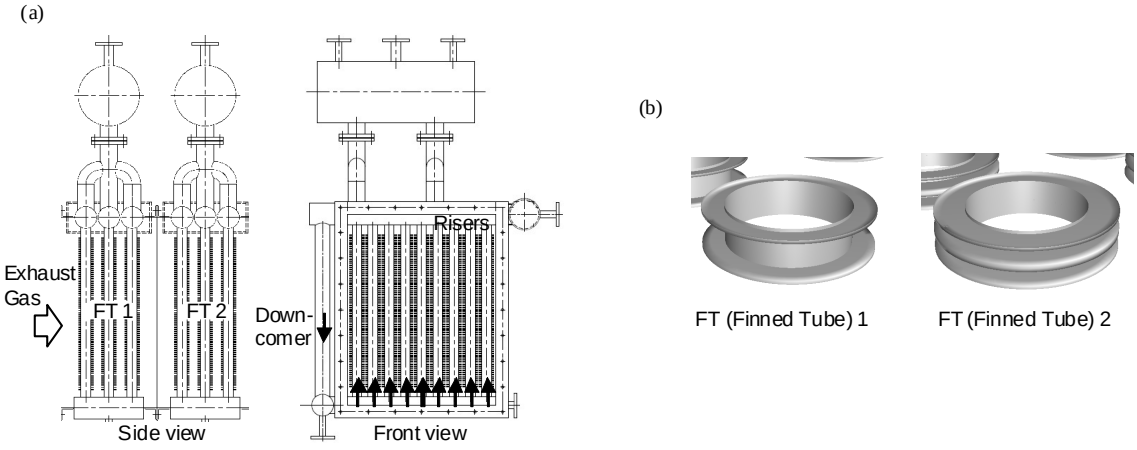

Figure 4 Heat exchange module for waste heat boiler; (a) schematics; (b) finned tube details

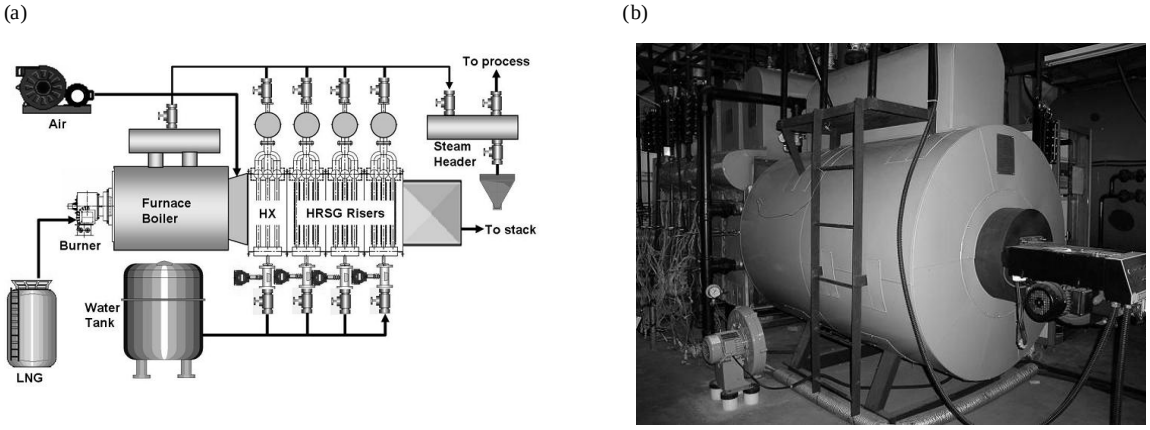

Figure 5 Experimental setup for the waste heat boiler; (a) schematics; (b) photograph

The heat transfer coefficient is as well evaluated from the gas temperature to be compared with the conventional correlation to predict it around the tube banks.

RESULTS AND DISCUSSION

Performance of Plate Type Heat Exchanger for the Heat Recovery from the Engine Coolant

The engine in the present study controls its coolant by adjusting its flow rate according to its operation load [1]. In the experiment, 2 m^3/h of water is supplied at the full load, while the flow rate is reduced 1 m3/h at the load of 50%. When the flow at the cold side is supplied at the room temperature, the heat exchanger shows high efficiency near unity for the low flow rate at the cold side of 2 m^3/h. The efficiency is deteriorated with the increase of the flow rate at the cold side. It decreases to 0.8 at the operation load of 50% when the cold side flow rate is 4 m^3/h.

The efficiency of heat exchanger is deteriorated when the water at the cold side is supplied at the higher temperature of 40 ^oC as shown in Figure 6 (a). With the higher inlet temperature at the cold side, the efficiency becomes more sensitive to the operation load of the engine. At the load of 50%, the heat exchanger efficiency is observed to decrease below 70%.

Figure 6(b) shows the surface margin from the experiment comparing with the prediction based on the correlation [3]. The experimental data deviate from the prediction as the flow rate at the cold

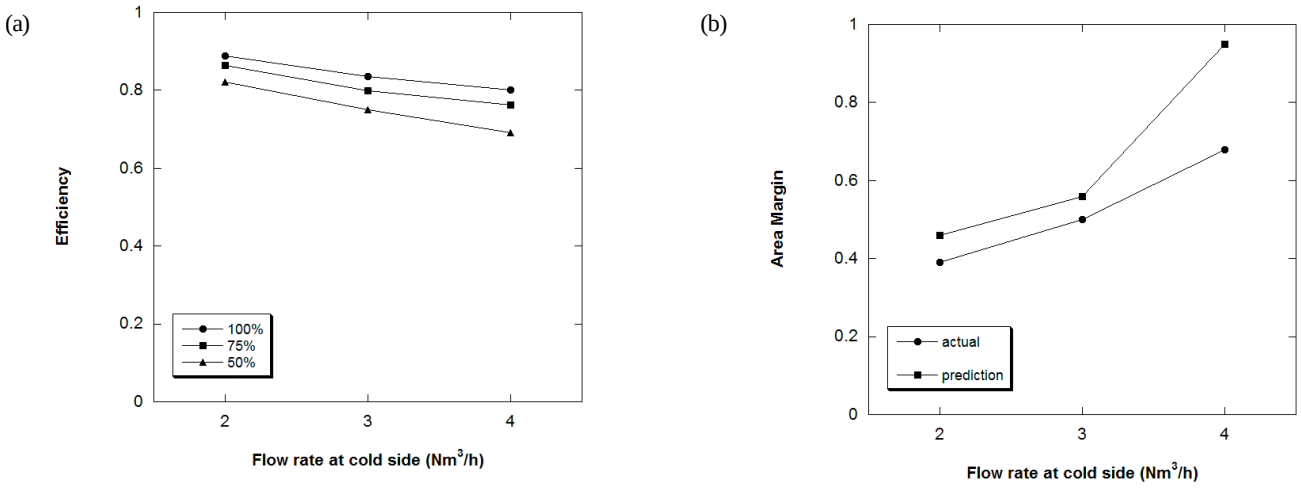

Figure 6 Jacket water heat recovery performance; (a) efficiency; (b) area margin

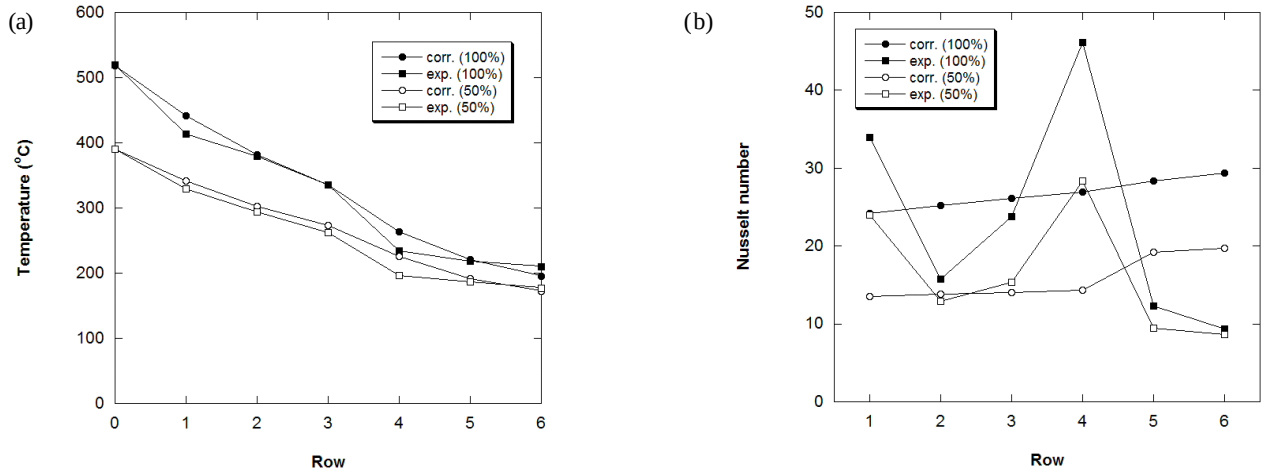

Figure 7 Jacket water heat recovery performance; (a) efficiency; (b) area margin

side increases from 2 m^3/h to 4 m^3/h. The surface margin, however, tends to increase as the flow rate at the cold side increase so that the heat exchanger will not be insufficient even at the off-design operation. Kumar's correlation [3] over-predicts the surface margin by 15% at the design point.

Performance of the Model Heat Recovery Boiler

The riser tubes of the model heat recovery boiler in the present study are designed to have different fin density along the streamwise direction as shown in Figure 4. The fin density is decided to yield uniform evaporation rate at each module based on Zhukauskas' correlation [4, 5]. The exhaust gas temperature variation along the streamwise direction agrees well with the prediction from the correlation as shown in Figure 7(a). However, the temperature from the experiment is lower than the prediction at the 1st and 4th row, where the fin density changes.

The Nusselt number evaluated from the enthalpy change of the exhaust gas shows much higher values than the Zhukauskas' correlation at the 1st and 4th row (Figure 7(b)). This trend is considered

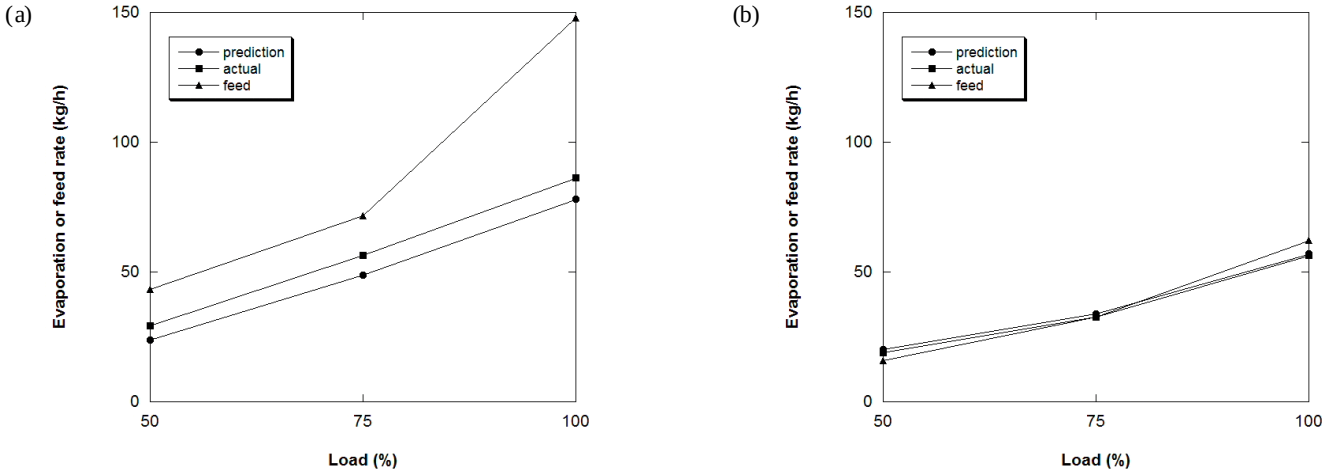

Figure 8 Evaporation rate; (a) at finned tube 1; (b) at finned tube 2

to be caused by the increase of the fin density at the location, which should accelerate the flow. Numerical simulation about the flow and heat transfer around this geometry is going to be conducted to clarify the mechanism.

The amount of evaporation is evaluated from the change in the enthalpy of the exhaust gas and compared to the flow rate of the feed water in Figure 8. They agree well and accurately predicted by the correlation for the module at the downstream (Figure 8(b)). However, the feed water supply is more than evaporation at the upstream module (Figure 8(a)). The droplet may not be completely separated at the drum so that the water feed may not be exactly balanced with the evaporation. This problem will be further explored by measuring the steam quality at the exit of the drum.

CONCLUSIONS

1. The heat exchanger efficiency of the engine coolant heat recovery system can decrease by 30%, in case the cold side water is supplied with the elevated temperature of 40^{o}C with the engine operation load of 50%.
2. Since the surface margin increases for the off-design operation, the heat recovery from the jacket water with plate type heat exchanger can be designed based on the Kumar's correlation.
3. For the finned-tube type heat exchanger, Nusselt number is under-predicted by conventional Zhukauskas' correlation where fins are newly installed.
4. Steam separation has been deteriorated at the upstream evaporators because of non-uniform heating.

INFLUENCE OF THE FLUID PROPERTIES ON CO-CURRENT TWO-PHASE FLOWS IN A HORIZONTAL CHANNEL CONNECTED TO A RISER

ABSTRACT. In order to investigate the two-phase flow behaviour in a complex reactor-typical geometry and to supply suitable data for CFD code validation, a model of the hot leg of a pressurised water reactor was built at Forschungszentrum Dresden-Rossendorf (FZD). The hot leg is composed of a horizontal pipe, a 50° upward bend and an inclined riser. The hot leg model is operated in the pressure chamber of the TOPFLOW facility of FZD, which is used to perform high-pressure experiments under pressure equilibrium with the inside atmosphere of the chamber. Consequently, parts of the flat test section could be equipped with large windows for the application of optical observation techniques, also at reactor typical boundary conditions.

Co-current flow experiments were performed in the hot leg model, simulating a two-phase natural circulation in the primary circuit of a PWR. The experiments were done with air and water at 3.0 bar and room temperature as well as with steam and water at pressures up to 50 bar and the corresponding saturation temperature (i.e. up to 264°C). The probability distribution of the water level measured in the RPV simulator was used to characterise the flow in the hot leg. It was found that the form of the distribution informs about the stationarity of the water flow to the steam generator: the broader the distribution, the more discontinuous the transport of water over time. This tendency was confirmed by the high-speed video observations, which were also used to identify the flow regime. Furthermore, generally the distributions are flatter for the cold experiments than for the hot ones. This shows that, due to the lower surface tension and viscosity, the transport of water induced by the gas is more constant in time for the steam/water flow.

INTRODUCTION AND MOTIVATION

In the event of a loss-of-coolant-accident (LOCA) in a pressurised water reactor (PWR), emergency strategies have to be mapped out in order to guarantee the reliable removal of the decay heat from the reactor core. During a hypothetical small break LOCA with failure of the high pressure emergency core cooling system, the decay heat has to be released to the secondary circuit over the steam generators (SG). Therefore, the primary circuit is designed to favour a natural circulation if the main coolant pumps are not available. Furthermore, if steam is generated in the primary circuit due to its depressurisation, stratified two-phase flow regimes can occur in the main cooling lines. The intermittent flow regimes especially could affect the core cooling and are consequently relevant for the

E-mail address: c.vallee@fzd.de

reactor safety. Therefore, the flow in hot leg geometries were investigated over the last decades in dedicated test facilities. Gardner (1989) and Petritsch & Mewes (1999) for example performed experiments with air and water in test sections with reduced scales. Extensive investigations were also conducted at original power plant scale in the Upper Plenum Test Facility (UPTF) with steam and water at pressures up to 15 bars (Weiss, 1992).

The objectives of the previous experiments were the validation and optimisation of accident management strategies as well as the development of models for the numerical simulation of LOCA scenarios. Currently, the state of the art calculation programs are so-called one-dimensional system codes, like *ATHLET* or *RELAP5*, which are principally based on empirical correlations and not on physical models. Consequently, the system codes are not able to simulate the flow phenomena, which limits their output possibilities to macroscopic effects. These limitations are particularly pronounced for the flows dominated by 3D effects, which require the use of a computational fluid dynamics (CFD) approach. However, the actual CFD codes applied to two-phase flows do not meet the high level of confidence needed in the field of nuclear reactor safety. Especially the closure models for interfacial transfer and turbulence field coupling embedded in CFD must be validated to allow reliable simulations. Therefore, high-resolution experimental data is needed for comparison with CFD calculations.

For the investigation of two-phase flows, the thermal fluid dynamics test facility TOPFLOW (Transient twO Phase FLOW) was built at Forschungszentrum Dresden-Rossendorf (FZD). This allows generic and applied experiments at boundary conditions typical for the power and process industries. The facility is equipped with a 4 MW electrical heater, which allows to produce steam flow rates up to 1.5 kg/s at the maximum operating pressure of 70 bar and the corresponding saturation temperature of 286°C (Prasser et al., 2006). TOPFLOW has become the major experimental facility of the *German CFD-network* initiated by the GRS (Gesellschaft für Anlagen und Reaktorsicherheit mbH).

In recent years, the TOPFLOW facility was extended with a pressure chamber which is used to perform high-pressure experiments under pressure equilibrium with the inside atmosphere of the chamber. For the first experiments, a model of the hot leg of a pressurised water reactor equipped with large windows was mounted in the chamber. The interfacial structure was visualised with a high-speed camera during co-current flow experiments under reactor typical boundary conditions (steam/water at pressures up to 50 bar and saturation temperature). First, the particularities of the new operation technique developed at FZD will be presented in details. As an example, one co-current flow experiment will be shown. From the water level measured in the reactor pressure vessel simulator, probability distributions were calculated and analysed. Furthermore, the characteristics of the distributions will be interpreted with the help of the high-speed camera images.

EXPERIMENTAL SETUP AND OPERATION PARTICULARITIES

High pressure experiments under pressure equilibrium

Usually, experiments with steam and water at power plant typical boundary conditions implicate to deal with two main constraints: the high pressure and the high temperature. These harsh boundary conditions limit strongly the measuring techniques to be considered and consequently the experimental investigation possibilities. In order to reduce somewhat these requirements, a new operation technique was developed at FZD which makes it possible to perform high-pressure steam/water experiments under pressure equilibrium.

Therefore, the test section is installed in the pressure chamber of the TOPFLOW test facility of FZD (Fig. 1). For steam/water experiments, a special heat exchanger condenses the exhaust steam from the

test section directly in the pressure chamber. This heat exchanger is designed with two openings and connects the test section to the pressure chamber. As a consequence, the condenser unit is operated with two gases: the steam to condense and a non condensable gas (air or nitrogen) which fills the pressure chamber. Both gases stratify because of the density difference: the lighter steam is injected from the top and the heavier non condensable gas stays at the bottom. The stratification layer in the condenser unit allows a self-regulation of the cooling power of the heat exchanger according to the arriving steam flow rate. In fact, by displacing the stratification layer up and down, the steam uncovers exactly the heat exchanger surface needed for its full condensation. In order to allow the free movement of the stratification layer inside the condenser unit while changing the steam flow rate, the cold end of the heat exchanger is permanently connected to the inner atmosphere of the chamber over large pipes (see Fig. 1), which guarantees the full pressure equilibrium at all times. The chamber can be pressurised with compressors up to 50 bar either with air for cold experiments or with nitrogen for steam experiments. Thanks to this experimental method, the test section does not have to support overpressures and can be designed with thin materials. Furthermore, this allows for example to equip the test section with large windows for optical observations of the flow.

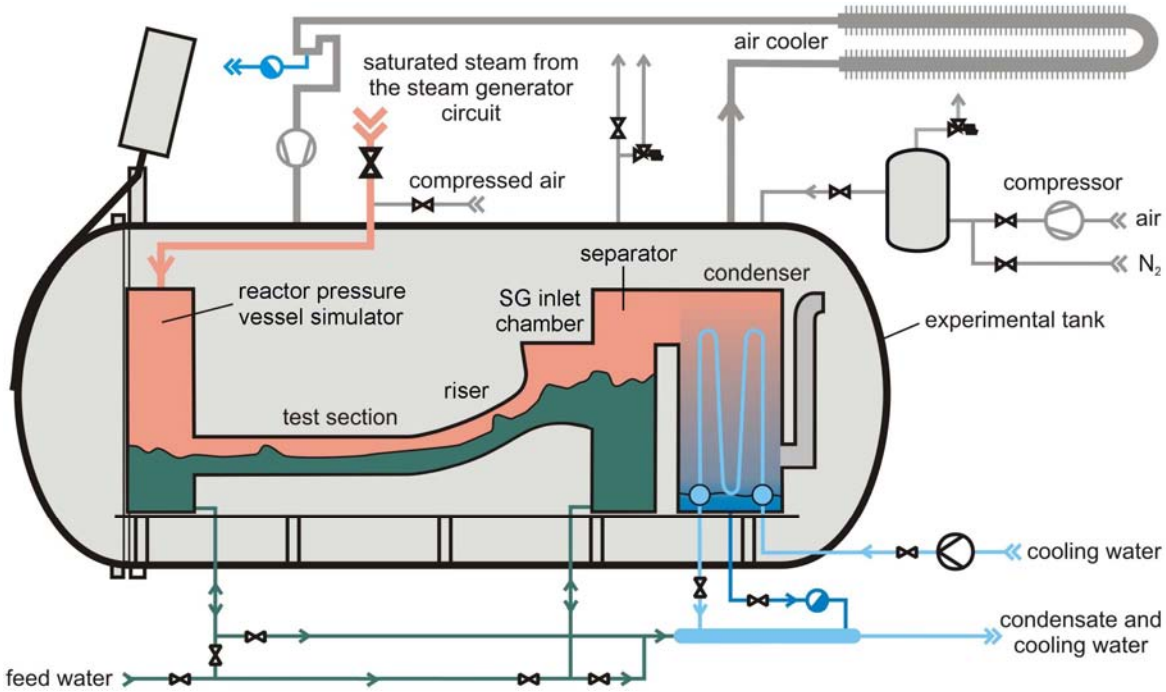

Figure 1. Schematic view of the experimental apparatus in the pressure chamber

Insulation of the test-section at high pressure levels

During steam/water experiments, all the components of the test section are heated up to the saturation temperature of water, i.e. to a maximum of 264°C at 50 bar. Because it is intended to put standard electronic measuring devices (e.g. high-speed video camera) inside the pressure chamber, the temperature of the atmosphere should be kept below their common maximum operation temperature of 50°C. Therefore, the warm components must be insulated and the inevitable heat losses removed to the outside.

First of all, conventional insulation materials like glass wool and mineral wool were used. During commissioning tests, these materials were found to present worse insulation properties with increasing pressure conditions and became insufficient at higher pressure levels. Due to the increasing gas density as well as to the increasing temperature of the components, the density difference between the cold and warm gas increases rapidly with the pressure. As a result, natural convection starts within the fibre packages of the material and reduces strongly its insulation properties. Many different commercial

materials were tested under high pressure conditions in house because of the lack of technical information delivered for our application by the manufacturers. Finally, compact micro glass-fibre materials were found to be suitable and were applied very carefully to the hot components. These materials were successfully tested in the pressure chamber up to the nominal pressure of 50 bar and showed good insulation properties.

Furthermore, the heat inevitably loosed through the insulation material is removed by an air/air heat exchanger installed on the roof of an auxiliary wing of the building. A forced convection of the gas inside the chamber is established by a pressure-proof electrical fan mounted in the circulation pipe (see Fig. 1).

One additional issue was to enable the observation of the hot steam/water flow without inducing substantial heat losses. For this, the high density difference between the hot and cold gas observed at high pressures was used as an advantage. In fact, the transparent part of the test section was surrounded with an insulation cap where the hot gas forms a stable stratification and stays like in a hot-air balloon. The insulation cap is only open to the bottom, which implies to place the camera vertically. Therefore, a 45° inclined mirror was placed under the insulation cap in order to deflect the light from the test section to the camera.

The hot leg model: test section and instrumentation

The test section of the hot leg model is schematically shown in Figure 2. The main components consist of the test section itself, the reactor pressure vessel simulator located at the lower end of the horizontal channel and the steam generator (SG) separator connected to the SG inlet chamber. The test section reproduces the hot leg of a PWR from the German *Konvoi* type at a scale of 1:3. In order to provide optimal observation possibilities, the test section is not composed of pipes like in the original power plant, it is a 50 mm thick channel representing a cut through the vertical mid-plane of the hot leg and of the steam generator inlet chamber. Consequently, the test section is composed of a horizontal rectangular channel, a bend that connects it to an upward inclined and expended channel, and a quarter of a circle representing the steam generator inlet chamber. The horizontal part of test section is 2.12 m long and has a rectangular cross section of 0.05 x 0.25 m². The riser is 0.23 m long, has an inclination of 50° to the horizontal plane and an expansion angle of 7.5°. Moreover, the SG and RPV simulators are identical vessels with 0.8 x 0.5 x 1.55 m³ (D x W x H) cubic shape. As shown in Figure 2, the test section is equipped with glass side walls in the bended region of the hot leg and of the steam generator inlet chamber in order to allow visual observation.

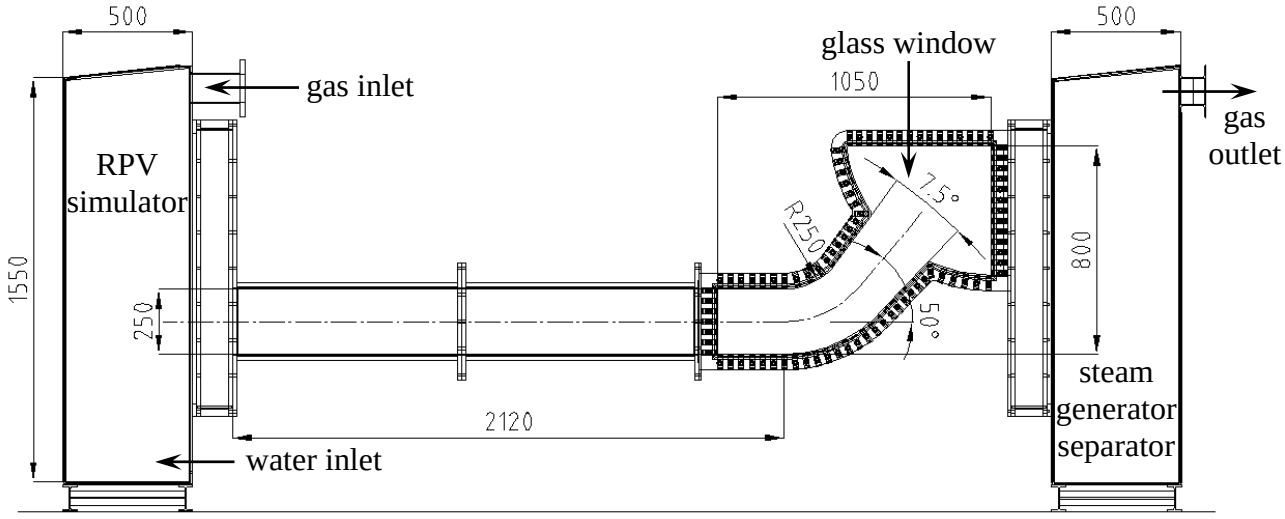

Figure 2. Schematic view of the hot leg model test section (dimension in mm)

The boundary conditions and global flow parameters were measured: a vortex meter was used to measure the injected water mass flow rate. The injected air mass flow rate was measured and controlled using thermal mass flow meters and the steam flow rate was measured with ISA-nozzles. The temperatures of the gas as well as of the water were measured at different positions by thermocouples. The water levels in both separators were determined by the measurement of the differential pressure between the top and the bottom of the vessels with differential pressure transducers. The differential pressure between the SG and RPV separators was measured by a differential pressure transducer. The signals of these global parameters were transmitted to a personal computer via a data acquisition system running at 1 Hz. Additionally to these measurands, a high-speed video camera was used to record the flow behaviour. The camera was put into a small pressure vessel equipped with a sight glass and was operated at frequencies of 100 Hz and a shutter speed of 1/500 to 1/1000 s.

CO-CURRENT FLOW EXPERIMENTS

Experimental procedure and test matrix

During the experiments, a constant flow rate of each fluid was injected in the RPV simulator (see Fig. 2) and flowed through the test section to the SG separator. In this tank, the liquid phase is separated from the gas, which flows to the condenser unit. The water is stored in the SG separator so that the water level increase can be used to check the mass balance. Because an accumulation of water in the SG separator could influence the two-phase flow in the test section, special attention was paid to the water level in this tank. The experiments were completed as soon as the water in the SG separator reached the level of the steam generator inlet chamber. Table 1 shows an overview of the varied boundary conditions. The co-current flow experiments were performed with air and water at 3.0 bar and room temperature as well as with steam and water at pressures up to 50.0 bar and the corresponding saturation temperature. In the experimental series, the water mass flow rate was varied between 0.3 and 0.9 kg/s and the gas mass flow rate between 0.01 and 0.84 kg/s.

Table 1
Co-current flow experiments in the hot leg model: overview of the test matrix

Gas [-]	Pressure level [bar]	Temperature [°C]	Water flow rate [kg/s]	Gas flow rate [g/s]	Number of runs [-]

Example of co-current flow experiment

As an example, one co-current flow experiment was chosen to illustrate the observed phenomena. This run was performed at a system pressure of 30.0 bar and a temperature of about 230°C, which is close to the saturation conditions. The mass flow rates were 0.30 kg/s for the water and 0.15 kg/s for the steam. Figure 3 shows the evolution in time of the water level in the separators and of the pressure drop over the test section. It is remarkable that the water level in the SG separator increases stepwise. This indicates that despite of the constant inlet flow rates, the water transport to the SG separator is discontinuous. This behaviour explains the periodic variation of the water level in the RPV simulator between 640 and 660 mm as well as the regular increase of the pressure drop over the test section.

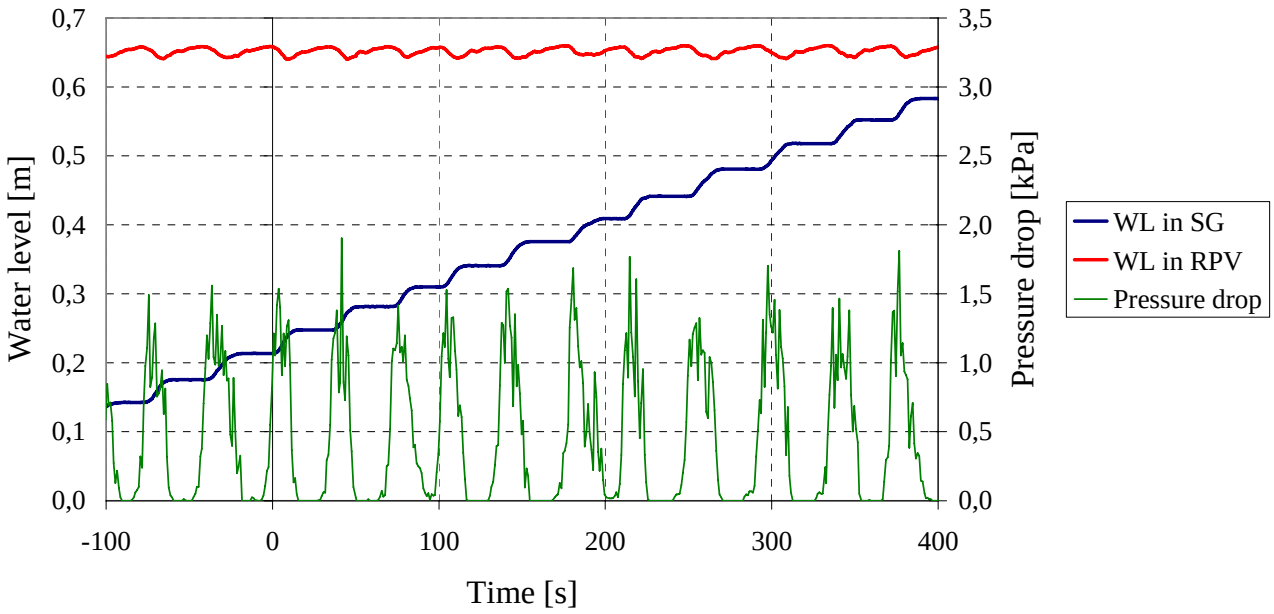

Figure 3. Evolution of the water levels and pressure drop in time during a co-current flow experiment at 30.0 bar and 230°C, with $\dot{m}_L = 0.30$ kg/s and $\dot{m}_G = 0.15$ kg/s

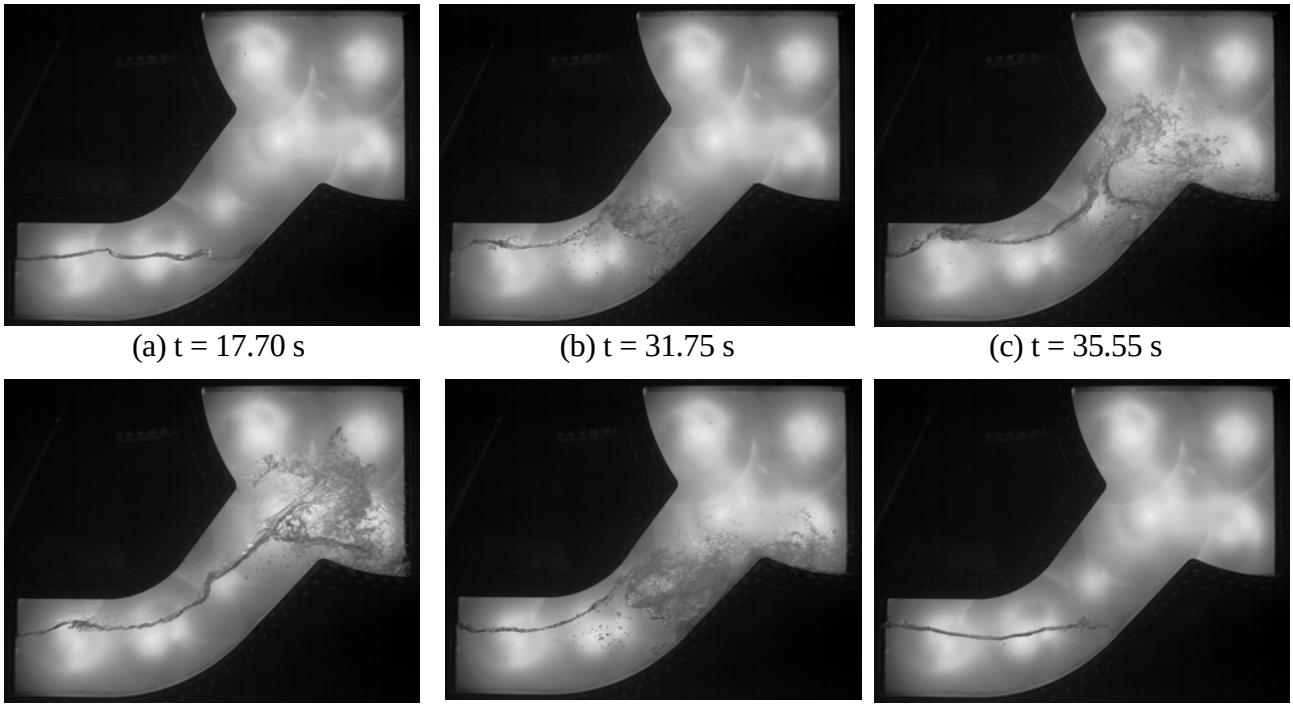

(a) t = 17.70 s (b) t = 31.75 s (c) t = 35.55 s

(d) t = 41.60 s (e) t = 46.80 s (f) t = 50.00 s

Figure 4. Evolution of the interphase structure during a co-current flow experiment at 30.0 bar and 230°C, with $\dot{m}_L = 0.30$ kg/s and $\dot{m}_G = 0.15$ kg/s

According to the flow structures observed with the high-speed camera over one period (c.f. Fig. 4), the following two flow regimes were observed:

1. First, for t < 31.6 s, the flow in the horizontal part of the channel is stratified wavy (Fig. 4-a) and no water is transported to the SG separator. This flow regime is characterised by a negligible pressure drop over the test section.
2. Afterwards, the water level reached in the horizontal part of the hot leg obstructs the steam flow enough to generate instable wave growth to plugs (Fig. 4-b and 4-c). Consequently, water is transported to the SG separator and the pressure difference between the separators increases

and becomes unstable. For 40 < t < 45 s, the plugs become bigger (Fig. 4-d) and the amount of water transported is higher than the injected flow rate. Therefore, the water level in the RPV simulator decreases, affecting the plug flow regime which can not be sustained after about 48 s (Fig. 4-e).

Subsequently, the flow in the horizontal part of the hot leg quiets and comes back to a wavy flow (Fig. 4-f), before the sequence starts over.

Evolution of the probability distribution of the water level measured in the RPV simulator

In order to reflect the variation over the time of the water level measured in the RPV simulator as shown in section 3.2., a statistical approach is proposed. The probability density distribution of the water level was calculated over the available measuring time (about 250 to 800 s, depending mainly on the water flow rate). The water level in the RPV simulator *l* was scaled relatively to the height *H* of the horizontal part of the hot leg model as follows:

$$L = \frac{l - L_H}{H - L_H} \tag{1}$$

with L_H the level of the lower edge of the horizontal channel.

The evolution of the probability distribution with the varied boundary conditions (shown in Table 1) is presented in Figure 5: the row defines the gas and pressure/temperature conditions, the column the water mass flow rate. The exact flow rates measured during each experiment are listed in Table 2, where the runs are numbered according to the diagram letter followed by the number of the curve. Figure 5 shows that the water level in the RPV simulator, and consequently in the test section, decreases with an increase of the gas flow rate. Furthermore, the form of the distribution varies with the boundary conditions: the air/water experiments at 3.0 bar with $\dot{m}_L \approx 0.3$ kg/s (Fig. 5-a) present very large and flat distributions whereas peaked curves were obtained with steam and water at 50.0 bar and $\dot{m}_L \approx 0.9$ kg/s (Fig. 5-f). The form of the distribution informs about the stationarity of the water flow to the steam generator: the broader the distribution, the more discontinuous the transport of water over time (see distribution 3 in Fig. 5-c, which corresponds to the example shown in section 3.2.). In this case, the broad distribution indicates that plug flow transports spontaneously more water to the SG separator than the water flow rate injected in the RPV simulator. This behaviour could mean that the water flow rate naturally entrained by the gas flow can not be reduced below a minimum value. In fact, when the injected water flow rate is lower than this value, the inequality in the input and output mass flow rates leads to an intermittent discharge of the water in the horizontal channel and consequently to a broad probability distribution.

A comparison between the columns of Figure 5 shows that at the same pressure and temperature boundary conditions, an increase of the water flow rate tends to sharpen the probability distributions of the water level. According to the theory developed in the previous paragraph, an increase of the water flow rate above the minimum possible discharge water flow rate leads to a continuous water transport and consequently to a peaked distribution. This could be the case between the experiments a-1 and b-1. However, some broad distributions become only slightly sharper with the increase of the water flow rate (e.g. experiments c-3 and d-3). This behaviour could be explained by the resulting reduction of the duration while no water is transported, which corresponds to the time during that waves at the water surface can quiet. Therefore, a higher water flow rate increases the probability for sustaining instabilities at the free surface to lead to an earlier begin of the next plug flow period.

The left column in Figure 5 shows the variation of the distributions with the pressure at a constant water mass flow rate of about 0.3 kg/s. It was observed that the distributions become more peaked and narrow with increasing pressure. However, the temperature was varied with the pressure and therefore

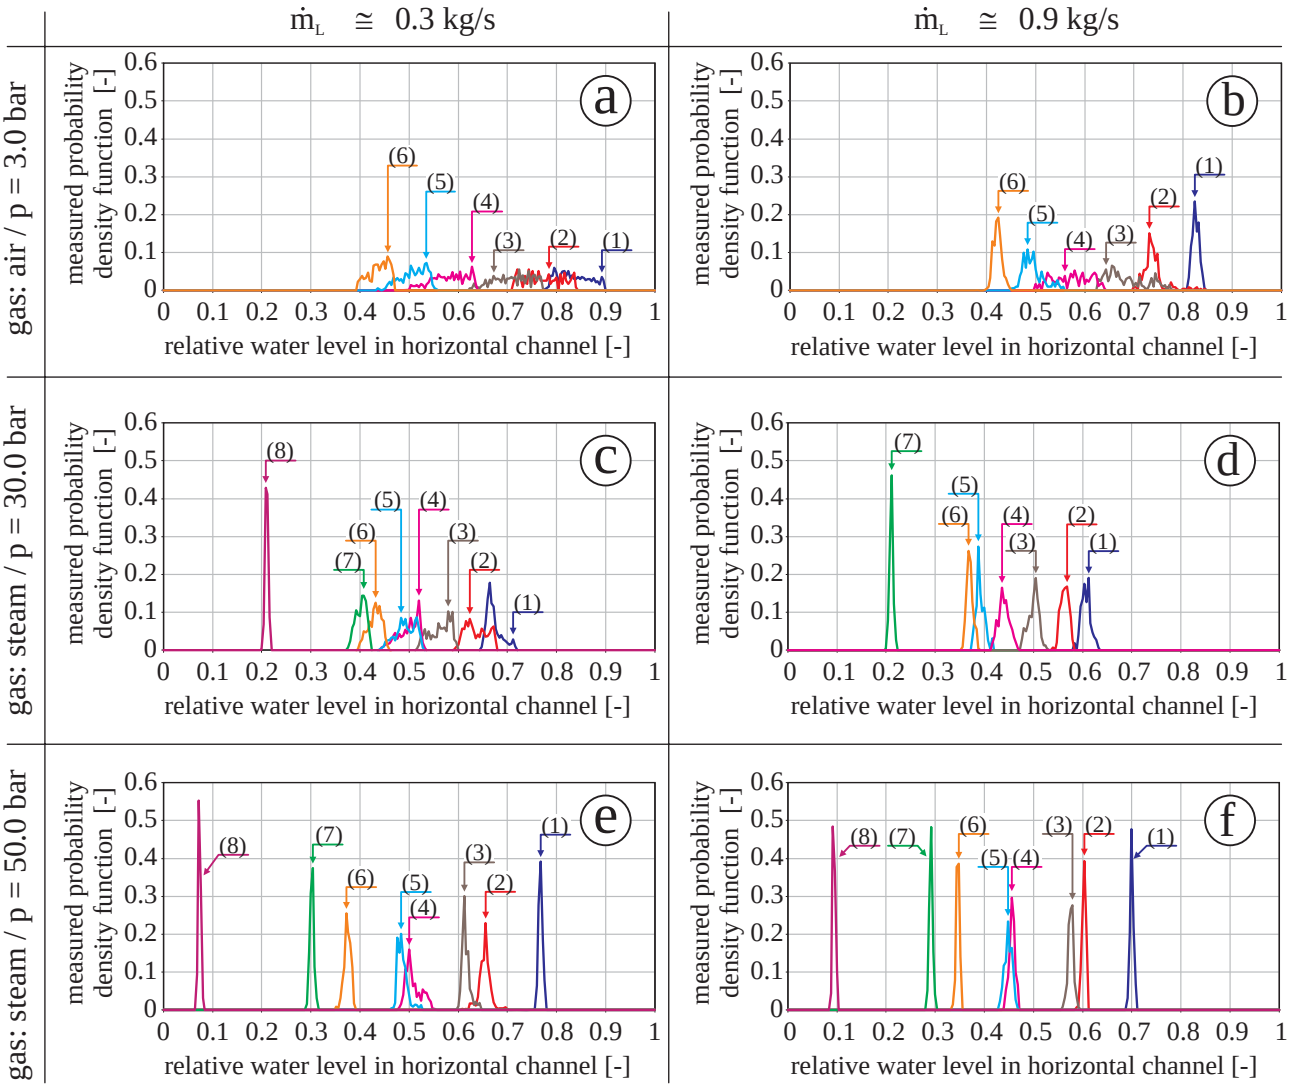

Figure 5. Evolution of the frequency distribution of the water level in the RPV simulator during co-current flow experiments under variation of the gas flow rate, for different water flow rates as well as pressure and temperature levels

the viscosity and the surface tension. Table 3 shows that especially the liquid viscosity as well as the surface tension decrease substantially between 20 and 264°C. This can explain the more continuous transport of the water to the SG separator by the gas flow at higher pressure and temperature levels. Moreover, this trend is not influenced by an increase of the water flow rate to about 0.9 kg/s (see right column of Fig. 5).

Comparison with high-speed video observations

In order to interpret the evolution of the form of the distributions shown in Figure 5 with the gas flow rate, typical flow pictures taken during different co-current flow experiments are presented in Figure 6. As an example, the experiments were chosen at the extrema of the available boundary conditions.

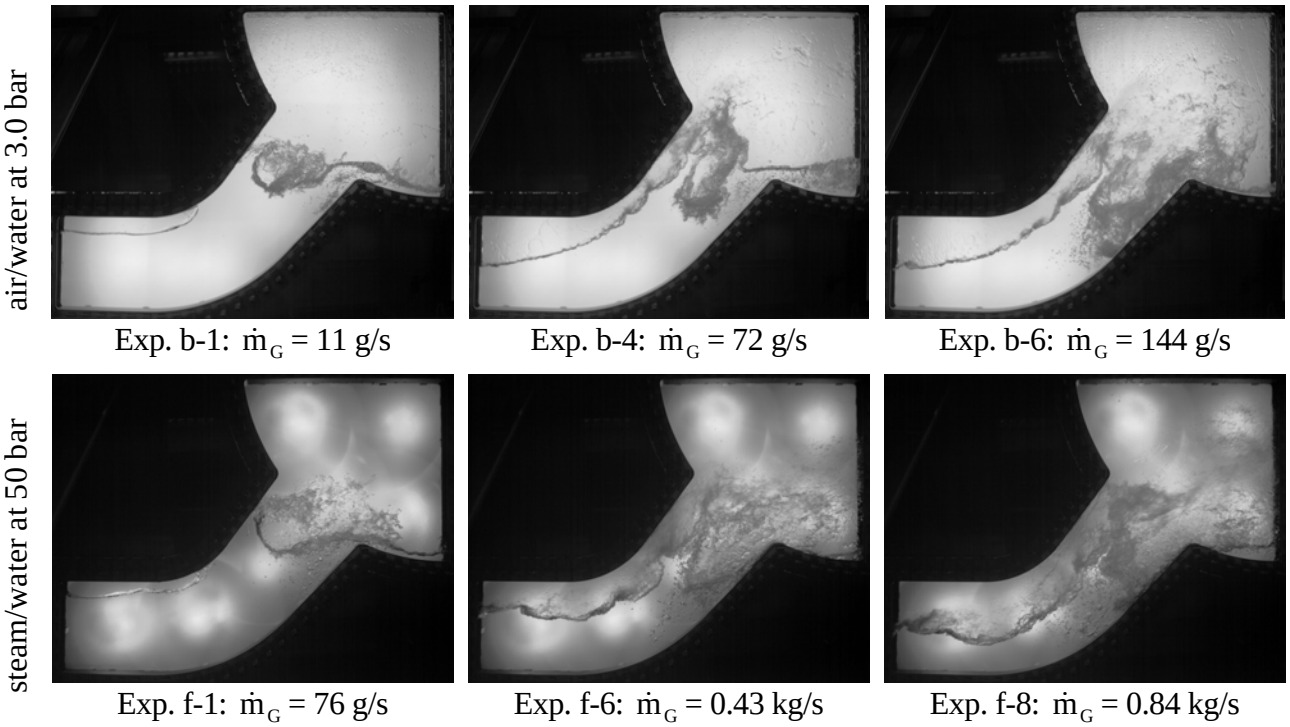

Figure 6. Typical flow pictures taken during different co-current flow experiments with $\dot{m}_L \approx 0.90$ kg/s

At low gas flow rates, the flow regime was identified as elongated bubble flow (Fig. 6, left column) and as slug flow at high gas flow rates (Fig. 6, right column). The probability distributions corresponding to these experiments are peaked. In the case of elongated bubble flow, the transport of water is continuous due to overflow as can be seen in the images. During slug flow, the transport of water occurs with droplets that detach from the wave front, which is also a continuous mechanism. At

intermediate gas flow rates (Fig. 6, middle column), the water transport is periodic and the probability distribution of the water level is flat, like in the experiment presented in section 3.2. These observations allow to conclude that a change in the form of the probability distribution from peaked over flat to peaked indicates a flow regime transition.

SUMMARY AND CONCLUSIONS

Co-current flow experiments were performed in a model of the hot leg of a pressurised water reactor, simulating a two-phase natural circulation in the primary circuit. The experiments were done with air and water at 3.0 bar and room temperature as well as with steam and water at pressures up to 50 bar and the corresponding saturation temperature (i.e. up to 264°C). Over this range of boundary conditions, the main fluid properties vary significantly. The frequency distribution of the water level measured in the RPV simulator was used to characterise the flow in the hot leg. It was found that the form of the distribution informs about the stationarity of the water flow to the steam generator: the broader the distribution, the more discontinuous the transport of water over time. Generally, the distributions are broader for the cold experiments than for the hot ones. This shows that, due to the lower surface tension and viscosity, the transport of water induced by the gas is more constant in time for the steam/water flows. Furthermore, the high-speed video observations were used to identify the flow regime. This shows that a change in the form of the probability distribution coincides with a flow regime transition: from elongated bubble flow at low gas flow rates to slug flow at high gas flow rates.

ABSTRACT. Thermal conversion of woody biomass into liquid oil has been fulfilled to investigate the effects of pyrolysis and condensing conditions. A bubbling fluidised bed reactor having cylindrical shape was used to give fast pyrolysis condition to sample biomass maintaining reaction temperature around 500°C and commonly used spiral quenching system was applied to condensing volatile gases issuing from the reactor. In the present study, flow and physical parameters such as wood and nitrogen supply rates, biomass supply rate, pyrolysis temperature and condensing temperature, etc. were considered to elucidate the thermal characteristics of volatile generation and its condensation. Especially, the focus was given to the condensing of volatile which was mixed with various gases having different molecular weights, which means different boiling point. From the results, the effects of heating and condensing heat transfer on the thermal conversion of biomass are fully investigated in the bubbling fluidised bed reactor. Also, the physical and chemical properties of the collected biocrude oil were figured out through various analysis techniques.

Keywords: *biocrude oil, biomass, fast pyrolysis, fluidised bed, heat transfer*

INTRODUCTION

Recently, the price of fossil fuels is rapidly increased and furthermore the conventions on climate change become more and more severe, especially for greenhouse gases which are mainly produced by using fossil fuels. Hence, to overcome this environmental problem caused by fossil fuels, biomass is one of the promising renewable energy sources and in particular, thermal conversion of biomass has been investigated in many countries [1-4]. Among the thermal conversion methods, in the present study, fast pyrolysis method is adopted for thermal conversion of biomass into biocrude oil and this biocrude oil can be directly used for heat and power generation and furthermore applied to bio-refinery [2]. The fast pyrolysis method is the rapid heating of biomass without oxygen resulting in conversion of biomass into volatile gases, non-condensable gases and char. In the method, higher heating rate to biomass and short vapour residence time are the main issues for increasing oil yield and its quality. In the present study, to fundamentally scrutinize the pyrolysis characteristics of biomass, a cylindrical bubbling fluidised bed reactor is devised and used for fast pyrolysis experiment. The effects of flow and physical parameters for production of biocrude oil are investigated and the chemical compound and physical characteristics of the collected biocrude oil are scrutinized. In the results, the flow characteristics of fluidised bed, vapour residence time, reaction temperature and condensing temperature are the major factors for controlling the yield of biocrude oil and furthermore condensing heat transfer plays an important role for elevating the quality of biocrude oil.

EXPERIMANTAL METHOD

The fast pyrolysis system is mainly composed of working fluid (nitrogen) injection device, biomass supply device, bubbling fluidised bed, condenser and measuring sensors for flow and temperature, etc. as depicted in Figure 1. To maintain constant pyrolysis temperature inside the bubbling bed, electrical heating furnace is used and the thermocouple is inserted into the center of the bubbling bed and the temperature control unit of the system adjusts the target pyrolysis temperature using the thermocouple signal. At the bottom of the bubbling fluidised bed reactor, a plenum chamber is made for pre-heating of nitrogen. The heated nitrogen is delivered to the bed for fluidisation and N_2 is adopted for maintaining pyrolysis condition without O_2. For the sample material of the present pyrolysis experiment, well-dried sawdust is used and the physical characteristics of the saw dust are illustrated in Table 1. For each experiment, totally 100g saw dust is consumed, respectively. In the fast pyrolysis experiment, major physical parameters that may affect heating rate of biomass and consequent thermal conversion of it are chosen such as pyrolysis temperature and condensing temperature. Also, the flow parameters associated with vapour residence time are nitrogen volume flow rate and biomass feeding rate. These physical and flow parameters are considered in the present experimental study to investigate the pyrolysis characteristics associated with the flow and heat transfer features of the bubbling fluidised bed reactor.
Also, the analysis of physical characteristics and chemical compounds of the collected biocrude oil is performed.

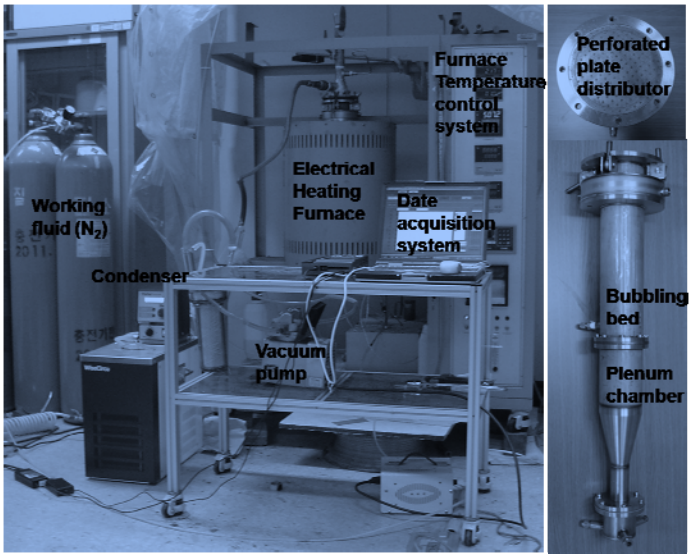

Figure 1. Experimental apparatus and bubbling fluidised bed reactor

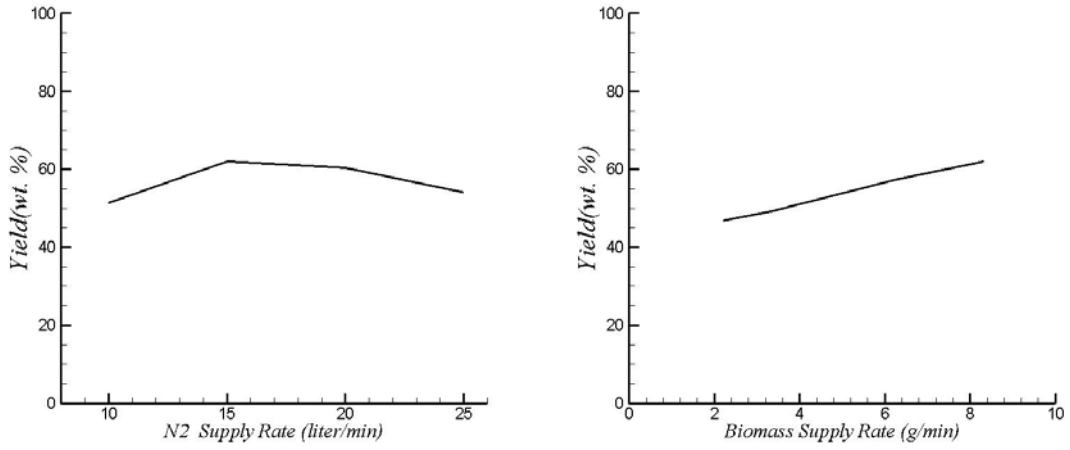
To measure the moisture content, Karl Fisher Titration method is used and for heating value, low heating value is measured by LECO AC-350 instrument. To find out the weight of solid contained in the collected biocrude oil, the filter of pore size 0.1 μm is adopted and for ash, to prevent the splashing of the sample, moisture and the volatile gases having low boiling point are evaporated then after combustion at 770 □, the weight of remnant is evaluated. The chemical elements for C, H, O, N and S are measured by thermo elementary analyser, FLASH EA1112 and the chemical compounds of biocrude oil are gauged by gas chromatography with mass selective detector.

RESULTS AND DISCUSSIONS

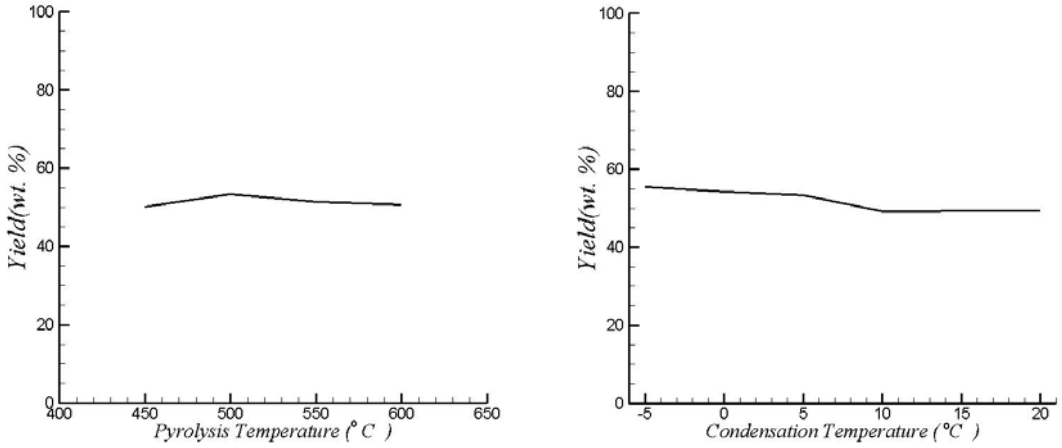
Figure 2 shows the effect of flow parameters i.e., inert gas (N_2) and biomass supply rates for biocrude oil yield, which is measured as Yield (wt. %) = the weight of collected biocrude oil / supplied biomass weight ×100 and "wt." means weight. As increasing N_2 supply rate from 10 to 15 *lpm*, the yield of biocrude oil is increased and then from 15 to 25 *lpm* it is decreased. Hereinafter, "*lpm"* indicates liter per minute. This can be explained that with increasing flow rate over 10 *lpm*, fluidization of sand is started and steady bubbling fluidisation is made around 15 *lpm*. Here, steady bubbling fluidisation means the flow motion representing spatially and temporally random distribution of bubbles in the bed and this is confirmed by cold flow test considering gas volume expansion at hot gas condition. In this case, sand and biomass may be well mixed by steady bubbling fluidisation and the heat transfer from sand to biomass is expected to be distributed uniformly over whole biomass surface. After 15 *lpm*, the flow transition from bubbling to slugging and finally turbulent motion occurs and then the efficient mixing between sand and biomass and consequent heat transfer are expected to be lowered compared with those of random bubbling fluidisation [5, 6]. Hence, for all the experimental tests appeared here, the N_2 supply rate is fixed as 15 *lpm*, the pyrolysis temperature is also kept constant as 480 □ and biomass supply rate is 3.33 *g/min* except for their tests. For biomass supply rate, biocrude oil production is increased with increasing the supply rate. This may be connected with vapour residence time in the reactor because long residence time may induce the secondary vapour cracking reaction [7, 8].

Figure 3 shows the effects of physical parameters such as pyrolysis temperature and condensing temperature. For pyrolysis temperature which is measured in the center of the bed, the production of biocrude oil is increased with increasing pyrolysis temperature until 500 □ and then decreased.



(a) (b)

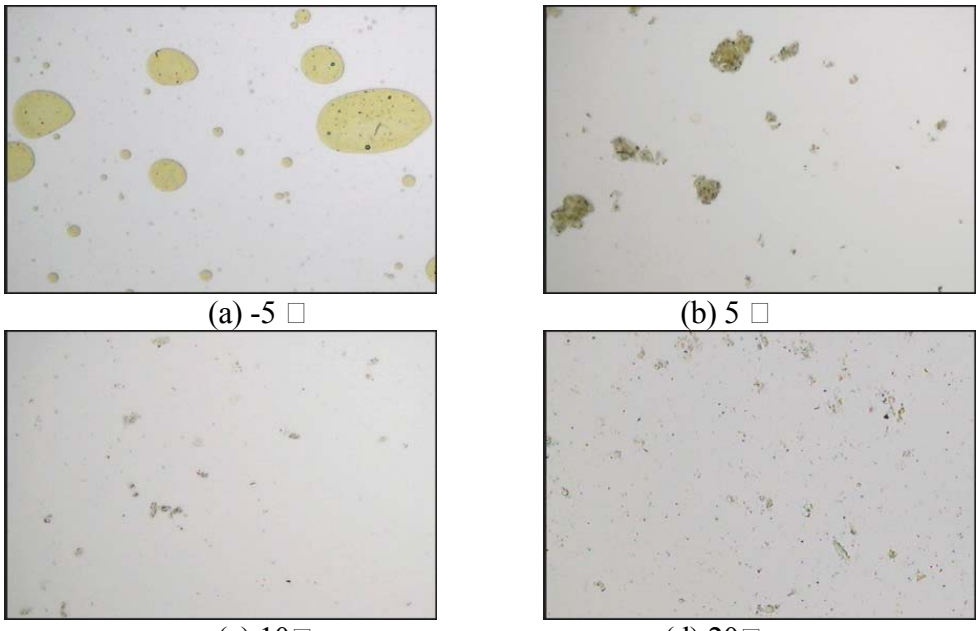
Figure 2. The effect of flow parameters; (a) for N_2 supply rate, (b) for biomass supply rate



(a) (b)

Figure 3. The effect of physical parameter; (a) for pyrolysis temperature, (b) for condensation temperature

From the pyrolysis kinetics of wood, it can be explained that as increasing reaction temperature above 500 □, the secondary reaction of primary tar becomes active and according to reaction kinetics, tar is cracked into non-condensable gas and char, etc. [7, 8]. Then the yield of biocrude oil is decreased. For the condensing temperature of produced condensable gases, it is decreased gradually from 20 □ to -5□ to investigate the effect of condensing temperature for the condensable gases having different boiling points. With increasing condensing temperature, the yield of biocrude oil becomes larger because the condensation heat transfer between hot gases and cold water is more and more activated in the heat exchanger and at the lower temperature case the vapour gases having light molecules can be condensed. It is noted that for the same flow rate of cold water, the decrease of cold water temperature leads to increase of heat flux from hot gas to cold water because of higher temperature difference.



(a) -5 □ (b) 5 □

(c) 10□ (d) 20□

Figure 4. The microscopic features of the produced biocrude oils for different condensing temperature

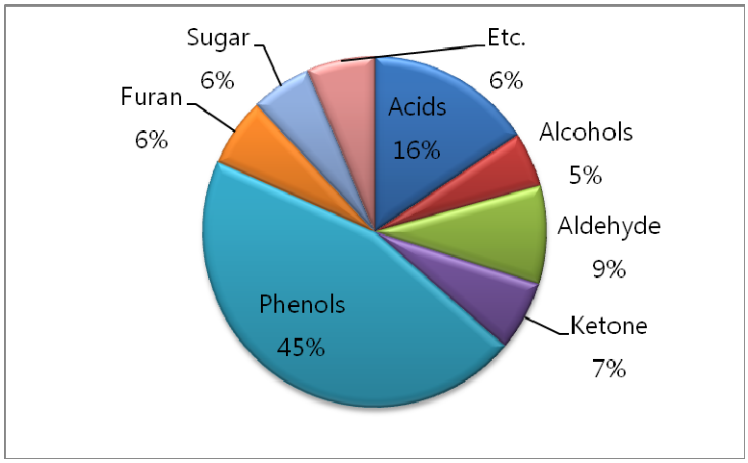


Figure 5. Chemical compounds of collected biocrude oil

However, it should be noted that the rapid quenching of hot vapours consisting of many different chemical species may result in a drop of biocrude oil quality. It will be discussed in the following. Figure 4 represents the microscopic pictures of the collected biocrude oil for different condensing temperature cases, which are enlarged 100 times. As can be seen in the figure, the solid particles such as char or a conglomerated lump appears remarkably below 5 □ and the size and population become larger and more frequent, respectively.

Table 2 shows the physical properties of collected biocrude oil at 3.33g/min for biomass supply rate, 15 *lpm* for N_2 supply rate, 480□ for pyrolysis temperature and 10□ for condensing temperature. This oil is brown liquid with pungent odour and compared with heavy oil for reference. Especially, the collected biocrude oil shows the lower PH and lower heating value compared with heavy oil but it contains no N and S, which are the source of NOx and SOx. In Table 2, it also has oxygen and this can explain the low heating value of biocrude oil. In Figure 5, the chemical compounds of biocrude oil are illustrated and organic compounds more than 100 ones are detected from the collected biocrude oil and it is mainly composed of organic acid, alcohols, sugar, aldehyde, ketone, phenols and furan, etc.

Table 2
Physical characteristics of biocrude oil

Contents		Biocrude Oil	Heavy Oil
Moisture (wt. %)		26.96	0.01

	S	-	2.3

Phenols have the largest portion of total chemical compounds however these portions become different case by case according to sample biomass material.

CONCLUSIONS

In the present study, the effects of flow and physical parameters for production of biocrude oil from biomass are scrutinized by fast pyrolysis experiment. For flow parameters, the optimum value of N_2 flow rate for the highest yield of biocrude oil is around 15 *lpm* corresponding to steady bubbling fluidization condition of the reactor. The increase of biomass feeding rate into pyrolysis reactor elevates the production rate of biocrude oil. Maximum pyrolysis temperature for its peak production is located just below at 500 □ and it is closely related to the secondary cracking mechanism of tar. For the effect of condensing temperature, the yield of biocrude oil is increased with decreasing the temperature but it is noted that below 0 □, a conglomerated lump appears remarkably, which is composed of solids as char. From the chemical and physical analysis of the collected biocrude oil, the biocrude oil shows a lower heating value compared with heavy oil but it has been reported by many researchers that there is high possibility of the oil for the application to heat and power and furthermore bio-refinery [1,2].

EXCHANGE FLOW IN A RESERVOIR MODEL EXPERIENCING DIURNAL TEMPERATURE CHANGES AT THE WATER SURFACE

Tomasz P Bednarz*, John C Patterson, Chengwang Lei, Feng Xu
School of Engineering & Physical Sciences, JCU, Townsville QLD 4811, Australia

ABSTRACT. In the present experiment, a reservoir model is subjected to diurnal temperature changes at the water surface. The transient thermal forcing acting on the system results in an unsteady quasi-periodic flow response. During the heating phase, a stable stratification of the water body is develops and during the cooling phase a very unstable rapid flow mixing over local water depth can be clearly observed. The thermal instabilities that occur after the thermal forcing switches from heating to cooling play an important role in breaking up a residual circulation and initiating a reverse flow. Inversely, when the system is in the heating phase, a stable large-scale convective roll is clearly observed. Understanding of the flow mechanisms pertinent to this problem is important for predicting the transport of nutrients and/or pollutants across reservoirs. Accordingly, the transient flow characteristics are analysed based on the temperature and velocity fields extracted non-invasively from experimental photographs of thermo-chromic liquid crystal patterns using concurrent Particle Image Thermometry and Particle Image Velocimetry techniques. The present work extends our previous experimental and numerical investigations of the exchange flows in reservoirs.

INTRODUCTION

The mechanisms that govern the transport of heat and mass in the near shore regions of lakes and reservoirs are of great significance for proper understanding and management of these resources. In a typical diurnal cycle, the ambient temperature changes periodically, resulting in varying thermal forcing acting on the water body. This has a direct impact on the convective circulation in the water, and can cause transport of small suspended pollutant or biological particles or dissolved constituents into or from deep water regions. Therefore an understanding of transport phenomena driven by the external thermal forcing is essential for understanding particle transport.

During a typical fine day, absorption of solar radiation entering through the water surface results in relatively warm shallow regions and a stable stratification in deep regions [1, 2]. In shallow waters, the water depth is less than the penetration depth of solar radiation, and thus a fraction of the radiation reaches the bottom where it is absorbed and re-emitted into the water layer above the bottom. This bottom heating is a destabilizing mechanism, which competes with the stable stratification. The bottom heating however, will not occur during cloudy weather and in this caseonly a vertical stable stratification will occur as the result of the ambient temperature increasing. This case is the focus of the present experimental results. Conversely, during the night, near-shore horizontal temperature gradients are developed from unequal cooling rates since the shallow region cools relatively faster than the deeper region. The result is a cold water undercurrent proceeding toward the deeper regions. At the same time, cooling at the water surface may generate plunging plumes from the surface. The cooling configuration is potentially unstable in a Rayleigh-Benard sense, depending on the cooling rate [3, 4]. Typical flow characteristics observed during the cooling phase is depicted in Figure 1.

In natural water bodies, all the above-mentioned mechanisms work together in a complex way over diurnal cycles. This problem has attracted significant research attention over the last two decades. Lei & Patterson investigated by numerical simulations the flow response to periodic heating and cooling by means of a varying surface heat flux, including depth-dependent absorption during the heating phase [5]. The results showed a time lag in the overall flow response when thermal forcing is switched between heating and cooling. This outcome is consistent with the field observations of Adams & Wells [6] and Monismith et al. [7], and the analysis of Farrow & Patterson [8] and Farrow [9]. They also concluded that, during both the cooling and heating phases, thermal instabilities break the residual circulation and reverse the flow in deep waters.

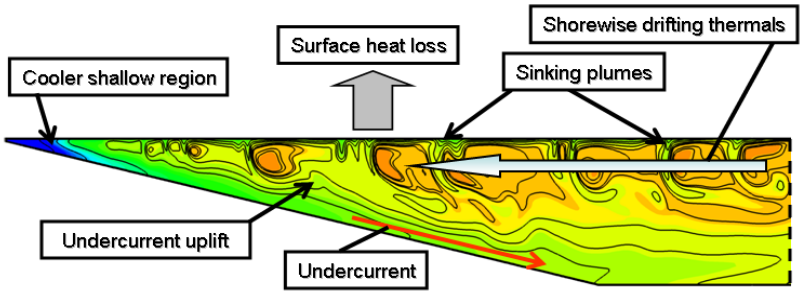

Figure 1. Flow characteristics observed during cooling experiments [3].

The present work extends, through physical experiments, the previous numerical investigations in a reservoir model with a periodic forcing applied at the water surface. In this case, the periodic forcing is by means of a varying surface temperature, corresponding to the effects of a varying ambient temperature but with no radiation input, as might be experienced during cloudy atmospheric conditions.

EXPERIMENTAL APPARATUS AND PROCEDURES

Experimental setup

The experimental apparatus used in the present study is shown in Figure 2(a). An enclosure, a chamber which provides alternate heating and cooling to the water surface and a wedge are all made of transparent Perspex except the lower surface of the chamber. The cavity is 30 cm long, 6 cm wide and 1.5 cm high. A wedge of an inclination 0.1 is placed inside the enclosure and fixed to the bottom and sidewalls. The heating and cooling chamber has two inlets and two outlets, respectively, each located at the centres of the vertical walls. The lower surface of the chamber is a copper plate painted black, through which the water in the experimental cavity is heated or cooled by water of a varying temperature passing through the chamber. All those parts are then joined together with eight screws.

Figure 2(b) shows the experimental setup of which the main part is the model described above. For visualization purpose the enclosure is filled with distilled water premixed with thermo-chromic liquid crystal slurry KXN-20/30 with a concentration approximately 0.1 ml per litre of water. The heating and cooling chamber is connected through hoses to a thermo-stating water bath (Julabo HE of 2000-W heating capacity) controlled by a personal computer. The central vertical cross-section of the enclosure is illuminated by a white light sheet generated by a halogen lamp of a 150-W Liesegang 3000AF projector, located about 2 m from the mirror, which is placed underneath the enclosure. A thin slit film is placed at the film location of the projector so that a thin light sheet is obtained over a long distance. The horizontal light sheet is reflected by the mirror and then redirected vertically to illuminate the entire middle section of the enclosure. The thickness of the light sheet is about 4 mm. All experimental photographs are taken by a high-resolution 12.8 Mega-Pixel of 4368×2912 pixels, SLR digital camera Canon EOS 5D with Canon EF 70-200 f/2.8L lens. The time interval between consecutive experimental shots is controlled using Canon TC-80N3 timer remote controller. The shutter speed of the camera is set to 1/4 s, the focal length to 200 mm, ISO speed to 800 and the lens aperture to f/4.0.

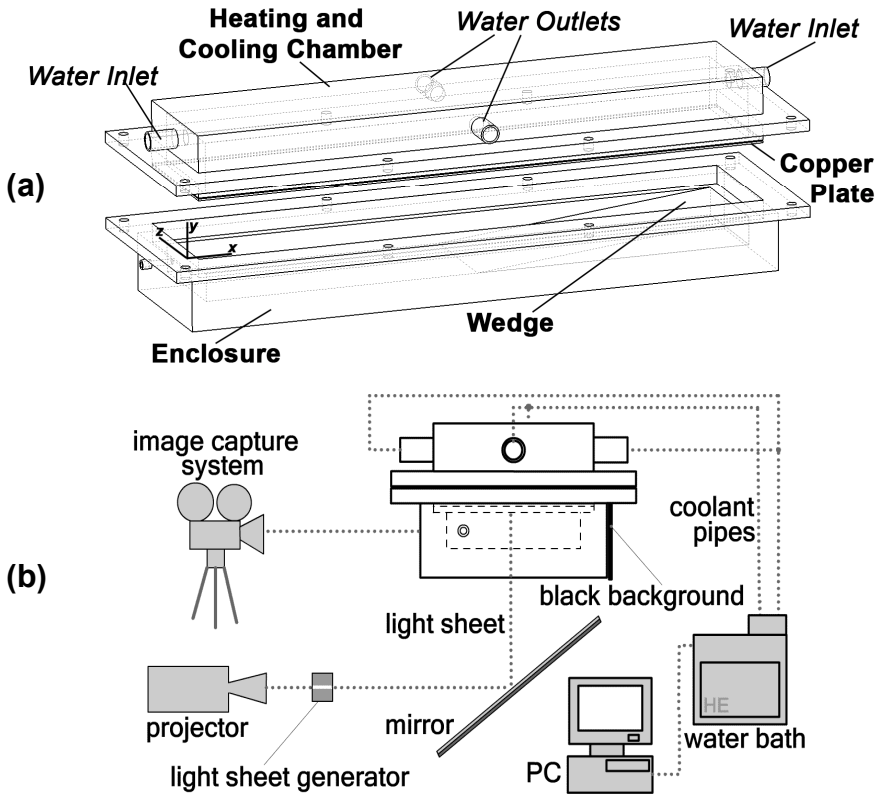

Figure 2. (a) Experimental model, (b) Setup for flow visualisation and temperature control.

Concurrent PIV / PIT measurements and flow visualization

The present experiment includes flow visualization and simultaneous temperature and velocity measurements with the application of thermo-chromic liquid crystals (TLCs). This approach uses two main features of the TLCs, that is, their colour response to local temperature changes and their seeding particle appearance. The first feature can be used to directly convert colour information captured by a digital camera into temperature values, the so-called Particle Image Thermometry (PIT), using hue-temperature calibration curve as described in [10-13]. If the TLC particles are sufficiently large (50-100 μm), they can also be successfully used as tracers of the flow field. The motion of scattering particles in an illuminated plane can be successfully analysed to provide instantaneous velocity vector maps in a cross-section of the flow field. The Particle Image Velocimetry (PIV) technique is based on image processing and pattern recognition algorithms and is described in [13-15]. Therefore, the general procedures for the concurrent PIV/PIT measurements include seeding the flow field with the TLC particles, illuminating a desired cross-sectional plane, and acquiring well focused photographs with sharp colours and clear patterns of the seeding particles. Then proper image processing techniques are applied to the experimental photographs (due to limitation of this paper, the visualisation procedures are not described here). The benefit of the concurrent PIV/PIT measurements is obvious: the temperature and velocity fields can be measured simultaneously, and the measurements are totally non-invasive.

Experimental conditions

For characterization of the natural convection flow in such a reservoir model, four non-dimensional parameters are defined. These quantify the important fluid, flow and geometrical properties of the system. These are: the Prandtl number (*Pr*) which characterizes the ratio of momentum diffusion to thermal diffusion, the Grashof number (*Gr*) which characterizes the ratio of buoyancy to viscous forces and therefore the relative strength of the thermal forcing, the aspect ratio

(A) which defines the geometry of the cavity, and the bottom slope (A_s) which characterizes the inclination of the slope:

$$Pr = \frac{\nu}{k}; \quad Gr = \frac{g\beta \Delta T H^3}{\nu^2}; \quad A = \frac{H}{L} = 0.05; \quad A_s = \frac{H}{L_s} = 0.1 \tag{1}$$

where ν is the kinematic viscosity, k is the thermal diffusivity, g is the gravity acceleration, β is the thermal expansion coefficient, ΔT is the maximum temperature difference ($\Delta T = T_{max} - T_{min}$), where T_{max} and T_{min} are respectively the maximum and minimum temperatures in the whole thermal cycle.

The present experiments were carried out in the reservoir model subject to periodic heating and cooling at the water surface as seen in Figure 3 for $Pr = 6.82$ and $Gr = 3.52 \times 10^4$. This can be related to a real situation with a very small temperature change over the diurnal cycles. The achieved period P of the thermal forcing in the laboratory environment was 14 minutes. Initially, the fluid in the enclosure was kept isothermal at 20.9 ºC for about 20 minutes ($t < 0$) before the periodic change of the water bath temperature was applied to the system ($t \geq 0$). The image capture started after ~34 minutes seen as $t/P = 0$ in Figure 3, i.e., after the start-up effect was minimized and the system response had become quasi steady. The points {a}–{e} marked on the imposed surface temperature curve in Figure 3 denote the times described below to quantify the flow development in a thermal forcing cycle with one additional time {f} for checking repeatability of the flow response.

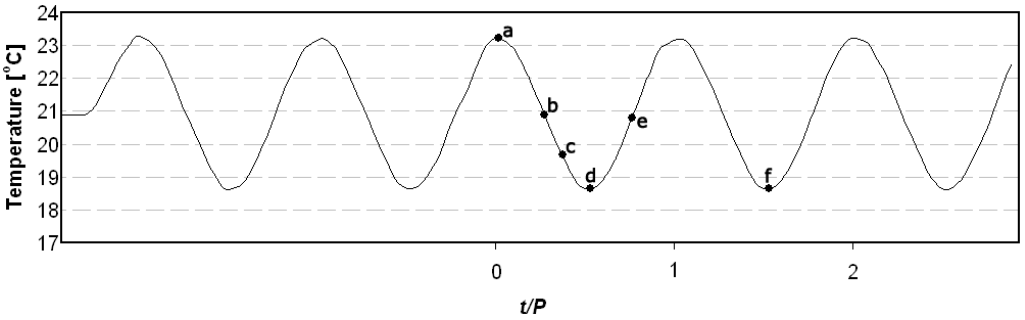

Figure 3. Time history of the temperature at the water surface.

EXPERIMENTAL RESULTS

In this section, the results of simultaneous flow and temperature measurements using TLCs are presented. Figure 4 shows six experimental unprocessed photographs corresponding to the times (a) to (f); Figure 5 presents corresponding isotherms extracted using the PIT technique; Figure 6 shows the results of PIV measurements with contours of the horizontal velocity component (left column) and the streamlines (right column).

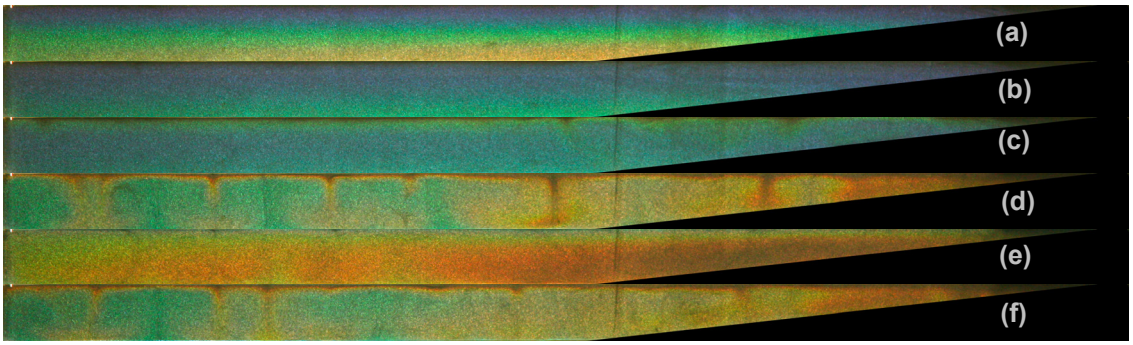

Figure 4. Raw photographs of the observed flow at $Pr = 6.82$ and $Gr = 3.52 \times 10^4$.

At the time instant {a}, the water surface temperature reaches a value of 23.3°C. The heating rate reaches its maximum value and the upper layer is clearly warmed, leaving the relatively colder fluid formed at the previous cooling stage below it (those affected layers will be described later for {e}). A

stable stratification of the temperature is established over almost the entire water body except a small region affected by cooling in the preceding cycle, as seen in Figures 4(a) and 5(a). Figure 6(a) show that a large counter-clockwise convective roll is created in the enclosure. The streamlines confirm that relatively warmer fluid is moving up along the bottom slope and moving out toward the deep-end under the water surface. The strongest flow is observed below the water surface (Figure 6a). However, the overall flow strength is very weak at this stage.

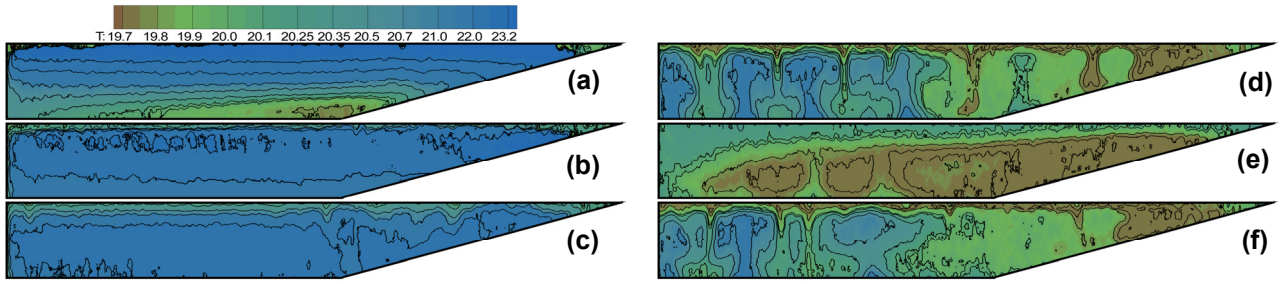

Figure 5. Temperature contours.

At the time instant {b}, the cooling effect at the water surface is distinct, but the majority of the water body is still vertically stratified, as seen in Figures 4(b) and 5(b). A clockwise convective roll has been created and occupies the half of the enclosure (deep water region) as seen in Figure 6(b). The strongest flow takes place beneath the surface above the slope (Figure 6b). In the rest of the enclosure (the deeper region), the flow becomes very weak as cooling proceeds as seen from the streamline contours.

At the time instant {c} convective instability below the water surface can be clearly observed (Figures 4c and 5c). Since the cooling is from the top, the fluid immediately below the surface becomes denser and heavier relative to the interior region. Thermal instabilities occur, in the form of Rayleigh-Bernard plumes when the local Rayleigh number in the surface layer exceeds a critical value, as determined in [3, 4]. At this stage, the plumes are relatively weak and are just starting to penetrate the local water depth. They will intensify as the cooling at the water surface continues. In the region above the slope, where the instabilities at this time are the strongest, intensive mixing is observed from the streamlines in Figure 6(c). In the deep water region, the clockwise convective roll developed earlier still dominates the flow.

At the time instant {d}, the surface temperature reaches its minimum of 18.6^{o}C. Distinct plunging thermals can be observed at this time (Figures 4d and 5d). These thermals penetrate the local water depth in the form of Rayleigh-Benard convection, carrying colder surface water to the bottom, where they are prone to overturning and mixing with the ambient fluid. The cooling of the water body occurs at a faster rate in the shallow region, as the thermals have less distance to travel through, and thus a horizontal temperature gradient is established in that region. Figures 6d suggest that the Rayleigh-Benard convective circulations occur in the whole fluid body, enhancing the local mixing. This is also confirmed by the streamline contours.

At the time instant {e}, the temperature at the water surface is increasing, and a layer of relatively warmer fluid is forming just beneath the water surface. There are no distinct plunging thermals present in the enclosure at this stage, and the convective motion is much weaker compared with that at time instant {c}, as seen in Figure 5. A cold undercurrent proceeding down the bottom slope can be seen in Figure 6e and is evolved into a clockwise convective circulation taking place on the right-hand side region of the reservoir model. The heating from the water surface slowly stabilises the convective motion.

For comparison purposes, the temperature and flow structures at time instant {f}, corresponding to {d}, is presented. As seen in Figures 4-6f the general characteristics of the temperature and flow fields at time instant {f} is very similar to that described for time instant {d}. However, at time instant {f}, the plunging thermals appear in slightly different locations from those appearing at time instant {d}.

This is due to the randomness of the Rayleigh-Benard instabilities and the three-dimensionality of the flow.

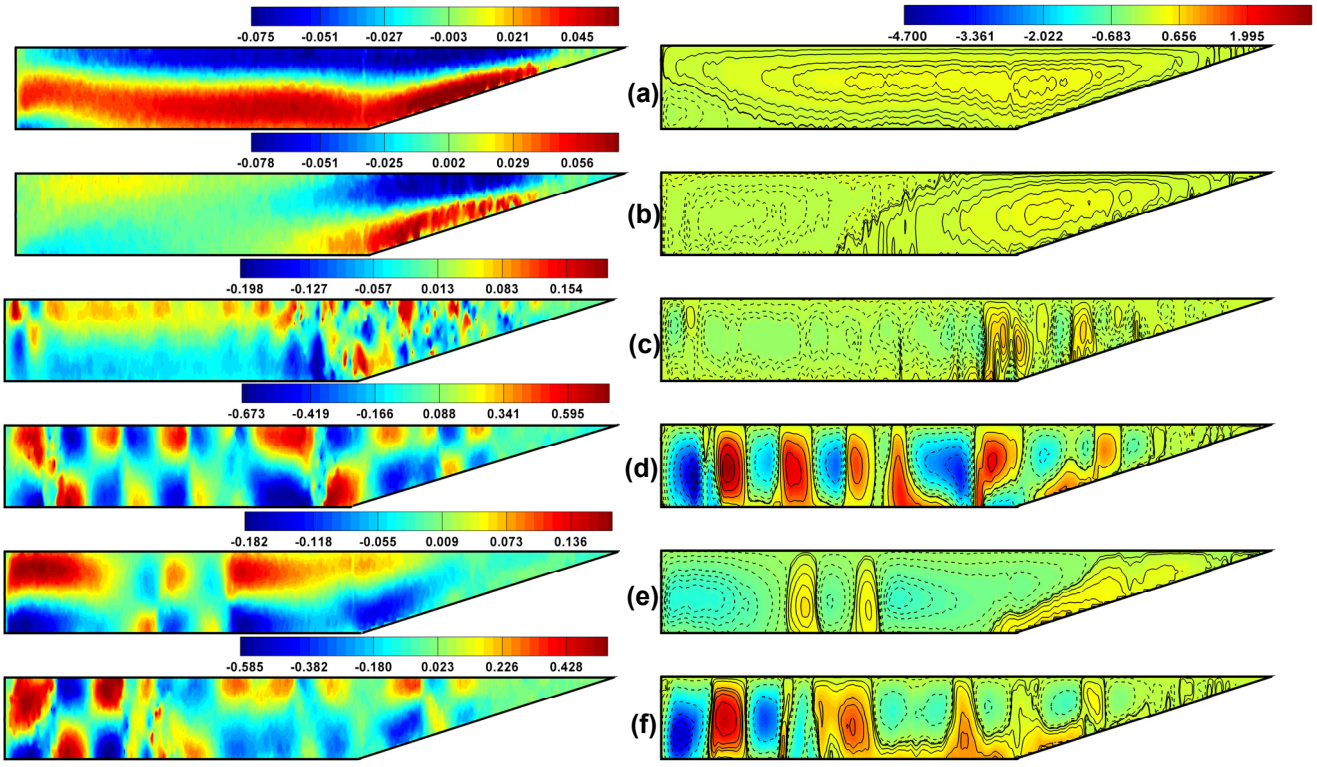

Figure 6. Horizontal velocity component contours (left column) and streamlines (right column).

Horizontal exchange flow rate

The horizontal volumetric flow rate per unit width across a vertical sectional plane at a given x location is defined as [1-3]:

$$Q(x) = \frac{1}{2}\int_{-h_x}^{0} |u|\, dy \tag{2}$$

where h_x is the local water depth at a given x location, and $Q(x)$ quantifies the horizontal exchange flow at that location. An averaged volumetric flow rate Q_m is obtained by integrating these quantities along the horizontal direction.

$$Q_m = \frac{1}{L}\int_{0_x}^{L} Q(x)\, dx \tag{3}$$

Figure 7 plots the time history of the horizontal exchange flow rate calculated for the Grashof number $Gr = 3.52\times10^4$ along with the time history of the water surface temperature measured during the experiments. In this plot, the exchange flow rate Q_m is normalized using the scale ~k, and the time is normalized by the period P of the thermal forcing cycles. The horizontal solid line in Figure 7(a) represents the mean temperature in the reservoir model. Accordingly, a temperature value above the horizontal line represents day-time heating, and a temperature value below the horizontal line represents night-time cooling. The cycles in both figures start when the temperature at the water surface is at the maximum value. At $t/P = 0.25$, the thermal forcing is switching from the day-time heating to the night-time cooling, whereas at $t/P = 0.75$ the switching is from night-time cooling to daytime heating. The horizontal flow rate Q_m is calculated from the PIV data after the fluid flow is assumed to be in a quasi steady state. The point $t/P = 0$ in Figure 7 corresponds to time instant {a} marked in Figure 3.

It is seen in Figure 7(b) that two minima and two maxima of Q_m appear over one thermal forcing cycle from $t/P = 0$ to 1.0. At $t/P = 0$ a small maximum of Q_m is observed. This time instant

corresponds to the heating up stage and the maximum is in phase with the thermal forcing. At this time, a weak anti-clockwise convective circulation is present. When the surface temperature starts to decrease, the warm upper layer of the water body continues to grow downwards and a convective circulation is still present as described above. The exchange flow rate Q_m remains at approximately the same level for some time until at around $t/P = 0.16$ when it starts to decrease. Slightly after $t/P = 0.26$ the averaged horizontal flow rate reaches a minimum, and this moment approximately corresponds to the switch from day-time heating to the night-time cooling. Also at this time, plunging thermals are observed in the system. Further cooling at the water surface results in enhanced local mixing in the enclosure. As a consequence, the calculated exchange flow rate increases abruptly and reaches a maximum at around $t/P = 0.5$, when the surface cooling peaks. Subsequently, the cooling from the top surface remains in place for some time although the water surface temperature is actually increasing. Another minimum of Q_m is observed at $t/P = 0.86$, indicating that there is a time lag of the flow response to the switch of the thermal forcing from cooling to heating, which corresponds approximately to 11% of the forcing period. After $t/P = 0.86$, Q_m increases to reach another maximum at $t/P = 1.0$ that corresponds to the maximum heating rate.

It is also noticeable in Figure 7 that the overall strength of the circulation in the heating phase is significantly weaker than that in the cooling phase. This indicates that during cloudy whether conditions, i.e., when solar radiation is not present, the cooling effect dominates the convective motion in reservoirs.

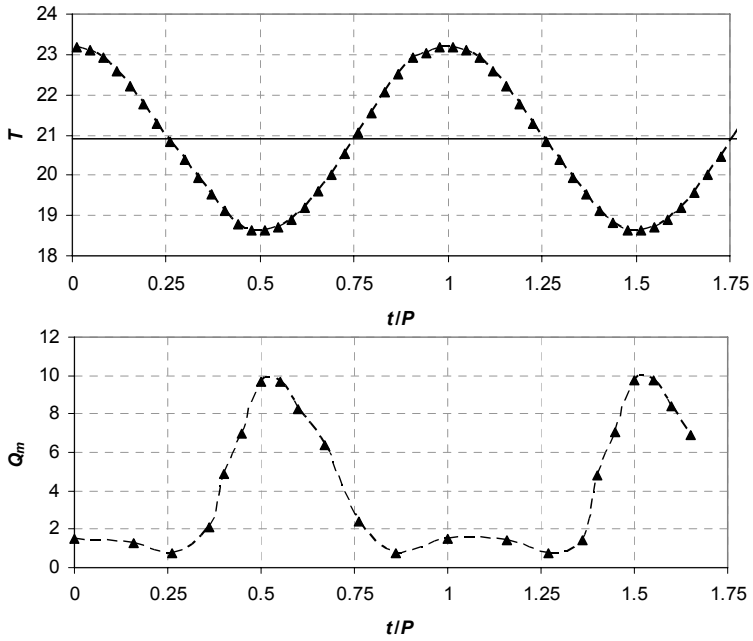

Figure 7. Time histories of (a) temperature at the water surface; (b) horizontal exchange flow rate.

CONCLUSIONS

In this study, the quasi-steady natural convection flow in a reservoir model subject to periodic thermal forcing at the water surface is described based on experimental flow visualisation and quantitative temperature and velocity measurements by means of concurrent Particle Image Thermometry and Particle Image Velocimetry. The present experiment has revealed the general characteristics of the flow development relevant to cloudy atmospheric conditions when solar radiation is not present in the system and the flow is driven solely by the ambient temperature changes. It is observed that the primary convective circulation in the reservoir changes its direction when the thermal forcing switches from cooling to heating and vice versa. It is also revealed that there is a time lag of the flow response to the switch of the thermal forcing from cooling to heating which is approximately

11% of the forcing period in the present case. The calculated horizontal exchange flow rate based on the measured velocity field showed that the overall strength of the circulation in the heating phase is significantly weaker than that in the cooling phase, suggesting that during cloudy conditions, the cooling effect dominates the convective motion in reservoirs

EVALUATION OF METHODS OF THE IN-CONTAINMENT HEAT TRANSFER COEFFICIENT DETERMINATION FOR LOSS-OF-COOLANT ACCIDENTS SIMULATION PURPOSES

T. Bury*
Silesian University of Technology, Gliwice, Poland

ABSTRACT. This work deals with thermal-hydraulic analyses of loss-of-coolant accidents within containments of pressurized water reactors. Such accidents are initiated by a rupture of the primary cooling circuit. For obvious reasons courses of these accidents can not be analysed by means of a full scale physical experiments. The mathematical modelling and numerical simulations are widely used for these purposes. It was found that the very difficult problem is to properly determine the heat transfer coefficient from in-containment gaseous atmosphere to walls and structures. This issue has been thoroughly investigated on a special test station at the Lucas Height Research Centre in Sydney, and results of the experiment have became a basis for numerical codes validation and development within the framework of the CASP-3 project. The main aim of this work is to validate a domestic computer code called HEPCAL and also to evaluate different methods for the heat transfer coefficient calculation. The results obtained shown that the use of standard correlations for Nusselt number gave effects the most comparable to the experimental ones.

Keywords: *pressurized water reactor, LOCA, heat transfer coefficient, CASP-3, numerical simulations*

INTRODUCTION

A rupture of the primary cooling circuit initiates one of the most dangerous accident which may happen in a pressurized water nuclear reactor unit. The worst scenario assumes the double ended break of the main coolant pipeline. It causes the loss of nearly whole coolant inventory in a few to a few dozen seconds. Some radioactive products of the coolant activation and fission products may be released from the primary circuit along with the coolant. To prevent release of these products and dangerous progress of the accident the reactors are fitted with the containment systems - hermetic buildings which enclose the primary circuit and all the safety and auxiliary systems. The whole is often called as the accident localization system. The coolant flowing out of the primary circuit evaporates immediately due to pressure difference and a mixture of air, steam and hydrogen fills up the containment building causing a rapid growth of the internal pressure and temperature. This is so-called loss-of-coolant accident (LOCA).

It is obvious that thermal-hydraulic analyses of such accidents can not be performed by means of a full scale physical experiments. Thus, the mathematical modelling and numerical simulations are widely used for these purposes. The nuclear industry developed two groups of the computer codes for thermal-hydraulic analyses of LOCA: one-dimensional system codes (also referred as lumped parameter codes) and three-dimensional field codes (mostly based on CFD). The lumped parameter codes reached high degree of maturity up to now and these codes are in common use and are also accepted by many nuclear authority bodies as proper tools for safety evaluation purposes.

Determination of a heat transfer coefficient from internal atmosphere to walls and structures is one of the most significant problems in thermal-hydraulic analyses of LOCA. This problem was investigated in detail on the special test station in Lucas Heights Science and Technology Center in Sydney (Australia) in the frameworks of the CASP-3 project (Containment Analysis Standard Problem).

The aim of this work was to simulate the CASP-3 experiment using the lumped parameter code HEPCAL as a part of the code validation process. Three versions of code have been used for simulations. Three different ways of the heat transfer coefficient determination from the gaseous atmosphere to walls and structures have been applied to these code versions.

THE CASP-3 PROJECT

The experiment performed by the Australian Atomic Energy Commission has been used by the OECD/CSNI Working Group on Water Reactor Containment Safety as Containment Analysis Standard Problem No. 3 [2]. The experiment was performed in October 1981 on the Lucas Heights blowdown/containment rig.

Test rig description

The general arrangement of the test rig with localizations of the measuring points is shown in Figure 1. The pressure vessel is insulated and contains an electric heater to boil water and raise pressure. The outlet pipe is heated by an electric heater tape wound around the pipe and is thermally insulated. The pipe is blocked by a cooper disc which is ruptured to start the blowdown [3]. The main element of the test rig is the containment model: steel vessel divided onto two compartments connected through the orifice plate and the pipe. The vessel is not insulated, it is freestanding within a large building. A circular deflector disperses the incoming blowdown flow around the chamber and prevents large crossflows at the intercompartment orifice.

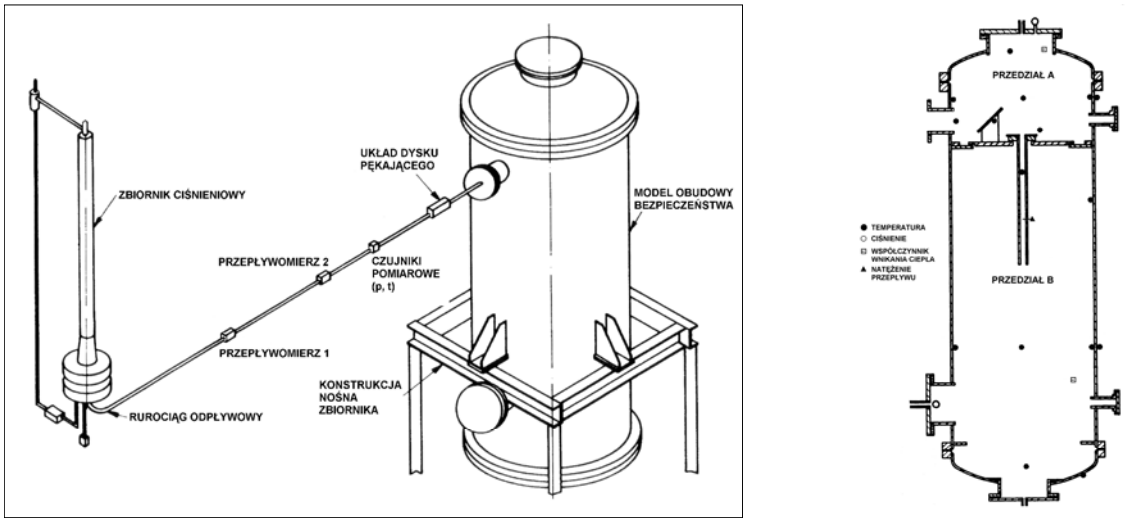

Figure 1. Test station – general view (left) and the containment vessel cross section with localization of measuring points (right)

The measurement instrumentation allow to record pressure, temperature, flow and heat transfer coefficient data.

Analyzed experiment scenario

The initial conditions are gathered in Table 1. Data related to the blowdown flow are presented in Figures 2 and 3.

Table 1
Initial conditions for the CASP-3 experiment [2,3]

Item		Value
Pressure vessel		
	Pressure, kPa	10 400
	Temperature, ºC	314
	Water mass, kg	8.5
Containment (both compartments)		
	Pressure, kPa	100.0
	Temperature, ºC	16.3
	Humidity, %	100
Ambient conditions		
	Pressure, kPa	99.3
	Temperature, ºC	16.5

The experiment was initiated by the rupture of the cooper disk (see Figure 1). The water from the pressure vessel started to evaporate immediately due to the pressure difference. The steam release into the compartment A lasted for 43 s. The recording period was 48 s – it started 5 s before the rupture. The coolant mass flow rate and its specific enthalpy is shown in Figures 2 and 3.

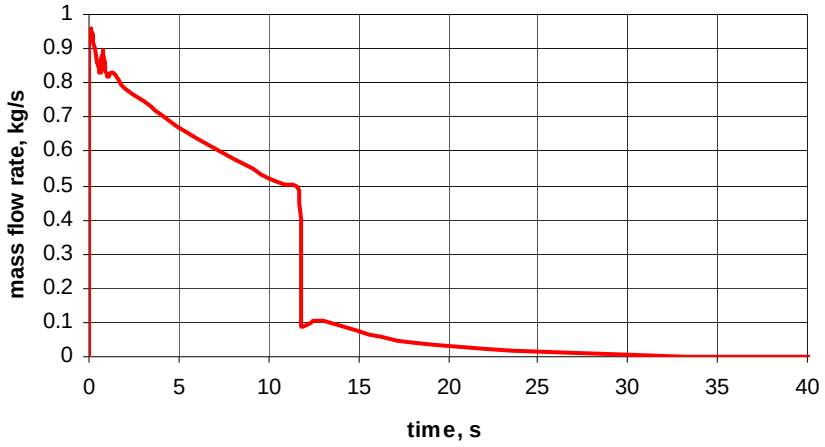

Figure 2. The steam mass flow rate during experiment [2]

The parameters shown in Figures 2 and 3 are very important for numerical simulations - the stand as the boundary conditions.

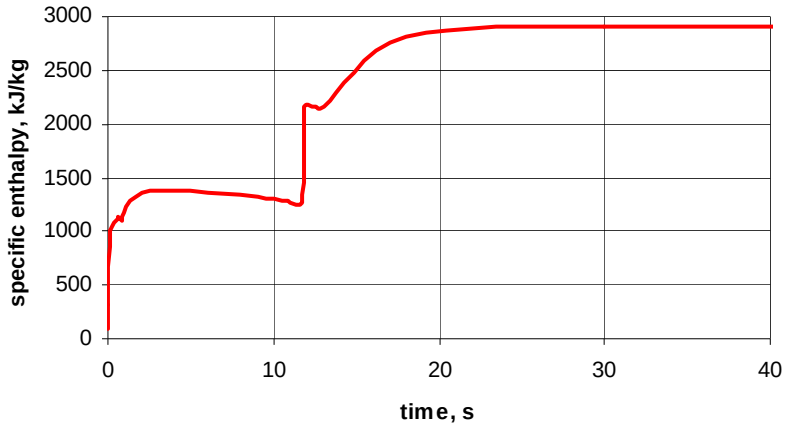

Figure 3. The steam specific enthalpy [2]

NUMERICAL MODEL

HEPCAL computer code

The results received here are an effect of simulations performed using the code HEPCAL, worked out at the Institute of Thermal Technology of the Silesian University of Technology [4,5]. Three versions of the code have been used which differ of the heat transfer coefficient determination methods (details given in the next subsection) [6]. This is a lumped parameter system code using so-called control volume method to reproduce physical phenomena.

The whole containment is simulated by a couple of zones (volumes), connected to each other in the given way. Usually the geometry and dimensions of a control volume correspond to the real dimensions of the specified compartment of the accident localization system. The control volumes are connected through opened channels, orifices, valves, membranes or siphon closures. For each zone homogeneous conditions (perfect mixing) are assumed. The mathematical basics of the model describing changes of thermodynamic parameters present equations of mass and energy balance for specified phases and equations of state [4-6]. The equations of mass and energy balance apply to the time step $\Delta\tau$, however the equations of state concern to the end of each time step. All the equations are nonlinear and their form depend on the state of the specified agents in the control volume. The basic set of equations constituting the mathematical model consists of:

- equations of the energy and mass balance for each control volume,
- equations describing intercompartment flows,
- equations of state for the specified gaseous agents (air, steam, hydrogen),
- equations describing additional phenomena, e.g. heat transfer to walls and structures.

The model applied in the HEPCAL code allows to determine the thermal parameters (temperature, pressure, density) in the specified volumes and the mass and energy flow rates between the control zones. The spraying system work is taken into account, and also heat transfer between phases and heat accumulation in the structures of the containment.

The calculations of the unknown quantities are realized in several steps. First, all the mass and energy fluxes are calculated (the leakage of coolant from the primary circuit, the flow rates of agents through the valves, orifices, water flow rate in the spraying system, heat accumulation in walls and structures). Heat transfer between gaseous and liquid phase is also determined. All these calculations refer to the thermal parameters at the beginning of time step and allow to determine the

internal energy of gas and liquid at the end of time step. Eventually, one obtains a set of *n* nonlinear equations which is being solved using the Newton-Rapshon method. At the last step of calculations all the remaining quantities (partial pressures, total volumes of gas and water etc.) are calculated. The computational procedure is repeated in the each time step for each control volume.

According to the code requirements the considered model of the containment has been subdivided onto two compartments, which correspond to the real partitions of the model.

Determination of the heat transfer coefficient

The heat transfer coefficient from internal atmosphere to containment walls and structures was calculated using three methods:

- Marshall-Holland's formula,
- Tagami's relationships,
- standard correlations for Nusselt number considering the mass and energy transport related to steam condensation or evaporation.

The first two method have been implemented into the HEPCAL-AU version of the code, and the last one in the HEPCAL-AD version [6].

The Marshall-Holland's correlation relies on experimental results [2] and it depends the heat transfer coefficient value HTC of the current mass of the air m_a and steam m_s into the considered control volume:

$$HTC = C \cdot \left(\frac{m_s}{m_a} \right)^{0,8} \tag{1}$$

The constant C in equation (1) is equal to 320 for concrete walls and 450 for steel walls. It is however not explicitly indicated either the phase change is considered or not. Moreover, the heat transfer coefficient value computed by this formula is limited to 1580 W/(m^2·K) in the HEPCAL code.

The maximum value of the heat transfer coefficient determined by Tagami's relationships is a function of the energy release rate from the primary circuit to the control volume [7]:

$$HTC_{\max} = f\left(\frac{energy\ released\ to\ the\ containment}{containment\ volume \cdot time\ of\ \ peak\ \ pressure\ appearance} \right) \tag{2}$$

Experiments have shown that the maximum pressure value is reached at the end of the blowdown phase of the accident usually. The maximum value of the heat transfer coefficient is given by the following formula:

$$HTC_{\max} = 425 \cdot \left(\frac{E_{coolant}}{V \cdot \tau_{blowdown}} \right)^{0,6} \tag{3}$$

where $E_{coolant}$ stands for the energy released along with the coolant from the primary circuit, V is the volume of the control zone where the break takes place and $\tau_{blowdown}$ is the blowdown phase time (it amounts to about 20 s for a large break LOCA and rises while the break became smaller).

The researches realized by Tagami [7] have proved that the growth of the heat transfer coefficient during the blowdown phase has a parabolic trend and it can be written by the equation:

$$HTC = HTC_{max}\sqrt{\frac{\tau}{\tau_{blowdown}}} \tag{4}$$

The heat transfer coefficient value falls down after the blowdown phase till the stagnation phase is achieved. This decrease is described by the following relationship:

$$HTC = HTC_{stag} + \left(HTC_{max} - HTC_{stag}\right)\cdot e^{-0,05\cdot\left(\tau-\tau_{blowdown}\right)} \tag{5}$$

The value of the heat transfer coefficient stabilizes in the stagnation phase and it is calculated as:

$$HTC_{stag} = 11,3 + 283,4\frac{m_s}{m_a} \tag{6}$$

The heat transfer coefficient values computed according to equations (3) - (6) are right for the steel walls. The values equal to 40% of them are assumed for the concrete walls.

The standard correlations for Nusselt number have been implemented into the HEPCAL-AD code. These relationships are well known (for example from [8]) and are not repeated in this paper. An important feature of this code version is taking into account the mass transfer during a change of phase. The attempt assumed in the numerical model differs slightly from a full mass and heat transfer analogy. The details may be found in [6].

RESULTS OF SIMULATIONS

The most important results obtained from numerical simulations are the heat transfer coefficient trends during the analysed experiment scenario. These trends are shown in Figure 4 - computational outcomes are compared with the experimental ones.

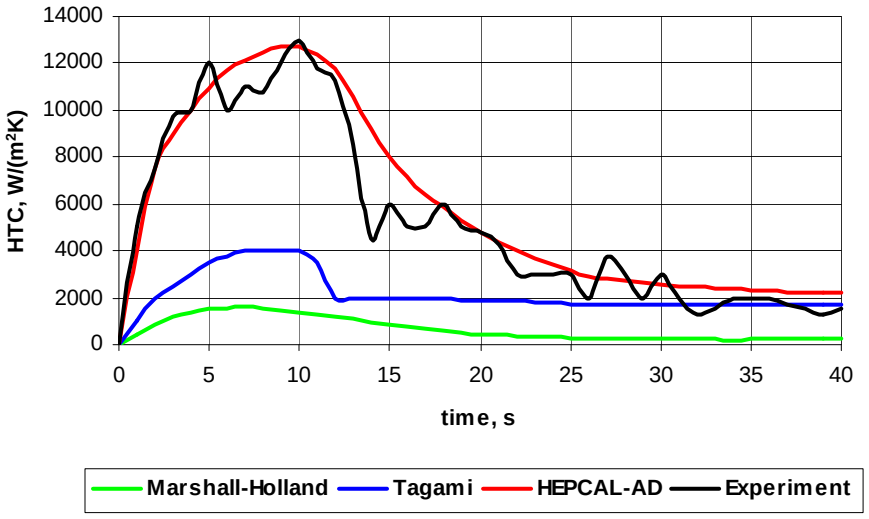

Figure 4. Heat transfer coefficient trend in compartment A

The worst results have been obtained using the Marshall-Holland formula. Tagami's relationships also give values of the heat transfer coefficient far below the measured data, but the trend is more similar to

the experiment. The best results have been achieved by applying standard equations for Nusselt numbers and considering the steam condensation on the containment model walls. Seems that the empirical correlations do not properly consider the phase change - this process significantly increases the heat transfer intensity.

The internal pressure is one of the most interesting parameters regarding thermal-hydraulic analyses of loss-of-coolant accidents within containments of nuclear reactors. The pressure trends in both compartments obtained by applying the HEPCAL-AD code are presented in Figures 5 and 6. One may note that the HEPCAL code results are in quite good conformity with the experiment.

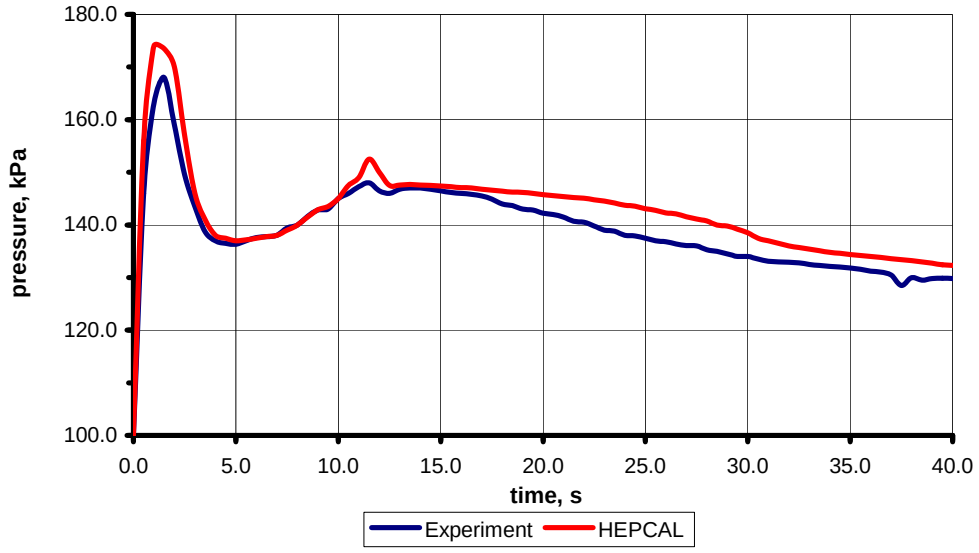

Figure 5. Pressure in compartment A

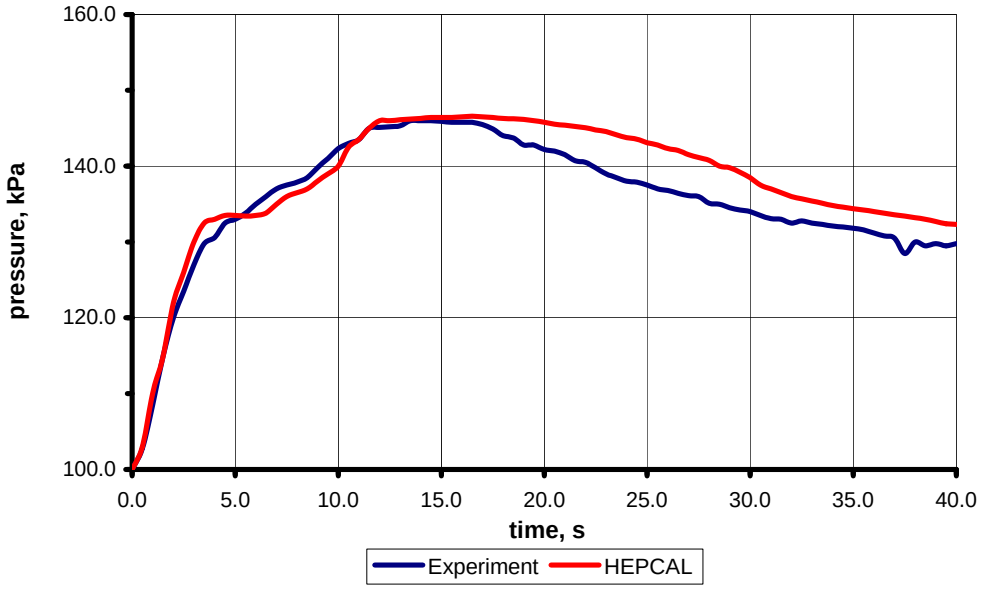

Figure 6. Pressure in compartment B

CONCLUSIONS

The main aim of this work has been to evaluate different methods for determination of the heat transfer coefficient from internal atmosphere to containment walls and structures. The analysis has been performed based on experimental results taken from the CASP-3 project. This experiment has been simulated using the domestic code HEPCAL. The heat transfer coefficient was calculated using three methods. Results of simulations were then compared with experimental data.

The usage of the standard correlations for Nusselt number and considering the mass transfer related to the steam condensation gave a comparable results only. Application of the methods based on empirical correlations for the heat transfer coefficient calculation resulted in its values much smaller than experimental. A probable reason for such situation is neglected or not fully implemented phase change phenomena. Although the empirical equations are very convenient to implement into the code and their application makes the simulation shorter, they may lead to wrong results. The third applied method for the heat transfer coefficient determination has given best results in the analysed case, but usage of this method requires a lot of data which may be not always available for a real plant simulation.

ACKNOWLEDGEMENTS

This work has been realized under the contract No. N N512 374535 financed by the Ministry of Science and Higher Education.

ENERGETIC AND ECONOMIC ANALYSIS OF A SMALL-SCALE TRIGENERATION PLANT WITH A LIQUID DESICCANT COOLING SYSTEM

M. Badami*, A. Portoraro[1]
[1] Dipartimento di Energetica, Politecnico di Torino, Torino, Italy

ABSTRACT. A small-scale trigeneration plant with 126/220/210 kW of electrical, heating and cooling capacities respectively is presented in the paper. The plant is going to be installed in the Politecnico di Torino (Turin, Italy) premises. The plant is characterized by an innovative natural gas fired internal combustion engine, that has been coupled to a liquid LiCl-water desiccant cooling system. The system is able to provide 20.000 m^3/h of cooled air to a building where there are several teaching classrooms. In this work, the main characteristics of the plant and the energetic performance are described. A detailed economic study, which has the aim of evaluating the financial profitability of the installation, is also presented.

Keywords: *Trigeneration, Combined Heat Cooling and Power (CHCP), Desiccant Cooling, Economic assessment, Energy Market*

PLANT DESCRIPTION

A small-scale trigeneration plant has been set up and installed at the Politecnico di Torino, Turin, Italy. The study, the design and the development of this installation is part of the HEGEL Project (High Efficiency polyGEneration Applications), that is a project co-financed by the European Commission within the 6th Framework Programme, under priority 6.1. The plant has been conceived to provide an air – conditioning service to a small building (about 2.105 m^2, see Figure 1), where several teaching classrooms are located.

E-mail address: marco.badami@polito.it

The main components of the plant are the cogenerator, which was developed and setup by the FIAT Research Centre (Turin, Italy), and the desiccant cooling system. Several humidifiers and exchangers are also needed to refine the temperature and humidity of the air supplied to the building. A schematic diagram of the installation is provided in Figure 2.

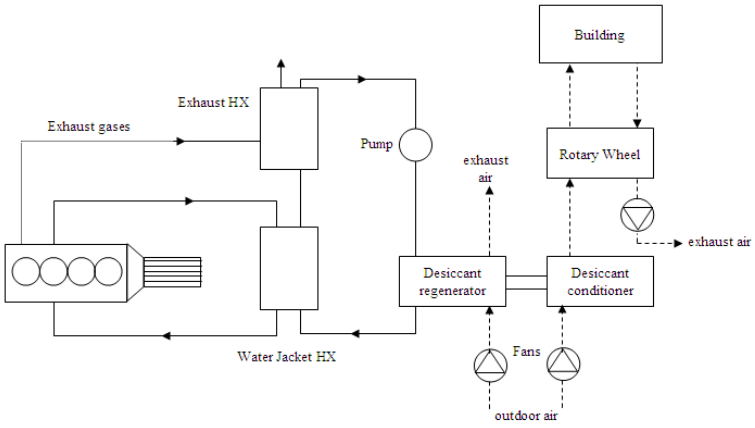

Figure 2. Schematic diagram of the trigeneration plant

The innovative natural gas combined heat, cooling and power (CHCP) system has electrical, heating and cooling capacities of 126/220/210 kW, respectively (see Figure 3). The heat is recovered from the engine through a water/water exchanger and a gas/water heat exchanger. The first one recovers heat from the engine cooling water, the second from the flue gases. The cogenerator has an electronic power unit, made up of an AC/DC-DC/AC converter, which allows the engine to operate at variable speed, while delivering 50 Hz AC to the grid. Due to the power electronics, the engine can operate at part load conditions by varying the rotating speed. This strategy allows the engine to achieve higher part load efficiency than conventional cogenerators [1] (see Figure 4).

Figure 3. The cogenerator

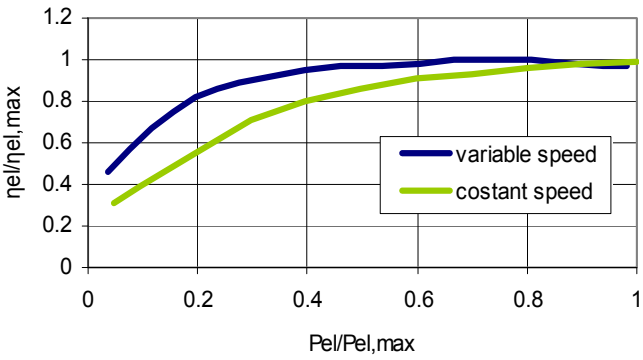

Figure 4. Part load efficiency of the CHP

The heat recovered from the engine is exploited in a Thermally Activated Technology (TAC) device, that is, the desiccant cooling unit. This unit is composed of two sections: a conditioner and a regenerator. The conditioner is able to produce a cooling effect from the dehumidification obtained through the sorption of the humidity in an external airflow of 20.000 m^3/h, by a LiCl-water solution. Then, the moisture is desorbed from the solution in the regenerator, by means of a second external 20.000 m^3/h air flow (see Figures 5 and 6). A rotary heat exchanger has been placed between the supply airstream, which is already treated inside the conditioner, and the return air flow. The heat is

transferred from the supply to the return stream. Moreover, a humidifier, placed after the rotary wheel, further decreases the supply air temperature (evaporative cooling).

ENERGETIC ANALYSIS

The energetic analysis of the plant has been performed on nominal data provided by the cogenerator (see Table 1) and the desiccant unit (see Table 2) manufacturers.

Table 1
Main cogenerator data

Engine type	Otto 4T
Displacement	5883 cm^3
Fuel	Natural Gas
Generator	Asynchronous water-cooled
Power electronics	AC/DC - DC/AC converter
Electric power	126 kW
Thermal power	220 kW
Fuel input power	427 kW
Electrical efficiency	0.295
Thermal efficiency	0.515
Energy Utilization Factor	0.810

Table 2
Main Desiccant unit data (single unit)

Number of units employed	4
Desiccant solution type	LiCl-water
Nominal air capacity (conditioner)	5000 m3/h
Nominal air capacity (regenerator)	5000 m3/h
Net weight	540 kg
Operating weight (including LiCl)	690 kg
Dimensions (L/W/H)	2240/1420/1575 mm
Nominal latent cooling capacity	~ 42 kW

The electrical, thermal and cooling power characteristics of the trigeneration plant are reported in Table 3.

Table 3
Electrical and thermal balance of the trigeneration plant

Cogenerator rated power	126 kW_{el}
Desiccant unit requirements	15.8 kW_{el}
Other plant component requirements	19.4 kW_{el}
CHCP net electrical rated power	90.8 kW_{el}
CHP recovered thermal power	220 kW_{th}
Cooling power supplied by the desiccant system	168 kW_{el}
Cooling power supplied by the rotary heat exchanger	42 kW_c
CHCP total cooling power	210 kW_c

The main hypotheses considered in this study are:

- as the plant capacities are much lower than the electrical, thermal and cooling load of the Politecnico di Torino user's, the whole energy production is considered to be self consumed inside the internal electric and thermal grids of the Politecnico;
- during the summer season, the plant is only turned on to guarantee the base load (about 600 hours). During these hours, the rated cooling power (210 kW) is entirely exploited. When only part of the maximum cooling power is needed, the plant is turned off, and the partial load is satisfied by a traditional vapour compression refrigeration group;
- the heat recovered from the engine during the summer season is all sent to the desiccant system to produce the cooling effect;
- during the entire considered period, the plant always works at rated power.

On the basis of the above presented hypotheses, the following yearly working hours can be assumed:

- Winter: about 1.900 h (13 hours/day for 6 days/week, for 6 months);
- Summer: about 600 h (10 hours/day for 5 days/week, for about 3 months)

Considering the aforementioned operating hours, and the nominal power reported in Table 3, the plant energy production can be calculated. The results are summarized in Table 4:

Table 4
CHCP plant energy production during the year

	Operating hours	Electrical production	Thermal production	Cooling production
	h	MWh_{el}	MWh_{th}	MWh_c
Winter	1900	236	412	-
Summer	600	55	133	127
Total	2500	E_{el} = 236+55	E_{th} = 412+133 E^*_{th} = 412	E_c = 127

A recognized way of assessing the energetic performance of a cogeneration / trigeneration plant, proposed by the European Union (EU), is through the calculation of the Primary Energy Savings (PES). The amount of PES provided by a CHP plant can be calculated on the basis of equation (1) [2]. A traditional boiler $\eta_{th,s}$ = 0.9 and an electrical efficiency value $\eta_{el,s}$ = 0.525 of the separate production

plant have been considered For the calculations, as indicated in [3]. Moreover, the Decision of the EU introduces two correction factors on the $\eta_{el,s}$ value:

- One factor is related to the average yearly temperature (12.5 °C registered in Turin in the year 2008);
- The other factor is related to the tension at which the electrical power is produced by the plant (380 V);

The electrical efficiency value for the separate production becomes [3]:

$$\eta_{el,s} = \{52.5 + [(15 - 12.5) \cdot 0.1]\} \cdot 0.860 = 45.4\% \quad (1)$$

Therefore:

$$PES = 1 - \frac{E_{fuel}}{\frac{E_{el}}{\eta_{el,s}} + \frac{E_{th}}{\eta_{th,s}}} = 15.2\% \quad (2)$$

where E_{fuel} is the total fuel energy input in the specified reference period (1 year); E_{el} is the total net electricity production and E_{th} is the total thermal energy recovered from the engine, in the reference year.
The regulations provided in European Union Directive 2004/08/CE, have set two different primary energy savings thresholds, which will be valid from the 1st January 2011; when the PES index is greater that the threshold, the plant is recognised as a "high efficiency cogeneration" plant. The two thresholds values are:

- PES > 0, when the rated electrical power of the cogenerator is less than 1 MW_{el};
- PES > 10% in the other cases.

In the present application, where the electrical rated power is 126 kW, there should be a PES > 0.
The calculation of the energy terms in equation (2) should be performed by considering a specified reference period (for instance, 1 year). Moreover, in this formulation, according to the Decision of the European Commission 2008/952/CE of 19th November 2008, the heat employed to produce a cooling effect can be considered as useful thermal energy. No cooling efficiencies of reference are indicated, and only the total amount of heat exploited is considered.
Some Authors [3] have suggested alternative methodologies to calculate the savings offered by a CHCP plant, and in particular they highlighted the cooling production efficiency. A Trigeneration Primary Energy Savings index (TPES) is introduced, which is defined as follows:

$$TPES = 1 - \frac{E_{fuel}}{\frac{E_{el}}{\eta_{el,s}} + \frac{E^*_{th}}{\eta_{th,s}} + \frac{E_c}{\eta_{c,s}}} \quad (3)$$

In this formulation, E_{el} is again the net electrical power produced by the CHCP during the considered period (one year); E^*_{th} is the useful thermal energy output produced by the cogenerator, excluding the part exploited in the desiccant unit during the summer season (with reference to Table 4, E^*_{th} = 412 MWh); E_c is the cooling energy produced by the plant over the year.
$\eta_{th,s}$ and $\eta_{el,s}$ are the separate thermal and electrical production efficiencies, while $\eta_{c,s}$ is the traditional reference efficiency for cooling power generation [2], which can be expressed as:

$$\eta_{c,s} = \eta_{el,s} * COP_s \quad (4)$$

where COP_s is the coefficient of performance of one equivalent compression electric refrigerator group. In the calculation, COP_s is assumed equal to 2.7.
From equations (3), (4), it results that:

$$TPES = 1 - \frac{E_{fuel}}{\frac{E_{el}}{\eta_{el,s}} + \frac{E^*_{th}}{\eta_{th,s}} + \frac{E_c}{\eta_{el,s} * COP_s}} = 12.1\% \quad (5)$$

It should be pointed out that the primary energy savings not only depend on the performance of the plant, but also on the efficiencies of the reference situation with separate production of heat and power. Figure 7 shows the PES = 0, PES = 10% and PES = 20% curves in a plan where X and Y axes are η_{el} and η_{th} respectively. The PES point is represented for the selected separated efficiencies. The position of the TPES point over the map has been determined by means of the two electrical and thermal equivalent production efficiencies, defined by equations (6).

$$\eta^{eq}_{el} = \frac{E_{el} + E_c / COP_s}{E_{fuel}}; \qquad \eta^{eq}_{th} = \frac{E^*_{th}}{E_{fuel}} \quad (6)$$

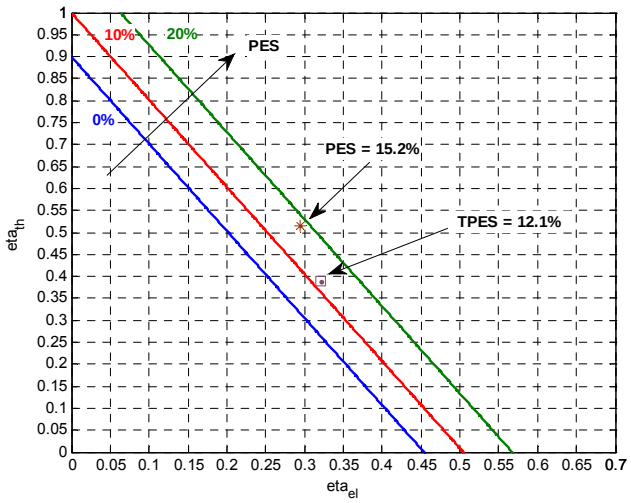

Figure 7. Primary Energy Savings curves in function of the electrical and thermal efficiency of the cogenerator, for $\eta_{el,s} = 0.454$ and $\eta_{th} = 0.9$

ECONOMIC ANALYSIS

An economic profitability analysis of the installation was carried out. The prices of buying/selling electricity, the personnel and maintenance costs and the fuel costs were considered, while the purchase and self-production of electrical, thermal and cooling energy were contextualized in the energy market of reference. Moreover, national subsides from Italian Legislation were taken into account in the calculations (the Government provides some money benefits for each toe of primary energy saved [5]). Some insurance and general costs were considered, and these were both assumed equal to 5% of the total costs. All the profit and cost unit prices are reported in Table 5.
The unit prices of the electrical and thermal energy represent the cost of the actual supply. Different costs were considered for the electricity supply, as the Italian National Electric System is organized in time bands. Furthermore, the actual Italian legislation foresees the detaxation of the natural gas

employed for cogeneration purposes (0.25 Sm^3 for each produced kWh_{el} should be paid without inland duties). Therefore, two different natural gas costs are presented.

Table 5
Profit and cost unit prices

Revenues	
Electrical energy price (self-consumption) [8.00 – 19.00]	166.3 €/MWh_{el}
Electrical energy price (avoided purchase) [8.00 – 19.00]	141.3 €/MWh_{el}
Electrical energy price (self-consumption) [other hours]	166.3 €/MWh_{el}
Electrical energy price (avoided purchase) [other hours]	158.9 €/MWh_{el}
Thermal energy price (from district heating service)	65 €/MWh_{th}
Subsidies	
Italian Legislation Subsidies (referred to February '09)	~ 80 €/toe
Costs	
Natural gas (with detaxation)	0.360 €/Sm^3
Natural gas (with detaxation)	0.569 €/Sm^3
Personnel	4 h/week, with a full cost of 40.000 €/year
CHP maintenance cost	16.0 €/MWh_{el}
Desiccant unit maintenance cost	8.0 €/MWh_c
National duty on electricity consumption	3.10 €/MWh_{el}
Regional tax on electricity consumption	11.36 €/MWh_{el}
General cost	5% of total costs

The avoided costs were calculated from these unit prices, and considering the energetic production of the plant reported in Table 4. The economic profitability was assessed, by means of two indices that are usually employed to evaluate the convenience of investment with high initial capital costs [6]: the Simple Payback period (SPB) and the Internal Rate of Return. The simple payback is the amount of time it will take to recover installation costs, based on annual energy cost savings. The SPB is calculated as the ratio of the annual energy cost savings, over the initial installation cost.

$$SPB = I / (R_i + S_i - C_i) \quad (5)$$

Where I is the total initial investment, R_i is the total revenue, S_i is the total subsidy and C_i is the total plant costs in the year i.

The IRR instead is the average annual return earned through the life of an investment. The IRR is the value of the discount rate s that satisfies equation (6) for a given N, where N is the total plant life, in years. For the calculations, N = 15 years is assumed.

$$\sum_{i=1}^{N} \frac{Ri + Si - Ci}{(1+s)^i} = 0 \quad (6)$$

Due to the high volatility of the fuel cost over the last few years, the profitability analysis of the investment has been related to several natural gas cost values. The estimation of the plant investment cost is marked by a vertical dotted band [6], and the results of the economic simulation are reported in Figures 9 and 10.

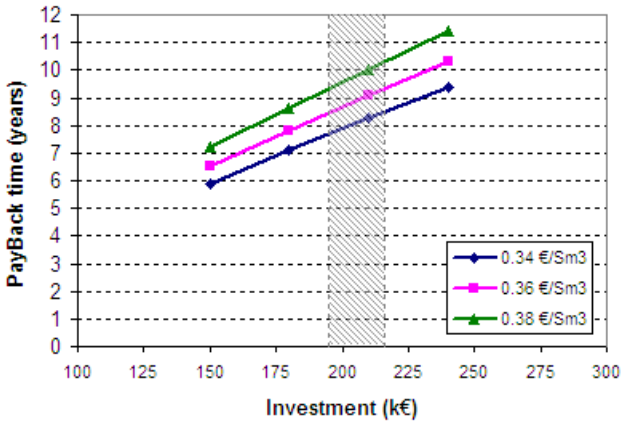

Figure 9. Payback time of the investment for different natural gas cost

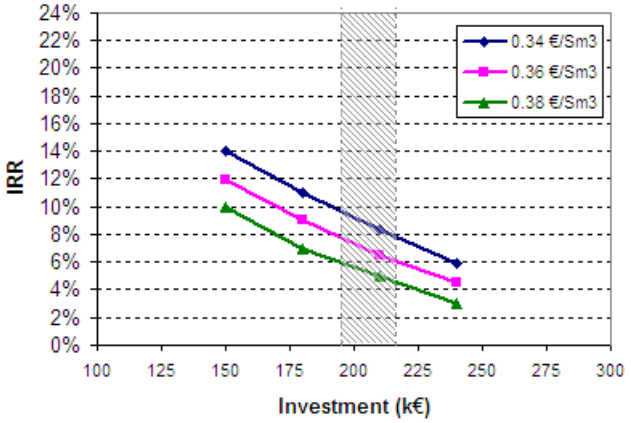

Figure 10. IRR at 15 years of the investment for different natural gas costs

CONCLUSIONS

A small-scale trigeneration plant, with a natural gas ICE and a liquid desiccant cooling system, is presented in the paper. An energetic analysis, based on the nominal data of the cogenerator and of the desiccant unit, has been performed. The Primary Energy Savings achievable from the plant operation have been calculated, referring both to EU Directive 2004/8/CE and to another methodology proposed in literature. The results of the comparison are described and discussed in detail. An economic analysis has also been carried out; the paper describes the main hypotheses, and illustrate the methodology adopted to assess the profitability of the investment. Two commonly used indices have been calculated, the Simple Payback Period and the Internal Rate of Return. As the fuel cost has had a high volatility in recent months due to the international market situation, the paper has the aim of illustrating the relationship between such indicators and the fuel cost. National Subsidies have also been considered in the study.

ACKNOWLEDGMENTS

The support provided for this work under EU Sixth Framework Programme Priority 6.1 (contract TREN/05/FP6EN/S07.56687/020153, HEGEL Project, “High Efficiency polygeneration appLications) is gratefully acknowledged. The Authors also wish to express their thanks also to Dr. Pasquale Campanile, Dr Franco. Anzioso and Dr. Paolo Chiantore from FIAT Research Centre, Turin (Italy) for their support and collaboration.

METAL FOAM CONDENSERS FOR MINIATURE-SCALE REFRIGERATION SYSTEMS

G. B. Ribeiro, J. R. Barbosa Jr.*, A. T. Prata
Federal University of Santa Catarina, Florianópolis, Brazil

ABSTRACT. This study consists of an experimental analysis of the thermal-hydraulic performance of microchannel condensers with open-cell metal foams to enhance the air side heat transfer. The condensers were designed to be part of a miniature-scale refrigeration system. Three different metal foam samples were tested with distinct numbers of pores per inch (10 and 20) and porosity (89.30 and 94.70%). A conventional condenser with plain fins was also tested for a performance comparison. On the refrigerant side, seventeen micro-channels with diameter of 1.5 mm were used in all condensers. The experimental apparatus is composed of an air loop (a closed-loop wind tunnel calorimeter) and a refrigerant loop which allows the specification of the mass flow rate and the thermodynamic state of the refrigerant at the condenser inlet. Iso-butane (R-600a) was used as the working fluid. The experiments were performed at the condensing temperature of 90°C, with coolant inlet temperature of 50°C. Air side flow rates ranged from 1.4×10^{-3} m^3/s to 3.3×10^{-3} m^3/s. The refrigerant mass flow rate was maintained at 2.9×10^{-4} kg/s. The heat transfer rate, the overall thermal conductance *UA*, the Colburn factor *j*, the friction factor *f* and the pumping power were calculated as part of the analysis of the prototypes.

Keywords: *condenser, metal foam, porous media, miniature refrigeration system*

INTRODUCTION

The current generation of transistors used in computer processors are responsible for severe rates of heat dissipation per unit area which, if not appropriately controlled, can reduce the performance and compromise the reliability of electronic devices. Thus, the heat management of processors has become a cornerstone of computer technology. A large number of studies have been devoted to engineering the removal of heat from these devices. According to Ortega and Birle [1], natural and forced convection of air are no longer capable of maintaining the processor temperature below acceptable values.

Cooling technologies as diverse as liquid jet and spray impingement, liquid loops and heat pipes have been considered for high heat flux applications. According to Trutassanawin and Groll [2], the vapor compression refrigeration cycle is the only technology capable of removing high heat fluxes in a high-temperature environment. However, space restrictions (which impose a limit on the size of the refrigeration system) are among the most challenging aspects on this thermal solution. Therefore, the design of compact components of the cycle, such as compressors and heat exchangers, is essential for advancing the technology.

This paper presents an experimental analysis of compact microchannel condensers for a miniature-scale refrigeration system. Copper metal foams were used as extended surfaces for enhancing the air side heat transfer. Metal foams have several attributes often pursued in high performance heat

exchangers, such as a large surface area per unit volume, a high thermal conductivity of the solid matrix and large heat transfer coefficients.

Floyd et al. [3] investigated analytically and experimentally the behaviour of copper metal foam heat exchangers in an impinging water flow arrangement, for which a performance similar to that of a microchannel heat exchanger has been observed. They also showed that the foam porosity has a high influence on the surface temperature and on the water flow rate. Haack et al. [4] presented an overview of metal foam materials for high performance heat exchangers. They showed that, for a fixed coolant flow rate, both the heat exchanger effectiveness and the pressure drop increase with decreasing pore size. Boomsma et al. [5] presented an experimental apparatus for evaluating metal foam heat exchangers. In their tests, the performance of aluminium metal foam exchangers under forced convection was compared with that of commercial heat exchangers, using water as coolant. The thermal resistance of the metal foam heat exchangers was 2 to 3 times lower than that of the commercial heat exchanger for a fixed pumping power.

In the present paper, the influence of the number of pores per inch (PPI) and of the porosity on the performance of metal foam condensers is investigated experimentally for conditions typical of small scale refrigeration systems for electronic cooling applications. The heat transfer and the air side pressure drop were observed to increase with the number of PPI and decrease with increasing porosity.

EXPERIMENTAL APPARATUS

Air loop

The air loop is presented schematically in Figure 1. It consists of a thermally insulated, fully instrumented, closed loop wind tunnel calorimeter. Two direct current (DC) blowers with a variable power input control were used to supply air through the test section. In order to measure the air flow rate, four calibrated nozzles with different diameters were installed together with two differential pressure transducers; one of them measures the pressure difference between the inlet of the nozzles and the atmospheric pressure, and the other measures the pressure drop across the nozzles. A humidity transducer was also placed upstream of the nozzles.

A two-transducer arrangement identical to the one described above was used in the test section to measure the condenser pressure drop. On the whole, fifteen T-type thermocouples were installed in the air loop. Five of them were installed upstream of the condenser test section and another five were positioned downstream of the condenser. Three thermocouples were placed outside the air loop for room temperature control. The two remaining thermocouples were used to measure the air temperature upstream of the nozzles. To control the inlet temperature, a set of electric heaters and a cooling coil connected to a thermostatic bath were used. The use of diffusion baffles, porous media and a fan ensures the uniformity of air temperature and velocity at the tunnel cross section.

Refrigerant loop

The refrigerant loop is shown schematically in Figure 2. A variable-speed compressor was used to pump iso-butane (R-600a) through the loop and an oil filter was used to separate residual oil from the discharged refrigerant. An accumulator was placed downstream of the condenser. The expansion device is a hand-operated needle valve. The refrigerant mass flow rate was measured with a Coriolis-type mass flow meter placed between the accumulator and the needle valve.

Resistance temperature detectors (RTDs) were placed upstream of the compressor and mass flow meter. At the condenser inlet, the pressure was measured by means of an absolute pressure transducer. Two immersion-type thermocouples were installed upstream and downstream of the condenser. The tests conditions are controlled through proportional-integral-derivative (PID)

microcontrollers. The compressor inlet temperature, the mass flow meter inlet temperature and the condenser inlet temperature were controlled by electric heaters positioned around the connection tubing. The condenser inlet pressure was controlled by an electric heater wrapped around the accumulator. The specification of the test conditions is such that the refrigerant is in the superheated vapour state at the inlet of the mass flow meter and of the compressor.

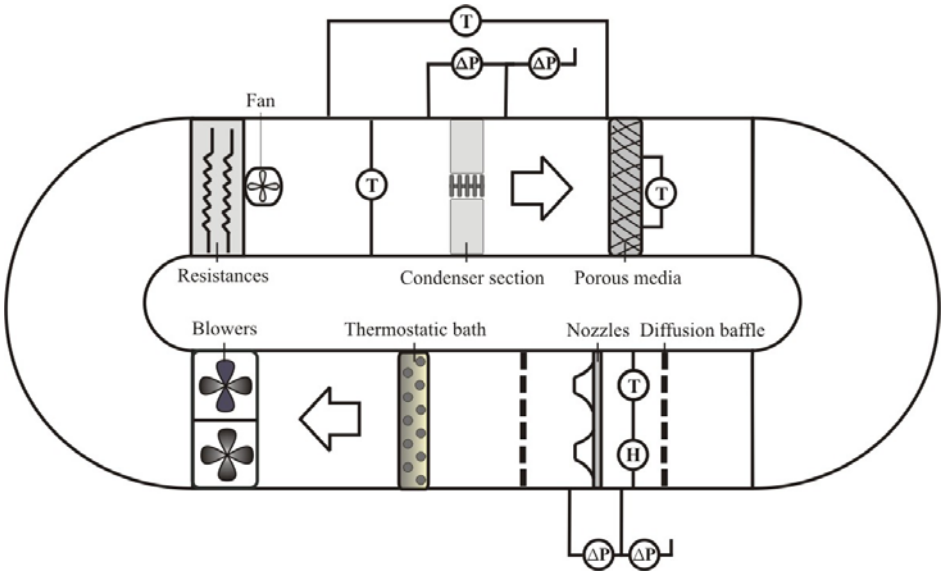

Figure 1. Schematic representation of the air loop

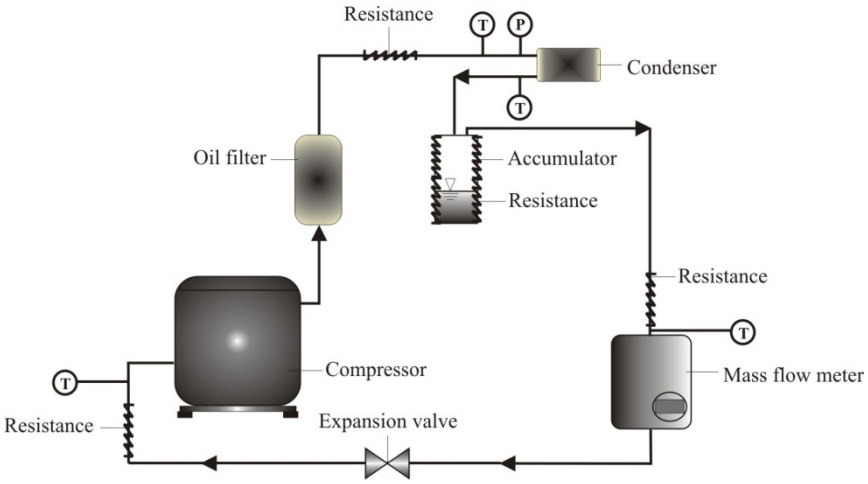

Figure 2. Schematic representation of the refrigerant loop

METAL FOAM CONDENSERS

All condensers were manufactured from copper, and three metal foam samples were used with different number of pores and porosity. The number of pores is defined as the quantity of pores encountered in an inch of structure, whereas the porosity can be defined as the volume fraction occupied by the fluid. Here, numbers of pores per inch (PPI) equal to 10 and 20, and porosities of 89.30 and 94.70% were used. The metal foams were brazed at the top and bottom of a 3 mm thick copper plate with seventeen circular parallel microchannels with a diameter of 1.5 mm.

As illustrated in Figure 3, air flows through the porous media, extracting heat from the refrigerant fluid that flows (in a cross-flow arrangement) inside the microchannels. The length (in the direction of the air flow), height and width of the metal foam samples brazed on the plate were 35, 7 and 48 mm, respectively. A condenser with sixty 0.5 mm thick, brazed plain fins was tested for performance comparison purposes. All prototypes had the same frontal area.

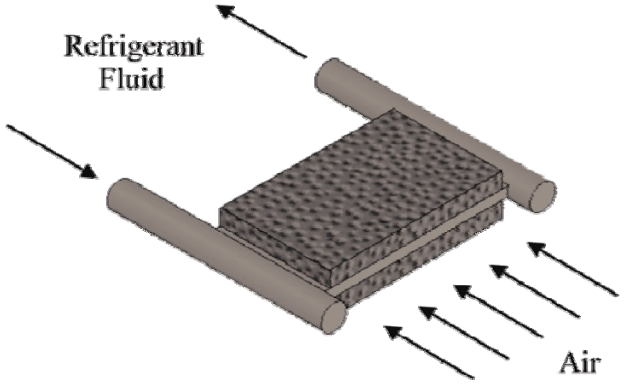

Figure 3. Illustration of a metal foam condenser

EXPERIMENTAL PROCEDURE

To evaluate the performance of the miniature-scale condensers, a condensing temperature of 90°C was used for all experimental runs. A 2°C inlet superheat was maintained during all tests. The air inlet temperature was kept at 50°C, whereas the air flow rate was set at three different values: 1.4×10^{-3} m^3/s, 2.3×10^{-3} m^3/s and 3.3×10^{-3} m^3/s. The refrigerant mass flow rate was kept at 2.9×10^{-4} kg/s. Overall, three different conditions were evaluated for each condenser. Each test was performed twice, which resulted in six tests for each heat exchanger.

DATA REDUCTION

The heat transfer rate measured on the air side $\dot{Q}_{air}$ is calculated through equation (1), where $\dot{M}_{air}$ is the air mass flow rate, $c_{p,air}$ is the specific heat, and $T_{in,air}$ and $T_{out,air}$ are the air inlet and outlet temperatures respectively.

$$\dot{Q}_{air} = \dot{M}_{air} c_{p,air} (T_{out,air} - T_{in,air}) \tag{1}$$

Similarly, the heat rejection from the refrigerant side $\dot{Q}_{ref}$ can be evaluated from

$$\dot{Q}_{ref} = \dot{M}_{ref} (h_{in,ref} - h_{out,ref}) \tag{2}$$

where $\dot{M}_{ref}$ is the refrigerant mass flow rate, and $h_{in,ref}$ and $h_{out,ref}$ are the enthalpies at inlet and outlet of the condenser. The overall heat conductance UA can be obtained from the ratio of the heat transfer rate $\dot{Q}_{air}$ and the logarithmic mean temperature difference, ΔT_{lm}.

$$UA = \dot{Q}_{air} / \Delta T_{lm} \tag{3}$$

As proposed by Boomsma et al. [5], the following dimensionless quantities can be used to correlate the air-side heat transfer and pressure drop

$$f = \frac{\Delta p_{cond}}{\left(L_{cond} / D_h\right)\left(\rho_m u_{air}^2 / 2\right)} \tag{4}$$

$$\rho_m = (\rho_{in,air} + \rho_{out,air}) / 2 \tag{5}$$

$$D_h = 4A_{pm} / L_{cond} \tag{6}$$

$$u_{air} = \dot{V}_{air} / A_{pm} \tag{7}$$

where f is the friction factor, $\dot{V}_{air}$ is the air flow rate and A_{pm} is the frontal area of the porous media. In the equations above, $\rho_{in,air}$ and $\rho_{out,air}$ are the inlet and outlet air densities, respectively, L_{cond} is the heat exchanger length along the air flow, and Δp_{cond} is the measured pressure drop.

The Colburn *j*-factor was calculated as follows

$$j = \frac{h_{air} A_{pm} \,\mathrm{Pr}_{air}^{\,2/3}}{\dot{M}_{air} c_{p,air}} \tag{8}$$

where h_{air} is the heat transfer coefficient from the air side calculated in the form [5]

$$h_{air} = \frac{\dot{M}_{air} c_{p,air} (T_{out,air} - T_{in,air})}{A_{con}\left(T_{cond} - T_{air,in}\right)} \tag{9}$$

A_{con} is the interface area between the porous media and condenser plate, and T_{cond} is the condensing temperature. The Reynolds number, as suggested by Kaviany [6], can be obtained from

$$\mathrm{Re} = \frac{\rho_m u_{air} \sqrt{K}}{\mu_m} \tag{10}$$

$$\mu_m = (\mu_{in,air} + \mu_{out,air}) / 2 \tag{11}$$

where $\mu_{in,air}$ and $\mu_{out,air}$ are viscosity of the air at the inlet and outlet, respectively, and K is the permeability of the metal foams. The permeability can be calculated from a linear regression of Darcy's law as follows

$$\dot{V}_{air} = -\frac{KA_{pm}}{\mu_m L_{cond}} \Delta p_{cond} \tag{12}$$

The air side pumping power $\dot{W}$ is calculated from

$$\dot{W} = \Delta p_{cond} \dot{V}_{air} \tag{13}$$

RESULTS

As part of the validation procedure of the experimental setup, the energy balance on both sides of the condenser, i.e., the air side and the refrigerant side, were compared yielding a deviation of ±10%. The main source of uncertainty was the heat loss from the air loop to the environment through the duct walls. It should be noted that the refrigerant side heat transfer rate was measured only at conditions where the refrigerant was a subcooled liquid at the condenser outlet. An uncertainty propagation analysis was performed based on the data reduction equations. The estimated measurement uncertainties of the pressure drop, friction factor, heat transfer, *UA* and Colburn factor were ±1.2%, ±2.1%, ±5.0%, ±5.7% and ±5.7%, respectively.

The effect of the number of pores can be analysed by a direct comparison between condensers A and B. Similarly, the influence of the porosity can be evaluated by comparing condensers B and C. Figure 4 shows the pressure drop as a function of the air volumetric flow rate for the three metal foam condensers. As expected, the pressure drop increases with the increasing air flow rate. By comparing condenser A and B, it can be seen that increasing the number of pores increases the pressure drop. Furthermore, decreasing the porosity increases the pressure drop, as seen in Figure 4.

Results for the friction factor are shown in Figure 5. The friction factor decreases with increasing Reynolds number. Like the pressure drop, the condenser with the higher number of pores and the lower porosity presents the highest friction factor. The metal foam condenser with lower porosity and higher number of pores presented a more compact solid matrix and more tortuous air flow passages, making the fluid flow more difficult.

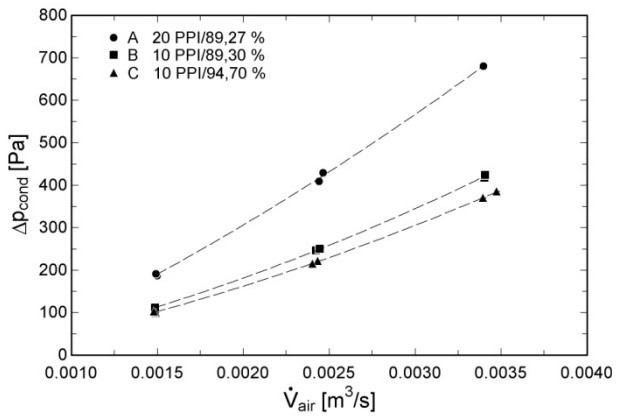

Figure 4. Pressure drop versus air flow rate

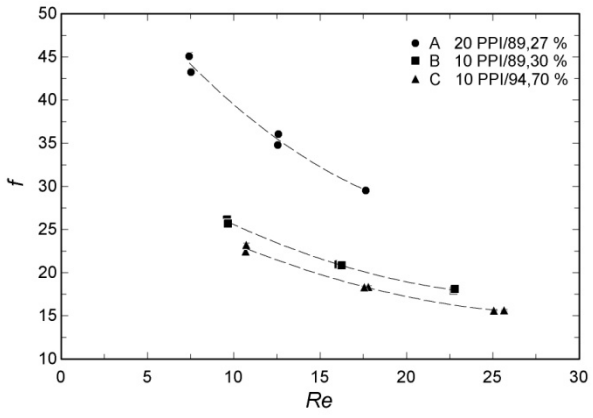

Figure 5. Friction factor versus Reynolds number

Figures 6 and 7 show the heat transfer rate and the overall thermal conductance *UA* as a function of the air flow rate. As expected, the heat transfer rate increases with increasing air flow rate. In Figure 6, condenser A presented higher heat transfer rates than condenser B. Thus, a higher number of pores resulted in higher heat transfer rates. Similarly, lower porosity also resulted in higher heat transfer rates.

It can be seen in Figure 7 that, as expected, *UA* increases with increasing air flow rate. Like the heat transfer rate, the metal foam condensers with a higher number of pores and a lower porosity presented higher heat transfer coefficients. The increase in the number of pores for a fixed porosity

results in a higher interface area between the solid matrix and the air. The decrease in porosity for a fixed number of pores results in a smaller area available for heat transfer. However, it also results in a larger volume of the solid matrix. This larger volume has become more significant for the heat transfer due to a low thermal resistance between the refrigerant fluid and the coolant.

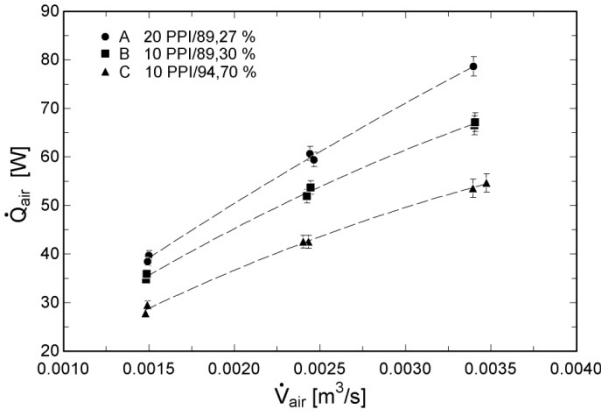

Figure 6. Heat transfer versus air flow rate

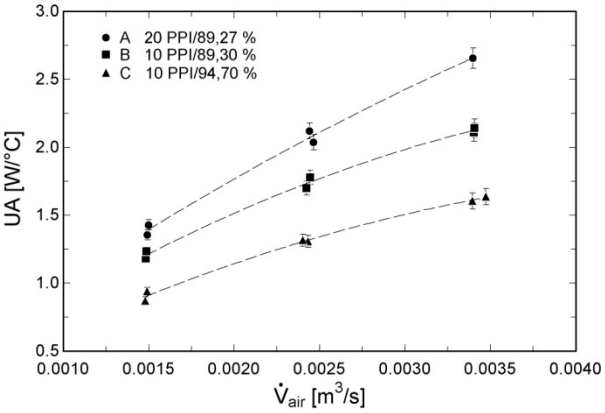

Figure 7. *UA* versus flow rate

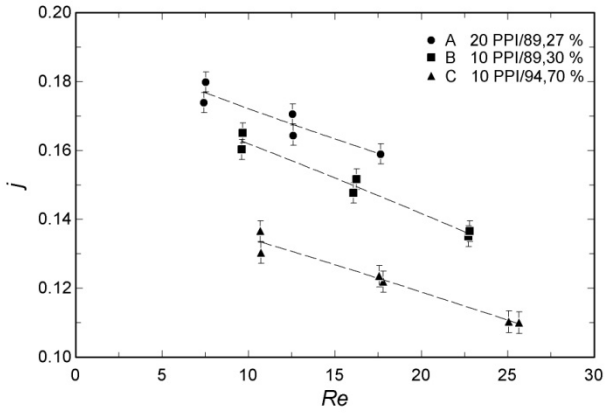

Figure 8. Colburn factor versus Re

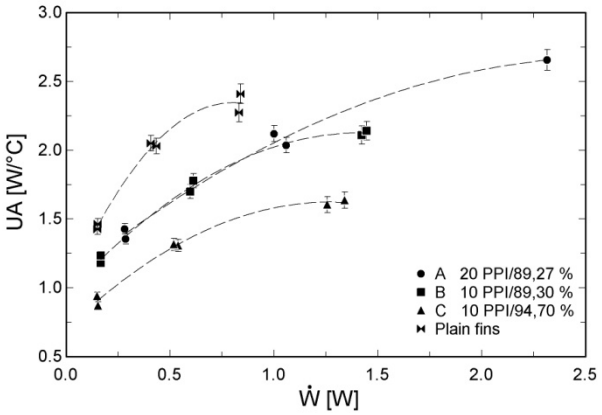

Figure 9. *UA* versus pumping power

The results of the Colburn *j*-factor as function of the Reynolds number are shown in Figure 8. Like the friction factor, the *j*-factor decreases with increasing Reynolds number. It can be concluded that the increase in the number of pores and the decrease in porosity results in higher Colburn factors. Hence, a higher number of pores and a lower porosity improved the thermal performance of the metal foam condensers investigated here.

Figure 9 presents *UA* as a function of the required pumping power. For the lower values of pumping power, condensers A and B presented a similar behaviour. Higher values of thermal conductance could be obtained with condenser A, but at the expense of a more elevated pumping power. By comparing condensers B and C, it can be seen that a lower porosity resulted in a higher thermal conductance, for approximately the same pumping power. In addition, Figure 9 also shows that the required pumping was lower in the conventional (plain fin) condenser than in the metal foam condensers. So, at least for the conditions investigated, the use of a metal foam condenser in a miniature-scale refrigeration system may not be advantageous.

CONCLUSIONS

In order to consider the feasibility of their application as part of a small scale refrigeration system, a series of tests was performed to assess the thermal-hydraulic performance of three metal foam condensers using air as coolant. The number of pores per inch (PPI) and the porosity were varied and their influence on the condensers' performance was analysed.

A refrigerant loop facility that uses iso-butane as refrigerant and a wind tunnel calorimeter to control the air flow conditions were utilized for the miniature-scale heat exchangers performance evaluation. The condensing temperature used in the experiments was 90°C and the air inlet temperature was set at 50°C. Three different air flow rates and one refrigerant mass flow rate were tested.

It was observed that the increasing the number of PPI and decreasing the porosity resulted in a higher air-side pressure drop and in a higher overall thermal conductance. For a fixed pumping power, the overall thermal conductance of the metal foam condensers was lower than that of a plain fin condenser with similar characteristics.

ACKNOWLEDGEMENTS

This study was performed under a joint research programme between the Federal University of Santa Catarina and EMBRACO. The support from Eng. Augusto P. Zimmermann (EMBRACO) is greatly appreciated. Financial support from CNPq and FINEP is also acknowledged.

ABSTRACT. Two-phase steam-water injectors may be applied as a feeding pump device or as a condensing device in many applications. In such injectors steam is a motive fluid while cold water is a secondary fluid. One-dimensional model of two-phase injector has been proposed in the paper. Model is based on two-fluid model of two-phase flow along with a set of closure equations. The results of calculations have been compared with experimental results showing reasonably good agreement.

Keywords: *two-phase flow, injector, two-fluid model, condensation*

INTRODUCTION

Steam –water two-phase injector investigated in the present paper consists of motive steam nozzle, water nozzle, mixing chamber and diffuser. Two different kinds of such injector may be distinguished with respect to the arrangement of the steam nozzle: with a central or outer (annular) nozzle. Figure 1 shows a schematic sketch of the injector with the central arrangement of the steam nozzle which is investigated in the paper. In this case steam is a motive fluid while water is a secondary fluid.

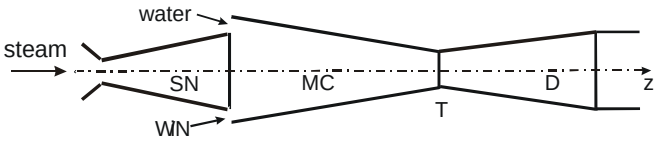

Figure 1. Schematic sketch of steam-water injector:
SN – steam nozzle, MC – mixing chamber, D - diffuser, T- throat, WN – water nozzle.

Having a converging-diverging nozzle shape, the steam is accelerated to the supersonic velocity at the inlet to the mixing chamber. Transfer of heat, momentum (due to the temperature and velocity differences) and mass (due to condensation of steam on water) occur in the mixing chamber. Usually the condensation process is terminated at the throat, followed by a rapid increase of pressure in this region called the shock wave. Then, water is decelerated in the diffuser, which causes a further increase of pressure.

It is seen that the steam injector can be simultaneously used as a water pump and/or a heat exchanger. The exemplary applications of such injector are presented in Fig. 2. The injector can be used as a pumping device in safety passive systems in nuclear power stations (Fig. 2a) in order to

deliver cooling water to the reactor under breakdown conditions. The other possible application is shown in Fig. 2b where the injectors are used as a feedwater heaters, i.e. as a condensing devices (mixing condensers). Details concerning such applications can be found in papers by Cattadori [5] and Narabayasi [7].

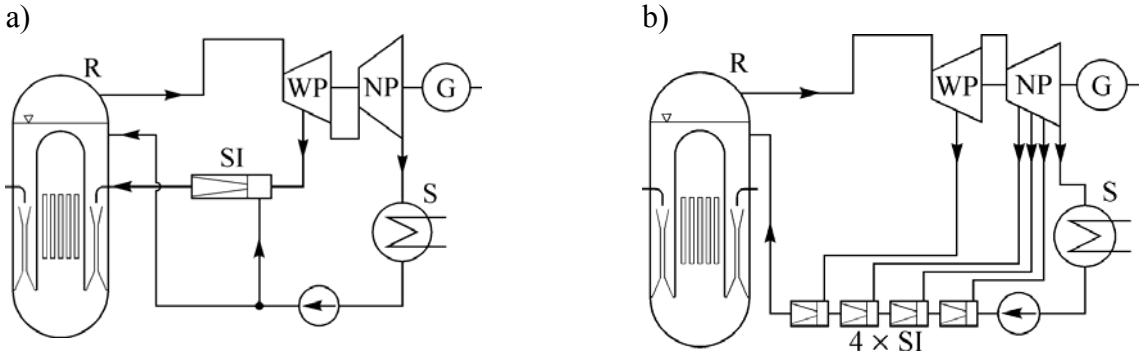

Fig. 2. Exemplary applications of two-phase injectors in nuclear power systems: a) as a cooling water feeding device; b) as a feedwater heating device; R – nuclear reactor; WP – high pressure turbine; NP – low-pressure turbine; S – condenser; G – electric generator.

In many applications of two-phase injector in power generation systems dedicated codes are used to calculate the injector, e.g. RELAP, TRAC, CATHARE – see papers by Pokharna [8]; Carlson [4], Bestion [1]. Various models of two-phase flow are used in order to describe operation of component of power generation systems, mainly: homogenous based on three equations of conservation of mass, energy, and momentum, and two-fluid models based on six equations of conservation for both phases with interphase transport equation, see Ishii [8].

MODEL ASSUMPTIONS

The present paper deals with modelling of two-phase supercritical injector. Two-fluid steady-state model of two-phase flow has been applied for the injector along with closure equations based on the so-called WAHA-3 code equations [11].

The following general assumption has been applied:

- model is steady state;
- all parameters may be averaged through the cross-section area of low, i.e. one dimensional model is applied;
- vapour phase is saturated;
- liquid phase is subcooled.

Moreover, separated flow model have been applied for the closure equations describing the following model quantities: CVM – virtual mass, S – stratification parameter, C_i – interphase shear stress, F_{wall} – flow resistance at the wall. The closure equations of the WAHA-3 code have been used in our calculations [11].

FORMULATION OF THE MODEL

The model of the two-phase stream-water supercritical injector is formulated below. This model consists of the following conservation equations:

a) mass conservation for gas phase:

$$\frac{d}{dz}\left(A\rho_g v_g \alpha\right) = A\Gamma \tag{1}$$

b) mass conservation for liquid phase:

$$\frac{d}{dz}\left(A\rho_l v_l(1-\alpha)\right) = -A\Gamma \tag{2}$$

c) momentum conservation for gas phase:

$$\frac{d\left(A\alpha\rho_g {v_g}^2\right)}{dz} + A\alpha\frac{dp}{dz} + A\cdot C_{VM}\left(v_l\frac{dv_g}{dz} - v_g\frac{dv_l}{dz}\right) + Ap_i\frac{d\alpha}{dz} = \\ = A\alpha\rho_g g\cos\theta - AC_i|v_r|v_r + A\Gamma v_i - AF_{g,wall} \tag{3}$$

d) momentum conservation for liquid phase:

$$\frac{d\left(A(1-\alpha)\rho_l {v_l}^2\right)}{dz} + A(1-\alpha)\frac{dp}{dz} - A\,C_{VM}\left(v_l\frac{dv_g}{dz} - v_g\frac{dv_l}{dz}\right) - Ap_i\frac{d\alpha}{dz} = \\ = A(1-\alpha)\rho_l g\cos\theta + AC_i|v_r|v_r - A\Gamma v_i - AF_{l,wall} \tag{4}$$

e) energy conservation for liquid phase:

$$\frac{d\left(A(1-\alpha)\rho_l e_l v_l\right)}{dz} + \frac{d\left(A(1-\alpha)pv_l\right)}{dz} = AQ_{il} - A\Gamma\left(h_l + \frac{v_l^2}{2}\right) + A(1-\alpha)\rho_l g v_l\cos\theta \tag{5}$$

In conservation equation for liquid phase e_l is the sum of specific internal energy and kinetic energy:

$$e_l = h_l - \frac{p}{\rho_l} + \frac{{v_l}^2}{2} \tag{6}$$

It is import ant to note, that vapour is saturated. Because of relation between temperature and pressure under saturated state: $T_s = f(p); T_g = T_s$, there is one independent variable less. Therefore, in this case five conservation equations have been used. The following vector of the state variables is proposed for considered case of the ejector:

$$\varepsilon = \left(\alpha, p, v_g, v_l, h_l\right)^T \tag{7}$$

The further simplifications are possible in the particular case of the ejector. We have assumed that vapour phase is always saturated, therefore:

$$\rho_g = \rho_g(p, x=0)\,. \tag{8}$$

Liquid chase may be treated as incompressible. Taking into consideration above additional assumption the following set of conservations equations have been developed:

a) mass conservation for gas phase:

$$A\rho_g v_g\frac{d\alpha}{dz} + Av_g\alpha\frac{d\rho_g}{dp}\frac{dp}{dz} + A\rho_g\alpha\frac{dv_g}{dz} = A\Gamma - v_g\alpha\rho_g\frac{dA}{dz} \tag{9}$$

b) mass conservation for liquid phase:

$$A\rho_l(1-\alpha)\frac{dv_l}{dz} - Av_l\rho_l\frac{d\alpha}{dz} = -A\Gamma - v_l\rho_l(1-\alpha)\frac{dA}{dz} \tag{10}$$

c) momentum conservation for gas phase:

$$A\alpha\left(v_g^2\frac{d\rho_g}{dp} + 1\right)\frac{dp}{dz} + \left(Av_g^2\rho_g + Ap_i\right)\frac{d\alpha}{dz} + \left(2Av_g\alpha\rho_g + AC_{vm}v_l\right)\frac{dv_g}{dz} - AC_{vm}v_g\frac{dv_l}{dz} = \\ Ag\alpha\rho_g\cos\theta - v_g^2\rho_g\alpha\frac{dA}{dz} - AF_{g,wall} - AC_i|v_r|v_r + Av_i\Gamma \tag{11}$$

d) momentum conservation for liquid phase:

$$A(1-\alpha)\frac{dp}{dz} - \left(Av_l^2\rho_l + Ap_i\right)\frac{d\alpha}{dz} - AC_{vm}v_l\frac{dv_g}{dz} + \left(2Av_l\rho_l(1-\alpha) + AC_{vm}v_g\right)\frac{dv_l}{dz} = \\ Ag(1-\alpha)\rho_l\cos\theta - v_l^2\rho_l(1-\alpha)\frac{dA}{dz} - AF_{l,wall} + AC_i|v_r|v_r - Av_i\Gamma \tag{12}$$

e) energy conservation for liquid phase:

$$A\rho_l(1-\alpha)\left(h_l+\frac{3v_l^2}{2}\right)\frac{dv_l}{dz}-Av_l\rho_l\left(h_l+\frac{v_l^2}{2}\right)\frac{d\alpha}{dz}+Av_l\rho_l(1-\alpha)\frac{dh_l}{dz}=$$
$$Agv_l(1-\alpha)\rho_l\cos\theta-v_l\rho_l(1-\alpha)\left(h_l+\frac{v_l^2}{2}\right)\frac{dA}{dz}+AQ_{il}-A\Gamma\left(h_l+\frac{v_l^2}{2}\right) \quad (13)$$

The above set of equations can be transform into the matrix form:

$$B\frac{d\varepsilon}{dz}=C\,, \quad (14)$$

and it further can be transformer to the following relation:

$$B^{-1}B\frac{\partial\varepsilon}{\partial z}=B^{-1}C\,. \quad (15)$$

The injector may be treated as the momentum exchanger, therefore a key role in the model play the closure equations, especially for variable in momentum conservation equations. The following terms influence on momentum transfer between two phases in the model:

- $\Gamma(v_i-v_k)$ is the momentum transfer between phases at the interface; here Γ is vapour mass condensed. In our case we assume that: $v_i=v_l$ and v_k is the velocity of phase (liquid or vapour).
- $AC_i|v_r|v_r$ describe the frictional stress at the interface. Here: $v_r=v_g-v_l$.
- $A(1-S)C_{VM}\left(v_l\frac{\partial v_g}{\partial z}-v_g\frac{\partial v_l}{\partial z}\right)$ describes momentum transported with virtual mass due to movement of vapour bubbles. Term $(1-S)$ describes influence of flow structure on momentum transfer. The stratification parameter S enables the discussed set of equations is hyperbolic, Drew in [6].
- $Ap_i\frac{\partial\alpha}{\partial z}$ is the term where the so-called interphase pressure is used. In our case the interphase pressure has not a strict physical interpretation and is used in order to ensure the hyperbolic character of the discussed set of equations. For the separated two-phase flows the following relation is proposed by Tiselj in [11]

$$p_i=\alpha(1-\alpha)\Delta\rho g D_h \quad (16)$$

- The stratification parameter S defined by Carlson in [4] and Tiselj in [11] is used in the paper. The parameters C_{VM} and p_i depends on the stratification parameter. For separated flow $S=1$. The consequence of separated flow is diminishing of influence of C_{VM} on momentum transfer as well as increasing of the role of p_i. The following relation is proposed by Tiselj in [11]:

$$S=S_nX_iX_{\rho v}X_\alpha X_{1-\alpha} \quad (17)$$

where the factors describe influence of various effects on the flow structure:
S_n - factor of Kelvin-Helmholtz instability;
X_i - factor of channel inclination;
$X_{\rho v}$ - factor of very high mass fluxes;
X_α - factor of very high or very small void fraction;

Condensation heat transfer plays a key role for the operation of the discussed injector. Based on the systematic experimental investigations Trela and Butrymowicz [12] proposed the following correlation describing condensation heat transfer in the injector:

$$Nu = 210.8943 \cdot 10^{-6}\ \mathrm{Re}_v^{0.8-3.09561\Delta-0.134536X} \\ Ja^{-1.86626+8.948750\Delta-0.067246X}\, Oh^{-0.362097-8.86765\Delta-0.211543X}. \tag{18}$$

in the above equation is used dimensionless water feeding gap thickness:

$$\Delta = \frac{\delta}{D_{th}}. \tag{19}$$

The further details of the model are presented in the report of Butrymowicz et al. [3].

RESULTS OF NUMERICAL CALCULATIONS

Two geometry configurations of the injector are presented in Fig. 3. There is a cylindrical throat of the mixing chamber in the case 'B' while in the case 'A' there is a sharp-edge throat. The case 'A' was investigated previously by the authors in paper [13]. The numerical calculations have been carried out for the geometry of the injector investigated in [2]. The calculations of the operation of steam-water injector have been carried out for the operating parameters used in the experiments [2]. The operating parameters for various geometries are given in Table 1.

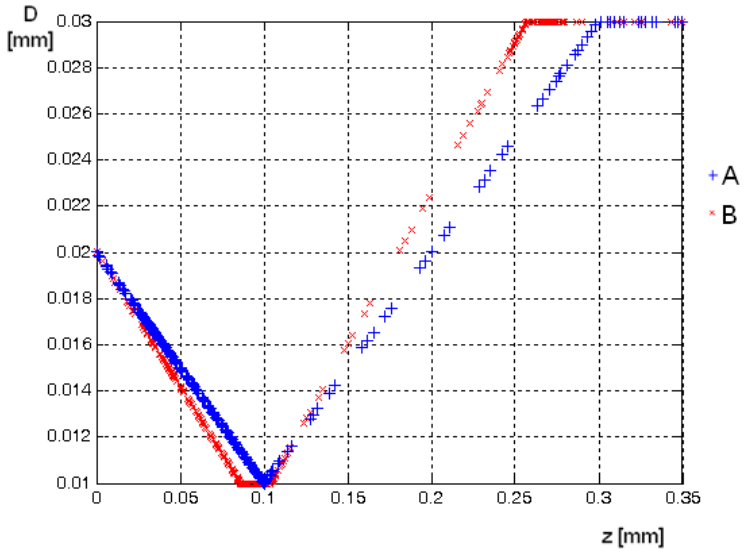

Fig. 3. Geometry of mixing chamber and diffuser with mesh grid of investigated injector. A - injector with sharp-edge throat; B - injector with cylindrical throat

Table 1. Operating parameters for the injector calculations

ejector with sharp-edge throat			ejector with cylindrical throat		
run No.	discharge pressure $[Pa]$	volume rate of liquid $[dm^3/h]$	run No.	discharge pressure $[Pa]$	volume rate of liquid $[dm^3/h]$
A	$p_{out} = 448500$	$\dot{Q}_l = 4895.8$	A	$p_{out} = 492925$	$\dot{Q}_l = 4692$
B	$p_{out} = 349000$	$\dot{Q}_l = 4876.2$	B	$p_{out} = 454552$	$\dot{Q}_l = 4769.6$
C	$p_{out} = 199100$	$\dot{Q}_l = 4000.7$	C	$p_{out} = 388463$	$\dot{Q}_l = 4710.0$
D	$p_{out} = 191700$	$\dot{Q}_l = 3005.8$	D	$p_{out} = 279994$	$\dot{Q}_l = 4777.8$

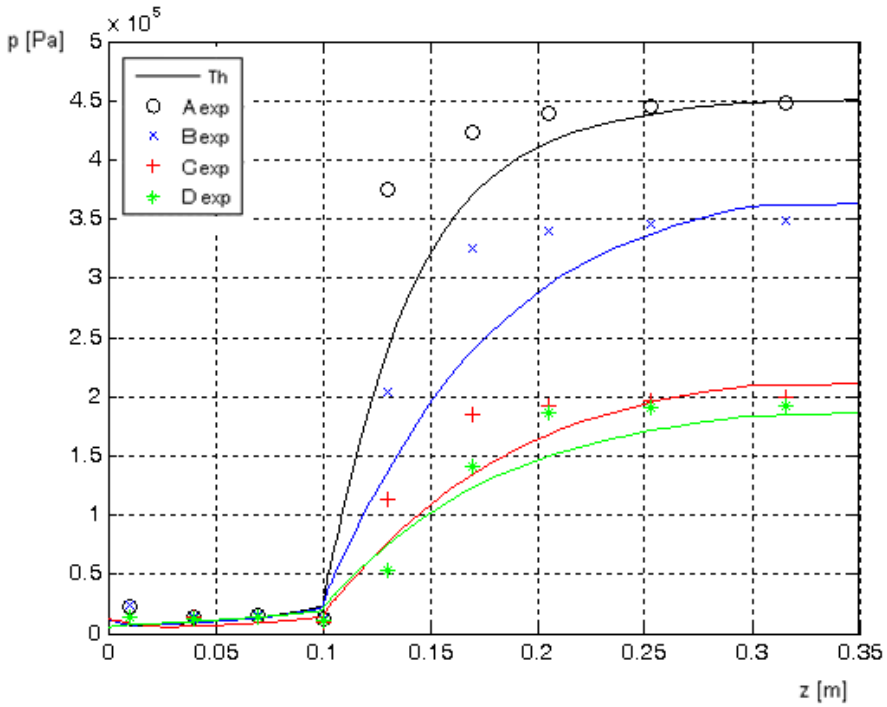

Fig. 4. Comparison of pressure profile calculated (lines) with experimental data for ejector with sharp-edge mixing chamber throat.

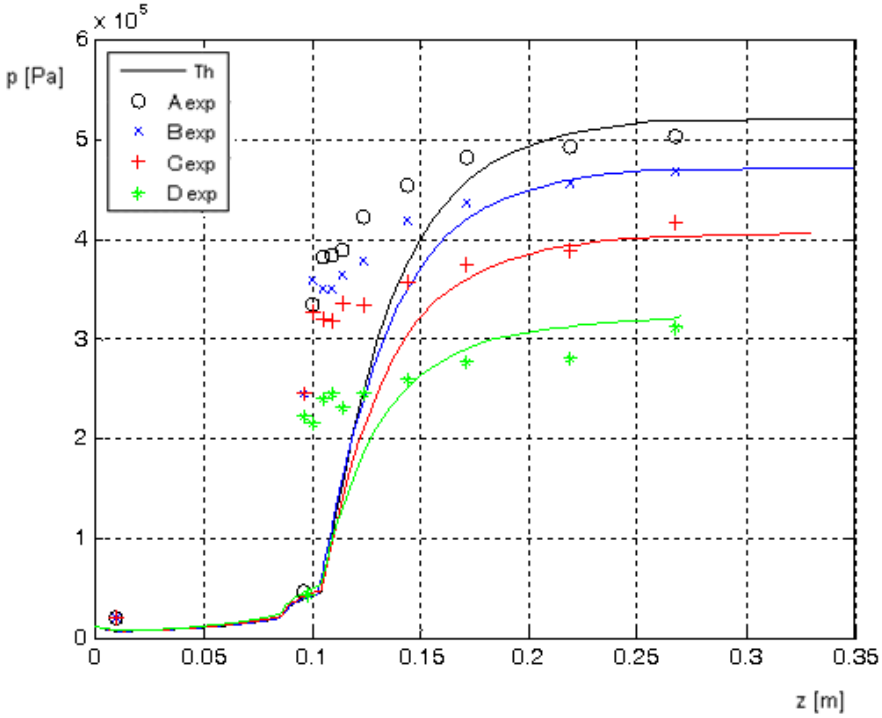

Fig. 5. Comparison of pressure profile calculated (lines) with experimental data for ejector with cylindrical throat of mixing chamber

The calculation results are compared with experimental data in Fig. 4 and 5 for the case of sharp-edge throat and cylindrical throat of mixing chamber, respectively. A reasonably good agreement between calculation results and experiments was shown for the case 'A'. In the case 'B' however, the calculated discharge pressure agrees very well with experiments, there is not very good prediction of the position of condensation shock wave (see Fig. 5). In the case 'B' experiments proved that shock-wave produce relatively higher pressure gradient in comparison with case 'A' which has been also obtained in presented calculations.

CONCLUSIONS

Two-fluid model have been applied to calculate pressure distribution in two-phase injector along with a set of closure equations used in the WAHA-3 code [11]. There is reasonably good agreement between experimental data and calculation results. However, there is a clear need to improve stratification model in order to better describe pressure rise within condensation shock wave, especially in the case of the injector with cylindrical throat of the mixing chamber.

VAPORISATION OF HFC REFRIGERANTS AT HIGH TEMPERATURE

D. Del Col*, E. Lunardi, A. Padovan
Dipartimento di Fisica Tecnica
University of Padova, Padova, Italy

ABSTRACT. Several correlations are available in the open literature for computing the heat transfer coefficient during vaporisation inside plain channels. With respect to halogenated refrigerants, these correlations are usually compared to data taken in a limited range of saturation temperature and reduced pressure. More recently, the adoption of new refrigerants, such as high pressure HFCs and carbon dioxide, requires to largely extend the pressure range of application of such correlations. Besides, the design of evaporators for some heat pumping applications, where evaporation temperatures are set at higher values as compared to usual evaporating temperatures in air-conditioning, requires proper validation of the computing methods.
The present paper presents two sets of heat transfer coefficients measured at high saturation temperature in a 8 mm internal diameter tube with R134a and R410A. This database is characterized by reduced pressure spanning between 0.19 and 0.53. Mass velocity ranges between 200 and 600 kg $m^{-2}s^{-1}$ and heat flux between 14 and 31 kW m^{-2}. Present data are compared against four predicting models.

Keywords: *vaporisation, refrigerants, high pressure*

INTRODUCTION

Much research has been done in the field of in-tube flow boiling in the last decades and much experimental data regarding flow boiling in plain channels is now available, covering a large number of fluids. Nevertheless, with regard to halogenated refrigerants, most flow boiling data sets refer to a narrow range of saturation temperatures, which is typical of common refrigeration and air-conditioning applications. This also leads to a limited range of reduced pressure in the refrigerant vaporisation data sets.
Nowadays, the adoption of new refrigerants, such as carbon dioxide, with different thermodynamic and thermophysical properties, represents a challenge to the capability and accuracy of previous established correlations. In the case of carbon dioxide, for instance, 2°C saturation temperature corresponds to 3670 kPa saturation pressure and 0.5 reduced pressure, which is far higher as compared to common halogenated refrigerants.
An example of high evaporating temperature application of HFC refrigerants is represented by the heat pump clothes dryers, where the evaporating refrigerant subtracts heat from the hot air stream and thus the evaporating temperature can reach higher values as compared to conventional air-conditioning applications. In the recent years, there is an increasing interest on heat pump dryers due to the significant energy savings compared to standard electric resistance dryers.
A higher operating saturation pressure results in high vapour density, low surface tension, high vapour viscosity and low liquid viscosity, and thus yields flow boiling heat transfer and two-phase

E-mail address: davide.delcol@unipd.it

flow characteristics quite different from those of conventional data. High pressure and low surface tension have major effects on nucleate boiling heat transfer characteristics.
The present paper reports new data, measured during flow boiling of R134a and R410A at high saturation temperature, which is interesting both for practical applications and for models assessment.
The heat transfer coefficients were measured during flow boiling of halogenated refrigerants inside a 8 mm plain copper tube. The test section is a counter flow tube-in-tube evaporator, where the refrigerant flows in the inner tube while the cooling water flows in the annulus.
This new data is compared against some models available in the literature with the aim of discussing the capability and the accuracy of those models in the prediction of the heat transfer coefficient for a wide range of reduced pressure. They are the correlations by Gungor and Winterton [1], Liu and Winterton [2], Kandlikar [3] and Wojtan et al. [4, 5].

EXPERIMENTAL APPARATUS

A schematic of the apparatus is provided in Figure 1. The experimental facility consists of two loops: the refrigerant loop and the water loop. In the first loop the refrigerant is pumped as subcooled liquid and then it is heated, and in some cases partially evaporated, in the preheater to achieve the desired quality at the inlet of the test section. The refrigerant enters the tube side of the test section at a known mass velocity and vapor quality and then it is vaporised against the cold water flowing in the annulus. After the two-phase mixture leaves the test section and goes to a braised plate type condenser, where it is fully condensed and subcooled. A bladder accumulator connected to a nytrogen bottle and a pressure regulator are installed in the refrigerant loop. The refrigerant flow can be independently controlled by a magnetic coupled gear pump.
The inlet vapor quality to the test section is determined by the heat extracted in the preheater, which can be controlled varying water temperature and flow rate. In the same way, the heat transfer rate in the test section can be varied by adjusting water temperature and flow rate. Thus vapor quality, mass velocity, and heat flux can be independently controlled.
The preheater and the test section are coaxial tube-in-tube heat exchangers, in which the refrigerant flowing inside the tube is heated and vaporised by hot water flowing in the annulus side. In the hot water circuit, an electrical heater supplies the water with the power transferred to the refrigerant. A by-pass system is used to vary the water flow rate. Water flow rates are measured by magnetic type flow meters.
The temperature of the hot water entering the preheater and the test section is controlled by a secondary water circuit. The water from the test section and from the electric boiler are mixed together in a storage tank, where the water temperature is maintained constant. Thermostatic control of the water is accomplished by adjusting the electrical power supplied to the heater.
The test section is divided into two different parts: a pre-conditioning section around 300 mm long, where the refrigerant flow, under vaporisation, achieves a fully developed flow regime, and the measuring section, around 1.0 m long, in which the heat transfer coefficient is measured. This structure is obtained using a single 1.6 m long inner tube and two separate heating water jackets, connected in series on the water side.
The inner tube, which is the test tube, is instrumented with eight copper-constantan (type T) thermocouples embedded in its wall to measure surface temperature. The thermocouples are inserted and soldered into four equidistant axial groves. Four thermocouples are located 100 mm past the inlet of the measuring section. The other four thermocouples are located 100 mm before the outlet.
The water temperature change in the test tube is measured by a four junction copper-constantan thermopile inserted into appropriate mixing chambers. A metal helix is wound around the test tube inside the annulus, in order to avoid stratification in the water flow and to get high heat transfer coefficient on the water side together with appropriate values for the water temperature decrease.

Two digital strain gauge pressure transducers (absolute and differential transducers) are connected to manometric taps to measure the vapour pressure upstream and downstream of the test tube. Refrigerant temperatures at inlet and outlet of the test section are measured by means of adiabatic sections, with thermocouples inserted into both the refrigerant flow and the tube wall.
The heat flow rate trasnferred in the test tube is derived from an enthalpy balance on the heating water side. The average heat transfer coefficient α is obtained from the equation:

$$\frac{q}{A} = \alpha \frac{(T_{w1} - T_{w2})}{ln \frac{T_{w1} - T_s}{T_{w2} - T_s}}$$

where q is the heat flow rate exchanged in the tube, A is the heat transfer surface area, T_s is the mean saturation temperature, T_{w1} and T_{w2} are the wall temperatures at inlet and outlet.
Enthalpy change and vapour quality change in the test section are obtained from the heat flow rate and the refrigerant mass flow rate, which is measured by a Coriolis effect mass flow meter having an accuracy of 0.4% of the measured value and inserted downstream of the pump.
All the thermocouples were calibrated using a bath with a Kaye reference thermometer (accuracy 0.02°C). The average accuracy for the thermocouples is estimated to be equal to 0.05°C. For the thermopiles, the average accuracy is around 0.03°C. Comparison between flow temperature and wall temperature inside the adiabatic sections gives a maximum deviation of 0.04 K.
The refrigerant pressure is measured at the inlet of the test section by a digital strain gauge transducer with an accuracy of ±2 kPa for low pressure fluids and ±7 kPa for high pressure fluids.
Experimental heat transfer coefficients are reduced from the measured values of saturation temperature and wall temperature. The saturation temperature is obtained from the pressure and is compared to the refrigerant temperature directly measured in the adiabatic sections before and after the test section. When saturated refrigerant flows in the tube, the difference between saturation temperature determined from pressure and directly measured refrigerant temperature was within the experimental uncertainty of the two sensors. For pure fluids, the two values differ by less than 0.1°C at high mass velocity. Higher deviations are found at low vapour quality, and are probably due to non-equilibrium in the flow and to local sub-cooling at the inlet of the test section. Since an important contribution to the experimental uncertainty is associated to the determination of the saturation temperature, the saturation to refrigerant temperature difference has been compared to the wall superheat for each test run: the data points characterized by ratios of temperature difference (saturation minus refrigerant) to wall superheat higher than 5% have not been considered in the present work.

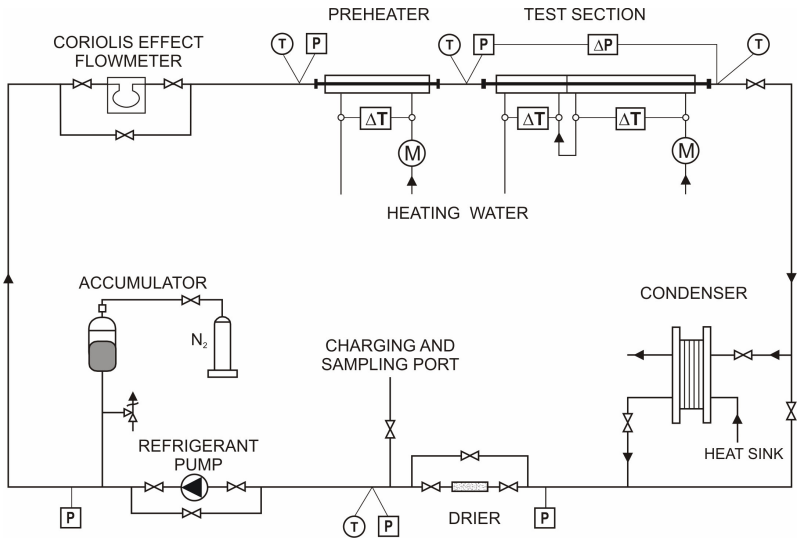

Figure 1. Sketch of the test rig

Table 1
Accuracy for sensors and parameters

Temperature	± 0.05°C	Temperature difference	± 0.03°C
Refrigerant flow rate	± 0.4%	Heat flow rate	± 4.6%
Vapour quality	± 0.05	Heat transfer coefficient	± 7.6%

The heat flux transferred to the refrigerant is derived from an enthalpy balance on the water side. Water flow rates in the test section and the preheater are measured by magnetic-type flow meters with an accuracy around ± 0.5% of the measured value. A Keithley data acquisition system is used to acquire the data.
The average uncertainty for the heat flow rate is around 4% while the average uncertainty for the heat transfer coefficient is around 6%. It was estimated from a propagation of error analysis that the heat transfer coefficients were measured to an accuracy ranging between 4.7 and 7.6 %. A list of accuracies for sensors and parameters is reported in Table 1.

Table 2
Experimental conditions of the present database

	G [kg m^{-2} s^{-1}]	q [kW m^{-2}]	x [/]	p_{RED} [/]
R134a	200-600	13.4-31.2	0.08-0.85	0.19-0.29
R410A	200-400	15.2-25.9	0.12-0.83	0.49-0.53

TEST RESULTS

The experimental data used in the present paper was taken during flow boiling of R134a and R410A inside a 8 mm plain commercial copper tube. The experimental heat transfer coefficients are quasi-local values, obtained during saturated flow boiling from the direct measurement of the wall temperature.
The experimental operating conditions in the present database is reported in Table 2. Mass velocity ranges from 200 up to 600 kg m^{-2}s^{-1}, the heat flux goes from 14 to 31 kW m^{-2} while the reduced pressure spans between 0.19 and 0.53. Data points cover the entire range of vapour quality. The wall superheat goes from 2.5 to 8 K.
R134a and R410A present different thermophysical properties: in fact at 40°C saturation temperature the reduced pressure is considerably higher for R410A, leading to a much higher vapor density (103 kg m^{-3} for R410A vs. 50 kg m^{-3} for R134a) and much lower vapour velocity in the tube, at same mass velocity.
Figure 2 reports the heat transfer coefficients measured during flow boiling of R134a at around 43°C saturation temperature, corresponding to 0.29 reduced pressure. Mass velocity G spans between 200 and 600 kg m^{-2}s^{-1}, while heat flux q goes from 14 to 30 kW m^{-2} . As one can see, the heat transfer coefficient is approximately constant up to 0.6 vapour quality, no matter what the mass velocity and heat flux conditions are. Recently, R134a data have been reported by Silva Lima et al. [6], showing the dependence of the heat transfer coefficients on saturation temperature (ranging between 5 and 20°C in their data). In their work it can be seen that the experimental *HTC* trend vs. vapour quality becomes more flat when increasing saturation temperature.
For the test runs performed at 400 kg m^{-2}s^{-1} and 26.5 kW m^{-2} average heat flux, the heat transfer coefficient shows an abrupt decrease at 0.85 vapor quality, due to the dryout of the liquid film at the wall. The strong effect of the heat flux on the heat transfer coefficient was evidenced by comparing data sets at same mass velocity but different heat flux.
In the test runs at G200-q14 and G400-q26.5 there is a local minimum, since the heat transfer coefficient decreases at low values of vapour quality and then increases with vapour quality. The

presence of this minimum is the result of the competition between nucleate and convective boiling mechanisms and was noted by other studies in the literature [6]. As the vapour quality increases, the flow pattern is expected to be annular type, the liquid film thickness decreases and the vapour velocity increases. Both phenomena promote heat transfer increase. By comparing the R134a test runs at *G*400 and *G*600, which have been performed at similar values of heat flux, one can see that heat transfer coefficients increase with mass velocity and the heat transfer increase due to mass flux increase depends on the vapour quality, showing a stronger effect of the convective mechanism at higher *G*.

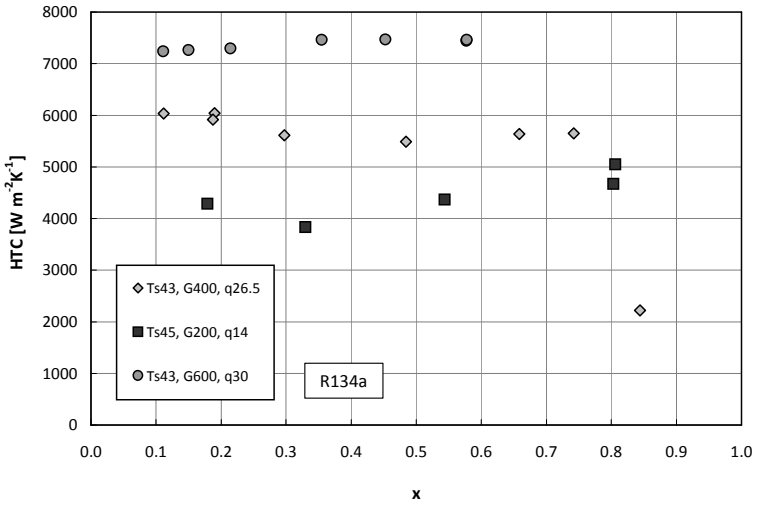

Figure 2. R134a heat transfer coefficients vs. vapour quality. Average values of saturation temperature *Ts*, mass velocity *G* and heat flux *q* are reported for each set.

Some values of heat transfer coefficient measured with R410A at around 40°C saturation temperature are plotted in Figure 3. Test results are reported for two values of mass velocity and heat flux. As compared to Figure 2, the experimental heat transfer coefficient diminishes when increasing vapour quality, for the entire range. This trend is not usual for halogenated refrigerants, whereas an increase of the heat transfer coefficient with vapour quality is usually expected. Nevertheless, this trend is similar to what one measured for the high pressure fluid carbon dioxide [7, 8]. Both papers [7, 8] have shown that the effect of mass velocity on the heat transfer coefficient of CO_2 is negligible at low vapour quality (up to 0.4), while the heat transfer is heat flux dependent, suggesting that the nucleate boiling mechanism is dominant in this region. For carbon dioxide, the drop in heat transfer coefficient is due to the large dominance of nucleate boiling at low vapour qualities and to partial dryout of the liquid film. The dominance of nucleate boiling at low qualities is caused by the thermophysical properties of the fluid, such as a low surface tension and a low liquid to vapour density ratio. These parameters are compared for R134a, R410A and CO_2 in Table 3, providing this way an explanation for the unusual behaviour of R410A and its similarity to CO_2 heat transfer experiments.
The *HTC* difference between the two test runs reported in Figure 3 is mainly due to the different heat fluxes, at low vapour quality, while at higher vapour quality both heat flux and mass flux may play a role since the rise of mass flux provides an enhancement of convective evaporation.

Table 3
Properties of saturated vapour

	R134a @ 40°C	R410A @ 40°C	CO_2 @ 0°C

Surface tension (N $m^{-3} \cdot 10^3$)	6.1	3.2	4.5

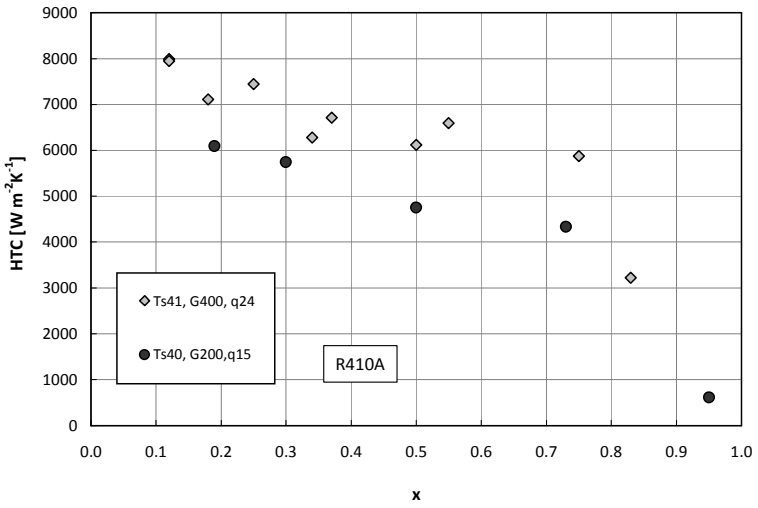

Figure 3. R410A heat transfer coefficients vs. vapour quality. Average values of saturation temperature *Ts*, mass velocity *G* and heat flux *q* are reported for each set.

ASSESSMENT OF CORRELATIONS

Four well-known models have been chosen for comparison with the present database. They are the correlations by Gungor and Winterton [1], Liu and Winterton [2], Kandlikar [3] and Wojtan et al. [4, 5]. All these models consider the Chen's basic postulate, which associates convective and nucleate boiling heat transfer mechanisms in the flow boiling heat transfer coefficient prediction.
The comparison was made for all the data points, excluding the tests with dryout and mist flow regimes for which those methods, except the one by Wojtan et al. [5] is not applicable. In total, 34 runs with R134a and 16 runs with R410A are compared against the models.
Table 4 reports average, mean absolute and standard deviations obtained from the comparison between experimental and calculated heat transfer coefficients for the two data sets.
Both the correlations by Gungor and Winterton [1] and by Liu and Winterton [2] are based on the superposition of the convective and the nucleate contribution. On average, the correlation by Gungor and Winterton underpredicts the experimental data by 20 % (Figure 4). The prediction capability is not significantly affected by any parameter (vapour quality, mass velocity, heat flux, reduced pressure), as suggested by the low value of standard deviation for both data sets. The correlation by Liu and Winterton provides a better agreement in the case of R134a data, but overpredicts most R410A experimental heat transfer coefficients (Figure 5).
When using the model by Wojtan et al. [4, 5], the prediction of the heat transfer coefficient is based on a diabatic two-phase flow pattern map. This map was significantly updated from previous work by Kattan et al. [9]. The stratified-wavy region has been subdivided into three sub-zones and the annular-to-dryout and dryout-to-mist transition curves have been added. The heat transfer coefficients are calculated from attribution of appropriate wet and dryout perimeters, obtained from the relative flow pattern. The authors have proposed an asymptotic model with exponent n = 3 for convective and nucleate boiling term of the heat transfer coefficient for the wet perimeter. The model by Wojtan et al. (Fig. 6) shows a similar behaviour as the Liu and Winterton correlation, providing a fair agreement with R134a data, but overestimating R410A by more than 20%.
Kandlikar [3] proposed a correlation for saturated two-phase flow boiling heat transfer inside horizontal and vertical tubes, which includes a fluid dependent parameter in the nucleate boiling term. Kandlikar [3] provided the fluid parameter for R134a which is equal to 1.63. The value for the azeotropic mixture R410A is taken from Wattelet et a. [10]: they determined a value of 3.3 using their data set. Although the average deviation between experiments and calculated values is low for both fluids, the Kandlikar correlation is not able to catch the experimental trend and the values of standard deviation are the highest among those models.

Table 4
Comparison between experiments and models

	R134a			R410A

CONCLUSIONS

New heat transfer data measured during flow boiling of R134a and R410A at high saturation temperature, and thus high reduced pressure, are presented in this paper. Experimental trends of heat transfer coefficient are roughly constant (R134a) or decrease (R410A) with vapor quality, showing that nucleate boiling must play a key role at these conditions. Experiments are compared against four correlations available in the open literature. Gungor and Winterton correlation shows little scattering but a general underprediction of experimental data. Both the models by Liu and Winterton and Wojtan et al. overpredict R410A heat transfer coefficients.

NOMENCLATURE

EXPERIMENTAL EVALUATION OF A DIRECT EXPANSION EVAPORATOR USING MULTIPLE U-TUBE HEAT EXCHANGERS IN PARALLEL

B. Beauchamp[1], L. Lamarche[1,*], S. Kajl[1]
[1]Ecole de technologie supérieure, Montreal, Canada

ABSTRACT. This paper presents the experimental evaluation of a thermostatic expansion valve (TXV) - dry evaporator system using multiple U-tube heat exchangers in parallel. The system studied is part of a commercially available direct expansion ground source heat pump system. When operated in heating mode, this heat pump uses multiple U-tube heat exchangers in parallel and each U-tube is controlled by an independent TXV. Experimental measurement showed that the actual TXV-evaporator system presents TXV hunting and refrigerant flow mal-distribution behaviour. Those phenomena are both known to impact the operating stability and cooling capacity of a heat pump and should not be accepted as normal operating characteristic of a system. Several experimental tests were made to obtain stable operating conditions of the system by adjusting the TXV's static superheat spring of the parallel U-tubes. Despites the attempts made, the system never reached at stable operating behaviour. This undesirable operating behaviour can lead liquid refrigerant entering the compressor and cause damage. Furthermore, cooling capacity and system performance can be severely penalized.

Keywords: *Direct Expansion, Evaporator, Thermostatic expansion valve, Ground heat pump, Ground heat exchanger*

INTRODUCTION

Ground-coupled heat pumps are attractive, efficient systems for residential and commercial air conditioning applications. Vertical direct-expansion ground heat pumps (DX-GCHP) are recently receiving a particular attention since they are considered to have a lower installation cost and similar performance compared to conventional secondary ground loop heat pumps. A DX-GCHP has its evaporator/condenser directly inserted into the boreholes and being an integral part of the refrigeration cycle therefore eliminating the secondary loops components. Furthermore, the drilling cost of a DX-GCHP should be lower than that of a conventional heat pump since the DX ground exchanger is usually smaller as a result of the copper tube used and the phase change flowing fluid [1]. The long remote buried evaporator/condenser needs particular attention to ensure proper system performance as opposed to conventional ground heat pump with a secondary ground loop [2, 3].

Because of the increasing interest for DX-GCHP and the lack of documentation found in the literature for those systems, it is relevant to conduct detailed experimental studies describing their performance and thermal behavior.

TXV - evaporator system stability was investigated by a number of researchers [4,5,6]. These studies clearly show that it is the combination of the TXV and evaporator characteristics that influences the stability of the control loop system. As noted above, the vertical buried heat exchanger of the type of heat pump studied in the present paper can be constituted of long copper tubing (in the range of 65 to over 110 meters long). Furthermore, each vertical U-tube constituting the evaporator has its independent operating TXV. Several researches have been conducted on refrigerant flow mal-distribution but concerned parallel paths from a manifold after a unique and single TXV [7,8,9]. Therefore, the particular TXV - evaporator configuration experimented in this paper followed with the slow transient heat transfer from the boreholes to the ground was not found to be investigated.

This paper first presents the particular evaporator constituted of multiple parallel U-tubes each controlled by an independent TXV. Followed is an experimental evaluation of the hunting behavior of the TXV - evaporator system for a unique U-tube. Finally, hunting behavior and refrigerant flow mal-distribution of multiple parallel U-tubes are presented.

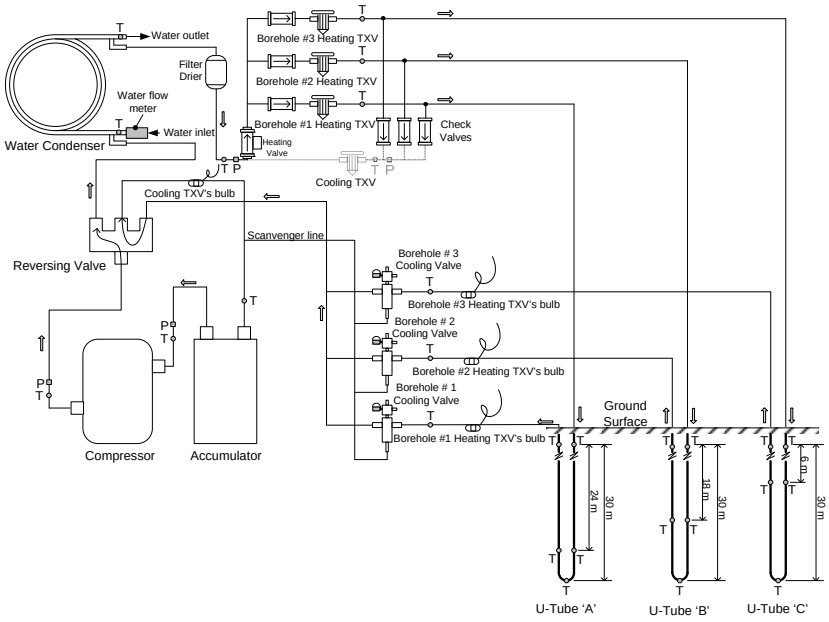

Figure 1. Schematic of the heat pump operated in heating mode

OPERATION OF THE HEAT PUMP IN HEATING MODE

To realize experimental measurements, a commercially available heat pump was instrumented and installed in the laboratories of the university. The system is a direct expansion ground source heat pump with a 10 kW nominal heating capacity using refrigerant R22 as the working fluid. It is a *ground direct expansion-to-water* system. The heat pump is instrumented with 4 refrigerant pressure transducers and 15 refrigerant temperature transducers of type 'K'. Water flow rate is acquired using a turbine type flow meter. The compressor power is acquired using an ammeter probe and a voltmeter. The heat pump is connected to three copper U-tubes of 30 m length each inserted in a different borehole drilled at a 30 degree angle from vertical. Each U-tube includes one

12.7 mm (referred as vapor line) and one 9.5 mm (referred as liquid line) outside diameter tube. Five thermocouples of type 'T' are installed on each U-tube and are located at the inlet, the bottom and the exit of each U-tube and at depths (both pipes) of 24, 18 and 6 meters respectively for U-tube 'A', 'B' and 'C'.

When the heat pump is used in heating mode (figure 1), all the ground loops (so-called evaporator) are activated. The check valves, downstream of the cooling TXV, restrict the refrigerant from flowing through this TXV. Liquid refrigerant passes through the opened heating valve, is throttled through 3 heating TXVs and flows toward the ground loops via the liquid lines. Low pressure refrigerant then vaporizes in the ground loops and flows toward the vapor line header.

As depicted in figure 1, the evaporator is configured with 3 U-tubes connected in parallel and each controlled by an independent TXV. As per manufacturer's instruction, this particular configuration was realized to 'independently' control the refrigerant flow in each U-Tube. However, as it will be presented later, the dynamics behavior of each U-tube is influenced by the operating characteristic of the other U-tubes.

The *Danfoss* thermostatic expansion valves are externally equalized, unbalanced port, ballast charge and are rated at 2.5 kW each. This kind of TXV responds to three forces (figure 2). The spring force (F_s) results from the superheat spring adjustment and tends to close the valve. The superheat pressure force (F_b) results from the remote bulb pressure applied on the effective diaphragm area. This force is applied on the top of the diaphragm and tends to open the valve. The evaporator exit pressure force (F_e) results from the outlet evaporator pressure applied on the effective diaphragm area. This force is applied on the bottom of the diaphragm and tends to close the valve. Furthermore, in an unbalanced port TXV fluctuations in the condenser pressure can influence the power balance and cause instability. In fact, the differential pressure force (F_{dp}) resulting from the high and low side differential pressure force applied on the effective port area tends to open the valve and affects the valve superheat settings.

EXPERIMENTAL CONDITIONS

Based on experimental results previously obtained by the authors, the system operating condition in heating mode presented instabilities. Investigation was therefore necessary to analyse the possible causes of the instabilities. At first instance, experimental tests were conducted for an evaporator configured using only one U-tube. The remaining U-Tubes were kept closed. This configuration is appropriate for analysing the hunting behaviour of a TXV - evaporator system. Finally, experimental tests were conducted for an evaporator configured using 3 U-tubes in parallel to analyse the dynamic control loop nature of such a TXV - evaporator system and possible refrigerant flow mal-distribution.

When conducting the tests, the only parameter that could be externally adjusted is the spring force of the TXVs. When the spring adjustment screw is completely turned counter clockwise, the static superheat spring force is at its minimum setting. Static superheat can be increased but turning the adjustment screw clockwise. As per TXV's manufacturer, one clockwise turn adjustment should result in approximately 2.5 °C increase in operating superheat. The initial TXV spring setting is factory set at 4 turns from the completely turned counter clockwise position.

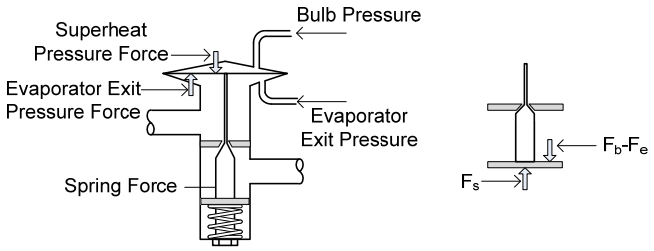

Figure 2. Schematic diagram of the thermostatic expansion valve (TXV)

Evaporator configured using one (1) U-Tube

Experimental tests have been conducted using only one (1) U-tube as depicted in figure (3). Under this configuration, the evaporator is not constituted of parallel branches. The tests have been conducted from an initial spring adjustment screw completely turned counter clockwise. The system was operated continuously and the spring screw was adjusted between 1/2 and 1 turn clockwise after 3 operating oscillations of the TXV were observed or after approximately 10 minutes if not oscillations occurred. Table 1 shows the tests spring screw adjusting parameters. For a spring screw setting varying between 0 and 2 turns, the evaporator outlet superheat is zero degree. A superheat of zero degree is not an appropriate operating condition for the heat pump as this could lead to compressor failure by liquid flooding this component. Furthermore, for the tests realized, the maximum number of turns that could be realized within the operating limits of the system was 8 turns. Over 8 turns, the system reached the maximum allowable high operating pressure (2150 kPa).

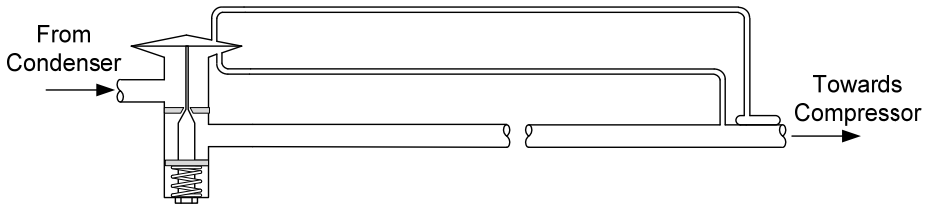

Figure 3. Schematic TXV - evaporator system configured using one U-tube

Table 1
Tests with evaporator configured using (1) one U-Tube: spring screw adjusting parameters

Adjustement No.	Time (minutes)	Number of turn from the completely counter clockwise position
1	0	0
2	33	1
3	43.3	2
4	54.2	3
5	76.7	4
6	98.9	5
7	124.6	6
8	161.6	7
9	195.7	8

The experimental data resulting from the operation of the system (with spring screw setting between 3 and 8 turns) with only one U-tube used in the evaporator are presented in figure 4. When the spring setting varies between 3 to 8 turns, the evaporator outlet superheat modulates severely. The cyclic behaviour of the measured evaporator outlet superheat is known as expansion valve hunting. Hunting is characterized by a cyclic action of the expansion valve resulting in the cyclic overfeeding and

underfeeding of the evaporator with liquid refrigerant. Hunting is known to considerably degrade the refrigerating capacity of the evaporator and to potentially lead to compressor failure by liquid flooding this component. Several possibilities are known to cause expansion valve hunting:

i. Incorrect sensor bulb location.
ii. Over-sized expansion valve
iii. Undersized evaporator tubing
iv. Thermostatic expansion valve adjustment
v. Time lag and transportation lag
vi. Flow mal-distribution in multi-circuit evaporator

For the experimental tests conducted using only one (1) U-tube in the TXV - evaporator system the following causes are not investigated: (i) incorrect sensor bulb location, (ii) over-sized expansion valve and (iii) undersized evaporator tubing. Furthermore, flow mal-distribution in multi-circuit evaporator is not applicable when only one (1) U-tube is used. Therefore, were investigated only: (iv) thermostatic valve adjustment and (v) time lag and transportation lag.

For the test presented, the static superheat spring was adjusted between 0 to 9 turns. It is a common troubleshooting procedure to adjust the static superheat spring when the TXV - evaporator system does not presents normal operating conditions. As depicted in figure 4, stable operating conditions with a minimum (non-zero) superheat value was not achieve. The system operated with either zero degree of superheat or under hunting conditions. Furthermore, high oscillations in the difference between high and low pressure are observed and could have lead to instabilities since the TXV in not a balanced port valve.

Under certain assumptions [5], the dynamic of a TXV - evaporator system can be represented using three different time constants and a transportation lag. The time constants represent the motion of the transition point, the thermal capacity of the tube wall and the TXV itself. It has been noted that it is the combination of all the time constants that can lead to system instabilities. Those time constants delay the time between a change in the TXV mass flow rate and its influence on the evaporator outlet superheat. The transportation lag in the TXV - evaporator system is caused by the time required by the change in refrigerant flow to travel the length of evaporator. It is mainly the evaporator length divided by the velocity of the refrigerant flow. This lag is quite complex to evaluate because of the two-phase flow characteristic. Important transportation lag is nevertheless known to be a cause of instability [4,5].

Based on the experimental results, the combined effects of the time constants and the transportation lag is estimated in the range of 6 to 12 minutes depending of the operating characteristics. Reported time constant [4,5,6], are usually in the order of 5 to 120 seconds. Transportation lag is usually considered to be around 5 seconds.

The experimental results demonstrate that the actual TXV- evaporator system exhibits unusual long time and transportation lag. It is not the scope of this paper to investigate the detailed cause of these particular phenomena. Nevertheless, long evaporator piping and slow transient ground heat transfer are believed to contribute significantly to the important lag observed.

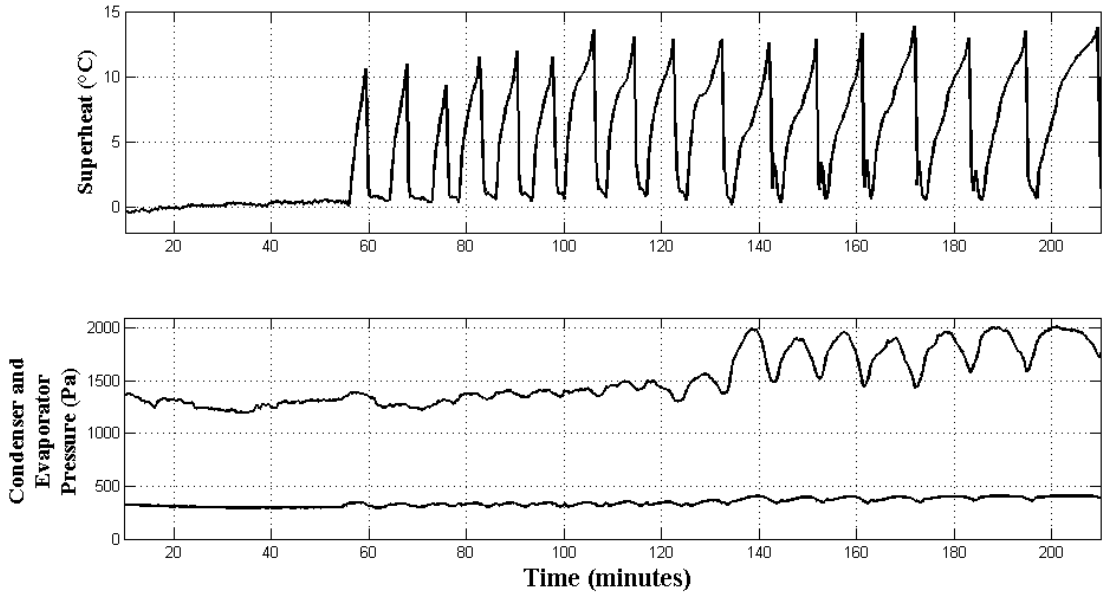

Figure 4. Superheat, Condenser and Evaporator pressures for evaporator tested with one U-tube

Evaporator configured using three (3) U-Tubes

Experimental tests have been conducted using three (3) U-tubes as depicted in figure (5). The tests have been conducted from TXV's initial spring adjustment screw turned 4 turns from the completely counter clockwise position. Under this configuration, the evaporator is constituted of parallel branches and is as per manufacturer's setting. The system was operated continuously and the different TXV spring screws were slowly adjusted in order to reach a global stable operation of the system and the three (3) U-tubes.

The U-tubes outlet superheats are evaluated with the measured outlet temperature (T_A, T_B and T_C) and the evaluated saturation temperature at the corresponding suction line pressure (P_{suc}). The suction line superheat is evaluated with the measured suction line temperature (T_{suc}) and the evaluated saturation temperature at the corresponding suction line pressure (P_{suc}). The suction line superheat is the resulting superheat from the operation of the three U-tubes and is of importance to insure no liquid refrigerant is directed towards the compressor.

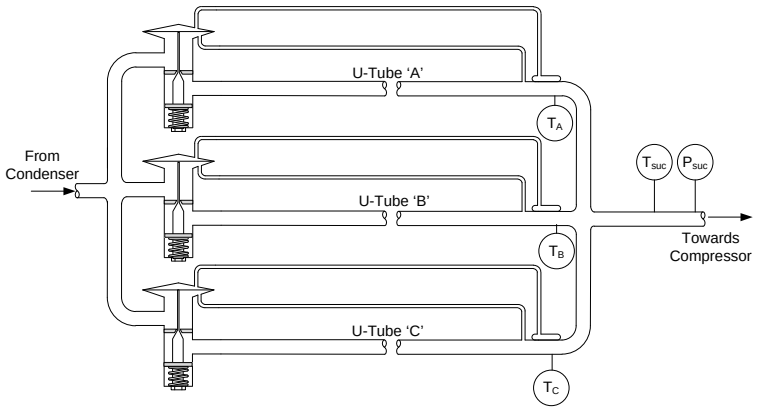

Figure 5. Schematic of the heat pump operated in heating mode

The first test series was conducted during 60 minutes. The system was operated continuously and was set as per manufacturer's instructions. No adjustment of the static superheat was realized.

Figure 6 shows the operating superheat of each U-tube and the common suction line. U-Tube 'A' and 'B' exhibit a thermostatic valve hunting behaviour as depicted in their excessively modulating outlet superheat. The quasi constant evaluated operating superheat of U-Tube 'C' indicates that the refrigerant flow in this U-Tube is low or non-existent. The common suction line superheat is observed to be a function of the operating characteristic of U-Tube 'A' and U-Tube 'B' only. This flow mal-distribution behaviour in the parallel paths was observed on several experimental tests realized by the authors.

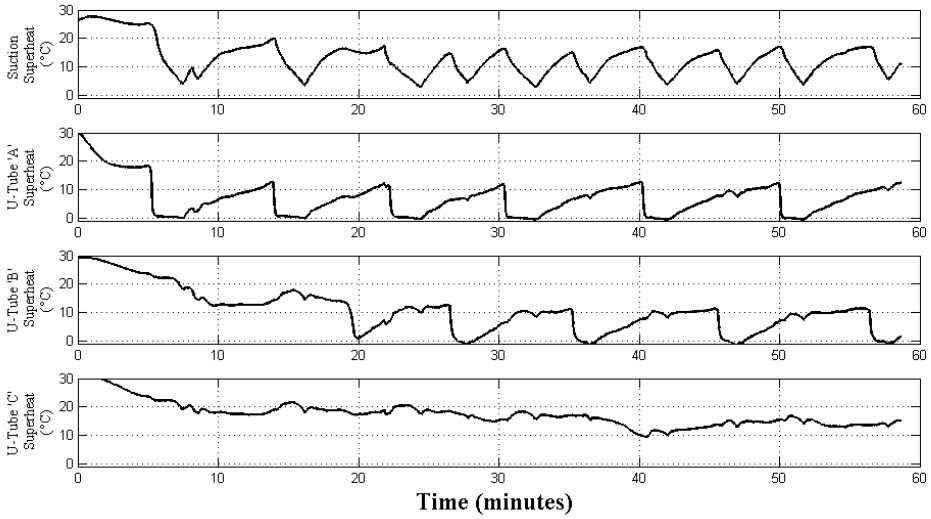

Figure 6. Operating superheat of first test series using multiple U-Tube

The second test series was conducted during about 720 minutes (12 hours). The system was operated continuously and the TXVs static superheats were manually adjusted with the purpose of obtaining a stable operating superheat for each U-tube and the common suction line. The results in figure 7 indicate that a stable operating condition was never reached. The three TXV presents an undesirable hunting characteristic with superheat oscillating between zero to about 18 °C. The common suction line superheat was also oscillating but the minimum observed value was about 5 °C therefore indicating that compressor was not fed with liquid refrigerant. The operational superheats measured again suggest that refrigerant flow mal-distribution is present in the evaporator parallel paths.

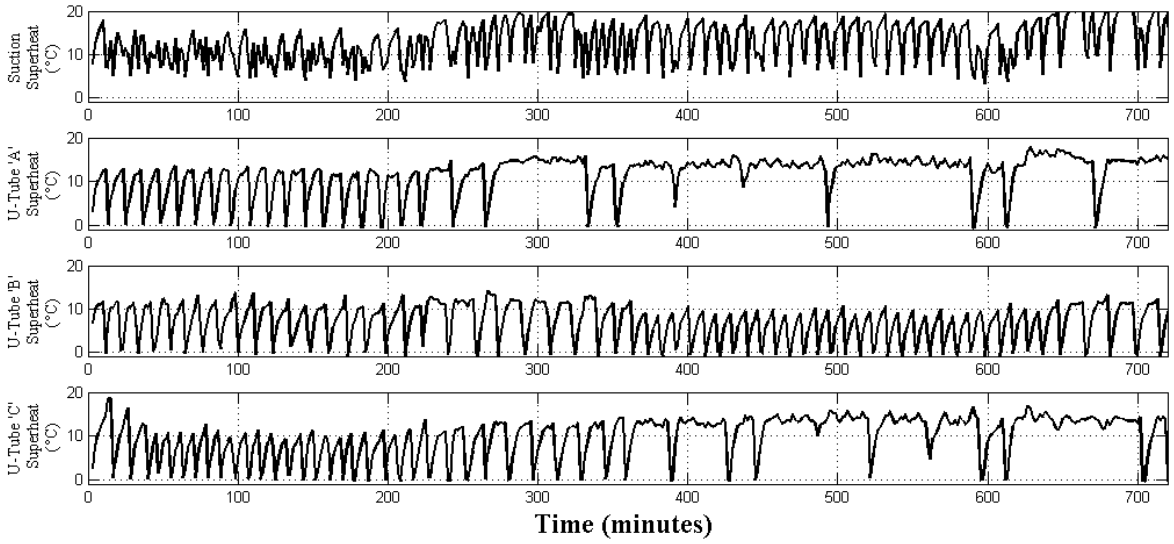

Figure 7. Operating superheat of second test series using multiple U-Tube

CONCLUSIONS

The experimental evaluation of a thermostatic expansion valve (TXV) - dry evaporator system using multiple U-tube heat exchangers in parallel was presented. The observed operating characteristic clearly indicate that this system present severe TXV hunting and refrigerant flow mal-distribution in the evaporator parallel paths. These two undesirable operational conditions are known to penalize and degrade the thermal performance of an evaporator and the whole refrigeration system. Further experimental and theoretical researches are now undertaken to investigate the detailed causes of these particular phenomena.

ABSTRACT. Magnetic refrigeration is a potentially environmentally-friendly alternative to vapour compression technology that is presented in this paper. The magnetocaloric effect in two magnetocaloric compounds in the $La(Fe,Co,Si)_{13}$ series is presented in terms of their adiabatic temperature change and the specific heat as a function of temperature at constant magnetic field. A 2.5-dimensional numerical model of an active magnetic regenerative (AMR) refrigerator device is presented. The experimental AMR located at Risø DTU has been equipped with a parallel-plate based regenerator made of the two materials. Experimental zero heat-load temperature spans are presented for different operating conditions and the results are compared to predictions of the numerical model. It is concluded that the model reproduces the experimental tendencies and when including thermal parasitic losses to ambient and the predictions from the model are within 1.5 K of the experimental results.

Keywords: *active magnetic regeneration, numerical modeling, magnetocaloric effect*

INTRODUCTION

Magnetic refrigeration and some of the challenges

Magnetic refrigeration is a research field covering a wide range of different physical disciplines. The basic physical property on which magnetic refrigeration is based is the magnetocaloric effect (MCE). This effect is exhibited by magnetic materials where increased ordering may be introduced by applying a magnetic field, thus lowering the magnetic entropy. This makes the MCE an inherently fundamental quantum mechanical effect. If the field is applied under adiabatic conditions the temperature of the material will rise. In order to maintain constant total entropy the decrease of the magnetic entropy must be compensated by an increase of the lattice and electron entropies thus increasing the temperature. This makes the MCE observable on the macroscopic level. The MCE is reversible for many magnetocaloric materials of interest but some materials exhibit some magnetic hysteresis [1].

For refrigeration applications the MCE can be used with the magnetocaloric material (MCM) as a refrigerant to accept a cooling load over a temperature span. However, the magnitude of the MCE is rather small – with an adiabatic temperature change with magnetization on the order a few K per tesla of magnetic flux density. This obviously limits the applicability of the MCE as a potential refrigerant. However, by implementing a regenerative, or active magnetic regeneration (AMR), cycle the

* Corresponding author: K.K. Nielsen
Phone: + 45 4677 4758
E-mail address: kaki@risoe.dtu.dk

technology can be used to absorb a cooling load at a temperature span that is higher than the adiabatic temperature change of the MCM. This process exploits the MCM in two ways; by using the MCE as work input to generate cooling and as a regenerator to store heat temporarily and build up a temperature gradient. This makes temperature spans larger than the adiabatic temperature change possible. The AMR process is composed of four sub processes. First the material is magnetized and thus the temperature in the solid regenerator rises. Second, a heat transfer fluid – typically water-based – is pushed through the material (which is designed in some porous configuration) from the cold to the hot end thus lowering the temperature of the material by rejecting heat to the ambient while still magnetized. The third step is demagnetization. This ensures the material to cool below the initial temperature. The fourth and final step is moving fluid towards the cold end, thus absorbing a heat load from the cooled space. Thus, magnetic refrigeration includes the fundamental MCE as well as macroscopic heat transfer and fluid dynamics.

The challenges are many within this area of research; issues like regenerator geometry (particle bed, parallel plates etc.), operating conditions (cycle frequency, fluid movement etc.) and the magnetocaloric properties of the MCM just to mention a few. The MCE is most pronounced over a relatively small temperature span around the Curie temperature (T_C) of the material (where a ferromagnetic material changes to its paramagnetic state). This limits the optimal operating temperature for any given MCM and thus constructing a regenerator of a series of materials each with its own working temperature range tuned to the local regenerator temperature experienced by each material can greatly increase the total MCE in the regenerator. This work is concerned with a first attempt to model an experimental setup with two materials configured in a parallel-plate stack of magnetocaloric plates of sintered La(Fe,Co,Si)13 made by Vacuumschmelze, Germany [2,3]. Using this material, experiments have been performed using the experimental AMR device located at Risø DTU, Technical University of Denmark. The device is a single regenerator reciprocating AMR that is discussed in more detail in [4] and [5]. Results of this and corresponding modeling results are the scope of this paper. Previous AMR modeling including comparisons with experimental results can be found in e.g. [6,7].

The magnetocaloric effect

The MCE is typically discussed in three different forms: The isothermal magnetic entropy change (ΔS_{mag}) when magnetizing a sample of a MCM, the adiabatic temperature change (ΔT_{ad}), i.e. the temperature change of a MCM when magnetized adiabatically and finally the specific heat capacity, c_H, as function of temperature, T, at constant magnetic field, H. The adiabatic temperature changes of two magnetocaloric materials are given in Figure 1. The materials are two different $La(Fe,Co,Si)_{13}$ compounds. The Fe/Co ratio has been varied in order to change the Curie temperature [2]. The figure shows the adiabatic temperature change when magnetizing from 0 T to 1.1 T. Some important details should be observed in the figure. Firstly, the clearly visible position of either material's transition temperature (in this case defined as the peak of the (ΔT_{ad}), curves). Secondly, the temperature ranges where each material exhibits a significant MCE overlap somewhat. Whether this overlap is sufficient for utilizing both materials in an effective refrigeration process is to be decided from modeling and experimental studies. In this paper we address some of these issues. It should be noted that the MCE for these materials is reversible. This is important since irreversibility associated with magnetization and demagnetization, known as magnetic hysteresis, is a serious degrading factor when considering the material's application as a refrigerant.

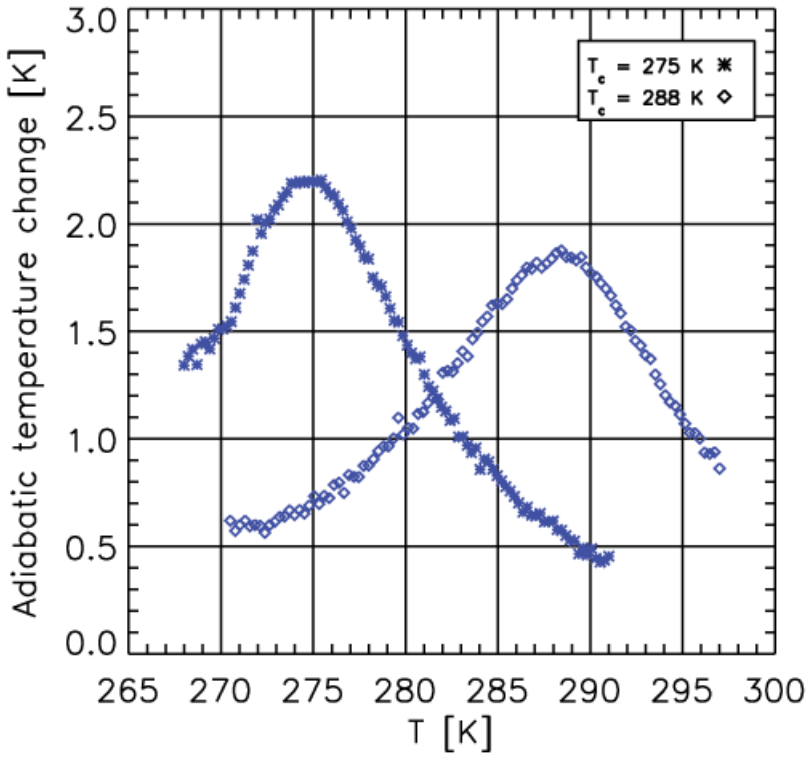

Figure 1: The adiabatic temperature change of two different compositions of $La(Fe,Co,Si)_{13}$ when magnetized from 0 to 1.1 Tesla. The indicated T_c in the figure legend is the Curie temperature of the materials.

The specific heat in an applied magnetic field has so far only been measured in detail on the compound with the low transition temperature and is given by [3]. Figure 2 shows the temperature dependence of the zero-field and the 1.0 T specific heat. Notice two important factors: First the peak value shifts significantly (3.5 K) between the two applied magnetic fields. Second, the zero-field specific heat has a higher and narrower peak than the 1.0 T specific heat curve has.

NUMERICAL AMR MODEL

The experimental device mentioned previously is modeled through a versatile 2.5-dimensional numerical model of a parallel plate AMR. The solution domains consist of a fluid domain and three solid domains; the MCM plate and a hot and cold heat exchanger (HEX). The governing equations are

$$\frac{\partial T_f}{\partial t} = \frac{k_f}{\rho_f c_{p,f}} \nabla^2 T_f + q_{bd,fc} + q_{bd,fh} + q_{bd,fMCM} + q_{loss,f} - u \frac{\partial T_f}{\partial x} \tag{1}$$

$$\frac{\partial T_{MCM}}{\partial t} = \frac{k_{MCM}}{\rho_{MCM} c_{H,MCM}} \nabla^2 T_{MCM} - q_{bd,fMCM} + q_{loss,MCM} \tag{2}$$

$$\frac{\partial T_c}{\partial t} = \frac{k_c}{\rho_c c_{p,c}} \nabla^2 T_c - q_{bd,fc} + q_{loss,c} \tag{3}$$

$$\frac{\partial T_h}{\partial t} = \frac{k_h}{\rho_h c_{p,h}} \nabla^2 T_h - q_{bd,fh} + q_{loss,h} \tag{4}$$

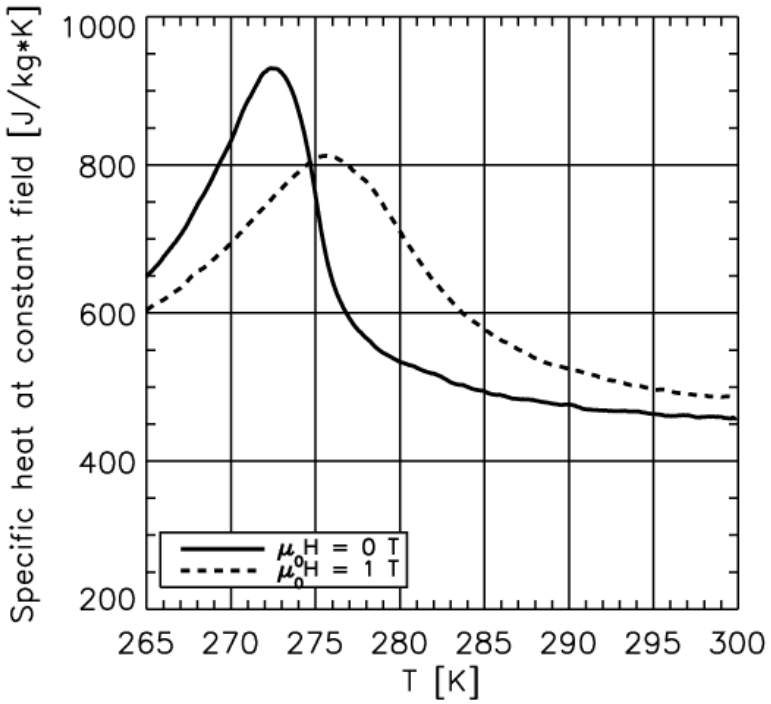

Figure 2: The specific heat capacity at constant magnetic field of the $La(Fe,Co,Si)_{13}$ sample with T_C = 275 K. Notice both the lower peak value as well as the lowering and broadening of the in-field specific heat.

The subscripts *f, MCM, c* and *h* indicate fluid, MCM, cold and hot HEX respectively. The thermal properties ρ and *k* denoting the mass density and the thermal conductivity have been introduced. The domains, as illustrated in Figure 3, are coupled via the boundary heat fluxes with subscripts *bd*.

The solution to Equations. (1)-(4) is determined for a number of cycles each divided in four sub processes further divided in time steps until cyclic steady-state is reached. The four sub-processes are: Magnetization (duration: τ_1 seconds), fluid flow from cold to hot end (hot blow, duration: τ_2 seconds), demagnetization (duration: τ_3 seconds) and finally flow from hot to cold end (cold blow, duration: τ_4 seconds). The cycle is assumed symmetric and thus $\tau_1 = \tau_3$ and $\tau_2 = \tau_4$. The numerical details can be found in [8]. The thermal properties used in the model are given in Table 1.

Thermal parasitic losses to the ambient are enabled through the q_{loss} terms in Equations. (1)-(4). These are formulated on the form

$$q_{loss} = \frac{T - T_\infty}{\sum_i R_i}. \tag{5}$$

The ambient temperature is denoted by T_∞ and the thermal resistances R_i are to be summed over for each numerical grid cell. An example of such a summation is

$$R_{fl,total} = \frac{1/2\Delta z_f}{k_f \Delta x \Delta y} + \frac{\Delta z_{pl}}{k_{pl} \Delta x \Delta y} + \frac{1}{h_{conv} \Delta x \Delta y}, \tag{6}$$

which is representative for the fluid channel. Here $\Delta x, \Delta y$ and Δz denote the dimensions of the grid cell and h_{conv} the passive convective heat transfer coefficient modeling the heat loss on the outside of the regenerator to the ambient.

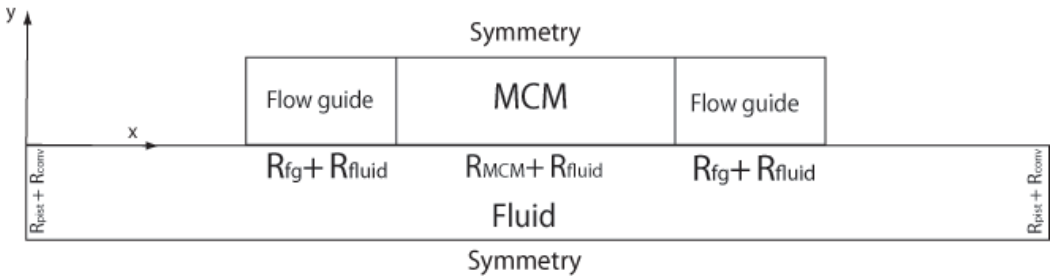

Figure 3: The four solution domains of the numerical AMR model. The domains denoted flow guide, are able to act as either passive plastic flow guides or as HEXs with perfect contact to the ambient (the hot HEX) or to a heat load (cold HEX). The symmetry lines indicate that only half a flow channel and half a solid domain are solved for. The indication of thermal resistances shows the internal thermal boundaries between the domains.

RESULTS

In the following results from both modeling and the experimental AMR device located at Risø DTU, are presented. The MCE was modeled discretely in the sense that at the first timestep of the AMR cycle the adiabatic temperature change from magnetizing was applied. Similarly, halfway through the modeled cycle (at the end of the hot blow) the adiabatic temperature change from demagnetizing was applied in one timestep. The specific heat was applied similarly. Here the data set from the 1.0 T measurements was used to temperature-interpolate the specific heat in the first half of the AMR cycle. In the last half of the cycle the zero-field specific-heat table was used. The adiabatic temperature change data is as previously shown in Figure 1. The specific heat is shown in Figure 2. However, since the specific heat of the high transition temperature material is not yet available, the specific heat data of the low-transition temperature material was used but shifted 13 K higher on the temperature scale (matching the difference between the peak values in the adiabatic temperature change values, see Figure 1).

The experimental approach is described thoroughly in both [4,5]. The range of the operating parameters are given in Table 2. Both experiments were performed with a regenerator using the two materials (each 20 mm long yielding in total a 40 mm long regenerator). The flow channel height was 0.5 mm and the thickness of the plates 0.9 mm. All experiments were performed at an ambient temperature, T_∞, approximately equal to 287 K, which was also used as the input ambient temperature to the model. A total of 11 plates were used.

The model is able to simulate thermal parasitic losses to the ambient modeled via thermal resistances as described in Equations. (5)-(6). Modeling both with and without this loss has been performed. The results from the two experimental situations are given in Figure 4 and Figure 5. Here it is clearly seen that including the thermal parasitic losses improves the model's ability to reproduce the experimental results.

Table 1
Thermal properties of the computational domains. Data for copper is used for the HEXs. The thermal conductivity of the MCM was estimated from the results of [9,10].

	ρ [kg/m^3]	c [J/kg·K]	k [W/m·K]
Fluid	1000	4200	0.6
MCM	7100	500-950	9
HEXs	8933	385	401
Housing	N/A	N/A	0.2

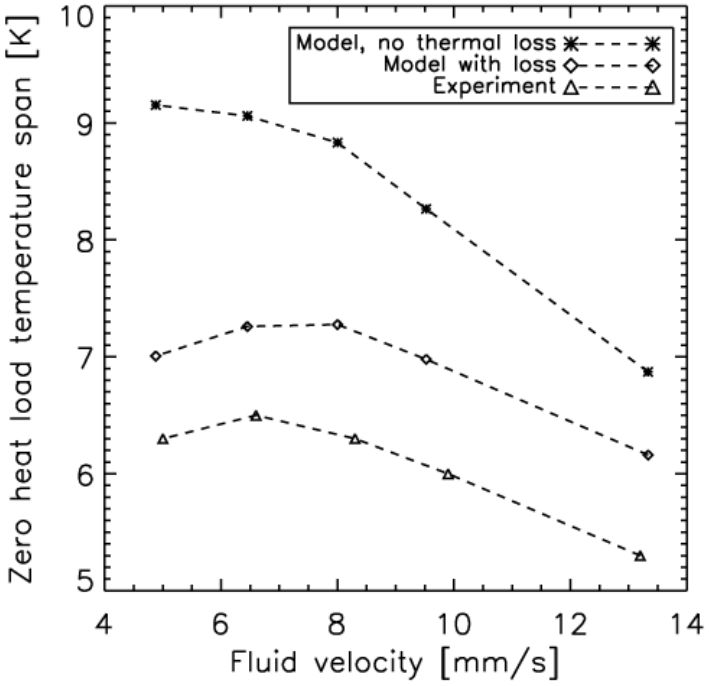

Figure 4: The no heat-load temperature span of experiment #1 (see Table 2 for details).

Overall, the predictions of the thermal loss model overestimate no more than 1.5 K in the worst case and in general about only 1 K, compared to the experimental results. The motivation for performing the two sets of experiments was to change the utilization defined as:

$$U = \frac{\rho_{fl} c_{p,fl} H_{fl} \Delta x}{\rho_{MCM} c_{H,MCM} H_{MCM} L_{MCM}}. \quad (7)$$

Where ρ_{fl} is the mass density of the heat transfer fluid, $c_{H,fl}$ is the specific heat of the fluid, H_{fl} is the thickness of the fluid channel, Δx is the stroke length, ρ_{MCM} is the mass density of the MCM, H_{MCM} is the thickness of the MCM plate, $c_{H,MCM}$ is the mean specific heat of the MCM, and L_{MCM} is the length of the MCM plate. Thus, the utilization expresses the fraction of thermal mass of fluid moved compared to the thermal mass of the MCM. The mean specific heat of the MCM was set to 550 J/kgK. Now, the two values of the utilization (which characterize the two experiments respectively) are kept constant by varying the fluid velocity and the timing of the AMR cycle. Thus, a low fluid velocity means a higher cycle time. Therefore, the fact that the model reproduces the experiment at low fluid velocities closer than at high is explained by the fact that thermal losses affect performance more in a slow cycle than a faster cycle. Also, the largest temperature span, and thus the highest conduction loss to the surroundings, is achieved with a relatively slow fluid velocity (not the slowest – the temperature span curves clearly have a peak fluid velocity).

Table 2
The operating parameters of the two experiments.

Experiment	Utilization [-]	Timing range [s]	Fluid velocity range [mm/s]
#1	0.51	5 s – 10.2 s	5.0 – 13.3
#2	0.81	7 s – 15.4 s	5.0 – 13.3

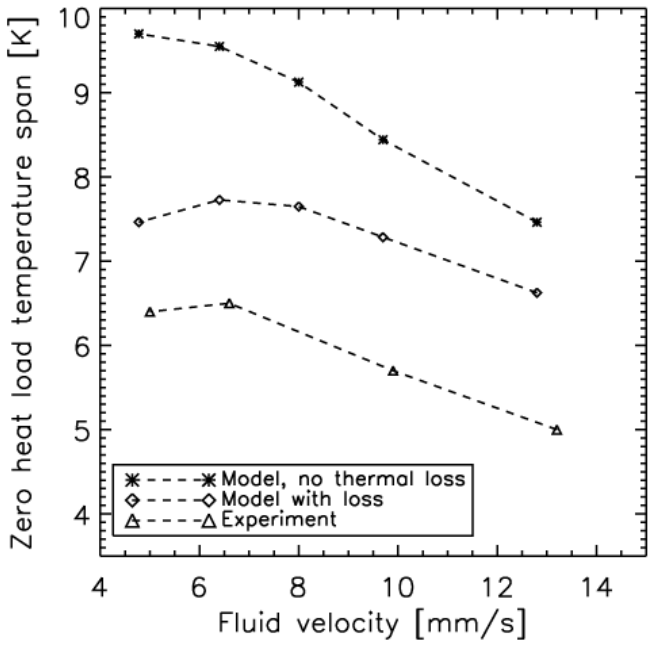

Figure 5: no heat-load temperature span of experiment #2 (see Table 2 for details).

DISCUSSION AND CONCLUSION

The comparison between experimental results and modeling of the experiment shows that the numerical AMR model presented here is able to reproduce the tendencies of the experiment. When including thermal losses to the ambient it is furthermore seen that the model results improve significantly in reproducing the experimental values. However, a discrepancy still exists. This may partially be explained by the use of the specific heat of the low-transition temperature material as the specific heat of the high-transition temperature material. Also the internal magnetic field in the MCM is somewhat reduced compared to the external field due to demagnetization [11]. Furthermore, the regenerator is comprised of 11 plates of MCM and will be subject to variation in thermal losses and spatially varying magnetic flux densities, which is not included by the model since the modelled geometry consists only of half a fluid channel and half a solid domain. Future work will include further modeling of the two-material regenerator in order to optimize for future choices of the transition temperatures of each individual material. As the maximum experimentally reached temperature span was about 6.5 K and the ambient was at 287 K the low-transition temperature material was clearly not as active as it could be and was thus not utilized fully.

ACKNOWLEGEMENT

We thank Mr. Jørgen Geyti for his technical help. Also, we thank Vacuumschmelze GmbH & Co. KG, 63450 Hanau, Germany for supplying the plates of $La(Fe,Co,Si)_{13}$. The authors further acknowledge the support of the Programme Commission on Energy and Environment (EnMi) (Contract No. 2104-06-0032), which is part of the Danish Council for Strategic Research.

PERFORMANCE OF DI COMPRESSION IGNITION ENGINE FUELLED WITH VEGETABLE OIL AND ITS ETHYL ESTER

L. Tarabet[1,*], S. Hanchi[1], M. Tazerout[2]
[1]Ecole Militaire Polytechnique, Bordj El Bahri, Algérie
[2]Ecole des Mines de Nantes, Nantes, France

ABSTRACT. Nowadays investigation about alternative sources of energy from species adapted in arid lands became a very important task for researches due to gradual depletion of world petroleum and the impact of environmental degradation. The aim of this study is to evaluate the effect of using the eucalyptus oil or its biodiesel on the DI compression ignition engine performances. Hence, a theoretical model, based on thermodynamic single zone model, is developed to simulate the engine cycle and to analyze the performance characteristics of the Diesel engine. The crude oil used in this work is extracted from sheets of eucalyptus trees. The biodiesel is obtained by transesterification of the oil with ethanol and catalyst (NAOH). In comparison with diesel fuel performances, the theoretical results showed that the biodiesel provides better performances than those of the eucalyptus crude oil.

Keywords: *biodiesel, combustion, thermodynamic model*

INTRODUCTION

We assist during these last years, to a climatic change due to a strong aggravation of the greenhouse effect caused mainly by the CO_2 emissions, which result from fossil hydrocarbon combustion. As result, intensive research is carried out to find appropriate substitution fuel to the fossil fuels. The use of the biofuels like ethanol, biogas, hydrogen, vegetable oil and the biodiesel in internal combustion engines is significant in this context [1-2].
The use of vegetable oil, biodiesel and animal fats for diesel engines applications is studied by various researchers. Some of the recent studies which dealt with transesterification, performance study and emission analysis are reported.
Dos Sontos [3] prepared biodiesel from the oil contained in the kernels of Terminalia Catappa fruits by transesterification with methanol and catalyst. It is reported that the oil extraction yield around 49% allow the possibility of economical exploitation, and its biodiesel physicochemical properties are close to the properties of Diesel fuel.
Pramanic [4] investigated the use of Jatropha curcas oil in diesel engine. It is found that the oil physicochemical properties are close to the properties of diesel fuel except for the viscosity which is much higher. The problem of high viscosity of this vegetable oil is resolved by blending the oil with diesel fuel in varying proportions. From the performance evaluation it is established that blends containing 40-50% of Jatropha oil can be substituted for diesel without any engine modification. In other previous works, the problem of vegetable oil high viscosity has been overcome by several techniques, such as preheating the oil, microemulsification with ethanol, transesterification or thermal cracking/pyrolysis [5-6].
Rakopoulos [7] developed a computational code based on thermodynamic multi-zone model for simulating the combustion process in the diesel engine fuelled with cottonseed oil or its methyl ester

(biodiesel). It is found that the results from the relevant computer program for the in cylinder pressure, exhaust nitric oxide concentration (NO) and soot density are compared favorably with the corresponding measurements from an experimental investigation.
Considering the great number of eucalyptus trees available in the arid regions, we decide to study the possibility to use the oil contained in its leaves as an alternative solution to the diesel fuels. This vegetable oil is extracted by steam training. The Eucalyptus oil properties allowed us to envisage using it as fuel oil. But the greatest difference between Eucalyptus oil and diesel fuel is the viscosity. To overcome this problem, this oil is esterified with ethanol. In order to show the advantages of using this biodiesel in diesel engine, a thermodynamic single zone model was developed to simulate the engine cycle and to analyse the performances. We used an explicit solution method in solving the system of ordinary differential equations that obtained from the first law of thermodynamics. The reliability level of the mathematical model is verified by comparing the predicted parameters with the measured ones when the engine is fuelled with diesel fuel. After the confirmation that the predicted values of pressure are in good agreement with those obtained experimentally in different loads, we introduced the crude oil and biodiesel thermo-physical properties into the theoretical model, and then the performances are calculated for the different fuels (eucalyptus oil, biodiesel and Diesel).

MATHEMATICAL MODELING

Single zone thermodynamic model is used for analysing the performance characteristics of four strokes DI compression ignition engine. The model governing equations are derived by applying the thermodynamic First Law to the cylinder charge. The cylinder charge is supposed as a homogeneous gas mixture of fuel vapour and air. Pressure and temperature inside the cylinder are uniform and vary with crank angle. Specific heats of the gaseous mixture are temperature dependant.

Cylinder geometry

Using engine kinematics the cylinder volume at any crank angle can be computed using the following equation

$$V(\theta) = V_{clear} + \frac{\pi D^2}{4} L \left(1 + R\left(1 - \cos(\theta)\right) - \sqrt{1 - R^2 (\sin(\theta))^2}\right) \quad (1)$$

where V_{clear} is the clearance volume, and D, L, R are respectively the cylinder bore, the rod length and the ratio of connected rod length to crank radius.

Energy equation

The model is valid only for the period of the compression and expansion cycles. For the closed system, the Thermodynamic 1st Law gives

$$\delta Q - \delta W = dU \quad (2)$$

$$\left(\delta Q_{in} - \delta Q_{loss}\right) - p\,dV = m\,c_v\,dT \quad (3)$$

Table 1
Specification of the engine used

Make	LISTER-PETTER
Type	Naturally aspirated four stroke single cylinder compression ignition
Bore and stroke	95.3 mm × 88.9 mm
Compression ratio	18:1
Displacement volume	630 cc
Connecting rod length	165.3
Fuel injection timing	20° before TDC
Rated power output	2.8kW at 1500 rev/mn

From the ideal gas equation, $pV = m\,R\,T$, we can write

$$m\,dT = \frac{1}{R}\left(p\,dV + V\,dp\right) \tag{4}$$

and

$$dU = \frac{c_v}{R}\left(p\,dV + V\,dp\right) \tag{5}$$

Rearranging equation (2) provides

$$\left(\delta Q_{in} - \delta Q_{loss}\right) - p\,dV = \frac{c_v}{R}\left(p\,dV + V\,dp\right) \tag{6}$$

$$\left(1+\frac{c_v}{R}\right)p\,\frac{dV}{d\theta} = \left(\frac{\delta Q_{in}}{d\theta} - \frac{\delta Q_{loss}}{d\theta}\right) - \frac{c_v}{R}V\,\frac{dp}{d\theta} \tag{7}$$

Introducing $R = c_p - c_v$ and $\gamma = c_p / c_v$, we obtain

$$\frac{dp}{d\theta} = \frac{\gamma - 1}{V}\left(\frac{\delta Q_{in}}{d\theta} - \frac{\delta Q_{loss}}{d\theta}\right) - \gamma\frac{p}{V}\frac{dV}{d\theta} \tag{8}$$

Heat transfer

Cylinder wall heats transfers are represented using the heat transfer coefficient Woschni correlation [8].

$$\frac{dQ_{in}(\theta)}{d\theta} = \frac{h_g(\theta)S(\theta)\left(T_w - T(\theta)\right)}{\omega} \tag{9}$$

where S is the surface area in contact with the gases, T_w, the wall temperature and h_g is the heat transfer coefficient which is given as

$$h_g(\theta) = 3.26\times10^{-3}D^{-0.2}p(\theta)^{0.8}w(\theta)^{0.8}T(\theta)^{-0.55} \tag{10}$$

with the cylinder bore D taken as the characteristic length, w as a local average gas velocity in the cylinder which is expressed as

$$w = \left[c_1\overline{S}_p + c_2\frac{V_d T_r}{p_r V_r}\left(p - p_m\right)\right] \tag{11}$$

here V_d is the displaced volume, p the instantaneous cylinder pressure, p_r, V_r, T_r the pressure, the volume and temperature at reference state (inlet valve closing), and p_m is the atmospheric pressure.

For the compression period: $c_1 = 2.28$, $c_2 = 0$

For the combustion and expansion period: $c_1 = 2.28$ $c_2 = 3.24\times10^{-3}$

Heat release analysis

Heat release due to combustion is calculated using single Wiebe's heat release correlation [9]

$$\frac{dQ_{loss}}{d\theta} = m_f\,LHV\,\frac{dx(\theta)}{d\theta} \tag{12}$$

Table 2
Properties of Diesel fuel, eucalyptus oil and its biodiesel

Properties	Diesel	Eucalyptus oil	Biodiesel
Specific gravity	0.830	0.950	0.826
Viscosity (mm^2/s) at 40°C	3	30	4.78
Lower heating value (kJ/kg)	42500	37195	39760
Carbon content (wt. %)	86	77.1	77.0
Hydrogen content (wt. %)	14	11.5	12.18
Oxygen content (wt. %)	00	11.4	10.32
Sulphur content (wt. %)	0.29	00	00
Stoichiometric air-fuel ratio	15	12.57	12.48

where *LHV* denotes lower heating value, m_f the fuel mass, $\left[dx(\theta)/d\theta\right]$ the combustion rate obtained from the Wiebe function

$$\frac{dx(\theta)}{d\theta} = 6.908\frac{b+1}{\Delta\theta_d}\left(\frac{\theta-\theta_0}{\Delta\theta_d}\right)^m \exp\left[-6.908\left(\frac{\theta-\theta_0}{\Delta\theta_d}\right)^{m+1}\right] \tag{13}$$

In this relation θ_0 is the start of combustion, $\Delta\theta_d$ is the total combustion duration, while *a* and *m* are adjustable parameters. The fuel injected inside the cylinder is directly connected to the fuel/air equivalence ratio

$$\phi^{-1} = \frac{(A/F)_{actual}}{(A/F)_{stoich}}$$

Then:
$$m_f = \frac{\phi m_g}{(A/F)_{stoich}} \tag{14}$$

where m_g is the mass of air, which entering the cylinder.

Ignition delay
To determine the ignition delay, the Wolfer's empirical relation is used and expressed as [9]

$$\int_{t_{inj}}^{t_{ig}} \frac{dt}{t(p,T)} = \frac{1}{K_{t_{inj}}}\int_{t_{inj}}^{t_{ig}} \frac{dt}{(p(t))^{-q}\exp(E/RT(t))} = 1 \tag{15}$$

where t_{inj} is the time at witch injection starts, t_{ign} is the time at witch the ignition starts. The values of various constants appearing in the above equation are

K = 2272, q = -1.19, E/R = 4650.

SOLUTION PROCEDURE AND APPLICATIONS

The mathematical model results in set of ordinary differential equations. These equations must be integrated simultaneously by Runge Kutta method. Two types of applications were performed. The first has been conducted to verify the applicability and the reliability of the presented mathematical model by comparing the predicted parameters with the measured ones in the Diesel fuelling case. The specifications of the engine used for comparisons are given in Table1. The second is performed to examine the effects of fuelling the engine with the eucalyptus oil and its ethylic ester on its performances such as the specific fuel consumption and the efficiency.

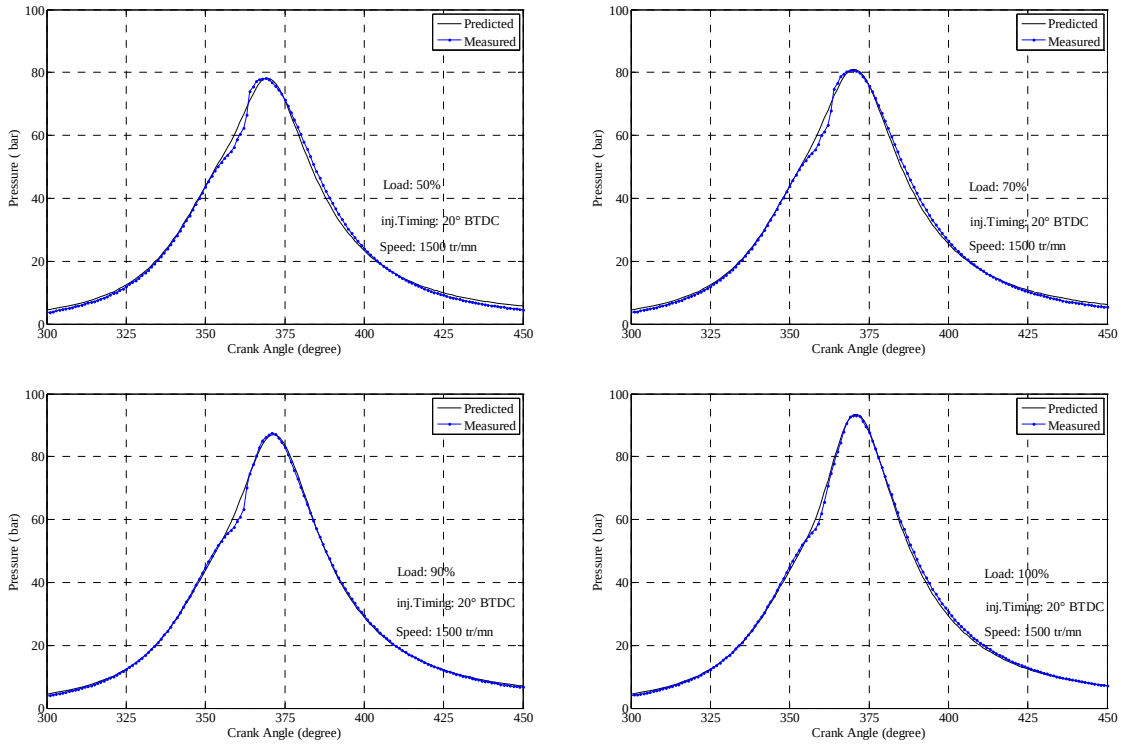

Figure 1: comparison of the predicted in cylinder pressure with the measured

The properties of the various fuels used in this study are measured at the Ecole des Mines of Nantes and are reported in the Table2. It is noticed, expect for the eucalyptus oil viscosity, that the other physicochemical properties of the crude oil and of its biodiesel are close with those of the Diesel fuel.

RESULTS AND DISCUSSIONS

Comparison with experimental data

To demonstrate the reliability of the mathematical model, predicted values of "in cylinder" pressure of the DI compression ignition fuelled with Diesel fuel are compared with measured ones in various engine loads. As seen from the Figure 1, the predicted "in cylinder" pressure are in good agreement with those experimentally obtained for all engine load. Thus, the simulation model can be applied for the different biofuels.

Parametric study

Compression ratio effect: The simulation model is run with compression ratio from 14:1 to 20:1 for the 3 different fuels. Figure 2 shows that for the compression ratio *CR=18*, the maximum "in cylinder pressure" is greatest in diesel fuel case due to their low volatility in comparison with eucalyptus crude oil and its biodiesel.

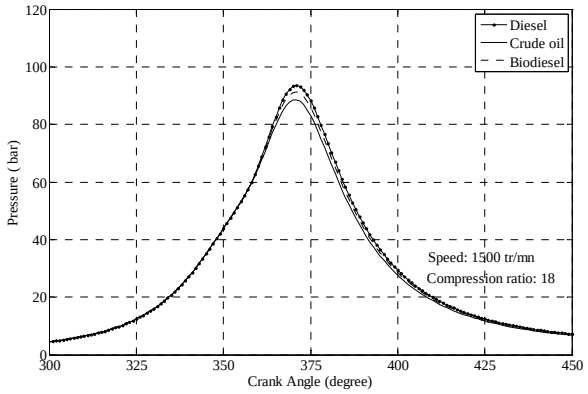

Figure 2: Variation of in cylinder pressure

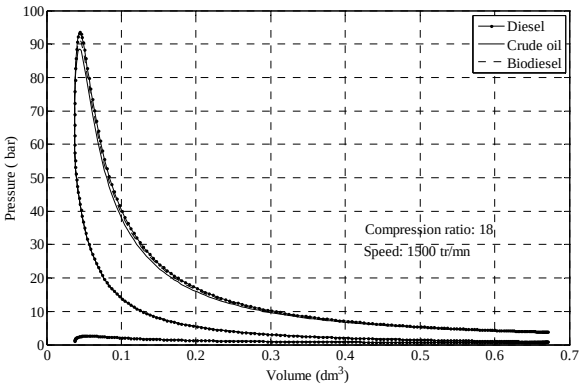

Figure 3: P-V diagram

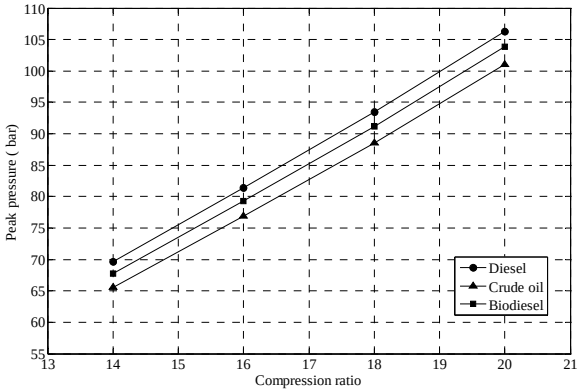

Figure 4: Effect of compression ratio on peak pressure at 1500rpm

The biodiesel peak pressure case is closer to the diesel fuel case one than to the eucalyptus crud oil. It can be seen also from the P-V diagram (Figure 3), that the enclosed area of the biodiesel fuel case is greater than the eucalyptus crude oil one.
In the Figure 4, the peak pressure inside the cylinder with various compression ratios is compared for the three fuels used. For all the fuels, the high pressure of compressed mixture is growth by 35% due to the compression ratio increasing.
Figure 5 shows that the indicated specific fuel consumption of the eucalyptus crude oil case is the highest in comparisons with the biodiesel and the diesel fuels cases. The indicated specific fuel consumption decreased on average by 16%, when the compression ratio is increased from 14 to 20 for all the fuels.
Figure 6 shows that the engine increasing compression ratio is expressed by an increasing in the indicated thermal efficiency for all the fuels. It can be seen also that the indicated thermal efficiency of biodiesel case is lower than that of diesel case, and higher than that of the crude oil. This is due to that the indicated thermal efficiency is directly dependant to the lower calorific value which is lowered by the presence of the higher percentage of oxygen molecule in the crude oil case and slightly lowered in the biodiesel case.

Engine speed effect: The performance evolution of DI compression ignition engine with respect to the engine speed is studied for the conventional diesel fuel, the eucalyptus crude oil and its ethylic ester (biodiesel).
From the Figure 7, the peak pressure of the mixture increased by 22% when the engine speed is 4000rpm. It can be seen also, that the biodiesel peak pressure is greater than that of the eucalyptus oil due to its higher calorific heating value which increase the heat release.
Figure 8 shows the engine power values for diesel fuel, eucalyptus crude oil and its biodiesel at different engine speeds. The maximum power values for the 3 fuels are obtained at 4000 rpm.

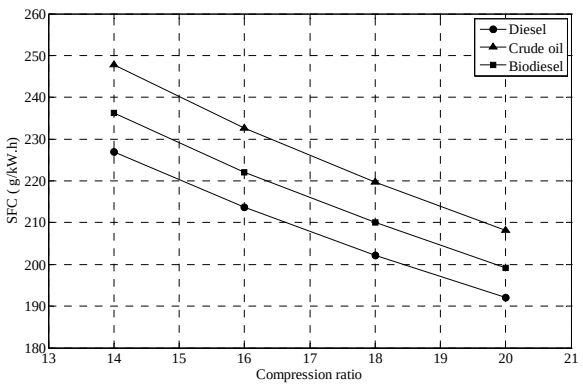

Figure 5: Variation of SFC with CR

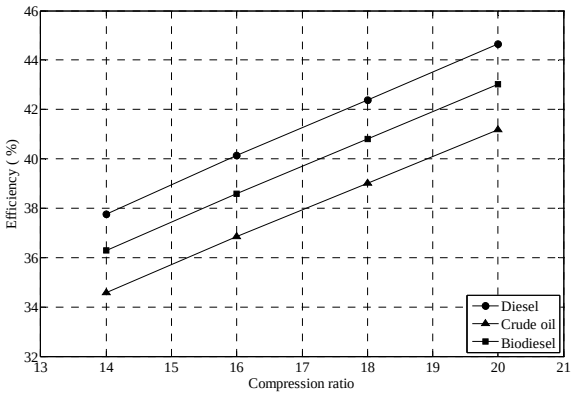

Figure 6: Variation of efficiency with CR

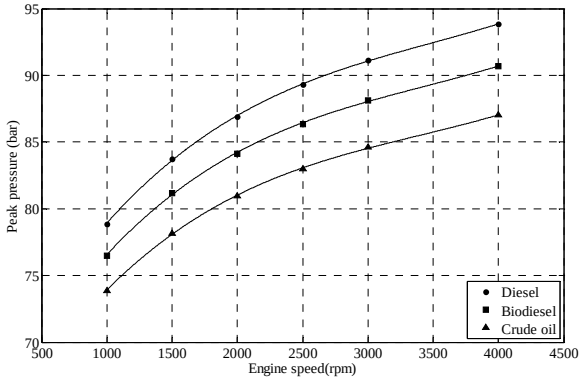

Figure 7: Effect of engine speed on peak pressure

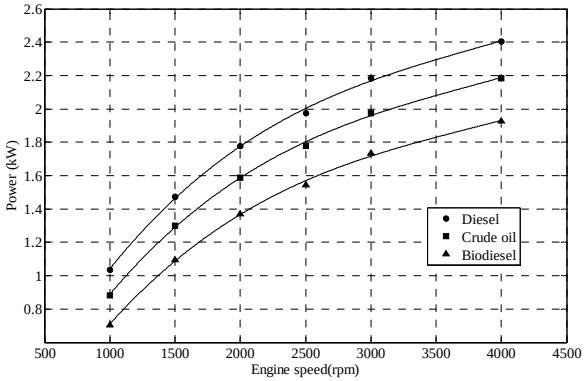

Figure 8: Variation of power values

According to these values, the traditional diesel fuel has the greatest power. It can be seen also that for all engine speed, that the power is decreased by 25% when the engine is fuelled by the crude oil and by 10% when it is fuelled by the biodiesel.

Figure 9 shows the specific fuel consumption (SFC) evolution with respect to the engine speed for these fuels. It can be seen that the SFC value is important at the lower engine speed, and decreased with engine speed increasing. At 4000 rpm, the minimum SFC value with conventional diesel fuel is 202.04 g/kW.h and with biodiesel and crude oil it is 222.41 g/kW.h and 251.99 g/kW.h, respectively.

Figure 10 shows the Efficiency evolution with respect to the engine speed for the 3 fuels. The power reduction due to the use of alternative fuel (eucalyptus or its biodiesel) is expressed by the efficiency decreasing. At 1000 rpm, the efficiency is decreased by 24 % and 10 % for the crude oil and its biodiesel respectively. But at higher engine speed (4000 rpm), the efficiency is slightly decreased by 10% and 5% for the crude oil and its biodiesel respectively.

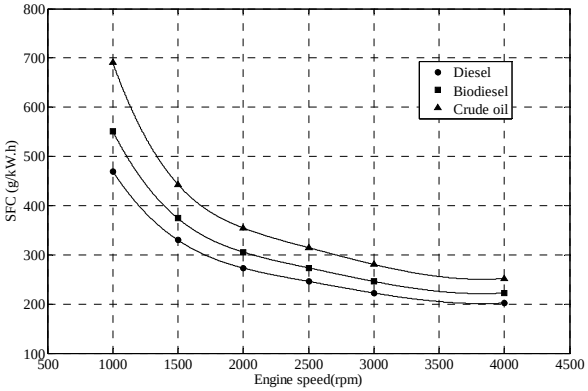

Figure 9: Variation of specific fuel consumption

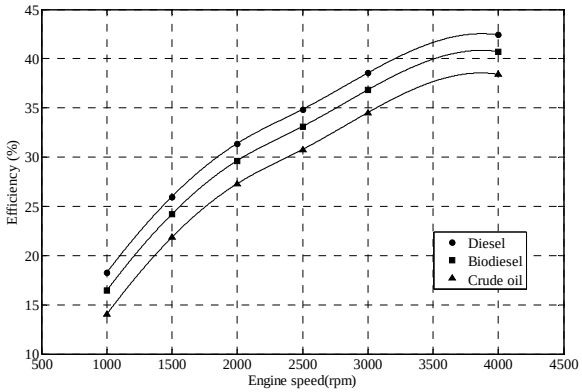

Figure 10: Variation of efficiency

CONCLUSION

The aim of the present investigation is to analyse numerically the usability of eucalyptus oil or its biodiesel as a substitute to diesel fuel in CI engine. A single zone thermodynamic model has been developed for theoretical determination of DI diesel engine cycles and engine performance parameters fuelled with various fuels. The numerical results obtained showed for the all treated cases that the engine performance characteristics follow the same trend. When the engine is fuelled with biodiesel, the performances are comparable to those of the diesel fuelling case. For the crude oil fuelling case, not only the performances are the lowest, but also its usability requires an implementation of an oil preheating system to reduce its high viscosity.
Finally, the reliability of the model is proven, and the biodiesel is an appropriate substitute to the diesel fuel.

ABSTRACT. The solar energy is limitless and pollution-free natural energy; however, the solar energy has not been utilized extensively due to its low density and restriction of availability.
The performance of the heating system with a burner and solar collectors is influenced by the efficiency. The solar collector and the thermal storage tank are controlled by different temperature controller. The controller has a temperature sensor which is being affected by the location of the sensor and also this location leads to make the properties of the controller.
This study was conducted to analyze operating characteristic of a solar assisted heating system for hot water supply and panel heating of a house. The main part of the system is a thermal storage tank which was designed to store energy that obtained from solar collectors and a burner. The heat exchanger is located on bottom of the storage tank which supplies solar energy to the water in the storage tank and is connected directly to the solar collectors. As an additional heat source, a burner was inserted to the top of the storage tank and supplies energy to water in the storage tank through indirect contact of the fire frame and stack flue. And also a small tank for hot water heating was attached at inside of the thermal storage tank. The water in the tank is heated by the water in the thermal storage tank.
In this study, the compact system with various heat sources and various function, performance test was conducted. As results, if design temperature of the boiler is increased, the efficiency of system is decreased. When the system uses hot water, system performance is decreased as increasing of the warm water usage. The developed system can be used as main heating equipment to the residential with the panel heating.

INTORDUCTION

Importation rate of fossil fuel or crude oil in Korea has been reduced a little due to development of gas field in outside country and participation in joint research petroleum business. However, 93-95% of consuming energy is relying on importation of the energy from other countries. The development of new and renewable energy are important issues in Korea not only necessity of the energy but also energy security of the country.
Research on fundamental technologies is not common due to demands for the predominant output or propagation of facility in the new and renewable energy industries. However, government will supply lots of fund to the renewable facility and R&D area to increase distribution rate of the new and renewable energy technology.

The solar is most applicable and accessible energy in renewable energy area by abundant solar distribution throughout the country. The rate of solar energy utilization is lower than the other renewable energy even though there is a lot of technology development for the solar energy area. The solar is limitless and pollution-free energy in the natural; however, the solar energy has not been utilized extensively due to its low density and restriction of availability.

Among the solar energy technology, water heating system is most popular device. It should be more useful if we extend the utilization of the solar energy from water heating application to panel heating for the residential house.

Ryu et. al. [1], Kim et. al. [2] and Paek et. al. [3] had studied a solar heating system to get optimum heat charge conditions for the thermal storage tank. They considered heat exchangers performance and design of return pipes that is a distributor of return water from residence panel. They delivered a more efficient thermal storage tank with changing the location of the return pipe at inside of the storage tank and system performance test was conducted with developed thermal storage tank.

Kim et. al.[4, 5] had constructed a heat pump system with solar collectors and a thermal storage tank as additional devices for a residential heating equipment. They alternated operating sequences from direct heat supply mode to heat pump operating mode for heat supply to the residence house from the thermal storage tank. The system controlled with well designed a differential temperature controller. As results, they show that it is possible to get more efficient thermal storage process with the developed differential temperature controller. And, there is more heat losses in the top side of thermal storage tank than bottom. It was founded that the energy bill can be saved about 30% with the solar collectors in the heat pump system compared with an electric heater and 90% of energy bill could be saved compared with an oil fired boiler.

As following researches, Park et. al.[6,7] had studied the same system with Kim's [4,5] to know optimum control temperature of the circulating pump in the solar collector. Han [8] had published a numerical calculation about effect of the water heating device on the system performance. Han [8] suggested that the water heating load is small enough to neglect compared with the heating load for the heating of the residential house.

This study was conducted to analyze operating characteristics of a solar assisted heating system for water heating and panel heating of a house. The main part of the system is a thermal storage tank which was designed to store energy that obtained from solar collectors and a burner. A heat exchanger located in bottom of the storage tank which supplies solar energy to the water in the storage tank and is connected directly with the solar collectors. As an additional heat source, a burner was inserted to the top of the storage tank and supplies energy to water in the storage tank through indirect contact of the fire frame and stack flue. And also a small tank for water heating was attached at inside of the thermal storage tank. The water in the water heating tank is heated by the water in the thermal storage tank itself.

In this study, an experimental study was conducted to improve efficiency of a heat storage tank with solar collector. Most of solar energy systems are used for water heating application with simple heat storage structures. However, by the solar energy application is extended to panel heating purposes, there is limitation in efficiency of the conventional heat storage tank. When the conventional heat storage tank used in solar assisted heating system, the water in the storage tank was heated in advance of heating operation by the solar heat, it makes reduction of utilization efficiency in the solar energy. Through analyzing flow characteristics and figuring problems out of a conventional heat storage tank, it is found that the system performance could be improved by optimization of the structure of the storage tank [9]. The experiments are conducted with real scale bases with designed thermal storage tank that has a distributor for return water from panel.

EXPERIMENTS

System configuration

The experimental apparatus is consisted with a 1.0 m^3 capacity thermal storage tank, solar collectors with 20 m^2 of surface area, a 5 RT capacity chiller to supply heat load to the system as work as thermal load at a residential house. The test rig is shown in Figure 1.

Solar heat of the solar collect is supplied to the thermal storage tank with control signal from a differential temperature controller. The controller checked a temperature difference between the solar collector fluid and water in the thermal storage tank. If the temperature difference between them reached at a specified temperate, the circulation pump started and supply the heat to the thermal storage tank through a heat exchanger which is inserted in the thermal storage tank.

On the other hand, room temperature controller controls another circulating pump for heat load. If the room temperature less than a specified setting temperature, the circulating pump starts and supplies the heat in the thermal storage tank to the heating load side. The heat load in this study is simulated by the chiller.

When the fluid temperature in the thermal storage tank has decreased to a specified degree, the burner started to increase the supply temperature of the thermal storage tank.

Hot water for shower and dish-washing can be supplied by a signal from the demand side opening of the valve. The heat of the hot water tank, which inserted in the thermal storage tank as shown in Figure 2, is indirectly supplied by the heat of the fluid in the thermal storage tank.

Experimental equipment

Solar collector. The solar collector which is used in this study is plate type solar collector with 20m^2 surface area. If we assume that a family with four persons are live in 90m^2, the house should be equipped about 6 to 10 pieces of solar collector to cover the heating load in the winter. Ten pieces of collectors are parallel aligned and inclined from the surface with 40^o.

Thermal storage tank. A tank in tank type thermal storage tank with a tank in coil type heat exchanger inserted was designed. The storage tank is consisted with a supply nozzle and a distributor type return

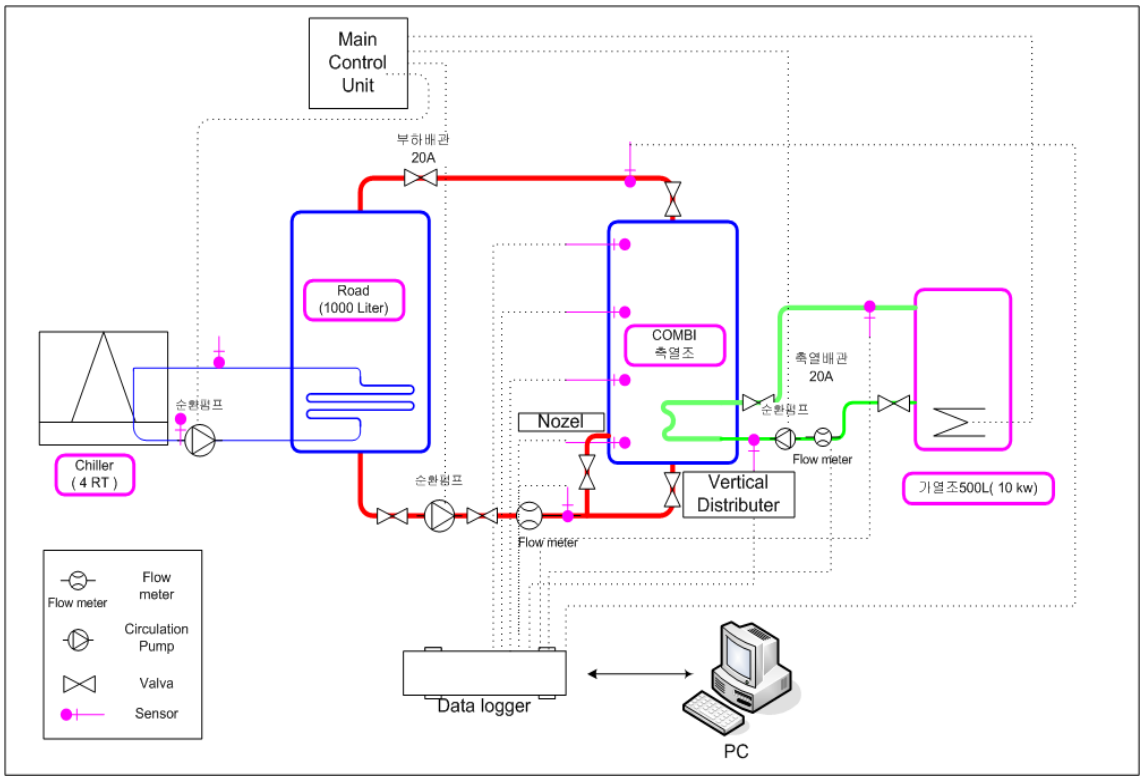

Figure 1. Schematic diagram of the experimental setup

nozzle for heating the panel of the residential house and couple of nozzles for hot water supply. Figure 2 shows the designed storage tank. The capacity of the storage tank is 1.0 m^3 and insulated with 50 mm thickness urethane foam.

Burner. The solar energy will be main heat source of the house. However, if the weather is not easy to get the heat from the sun in cloudy or rainy days, a burner is installed in the system to assist the deficient heat. To reduce the size of the system, the burner is inserted to the thermal storage tank as shown in Figure 2. The burner uses oil as fuel and a 17 W injector for the oil supply to the combustion chamber. The heat exchanger of the burner is modified to contact the flame with the fluid in the thermal storage tank and the stack of the flue gas bended 180^o from the flame direction.

Measurement devices

Temperature is measured with T-type thermocouple. The sheathed thermocouple is 200mm length and 1.6 phi diameter and inserted at all inlet and outlet of the component.

Electrical volume flow meters are installed at the solar collector outlet and return pipe to thermal storage tank from the heat load with 0-120 lpm flow range.

Solar radiation is measured with an Albedometer which is installed at the solar collector with 45^o inclination.

All measured data are achieved by a data logger (DR-230, Yokogawa) with 60 second time interval and stored at a personal computer simultaneously.

Experiment procedure

In this study, the setting temperature of the boiler is varied from 40 ^{o}C to 60 ^{o}C with 5 ^{o}C difference. The temperature difference setting between the solar collector and the thermal storage tank is fixed to 5 ^{o}C. And cut-off temperature values are 2^{o}C to avoid rapid hysteresis of the pump operation. The setting temperature of the main controller is varied with experiment.

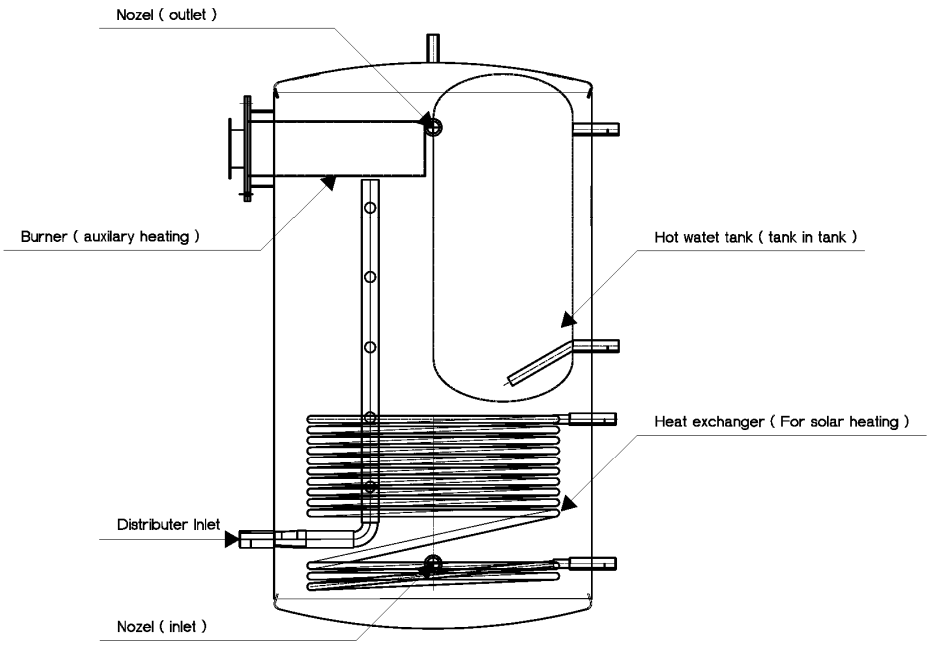

Figure 2. Schematics of the thermal storage tank

RESULTS AND DISCUSSION

Thermal storage tank performance

Solar energy utilization performance of the heat storage tank is improved with vertically installed distributor for return water compare to conventional horizontal type distributor's performance. It is found that the conventional heat storage tank is not suitable for heat storage tank for panel heating equipment and it is possible more improvement by modification of the heat storage tank.

The test conducted with variation of the volume flow rate of the supply heating water to the panel with changing of the return pipe installation method. When the thermal storage tank uses a nozzle type return pipe, the temperature of the fluid at 3/4 height of the tank (denoted to Tm_top in the Figure 2) decreases early stage of the operation and the fluid temperature at 2/4 and 1/4 height of the tank (denoted to Tm_bot and T bot in the Figure 2) increases by heat transfer from fluid at the 3/4 location. It is easy to understand the trend of temperature variation from right side graph in the Figure 3.

If the nozzle has replaced with the developed vertical type distributor, the heat transfer mechanism changes as shown in Figure 4. It shows that the temperature stratification with the height of the location is maintained for long time. Therefore, it is possible to supply a higher temperature fluid to the desired heat load rapidly without increasing all fluid temperature to the desired temperature.

Solar collector efficiency is calculated with equation (1). If the weather condition of Busan City in Korea is adapted to the equation (1), the efficiency of the solar collector with a developed vertical

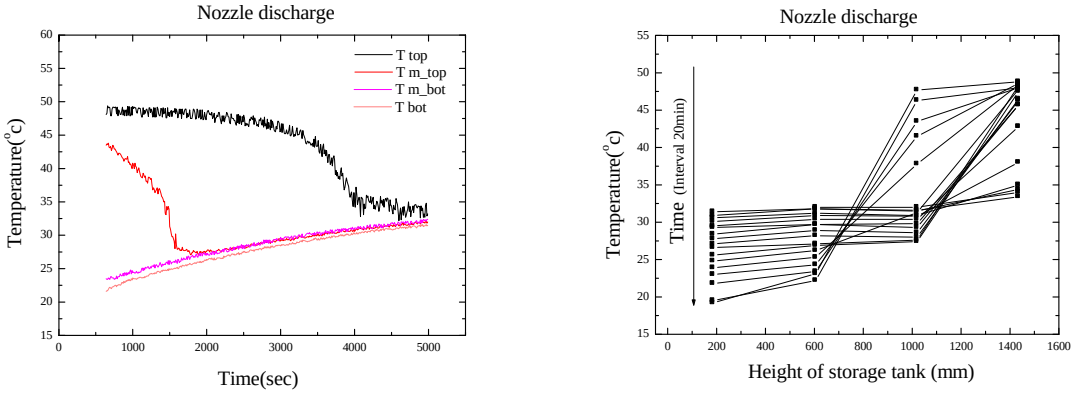

Figure 3. Temperature variation in the thermal storage tank with time in case of using a nozzle type return pipe

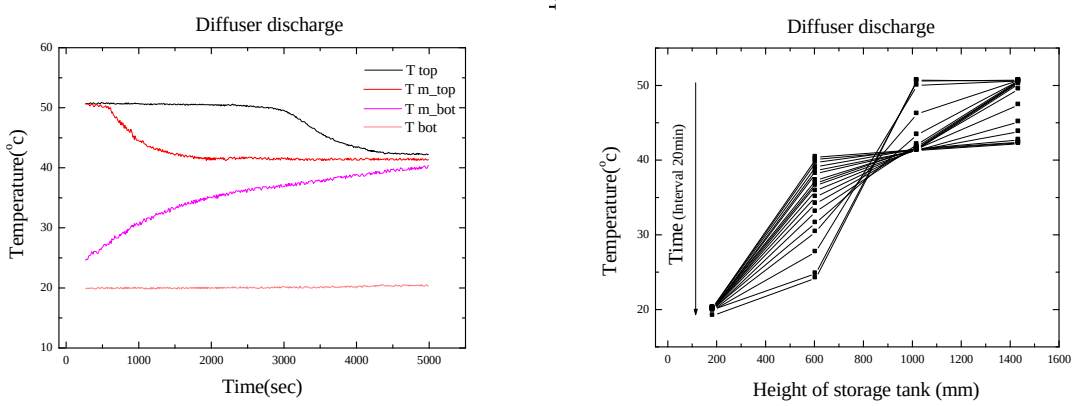

Figure 4. Temperature variation in the thermal storage tank with time in case of using a diffuser type return pipe

type distributor is increased about 7.25% than that of the nozzle type return pipe as shown in Table 1. The efficiency variation with temperature difference is shown in the Figure 5.

$$\eta = F_R(\tau\alpha) - F_R U_L\left(\frac{t_i - t_a}{It}\right) \tag{1}$$

Component performance

To know the performance of the thermal storage tank, heat loss through the wall of the thermal storage tank is needed. The storage tank was heated with auxiliary heating device up to 55°C and leaves the storage tank in the ambient temperature 26°C. It takes about 5 hours to release all energy in the storage tank as shown in Figure 6. The most of heat losses are occurs at the attaché part of the boiler in the storage tank due to that high temperature environment of that place makes difficulties for insulation. When the sun set downs at 6 o'clock, the temperature of the storage tank decrease about 18% from 55°C to 45°C during 1 hour until heating operation begins at 7 o'clock

Boiler performance is varied with maximum limit temperature settings. In this study, the control temperature set at 40 °C, 50 °C and 60 °C. When the boiler outlet water temperature reached at the specified temperature, the boiler stops and operating will began when the outlet temperature drops about 4 °C from the specified temperature. Fuel consumption is increased about 77% if the setting temperature increased from 40 °C to 50 °C and 81% of fuel consumption is increased when the setting temperature increased from 50 °C to 60 °C. The energy used to run the boiler with limit temperature 40

Table 1
Comparison between Theory and Experiment

Items		Value
$F_R(\tau\alpha)$		0.71
$F_R U_L$		-4.3
t_a		13°C
It		600[W/m^2]
t_i	Nozzle	37.6(Δt =7.6°C)
	Distributor	32.2 (Δt =2.2°C)
η	Nozzle	53.37%
	Distributor	57.24%

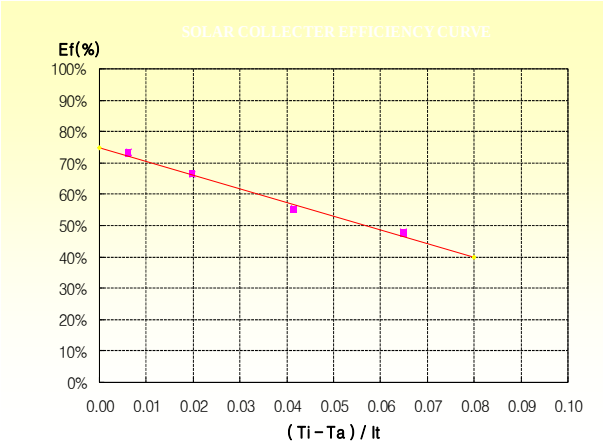

Figure 5. Efficiency variation with temperature difference between inlet of the collector and ambient temperature

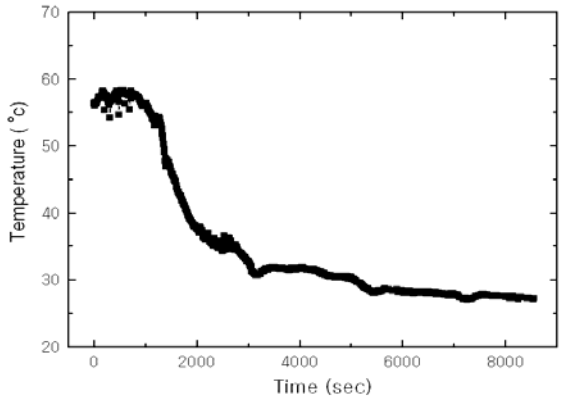

Figure 6. Heat loss variation of the thermal storage tank with time when the tank is exposed to the environment temperature

^{o}C , 50 ^{o}C and 60 ^{o}C is 6,427 kcal/day, 11,506 kcal/day and 20,855kcal/day, respectively. Figure 7 shows the temperature variation during the boiler performance test with time.

System performance

In this study, the system performance is tested with interval heat load to the system. Heat load is imposed 2 hours interval during daytime and 1 hour interval in the night. Figure 8 shows load, energy absorption from the sun and burner operation signals at 60^{o}C setting temperature of the boiler. The burner does not work during day time. However, in the night, the boiler runs accompany with the heating load. If the setting temperature varies from 40^{o}C, 50^{o}C and 60^{o}C, the solar fraction of the heating load is 97.9%, 84.5% and 59.5%, respectively.

When the system supplies hot water for shower and dish-washing, the energy consumption is measured with variation of flow rate of the hot water at 3 lpm, 5 lpm and 7 lpm. Figure 9 shows thermal storage fluid temperature variation with 7 lpm of supply water flow rate. The oil consumption increased with respect to the supply water flow rate. When the flow rate is set to 3 lpm, 5 lpm and 7 lpm, the oil consumption is 0.12 litter, 0.16 little and 0.22 litter during 20 minutes operation.

The total fraction of the solar energy in the system is shown in Figure 10. It shows that most of the month during a year could cover the heating load of the residential house by the energy from the sun except 5 months from October to March. However, during the winter season, the solar energy fraction to the heating load is about 47% approximately.

CONCLUSIONS

The developed compact system with various heat source such as solar and burner and various function such as water heating and panel heating, performance test was conducted. The performance of the heating system with a burner and solar collectors is influenced by its efficiency. The solar collector and the thermal storage tank are controlled by different temperature controller. As results, if design temperature of the boiler is increased, the efficiency of system is decreased. When the system works as water heater, system performance is decreased as increasing of the water usage. The developed system can be used as main heating equipment to the residential house.
The results in this study could be used in development of solar assisted heating system for the residential house and will be basic technology in home appliance industries with solar energy. The information which arouse during the development will be reference in regulation rule making process. This study also will contribute to distribution of the new and renewable energy in the country.
It is found that the system developed in this study will be commercialized by the developing company with obtained know-how during the developing process if the market of the water and panel heating solar system have a good circumstance in the future.

A STUDY ON RADIATIVE TRANSFER IN A TiO_2 PHOTOELECTRODE FOR THE DYE SENSITIZED SOLAR CELL PERFORMANCE ENHANCEMENT

M. Sangklinhom*, J. Yamada
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT. Nanoporous TiO_2 photoelectrodes of dye-sensitized solar cells (DSSC) fabricated from various sized TiO_2 particles were investigated to examine the effect of controlling radiative transfer on cell performance. The electrical performance of various cell types was measured. To clarify the effects of controlling radiative transfer on cell performance by using different TiO_2 particle sizes in multi-layered photoelectrodes, numerical simulation of the radiative transfer through TiO_2 photoelectrodes was developed. The results revealed that not only the total amount of light absorbed within the photoelectrode is important for improvement of the cell performance, but also that improved light absorption distribution within the photoelectrode is essential.

Keywords: *Dye sensitized solar cell, Radiative transfer, TiO_2 photoelectrode, numerical simulation*

INTRODUCTION

Dye-sensitized solar cells (DSSC) were first introduced in 1991 by O'Regan and Grätzel [1]. At that time, an energy conversion efficiency of 7.1% was reported, while nowadays the record efficiency has reached 11% [2], and the theoretical efficiency limit is above 30% for a single band gap junction [3], indicating that DSSCs are potential candidates for future solar energy conversion devices. However, significant improvement of the DSSC system is required for practical application.

The dye-sensitized TiO_2 photoelectrode, which is used to absorb incident light, is one of the main factors that plays an important role in efficiency improvement. The photoelectrode requires a large internal surface area to attach a large amount of dye molecules for electron generation, which can be achieved by using small TiO_2 particles (3-5 nm) [4]. The result is that a transparent photoelectrode can be obtained, but with poor light scattering characteristics. Simulations of light scattering in a TiO_2 photoelectrode of the DSSC has been reported for suitable mixtures of small (e.g., 20 nm in diameter) and larger TiO_2 particles (e.g., 250-300 nm in diameter) as effective light scattering particles that indicated significant enhancement of solar light absorption [5,6,7]. In addition, improvement of the TiO_2 photoelectrode has been reported using a double layer system [8], where the photoelectrode is separated into two layers; the first layer is a transparent layer composed of small TiO_2 particles (20 nm) and the second layer is a light-scattering layer composed of larger TiO_2 particles (400 nm). Other developing technologies, such as the multi-layer technique, where the structure of the TiO_2 photoelectrode consists of layers of different radius TiO_2 nanoparticles with a particular size [9], and the mixing of other metal oxides into the scattering

layer have been reported [10]. These techniques have potential for the improvement of dye-sensitized TiO_2 photoelectrodes. However, in order to sustain efficient electron injection at the photoelectrode and electron re-generation from the counter electrode, the sufficient iodide and triiodide level should be maintained. But, the iodide concentration varies along the thickness of the photoelectrode [11]. The highest iodide concentration is at the photoelectrode side that closes to the counter electrode, and it is the shortest pathway for redox species between the two electrodes, electrons can quickly transfer from counter electrode to the photoelectrode. Therefore, the photoelectrode side that closes to the counter electrode would be the effective area for the electrons generation, the radiative transfer should be controlled to efficient the electron generation in this photoelectrode area.

In this study, an attempt was made to control the radiative transfer in a nanoporous photoelectrode prepared with TiO_2 particles of different sizes, since the scattering characteristic of the particles depend on size and shape. TiO_2 photoelectrodes composed of single, double, and triple layers were fabricated, where each layer has different sized TiO_2 particles. The electrical characteristics of a solar cell with the fabricated photoelectrodes were measured to evaluate the performance. A numerical code based on the Monte Carlo method was used to clarify the radiative transfer within the TiO_2 photoelectrodes. The results indicate that the solar cell performance is significantly affected by the photon absorption distribution within the TiO_2 photoelectrodes. The DSSC performance can be enhanced by using different particle sizes for each layer, in order to control the photon absorption distribution within the photoelectrode.

EXPERIMENTAL AND NUMERICAL SIMULATION

Fabrication of TiO_2 photoelectrodes

A conventional doctor blade technique was employed to fabricate single, double, and triple layer system nanoporous TiO_2 photoelectrode films. Commercially available TiO_2 powders (P-25, Nippon Aerosil) with an average particle diameter of 21 nm were used, which is a widely used particle size for transparent photoelectrode films of DSSCs. Other TiO_2 powders, ST-01, and CR-EL, with average diameter sizes of 7, and 250 nm, respectively, were obtained from Ishihara Sangyo Kaisha, Ltd., Japan. To prepare the TiO_2 paste, 1.0 g of powder was ground in a mortar with the addition of a drop of an acetic acid solution in purified water, 1.0 g of polyethylene glycol (PEG), and then 0.5 mL of Triton-X 100. The TiO_2 paste was spread on a transparent conductive oxide (TCO) coated glass substrate, and the film thickness controlled by the doctor blade. The TiO_2 film was dried at room temperature for several minutes and then heated at 450 °C for 1 h to form a nanoporous TiO_2 film. Covering the TiO_2 surface with dye was performed by soaking the film for more than 24 h in a solution of ruthenium N3 dye (Peccell Technologies, Japan). The dye was adsorbed on the TiO_2 nanostructure surface. A counter electrode was prepared by coating a 20 nm thick Pt catalyst layer by the sputtering technique. The dyed-TiO_2 photoelectrode was assembled with the counter electrode as a sandwich-type cell. The electrolyte (0.05 M of I_2 and 0.1 M of LiI dissolved in acetonitrile) was introduced into the cell as a redox mediator.

Measurement

The electrical characteristics of the fabricated DSSC solar cells were measured using a potentiostat (Hokuto Denko HAL3001) with irradiation using a 150 W Xenon lamp.

Numerical simulation

A numerical code for radiative transfer by the Monte Carlo method was developed to clarify the effect of radiation transfer in the photelectrodes. The radiative properties of a photoelectrode are required as input parameters; Mie theory is used to calculate the scattering and extinction efficiency of a single uncoated particle. And the TiO_2 particles covered by dye, the scattering and extinction efficiency were calculated using the "coated sphere" code [12]. The general principal of radiative transfer problem solving by the Monte Carlo method is already well known, and has been developed by many researchers in field, and this numerical code has developed related to the light transport in multi-layered media [13]. The following is a brief description for scoring the absorption quantity in the medium of the present radiation transfer simulation based on Monte Carlo method.

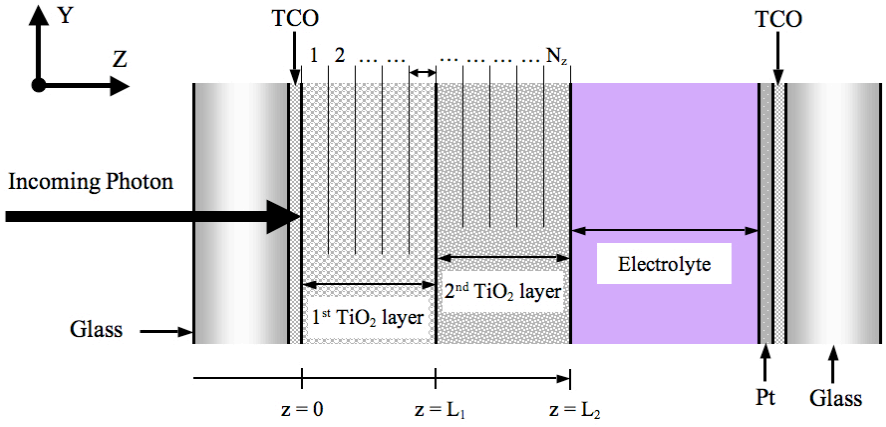

Figure 1. Schematic illustration of the TiO_2 photoelectrode (double-layered case) for the numerical simulation of radiative transfer based on the Monte Carlo method.

Launching a photon packet Each photon packet is initially assigned a weight W, which is equal to unity. The photon is injected orthogonally into the medium from the origin. The step size of the photon packet s, is calculated based on a uniformly distributed random number ξ, and a total interaction coefficient μ_t:

$$s = \frac{-\ln(\xi)}{\mu_t} \tag{1}$$

Photon absorption After the photon has taken a step, the photon weight will be reduced, due to absorption by the interaction site. A fraction of the photon present weight W, will be deposited in the local grid element. The amount of deposited photon weight ΔW, is calculated using

$$\Delta W = (\mu_a / \mu_t) W \tag{2}$$

where μ_a is an absorption coefficient, and μ_t is a total interaction coefficient or an extinction coefficient. This fraction of photon weight is scored as absorbance if the photon packet interaction site is in the medium:

$$A(z) = A(z) + \Delta W \tag{3}$$

Otherwise, if the photon packet exits the medium, the fraction of photon weight will be scored as reflectance or transmittance array, depending on where the photon packet exits.

The photon weight is then updated using

$$W = W - \Delta W \tag{4}$$

The photon packet with the new weight W, will undergo scattering at the interaction site and survive until the weight is too small or the photon packet has escaped the medium.

Internal photon distribution During the simulation, the absorbed photon weight is scored into the absorption array A(z), and is internally represented by $A[i_z]$, where i_z is the index for grid elements in the z direction and is computed from

$$i_z = \text{int}(z/L \times N_z) \tag{5}$$

where z is the distance from the origin to the photon packet interaction site, every photon that has taken a step, z will be re-evaluated. L is the thickness of the medium, and N_z is the total number of grid elements (sub-layers). The photon weight will be scored into the grid element absorption array as

$$A[i_z] = A[i_z] + \Delta W \tag{6}$$

The total photon weight absorbed in the medium A, is the summation of the total photon weight absorbed in each grid element $A[i_z]$, which is computed from

$$A = \sum_{i_z=1}^{N_z} A[i_z] \tag{7}$$

The absorption A, and $A[i_z]$, can be represented as the photon absorption probability in the medium and in each grid element (each sub-layer in Fig. 1.), respectively, by dividing by N (total photon weight).

$$A = A/N \text{ [-]} \tag{8}$$
$$A[i_z] = A[i_z]/N \text{ [-]} \tag{9}$$

where [-] represents dimensionless units.

Table 1.
Details of the photoelectrode types. The first number represents the first layer close to the glass substrate, as shown in Figure 1.

Photoelectrode type	Particle size in 1st layer (nm) / Thickness (μm)	Particle size in 2nd layer (nm) / Thickness (μm)	Particle size in 3rd layer (nm) / Thickness (μm)	Total thickness (μm)
7	7 / 15	-	-	15
21	21 / 15	-	-	15
7+21	7 / 5	21 / 10	-	15
21+7	21 / 5	7 / 10	-	15
7+250	7 / 15	250 / 3	-	18
21+250	21 / 15	250 / 3	-	18
21+7+250	21 / 5	7 / 10	250 / 3	18

RESULTS AND DISCUSSION

The measured electrical characteristics of the DSSCs are presented as current-voltage (*I-V*) curves in Fig. 2. The numerical simulation results of radiative transfer in the TiO_2 photoelectrodes are also shown here.

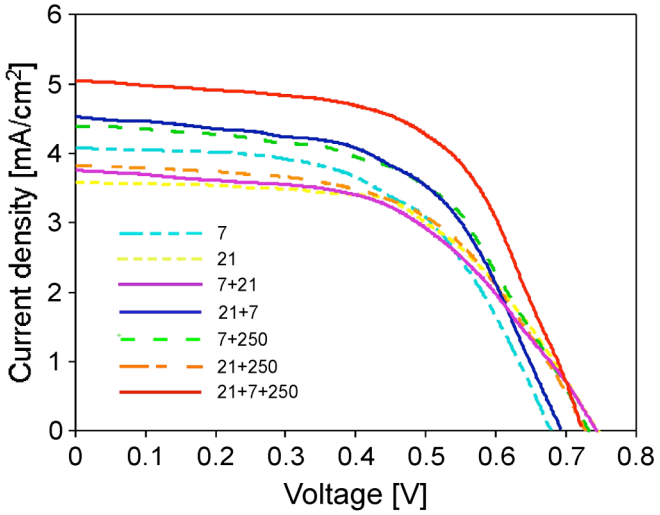

Figure 2. Measured *I-V* characteristics of DSSCs fabricated using different TiO_2 particle sizes for each photoelectrode layer. The numbers indicate the photoelectrode types given in Table 1.

Table 2.
Maximum electric power produced by the cells and the total photon absorption within the photoelectrode of the cells. Each group is ordered from high to low electric power.

Cell group	Photoelectrode type	Power, mW	Total absorption, %
A	21+7	1.759	15.95
	7	1.584	15.97
	21	1.505	15.39
	7+21	1.475	15.72
B	21+7+250	2.096	18.50
	7+250	1.765	18.26
	21+250	1.545	17.43

The cells were classified into two groups, *A* and *B*, as shown in Table 2. The cells in group *A* consist of single- and double-layered photoelectrodes without a scattering layer. The cells in group *B* consist of double and triple layered photoelectrodes with a scattering layer, that is, the layer composed of 250 nm TiO_2 particles.

The maximum electric power of each cell was calculated according to the measured *I-V* characteristics given in Figure 2. Figure 3 shows the spectral absorbance and internal photon absorption distribution within the photoelectrodes calculated using a numerical simulation code.

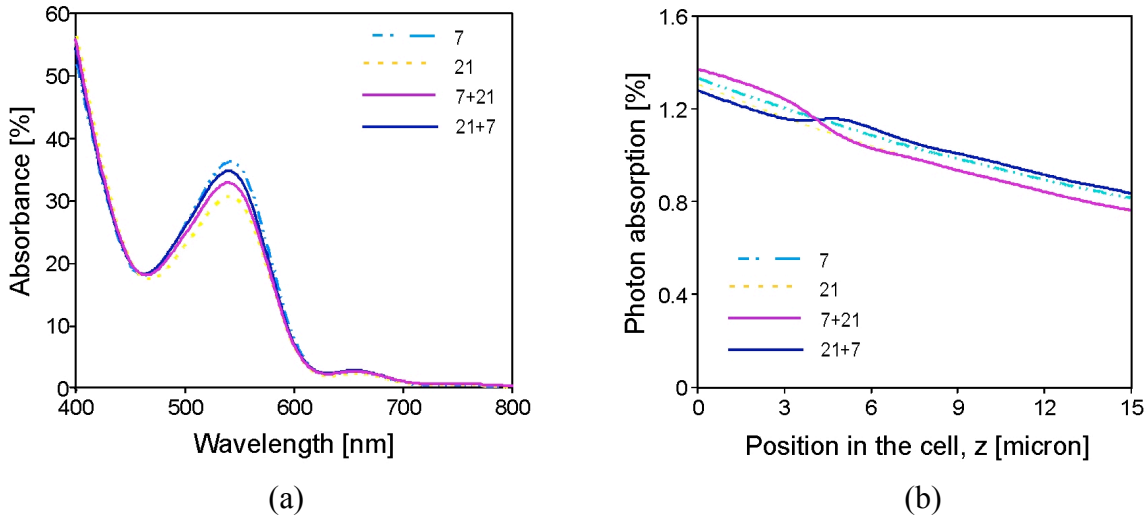

Figure 3. (a) Simulated spectral absorbance of single and double-layered photoelectrodes of group *A*, (b) photon absorption distribution profiles.

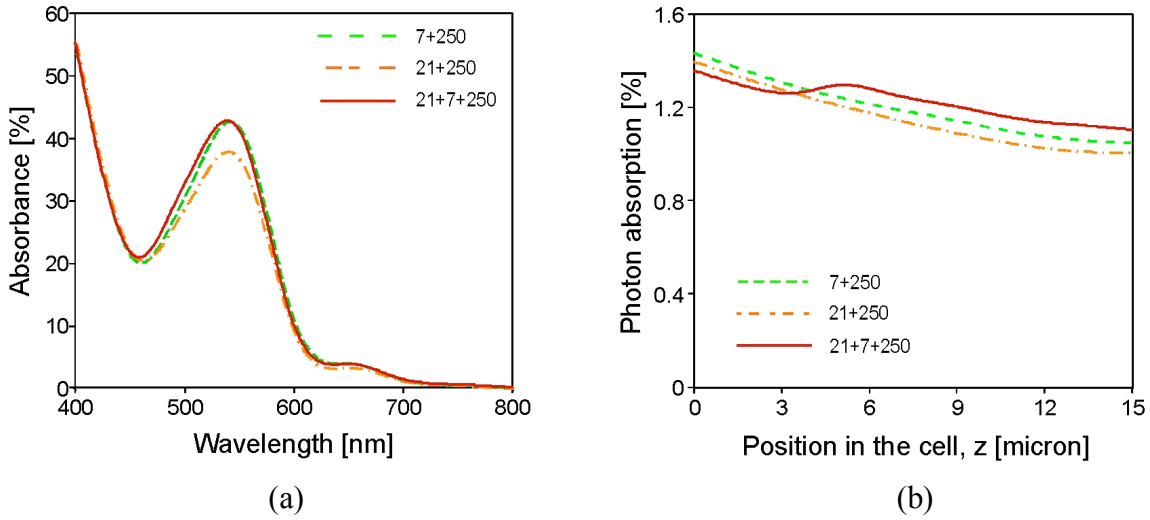
Considering the *I-V* characteristics in Fig. 2 and the total photon absorption in Table 2, the cell performance is dependent on the amount of photon or light absorbed within the photoelectrode of the cell. However, this is not the case for all cells examined. For example, considering the cells in group *A* of Table 2, the cell that has the highest efficiency (21+7-cell) does not have the highest photon absorption. In addition, the cell that has the lowest efficiency (7+21-cell) does not have the lowest photon absorption. To clarify this, the internal photon absorption within the photoelectrode was simulated, as shown in Figure 3(b).

Figure 3(b) shows the difference in absorptivity of each photoelectrode in each position of the cells in group *A*. Higher absorption in the deep region ($z > 5$ μm) significantly improves the cell performance more than high absorption in the shallow region ($z < 5$ μm). Considering the 21+7-cell, the cell has the highest photon absorption in the deep photoelectrode side ($z > 5$ μm) close to the electrolyte layer; therefore, it has the highest efficiency in group *A*, even though it has the lowest photon absorption in the shallow region ($z < 5$ μm). On the other hand, the 7+21-cell has the opposite absorptivity to that of the 21+7-cell; it is the least efficient cell in group *A*. This may also be due to the electron transfer mechanism; the shortest pathway for redox species between the photoelectrode and the counter electrode is the end of the photoelectrode close to the electrolyte layer side, and the longest pathway is the end of photoelectrode close to the TCO glass side (see Fig. 1). Therefore, if the radiative transfer to the deep photoelectrode region close to the electrolyte layer can be controlled, it might be effective to improve the cell efficiency, because electrons can be quickly transferred from the counter electrode to this photoelectrode area. As a result, we have shown that the highest efficiency solar cell is that which has the highest photon absorption in the deep region (Table 2, Fig. 3).

To support this reasoning of the light absorption effect, the effect on the illumination side to the photoelectrode has been proposed and discussed [11]. It is preferable to illuminate the cell from the counter electrode side (in this case, the photon absorption slope in Fig. 3(b) is the opposite side) for effective improvement of the cell efficiency. However, practically, illumination from the counter electrode side is not favorable, because it has higher incident light loss from passage through the counter electrode and bulk electrolyte layer. Therefore, illumination from the photoelectrode side is still preferable.



(a) (b)

Figure 4 (a) Simulated spectral absorbance of double and triple layered photoelectrode of group *B*, (b) photon absorption distribution profiles, the photon absorbed in the scattering layer is not included.

From the results, it is possible to control the radiative transfer by using different particle sizes for photoelectrode fabrication. Cells of double and triple layered photoelectrodes were fabricated (group *B*), and their performance was evaluated. The triple layered 21+7+250-cell has the highest efficiency of the cells examined in this study. This triple layered cell is a combination of the 21+7-cell in group *A* and a scattering layer. The numerical simulation results are shown in Fig. 4. It was revealed that the radiative transfer within the TiO_2 photoelectrode can be controlled, and the effect of the internal photon absorption distribution of the photoelectrode on the cell performance is supported. Therefore, the deep region close to the electrolyte layer should have high absorptivity in order to improve the cell performance.

CONCLUSION

The effect of radiative transfer in dye-sensitized solar cells was investigated. The amount of radiation absorbed in the deep region of the photoelectrode has an affect on cell performance. Therefore, control of the radiative transfer within the photoelectrode is essential for improved performance. We have proposed a method to control the radiative transfer for improvement of the cell performance using different TiO_2 particle sizes and a layered photoelectrode. However, to confirm these results, the influence of electrolyte-mass transport is currently under investigation.

EVOLUTION OF VORTICITY CHARACTERISTICS IN THE WAKE OF WIND TURBINES

C. Masson*, S.-P. Breton, C. Sibuet Watters
École de technologie supérieure, Montréal, Canada

ABSTRACT. The two-bladed wind turbine tested in the wind tunnel of the Technical University of Delft (TUDelft), the NREL phase III three-bladed rotor, and the theoretical case of a finite wing in translation are studied using the actuator surface (AS) method, which represents blades by using singular surfaces of velocity and pressure discontinuities. A 3D in-house Control-Volume Finite-element method is used to solve the Navier-Stokes equations in RANS form with appropriate adaptations to accomplish the AS action on the flow. Circulation is calculated in the wake of the wing and turbine rotors by performing contour line integrals of the tangential velocities along circles in the wake, allowing to track vorticity evolution, and to verify if the AS method correctly predicts vorticity conservation in the wake. The simulated vorticity is found to be conserved in a satisfactory way in the wake in the case of the finite wing in translation and the NREL rotor. However, this is not the case concerning the TUDelft WT, where problems were also found when calculating the circulation from experimental velocities.

INTRODUCTION

Vortex Modeling of wind turbine (WT) wake aerodynamics poses interesting challenges, especially in the region of the near wake where the blades' trailing vorticity is concentrated in tip and root vortices, subject to important deformation and turbulent diffusion. Study of the near wake is important both for rotor and far wake aerodynamic analysis and is therefore of concern to both WT and wind farm design. While full RANS-CFD models are more and more used to study WT aerodynamics, their use is still computationally prohibitive, especially when simulating configurations of several WTs. The actuator surface (AS) method, which represents WT blades using singular surfaces of velocity and pressure discontinuities, is a promising method for the study of WT wake interactions within a wind farm. This model is directly inspired by vortex and actuator disk approaches towards the determination of the blade aerodynamics. The actuator surface represents a potentially interesting concept to add to CFD toolkits with comparative advantages over existing volume forces approaches. Indeed, the action of the modeled device is spread over a surface rather than a volume, preventing arbitrary choices of volume thickness and forces distributions with subsequent dependency in the flow solution or computational instabilities. Furthermore, the actuator surface is perfectly compatible with the vorticity principles of creation and evolution of vortices, and by Kutta-Jukowski law to lift production, whereas volume force approaches fail to always complain with such principles and as a consequence, may not reproduce the genuine characteristics of the flow.

Validations of the AS concept have been realized for simple analytical cases and for the case of the finite wing in translation [1, 2] as well as the experimental rotors of NREL and Delft Technical

University [3], and have shown that the concept is useful to predict the flowfield and the values of induced drag or angles of attack. However, this method has not been validated yet for vorticity conservation, which could consist in a weakness. In this method, the presence of the blades is directly represented as vortices, making it similar to vortex wake methods, but contrarily to the latter, vortices are not directly represented in the wake, but are rather intrinsically handled by the CFD calculations. In this article, we will therefore focus on the capacity of the model to model vorticity in the wake, and correctly handle vorticity conservation throughout the wake. A method to calculate vorticity in the wake will be presented, after which the mathematical basis of the AS will be reviewed. Results will then be presented looking at vorticity evolution and conservation for three different cases, i.e. the finite wing in translation, the two-bladed TUDelft and three-bladed NREL phase III experimental rotors.

DESCRIPTION OF THE ACTUATOR SURFACE MODEL

Essential features of the actuator surface model

The actuator surface (AS) concept exposed here addresses the modeling of lifting devices aerodynamics, where strong viscous separation does not occur so that lift is linked to the circulation as in inviscid flow theory. In practice, for a wind turbine, using the AS to model the rotor aerodynamics consists in using an infinitely thin surface whose shape corresponds to the blade planform area, as shown in Figure 1. The AS is a vortex sheet that can be described by a vorticity vector $\vec{\gamma}$ which measures the integral sum of vorticity over the thickness of the sheet, if vorticity were spread over a finite thickness. Since here the sheet is infinitely thin, $\vec{\gamma}(x,y,z)$ is a Dirac-type function and has units of vorticity $\times$ distance.

Let (u,v,w) be the components of the Eulerian velocity field $\vec{V}$ in the (X,Y,Z) Cartesian system of coordinates (see Figure 1). It can be proven [4] that a particle of fluid that crosses the AS from $x < x_{AS}$ to $x > x_{AS}$ undergoes a sudden increase in velocity given by $\Delta\vec{V} = \vec{\gamma} \times \vec{n}_{AS}$, where $\vec{n}_{AS}$ is a unit vector normal to the AS (in the specific example of Figure 1, $\vec{n}_{AS}$ points in the X direction). When applying the principles of vorticity flux conservation to the vortex sheet, it is found that the divergence of the $\vec{\gamma}$ field must be null, hence:

$$\nabla \cdot \vec{\gamma} = 0 \tag{1}$$

This first equation implies that the distribution of discontinuities across the AS is constrained and not completely free; in practice, this equation serves to derive the lateral component of the velocity discontinuities while the component of the velocity jump along the aerodynamic lifting section is prescribed via knowledge of circulation from blade-element analysis (see section below).

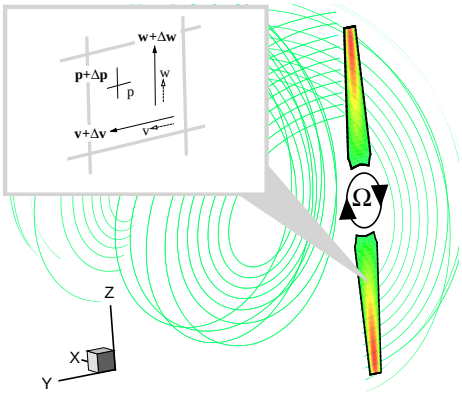

Figure 1. The actuator surface used to model wind turbine blade aerodynamics

A second consequence of the AS is to be analyzed dynamically. Indeed, a particle that crosses the AS undergoes step changes in velocities which must be related to an attached system of forces responsible for changing the particle's momentum. If the (*X*,*Y*,*Z*) system of Figure 1 is set to rotate at the same velocity as the AS modeling the wind turbine blades, it can be shown [3] that the force $\vec{f}_{AS}$ per unit area of the AS surface is given by:

$$\vec{f}_{AS} = -\rho \vec{V}_{rel,avg} \times \vec{\gamma} \tag{2}$$

where $\vec{V}_{rel,avg} = \left(\vec{V} + \Delta\vec{V}/2\right) - \vec{V}_{AS}$ is the average flow velocity relative to the AS and $\vec{V}_{AS}$ is the velocity of the AS at the point where $\vec{f}_{AS}$ is evaluated.

Velocity and pressure discontinuities, together with the associated system of forces (which is the force exerted by the AS on the flow per unit area of the AS), fully represent the action of the AS on the flow governed by the Navier-Stokes equations in the general form, or the Euler equations in this particular case. The determination of the AS loading starts with local blade-element analysis and calculation of the circulation around sections of the AS. In the next section, these steps are presented.

Determination of the AS loading

In this work, blade element analysis is used to determine the values of circulation along the airfoil sections of a wind turbine blade or a wing. The relative velocity seen by the blade, $\vec{V}_{rel}$, is evaluated from the flow solution calculated by the proposed numerical method, which solves the problem raised by the actuator surface whose loading depends on $\vec{V}_{rel}$ as well. This interdependence between actuator surface loading and flow velocities at the actuator surface results in an iterative process that takes place during the solution process.

In the case of the finite wing and the two-bladed turbine, relative velocities, as well as the angles of attack along the blade, are evaluated at the AS surface. In the case of the three-bladed turbine, where grid lines are not aligned with the blades (see below), flowfield characteristics are first determined on control points located 0.8 times the blade chord upstream of each blade. A correspondence between a point on an upstream line and a point on the blade is made through the distance from the root of the blade, measured in both cases on a line going perpendicularly towards the root. The relative velocity on a point *P* of an upstream line, $\vec{V}_{rel,\mathrm{P}}$, is found by an interpolation using the velocities calculated at the four closest grid points. This relative velocity, together with the pitch angle of the blade, and the local twist angle at a given distance from the root of the blade, is used to calculate an inflow angle at the position *P*, which is defined as the angle between the orientation of the local chordline of the blade and the relative velocity $\vec{V}_{rel,\mathrm{P}}$. The transition from an inflow angle at an upstream location to the angle of attack on a blade is made using the following transfer function, developed by NREL [5]:

$$\alpha = -5.427 \times 10^{-5} \alpha_m^3 + 6.713 \times 10^{-3} \alpha_m^2 + 0.617\ \alpha_m - 0.8293$$

With α the angle of attack, and α_m the inflow angle.

Using the definition of the lift coefficient and the Kutta-Joukowsky law, the circulation Γ can be written as [3]:

$$\Gamma = \frac{1}{2} c \left\| \vec{V}_{rel} \right\| C_l \tag{3}$$

Special care is needed in assuring a reasonable circulation distribution using blade elements as mentioned above in terms of numerical stability and physical accuracy. The simple use of blade elements as described above will not always guarantee a zero circulation at the blades tip and root, as expected in reality. Therefore, a zero circulation is imposed at the tip and root of the blades. Moreover, a radial distribution leading to too steep gradients might lead to too important velocity jumps that might prevent the calculation from converging. For example, the use of an elliptical distribution which leads to infinite circulation gradients at the tip and root of a blad or wing cannot be modelled in our method. For this reason, following the idea of Sant [6], an option is included that allows the circulation values at a chosen number of radial positions to be linked by cubic splines, leading to smoother variations of circulation along the blade. These two features were not implemented for the finite wing, where a smooth circulation distribution naturally fell to zero at the root and tip of the wing.

Distribution of discontinuities on planar actuator surface

Once the circulation Γ around a section of a planar AS is known, the task consists in distributing this circulation along the section in the most appropriate way, provided that $\int_0^c \Delta v dy = \Gamma$. In this work, a simple parabolic distribution is assumed to specify the Δv distribution along the chord. For the finite wing and the two-bladed rotor that are aligned with the grid lines (see below), the distribution of the lateral velocity discontinuity Δw can be deduced analytically from equation (1) and the boundary condition $\Delta w=0$ at $y=0$ [3]. For the three-bladed rotor, where the blades are not aligned with grid lines, the distribution of Δw is to be found from solving equation (1) numerically. This is done by integrating equation (1) on the surface S of each quadrilateral cell forming the rotor plane, which contains the actuator surfaces. Here, Green's theorem is used to transform this surface integral into a line integral along the cell contour C:

$$\iint_S \left(\frac{\partial \Delta w}{\partial y} - \frac{\partial \Delta v}{\partial z} \right) dydz = \oint \left(\Delta v dy + \Delta w dz \right) = 0 \tag{4}$$

Performing this line integral around each quadrilateral cell in the rotor plane will lead to a system of linear equations that is to be solved for Δw using the known Δv distribution, and imposing $\Delta w=0$ everywhere outside a given blade as a boundary condition. An explicit scheme is used in space to determine which values of Δv and Δw are to be used in calculating the integrals at the frontiers of each quadrangle, where upstream values at a given grid point are to act on the frontier downstream from this point.

The picture of the AS as a model for wind turbine aerodynamics is now complete. The reader is referred to [2, 3] for information about how to embed the AS model into a CFD method to solve for the flow around the AS, specifically the 3D Control-Volume Finite-Element Method (CVFEM) of Saabas & Baliga [7]. It is to be noted that in the following applications of the AS method, the system of reference is chosen fixed relative to the AS, hence the CVFEMs are used to solve for a steady flow.

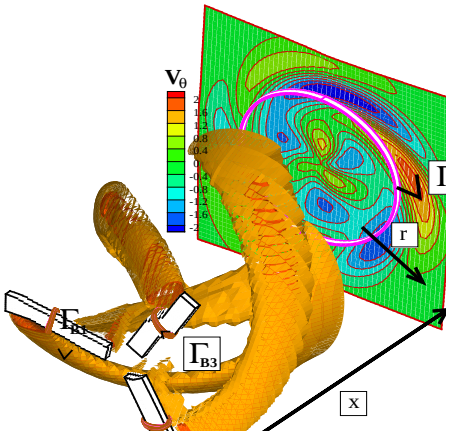

Figure 2. Illustration of the method used to calculate the vorticity in the wake of the turbine Γ_W

VORTICITY CONSERVATION ISSUES

The vortex system associated with a wind turbine rotor consists in bound vorticity that is attached to the blades, as well as trailing vortices forming the wake behind the rotor. This vorticity system originates at the blade from viscous forces affecting the flow close to its surface, in the boundary layer. The bound vorticity is modelled by the actuator surface itself in the AS method, which makes it in this sense similar to a vortex wake method. However, the trailing vortices are not represented as such in the wake of the turbine by this method as they are in a vortex wake method, but are rather intrinsically modelled by the CFD method. Helmholtz's third law for inviscid flows states that vortex filaments cannot end inside a fluid and must have the same strength throughout their lengths, imposing therefore vorticity conservation. This law applies to the studied case of blades or wings where viscous effects are approximated to be confined to the boundary layer and viscous forces are negligible elsewhere. In order for the AS method to be consistent, it must obey this law and predict vorticity conservation from its formation at the blade throughout its evolution in the wake of the blade. A method illustrated in Figure 2 was developed to verify if it is the case or not. It makes use of Green's theorem stating that the flux of vorticity through a circular surface as the one shown in the plane at the right of the figure is equal to the line integral of the tangential velocity around the perimeter of this surface. This line integral can therefore be used to find the circulation in the wake Γ_w at the axial position x of the circular plane relative to the plane of the rotor. If vorticity is conserved, and no wake expansion is present, the vorticity entering a circular plane of radius r should consist in three root vortices (for a three-bladed wind turbine), plus any change in the bound vorticity on the blades as one moves along the blades up to the position r, that would result in trailing vorticity leaving the blades into the wake. This is specifically equal to the addition of the bound vortices on the three blades Γ_{B1}, Γ_{B2} and Γ_{B3}, that can be calculated by performing contour line integrals around the blades as indicated in the figure. This method then makes it possible to track down vorticity evolution and verify if it fulfills Helmholtz's third law, keeping however in mind that wake expansion does occur, so that in reality one can only write $\Gamma_w \approx \Gamma_{B1} + \Gamma_{B2} + \Gamma_{B3}$.

RESULTS

Finite wing in translation

As a first verification, we study the distribution of vorticity in the wake of a finite wing. The actuator surface used to model the finite wing is a flat tapered plate parallel to the incoming flow. Four wing geometries are studied, all having identical span b of 10m and aspect ratio of 10, but different tip to root ratio (1.0; 0.8; 0.6; 0.4). The reader is referred to [2] for information and calculation parameters regarding the grid used to solve this problem. Let us only mention here that

grid lines follow the sides of the wing, and nodes are placed on the mid-chord of the wing to compute the induced angle α_i. The lift coefficient is then calculated using the thin airfoil relation $C_L = 2\pi(\beta - \alpha_i)$ where β is the wing pitch angle (here fixed to 5 degrees). Figure 3 shows the wake circulation Γ_W calculated at three downstream axial positions in the wake (2m, 10m and 100m) using the following equation :

$$\Gamma_W(x,y) = -\int_{-\infty}^{+\infty} w(x,y,z)dz \tag{5}$$

Where w is the component of the velocity measured along the z axis that is perpendicular to the AS (x is streamwise and y is spanwise, y=0 delimiting the middle of the wing). The results shown were obtained using the second order convection scheme available in the present numerical model [3]. Using the same reasoning than the one presented in the section above, we expect more or less that Γ_W be equal to the bound vorticity at the same spanwise location. This is indeed verified in Figure 3 where it is visible that in the near wake, distribution of wake closely matches the bound vorticity distribution, whereas further downstream the distributions are smeared out, due to numerical and viscous diffusion. However, the circulation is not found to reach zero for spanwise positions $y>b/2$, as it should. We believe that this undesired behavior is due to the choice of boundary conditions on the side of the calculation domain where velocities are imposed to be equal to the incoming velocity U_∞, which prevent the perturbations induced by the wing vortices system to be represented on the domain sides.

Wind turbines

The reader is referred to [3] for information regarding the discretization and grid parameters used to model the two-bladed TUDelft experimentatal rotor. Figure 4 shows the calculated Γ_W compared with the blade bound vorticity for this 0.6m-radius rotor at a tip-speed ratio of 8. The first order convection scheme available in the present numerical model [3] was used here. Results are also

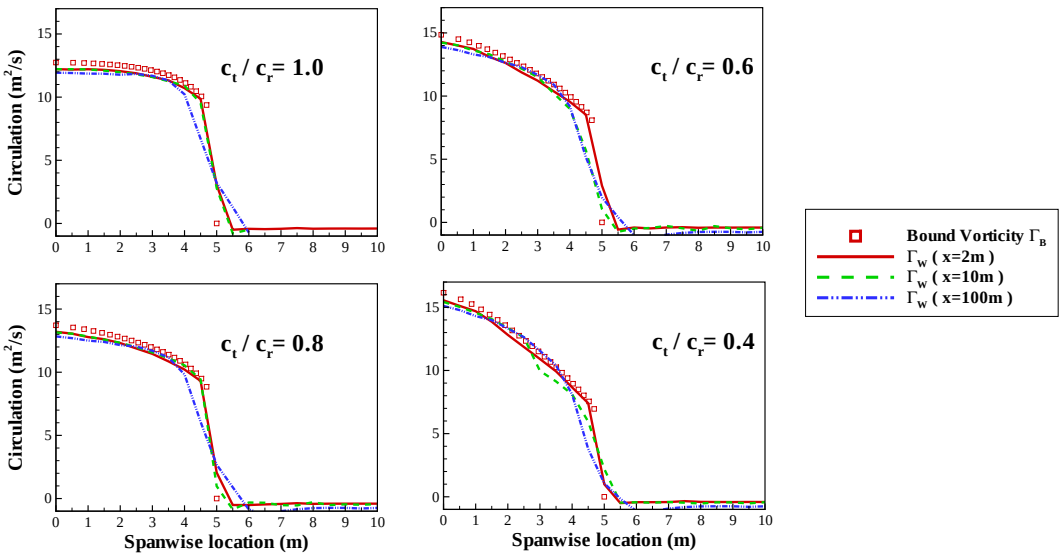

Figure 3. Results for the finite wing in translation

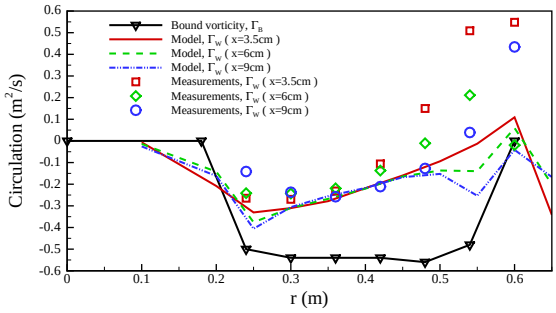

Figure 4. Results for the TUDelft experimental rotor

compared with experimental wake circulation values. The latter are obtained at three different downstream locations in the wake (d=3.5cm, 6cm and 9cm) by integrating around circular contours (as discussed in the section concerning vorticity conservation above) the tangential velocities measured using hot-wire anemometry, as described in [6]. It is observed that neither the simulation results nor the experimental results show satisfactory agreement between the circulations calculated in the wake and around the blades. It is however remarkable that numerical and experimental wake circulations agree well except at the wake outer boundary ($0.5 < r < 0.6$). Although we have not investigated this case in more details, we believe that this is essentially due to turbulent and viscous diffusion occurring in the wake of this rapidly rotating wind turbine (700rpm).

101x101x101 points are used to discretize the 3D grid around the three-bladed 10-m diameter (D) NREL rotor, with local refinement in the rotor plane. The rotor is represented by three rectangular ASs, each containing 110 nodes, and located in a 2D plane of dimension 4D x 4D oriented normally to the incoming flow. The 3D grid is obtained by extending this 2D plane 20D upwind and 1D downwind from the rotor plane. Figure 5 shows the circulation in the wake Γ_W compared with the blade bound vorticity for a tip speed ratio of 6. Results are shown for both the first and second order convection schemes available in the present numerical model [3]. The use of the second order convection scheme is seen to result in an improvement of the agreement between the bound circulation and the circulation in the wake. In previous studies, the second order convection scheme was also found to lead to more accurate results [3]. The shapes of the curves agree quite well, although a small difference in circulation amplitude is observed. The circulation at a radial position larger than the blade radius tends towards zero, which is expected. One has to note however that it should not reach 0 at a distance exactly equal to the radius of the blade due to wake expansion. The first order curves show that little dissipation is seen to occur as one moves further into the wake, but it is not possible at this moment to affirm if it consists in numerical or physical diffusion.

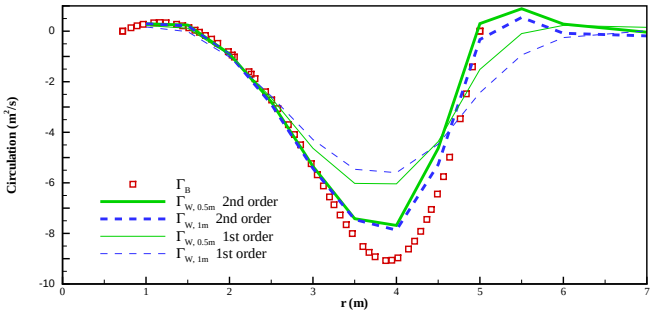

Figure 5. Results for the NREL experimental rotor Γ_W

CONCLUSION

The results obtained for the three-bladed rotating turbine and the finite wing in translation suggest that the AS method is able to correctly model and preserve vorticity in the wake, despite the fact that is does not explicitely model vortices in the wake, but leaves it in the hands of the CFD model. However, problems were obtained for the rapidly rotating TUDelft rotor concerning both the simulations and experimental results, and were expected to possibly be due to turbulent and viscous diffusion. Work will soon be performed to model the Mexico 4.5m diameter wind turbine recently tested in Europe's largest wind turbine, where velocities in the wake are measured using PIV, and should help in clearing that out. The nature of the diffusion that was observed in the wake still remains to be studied further in detail, as it was not possible at this time to determine it if consisted in numerical or physical diffusion. This is an important point that needs to be investigated to guarantee that the model is pertinent to study wind turbine wake aerodynamics.

ACKNOWLEGMENTS

We would like to thank TUDelft for providing access to their experimental data. This study received support from the Canada Research Chairs Program. S.-P. Breton would like to thank the Fonds Québécois de la recherche sur la nature et les technologies for financial assistance in the form of a post-doctoral scholarship.

STUDY ON THE HEAT TRANSFER CHARACTERISTICS IN THE LOWER SPLASH REGION OF CIRCULATING FLUIDIZED BED RISER

R.S. Patil[1], M. Pandey[1], P. Mahanta[1,*]
[1]Indian Institute of Technology, Guwahati, India

ABSTRACT. This paper presents the results of experimental studies on the wall to bed heat transfer behaviour in the lower splash region of a Cold Circulating Fluidized Bed (CCFB) riser of uniform cross sectional area (0.15 m × 0.15 m). Experiments were carried out with different superficial velocities of air (4.8 – 6.4 m/s) with a constant heat flux of 1600 W/m^2. Further, experiments were repeated with two different sand inventories of 10 kg and 16 kg with mean particle size of 271 μm. Heat transfer coefficient was evaluated along the riser height. Temperature distributions across the riser bed were also estimated at two locations along the riser height, i.e., 0.8 m and 1 m respectively. Trends obtained have been compared for different superficial velocities of air and sand inventories.

Keywords: *Circulating fluidized bed, heat transfer coefficient, bed temperature, riser*

INTRODUCTION

Use of circulating fluidized bed (CFB) boilers in power generation is gaining popularity because of its environmental compatibility and high efficiency. To increase the capacity of boiler, it is essential to increase the cross section of CFB boiler along with its height. However it is desirable to restrict the height of the furnace to about forty meters due to commercial constraints [1]. In such a case, additional heat transfer surface area is to be provided to complement the furnace wall area in order to accomplish the required heat absorption for the production of superheated steam. This is sought to be accomplished in practice by providing: (i) an External Heat Exchanger (EHE) at the bottom of the cyclone dipleg before recirculation of solids and/or (ii) in-furnace heat exchangers suspended in the core space of upper dilute zone of the riser in the form of wing walls, omega panels, and a division or a curtain wall. Knowledge of the heat transfer behaviour in different extraction methods is essential for a proper design and operation of a CFB boiler. Heat transfer characteristics at an axial tube located along the axis of the CFB riser were reported by Kolar and Sundaresan [1]. They have reported that heat transfer coefficient decreases with increase in superficial velocity and increases with increase in solid circulation rate.

Axial distributions of local heat transfer coefficient along the riser height in the upper dilute region of the riser were reported by Kolar [2], Basu [3], Zeng et al. [4], Bi et al. [5] and Ahn and Han [6].

Large-scale fluidized beds for commercial processes commonly require lager heat transfer surfaces. Design then demands that proper heat transfer coefficients be specified. Empirical correlations are unable to cover the wide range of variables and conditions encountered. Therefore, the mechanistic

E-mail address: pinak@iitg.ernet.in

model that incorporates the key factors influencing heat transfer to predict the heat transfer coefficient has been reported by Chen et al. [7].

From the literature review it is found that most of the heat transfer works on CFB were reported for the upper splash region of the riser. There will be erosion of the lower splash region during operation of CFB boiler, as lower splash region is having dense hot stream of coal, limestone and sand etc. For designing the entire CFB, the study on lower splash region is equally important and emphasis has been given in the present paper to find variation of heat transfer coefficient along the height of the heater and bed (air + solid mixture flow) temperature distribution across the heater. This will help in designing more efficient CFB boiler.

EXPERIMENTAL SETUP

The setup of CFB, designed and developed at IIT Guwahati, is shown in Figure 1. It consists of uniform cross sectional area (0.15 m × 0.15 m) made of plexiglass (to facilitate flow visualization). A positive displacement type blower powered by a 20 HP motor supplies air. Figure 1 indicates: 1.Motor, 2.Blower, 3.Bypass valve, 4.Main control valve, 5.Water manometer, 6.Orifice plate, 7.Riser column, 8.Cyclone separator, 9.Downcomer, 10.Sand measuring section, 11.Butterfly valve, 12.Distributor plate, 13.Aeration valve, 14.Insulated heater, and 15.Pressure tapings. Heater (shown in Figure 2) has 1.Nichrome wire, 2.Mica, 3.Mica, 4.Wall temperature thermocouple, 5.Asbestos sheet, 6.Ceramics wool, 7.MS wall, 8.Bed temperature thermocouples to measure the temperature at the along the height of the heater, and 9. Thermocouples used to measure the bed temperature across the heater at the sections taken 0.8 m and 1 m above the distributor plate perpendicular to the height of the heater.

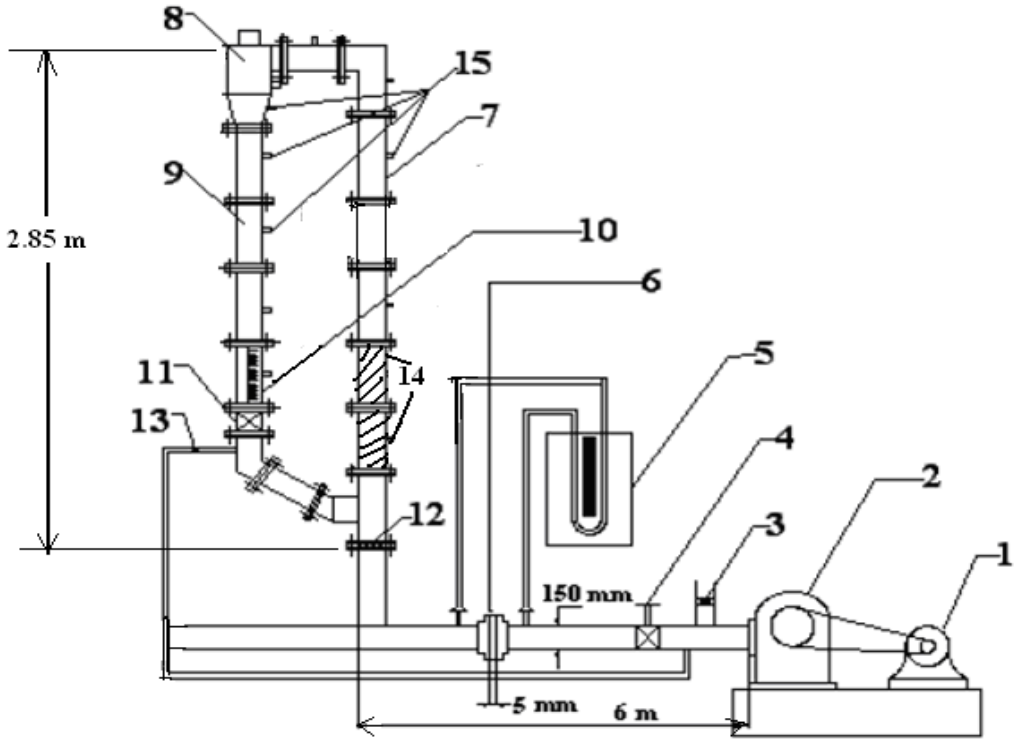

Figure 1. Experimental setup of Cold Circulating Fluidized Bed

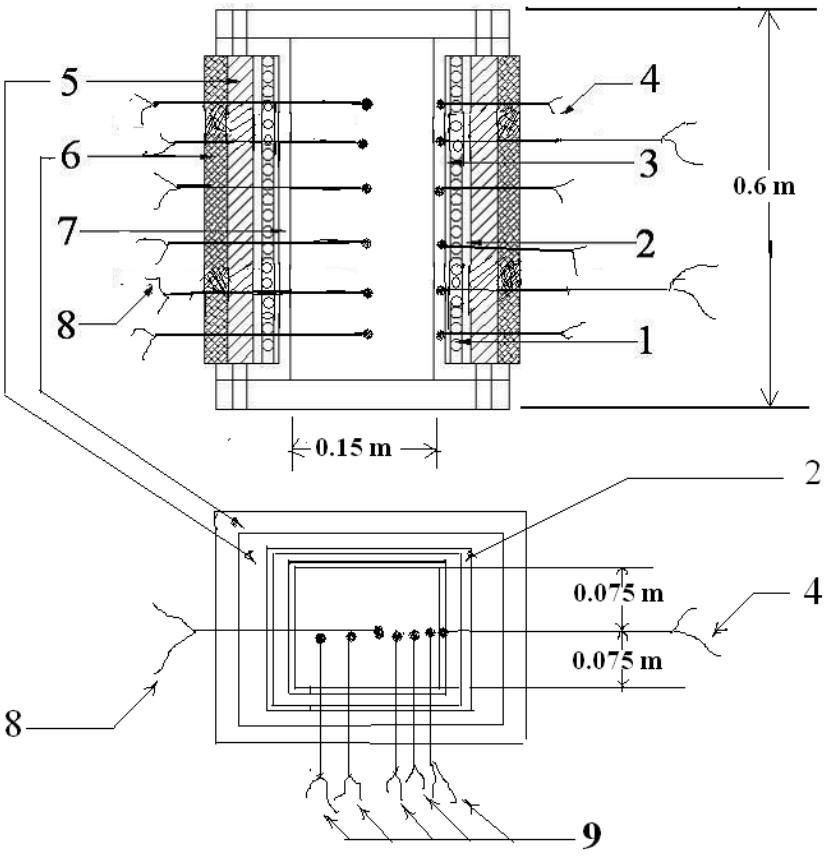

Figure 2. Heater

The main function of the heater (Figure 2) is to supply the heat flux externally for carrying out heat transfer studies. The heater has been fabricated from MS sheet of 2 mm thickness. Height of the heater was of 0.6 m and has been located 0.6 m above the distributor plate. Electric supply has been provided to the Nichrome wire of 2000 W capacity, wound on the mica sheet of 1.5 mm thickness which covers the MS wall of the heater. Another mica sheet, which acts as electric insulator, has been provided on the Nichrome wire. To avoid the heat losses by radiation, ceramic wool and 6 mm thick asbestos sheet has been provided on the mica sheet. Heat has been supplied to the wall of MS heater therefore wall to bed (solid + air mixture) heat transfer would occur at the heater. To measure the temperature of the surface of the heater and the bed temperature, calibrated T type thermocouples have been installed on the wall and inside the heater. The heat flux input to the heater wall has been controlled with the help of a variac.

Six thermocouples each have been used to measure the axial bed temperature and surface temperature of the riser column. These thermocouples have been placed at an equal distance of 0.85 m. Two cross sections have been taken in the heater at 0.8 m and 1 m above the distributor. Six thermocouples have been placed in each cross section to measure the non axial bed temperatures at non-dimensional distance of 0.3, 0.43, 0.5, 0.73, 0.83 and 0.9. Here the non-dimensional distance is the distance X (in m) measured from the left hand side wall of the heater to the thermocouple end, normalized with respect to the width B (0.15 m) of the heater.

HEAT TRANSFER STUDY

The heat transfer coefficient (h) [8] is calculated by

$$h = Q / A_S . (T_S - T_B) \quad W.m^{-2}.K^{-1} \qquad (1)$$

where T_B and T_S represent the bed and wall temperature, respectively, A_S is the surface area of the heater and Q is the heat supplied (in W) at heater, measured using a Wattmeter. T type calibrated thermocouples and data acquisition system with Dasy Lab software version 8.0 has been used to measure the T_S and T_B.

Experiments have been carried out at different superficial air velocities of 4.8 m/s, 5.4 m/s and 6.4 m/s, at the constant heat flux of 1600 W/m^2, for two different sand inventories of 10 kg and 16 kg having average particle size of 271 μm.

Following sections represent the results and discussions on bed temperature distribution and variation of heat transfer coefficient along the axis (height) of the heater.

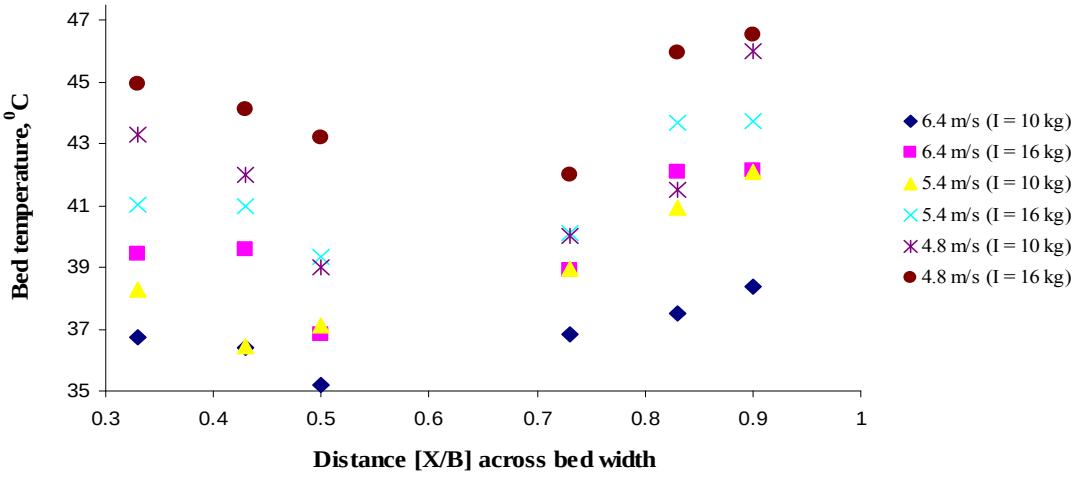

Figure 3. Bed temperature distribution at 0.8 m above the distributor plate

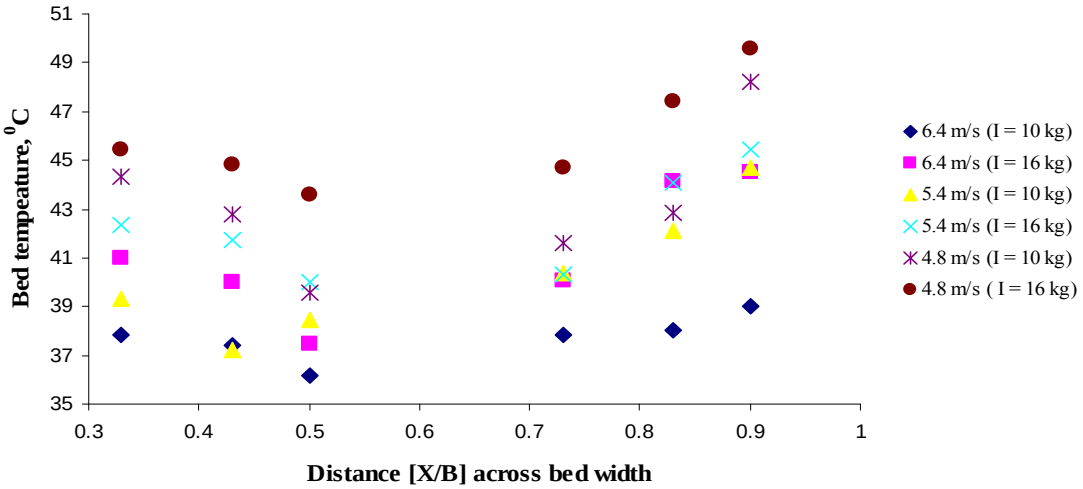

Figure 4. Bed temperature distribution at 1 m above the distributor plate

BED TEMPERATURE DISTRIBUTION ACROSS THE HEATER

Figure 3 and 4 indicates the bed temperature distribution for two cross sections taken at 0.8 m and 1 m above the distributor plate respectively. Bed temperature distribution have been compared for different fluidizing air velocities at two different sand inventories, I = 10 kg and I = 16 kg.

When superficial air velocity increases, bed temperature decreases and it was maximum near the both the heated walls of heater while less at the centre of heater. It has been observed that, for the same fluidizing velocity bed temperature increases with increase in inventory of sand.

It has been observed that corresponding bed temperatures were more at bed cross section taken at 1 m height above the distributor plate than respective bed temperatures measured at cross section taken at 0.8 m height above the distributor plate.

Bed temperature at right hand side wall was more than bed temperature at left hand side wall because of more particle concentration at right hand side wall due to incoming particles from dipleg, which were forced upward towards the right hand side wall in the riser by central high speed air flow coming from distributor plate. Thus particle concentration is important phenomena in bed temperature distribution.

HEAT TRANSFER COEFFICIENT DISTRIBUTION

Figure 5 indicates the axial distribution of heat transfer coefficient along the height of the heater. Heat transfer coefficient have been compared for different superficial air velocities at different sand inventories such as I = 10 kg and I = 16 kg.

It has been observed that, heat transfer coefficient increases with decrease in superficial velocity of air measured at the same sand inventory. It was observed that heat transfer coefficient measured at same superficial velocity of air but at different sand inventories decreases with decrease in sand inventory

At constant heat flux, the value of heat transfer coefficient decreases along the height of heater in the upward direction because of increase in temperature difference of wall and bed (T_S - T_B).

It has been observed that the heat transfer coefficient decreases rapidly in bottom dense zone as shown in Figure 5. It can be concluded that heat transfer coefficient decreases rapidly when the amount of sand particles in the mixture flow of air + sand decreases considerably. It means that sand particles had major role in carrying heat from wall of the heater.

CONCLUSIONS

Experiments based on the wall to bed heat transfer have been completed along the heater placed in the riser of the CFB. Bed temperature distributions across the heater have been obtained at two different sections, 0.8 m and 1 m above the distributor plate. Bed temperature decreases with increase in the superficial velocity of air and decrease in the sand inventory. Bed temperature at right hand side wall was more than bed temperature at left hand side wall because of more particle concentration at right hand side wall. Therefore particle concentration is important phenomena in bed temperature distribution.

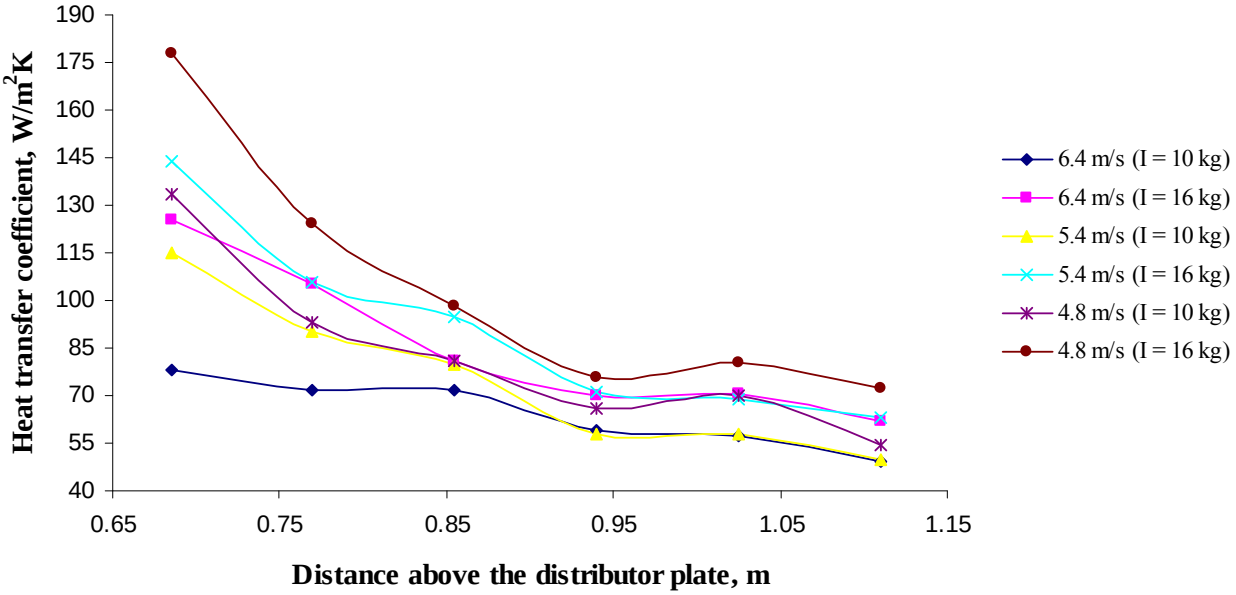

Figure 5. Axial distribution of the heat transfer coefficient along the height of the heater

Heat transfer coefficient has been estimated along the height of the heater. Heat transfer coefficient increases with decrease in the superficial velocity of air and increase in the sand inventory. It has been observed that the heat transfer coefficient decreases rapidly in the bottom dense portion of the riser. It can be concluded that heat transfer coefficient decreases rapidly when the amount of sand particles in the mixture (air + sand) flow decreases considerably. It means that sand particles had major role in carrying heat from wall of the heater. Thus study on estimation of the bed temperature and heat transfer coefficient in the lower portion of riser, which is comparatively hotter and denser region of solid particles, will be useful in designing more efficient CFB boiler.

ACKNOWLEDGEMENT

The experimental facility used in the present work was setup with financial support from the Ministry of HRD, Govt. of India.

PERFORMANCE EVALUATION OF DIRECT STEAM GENERATION TROUGH SOLAR ENERGY GENERATION SYSTEM IN 30 CITIES OF CHINA

D.H. Mei, Y.L.He*, Y.B. Tao, W.Q. Tao
School of Energy and Power Engineering, Xi'an Jiaotong University, Xi'an, China

ABSTRACT. In this paper, the integrative theory-model-simulation (TMS) study is performed to investigate the performance of the saturated steam turbine cycle direct steam generation (DSG) trough solar energy generation system (SEGS). Based on the solar radiation data in 30 provincial capital cities in China, the running of the whole system is simulated and the yearly performance is calculated, and the effects of day-and-night, seasons, years and latitude on the performances are analyzed. At last, the SEGS is combined with the conventional energy system, and the influence of different conventional energy on the SEGS cost is discussed. All the results obtained by the evaluation carried out in this paper may be useful in the initial stage when an SEGS is being constructed in China.

Keywords: *solar energy generation system, system simulation, direct steam generation, direct solar radiation*

INTRODUCTION

Nowadays too high construction cost is one of the main factors that restrict the commercialization of solar thermal to electric energy conversion system(STEECS), or simply, solar energy generation system (SEGS). It is a promising method to reduce the construction cost by utilizing the technology of direct steam generation (DSG) in SEGS. In 2003, DSG was proven feasible in the horizontal trough collector in the Direct Solar Stem (DISS) of Spain[1]. Many researchers have conducted various studies on SEGS to improve its efficiency. Eck , Schmidt and Eickhoff, et al [2] studied the performance of compact gas-liquid separator on steady-state cases, and the result showed that the suitable value of steam quality in the inlet of the compact gas-liquid separator is 0.7-0.8. To the flow conditions inside the absorber tube, Eck and Steinmann [3] simulated and designed the DSG collector field based on the flow stratification of hot fluid and stability of absorber tube. Natan, Barnea and Taitel [4] investigated the variation of working fluid flow conditions inside the tube with that of direct solar radiation on different working fluid mass flow. Their results indicated that water tends to flow in the tube which gains less solar radiation. Eck, Steinmann and Rheinlander [5] also researched the difference between the performances of tilted and horizontal absorber tubes. It is found that horizontal absorber tube has better performance because of its smaller temperature gradient when the steam quality is not so small. And to the flow conditions of the working fluid in the collector field, Eck, Zarza and Eickhoff et al [1] concluded that recirculation method is the best one among the once-through, injection and recirculation methods. On the other hand, automatic-control mode is one of the key technologies in the DSG trough SEGS. Valenzuela, Zarza and Berenguel et al [6] analyzed the controlling mode when different flow method was used. All such research results are benefit to the improvement the efficiency of SEGS in some extent. Obviously

when a new SFGS is to be constructed, the site selection is an important factor to be taken into account. In the existing solar energy references very few systematically discussed this factor. In this paper, the 30 provincial capital cities in China are taken into account, a model of saturated steam turbine cycle DSG trough SEGS is built, the variation trend of the total efficiency of the system with the change of day, night, seasons, years and latitude is analysed by using the meteorological data from different places during different times. In order to overcome the drawback of instability and discontinuity of solar radiation, different conventional fuel systems are combined into the SEGS. And the influences of them on the economy of the system are also investigated.

TREATMENT OF METEOROLOGICAL DATA PROVIDED BY WEATHER STATION

In order to provide fundamental data for the simulation of the whole system performance, we collected the meteorological data from the weather station of 30 provincial capital cities in China. Self-compiling programs were established to treat the global and diffuse solar radiation for the hourly, daily, monthly and yearly solar radiation. From the treated meteorological data, it can be seen:

1. Solar radiation is zero in almost half of the year in these regions because of the influence of day and night. The ratio of effective direct solar radiation time T_u to the global solar radiation time T_t, which is expressed as ξ, is more than 50% in only a few regions (Table 1). These regions are Lhasa, Hohhot, Kunming, Lanzhou, Taiyuan, Shenyang, Shijiazhuang, Beijing and Changsha. According to Eck and Steinmann research results [3], there is no usage value when the direct solar radiation is less than 250 $\mathrm{W\cdot m^{-2}}$. This limitation is called as Two-hundred and Fifty Principle in this paper. The symbol T_u shown above is the time when the direct solar radiation is large than 250 $\mathrm{W\cdot m^{-2}}$, while T_t is the time when the direct solar radiation is not zero.

Table 1

2. The yearly direct solar radiation of these 30 regions is shown in Figure 1. The digits of 1~30 on the abscissa represent these 30 regions respectively with the latitude ordered from small to large. It can be seen that there is no direct relationship between the yearly direct solar radiation and the latitude. If the yearly direct solar radiation is regarded as the basis on which to choose the place for construction of a the SEGS, Lhasa, Hohhot, Kunming, Lanzhou, Taiyuan, Changsha, Shenyang, Shijiazhuang, Urumchi,

Beijing and Hefei can be considered, as the yearly direct solar radiation in these places is larger than $1.0\times10^{6}\ \mathrm{W\cdot m^{-2}}$.

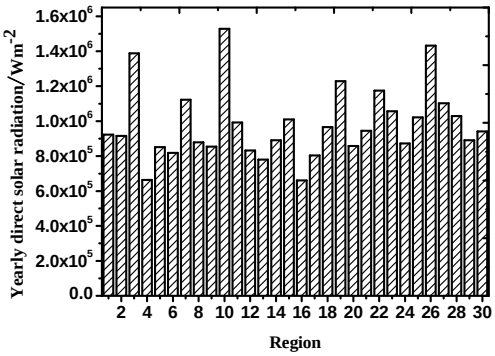

Figure. 1 Yearly direct solar radiation of the 30 regions

CONCEPTUAL COMPONENTS DESIGNOF THE SATURATED STEAM TURBINE CYCLE DSG TROUGH SEGS

In general, SEGS contains 6 parts: solar thermal collect subsystem, energy absorb and delivery subsystem, energy storage subsystem, steam generation subsystem, motive subsystem and power generation subsystem, and solar thermal collect subsystem and motive subsystem are the most important components. In this paper, these two components are designed to form the saturated steam turbine cycle DSG trough SEGS with other components.

Design of the DSG collector field

As mentioned above the feasibility of DSG has been proven in DISS project. In this paper, the collectors in the DISS project are used, and the parameters of these collectors [7] are shown in Table 2. Each collector was made up of eight thermal-absorbing units, and eight collectors were in series connection in the south-north direction. In order to make full use of the solar radiation, double-axis tracking system was selected to make sure that solar radiation beam is on the opening plane of the collector. According to Eck and Zarza's paper [8], there were nine collector-rows in the saturated steam turbine cycle, and the last collector in each row was connected to a header pipe; then the header pipes were connected to a vapor liquid separator, and the steam quality in whose inlet was 0.85. The saturated water from the vapor liquid separator was fed into the inlet of the collector field via pump and the saturated steam went to saturated steam turbine directly to work by expansion. Considering both the construction cost and steam quality, this paper takes the steam quality in the inlet of the vapor liquid separator being close to 0.85.

Table 2
Specification and performance parameter of the collector in DISS project

Item	Parameter
Total length of a collector: L /m	98.5
Opening width of a collector: W /m	5.76
Opening area of a collector: A_t /m^2	548.35
No. of thermal absorbing unit in a collector: N	8
Outer diameter of the absorber tube: D_o /m	0.07
Inner diameter of the absorber tube: D_i /m	0.055
Length of thermal absorbing unit: l /m	12.27
Optical efficiency of the collector: POE	0.765

The assumptions in the simplified model of the absorb tube are:

1. The glass casing is not considered, and the ceramal selective absorbing film is sticked to the outer surface of the absorber tube. The emissivity ε_{ab} of the film is given by equation (1) [9],

$$\varepsilon_{ab} = 0.00042 \times T_w - 0.0995 \tag{1}$$

In equation (1), T_w is the temperature on the outer surface of the tube, K.

2. The pipe wall thickness is neglected, and the mean value of inner and outer diameter is treated as the mean diameter of the tube.
3. Temperature in the cross section of the tube is invariable, and it only changes along the axial direction.
4. Temperature in the inlet of each calculation unit is regarded as the temperature on the surface of the unit.
5. Pressure drop along the whole tube and the thermal loss at the junction between every two tubes are not considered.

Usually in the DSG trough collector field, there are three sections: super-cooled water section, vapor-liquid mixture section and superheated steam section. In the super-cooled water and superheated steam sections, the absorber tube is divided into several calculation units, shown in Figure 2, where L and D are the total length and the diameter of the tube, and q is the density of direct solar radiation on the opening face of the collector. In each unit, T_{in}, T_{out} and Δl are the inlet and outlet temperature, axial length of the unit, respectively.

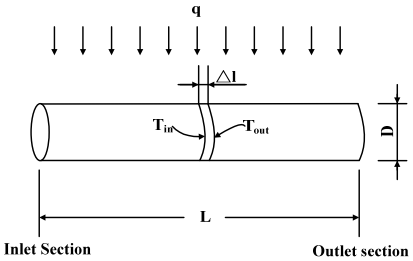

Figure. 2 Calculation diagram of the absorber tube

In these two sections, the temperature in the outlet of each calculation unit and the length of each section are calculated by

$$\Delta l \cdot W \cdot I_{dir} \cdot POE = q_m \left(h_o - h_i\right) + \sigma \varepsilon_{ab} A (T_w^{\,4} - T_e^{\,4}) + hA\left(T_w - T_e\right), \tag{2}$$

where q_m is the mass flow rate of the working fluid(water or steam) in this paper, W and A are the width of the opening face of the collector and the radiating area of each calculation unit respectively, h is the convection heat transfer coefficient between the tube and environment, σ is Stepan- Boltzmann constant, 5.67×10^{-8}. h_o and h_i are respectively the enthalpy of the working fluid in the outlet and inlet of each calculation unit. The water enthalpy can be determined by

$$h = 4348.52053T - 1.19399\times10^6,\ 283\text{K} < T < 553\text{K}, \tag{3}$$

and

$$h = 2482.16519T + 1.47293\times10^6,\ 563\text{K} < T < 1273\text{K}. \tag{4}$$

Equations (3) and (4) are valid only when p is 7 MPa, and they are both obtained by fitting according to the corresponding data between temperature and enthalpy on the water and steam thermodynamic property chart.

In vapor-liquid mixture region, the pressure and temperature of working fluid are invariable when all loss is not considered. So the temperature on the outer surface of the tube in this section is invariable based on the above-mentioned assumption. And the length of this section can be evaluated by

$$l_T \cdot I_{dir} \cdot POE = q_m (h^* - h') + \sigma \varepsilon_{ab} \pi D l_T (T_w^{\,4} - T_e^{\,4}) + h\pi D l_T (T_w - T_e), \tag{5}$$

where l_T is the length of this section, h^* and h' are the enthalpy of saturated steam and water respectively at the calculation point, and other parameters are the same with those in equation (2).

The program flow chart of designing the DSG collector field is shown in Figure 3.

Design of the saturated steam turbine cycle

In this paper, parameters of the SEGS in the design condition are as follows: I_{dir} is 850 $W \cdot m^{-2}$, T_e is 293K, the temperature of the given water T_{in} is 448K, and the efficiency of the generator is 0.96. The performance of the collector field and saturated steam turbine cycle at the design condition is indicated in Table 3.

PERFORMANCE EVALUATION OF THE WHOLE SYSTEM

Performance evaluation of the system without conventional energy system

The motive subsystem designed preliminarily is connected with the DSG collector field and other components, and the performance of the saturated steam turbine cycle DSG trough SEGS, in different time and different regions, is evaluated based on the direct solar radiation in different time and different regions. From the simulation results, the major points are as follows.

1. The system efficiency reaches its peak value at noon, then decreases on both sides, and turn to zero at night as the density of the direct solar radiation is zero. Figure 4 and Figure 5 show the system efficiency of the SEGS and the direct solar radiation in Xi'an in June 22nd, 2002. The shape of these two curves are generally similar except that the efficiency is zero at 6:00 and 18:00 while the direct solar radiation is not zero at that time, just because of the Two-hundred and Fifty Principle.

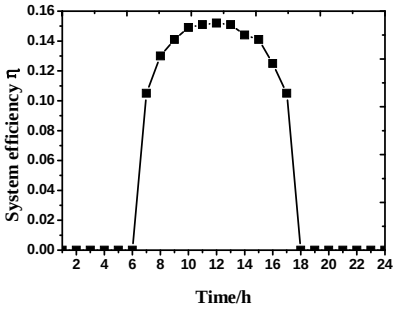

Figure.4 System efficiency of the SEGS in Xi'an in June 22nd, 2002

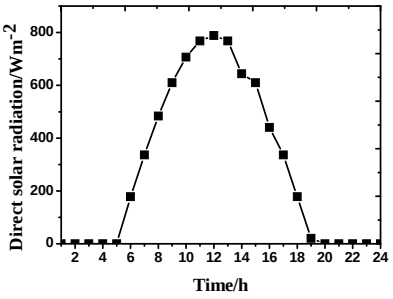

Figure.5 Direct solar radiation in Xi'an in June 22nd, 2002.

2. In accordance with the latitude from low to high in the order, Guangzhou (N23° 00'), Nanchang (N28° 40′), Xi'an (N34° 15'), Beijing (N39° 57') and Harbin(N45° 45') are selected as the places to build the SEGS and the evaluation of the performance is conducted. Figures 6, 7 and 8 indicate the variation of monthly effective working time, net generating capacity and system efficiency of the above five regions.

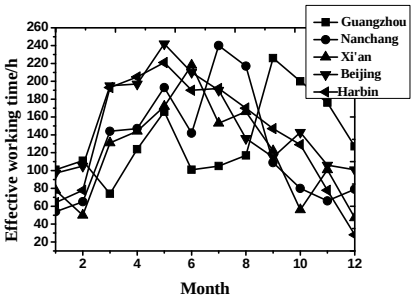

Figure. 6 Effective working time in different latitudes in 2002

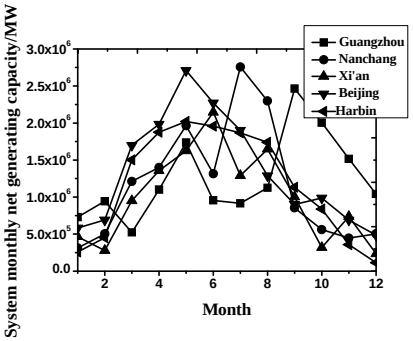

Figure. 7 Monthly net generating capacity in different latitudes in 2002

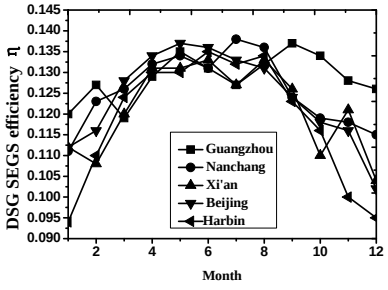

Figure. 8 System efficiency in different latitudes in 2002

It can be seen in Figure 6 that that the effective working time in low latitude regions is shorter than that in high latitude in summer, while opposite in winter. This may be related to the climate characteristics in China. China is in the East Asia monsoon climate zones. Annual rainfall reduces from the southeast coast to the northwest inland. The South not only takes a long rainy season, but also has a rainfall in summer and autumn in some places, while the north and northwest China has less rainfall. On the other hand, there is more snow weather in northern in winter.

From Figure 7 and Figure 8, some similarities between the variations of the monthly net generating capacity and system efficiency with that of latitude are shown. The monthly net generating capacity and system efficiency reduce with the rise of latitude. It can also be concluded that from summer and winter there is no appreciable change in system efficiency among low latitude regions, while there is an obvious change among high latitude regions.

3. The average efficiency of the system in different regions changes little in the year. As seen in Figure 9, average efficiency of the whole system in the 30 regions all keeps between 12.5% and 13.5%, the maximum of which is 13.5% in Lhasa and Changsha and the minimum is 12.5% in Guilin and Changchun. From this it can be seen that the average efficiency of the system can not be the main factor while the building address of the SEGS is being selected.

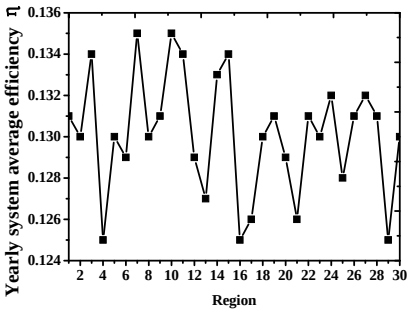

Figure. 9 Yearly system average efficiency of the 30 regions in 2002

Performance evaluation of the system with conventional energy system

It is well-known that the pure SEGS can not operate safely because of instability and discontinuity of solar radiation, leading the operating life of the system to reduce and the maintain cost to increase. In this paper, a conventional energy system is connected with the DSG trough SEGS. When the day and night, seasons and weather conditions change, automatic control device will drive the conventional energy system to work, such that the given water can reach the state requirements of main steam on the inlet of the saturated steam turbine on the designing condition. Hence the system can work steadily.

Diesel, natural gas and coal are selected as the optional conventional energy. The unit price and the combustion value of the three energies are shown in Table 4.

Table 4
Unit price and the combustion value of conventional energy

Conventional energy		Combustion value / $J \cdot kg^{-1}$	Unit price / $Yuan \cdot kg^{-1}$ 、 $Yuan \cdot m^{-3}$	Discount factor of standard coal
Coal	Bituminous coal	2.9×10^7	0.3	0.9285
	Anthracite	3.0×10^7	0.3	0.9855
	Coke	3.4×10^7	0.3	0.9285
Diesel		3.3×10^7	3.4	1.571
Natural gas		7.1×10^7	1.98	1.236

Lhasa is taken as the example, and the amount of the needed conventional energy and the economic cost are calculated. Table 5 indicates the calculation result. From this, it can be seen that when energy amount and economic cost are both considered, coke is a suitable choice when there are abundant coal resources, while natural gas can be selected when coal resources is going to be deficient. On the other hand, diesel is inadvisable as the conventional energy from these two factors. Generally speaking, what conventional energy will be selected depends on the realistic condition of the region where the SEGS is to be built, such as the types of mineral resources in and around the region, transport mode, etc.

Table 5
Amount and economic cost of needed conventional energy in Lhasa 2002

Conventional energy	Bituminous coal	Anthracite	Coke	Diesel	Natural gas
Amount	20033834kg	19366038kg	17087682kg	17605490kg	8182834m^3
Discounted standard coal amount/kg	18601414	19085230	15865913	27658224	10113982
Cost/Yuan	6010151	5809812	5126305	59858668	16202010

CONCLUSIONS

In this paper, the DSG trough SEGS is investigated, and the TMS analysis is conducted to investigate the performance of the saturated steam turbine cycle DSG trough SEGS. The hourly meteorological data of 30 cities in China provided by the weather station are adopted and treated with the self developed program, and the curves of solar radiation value with time and address are obtained. The whole DSG system model is built by the design of the collector field of SEGS and the saturated steam turbine system. Then, the running of the whole system is simulated, the yearly performance is calculated, and the effects of day-and-night, seasons, years and latitude on the performances analyzed according to the solar radiation data. At last, the SEGS is combined with the conventional energy system to discuss the influence of different conventional energy on the SEGS cost.

CHARACTERISTICS OF FLOW FIELD AROUND WALL INJECTION INTERACTING WITH INCIDENT SOCK WAVE IN SUPERSONIC AIRSTREAM

S. Ishida, Y. Sakimitsu, H. Nakamura, Y. Ogami, T. Kudo, H. Kobayashi *
Institute of Fluid Science, Tohoku University, Sendai, Japan

ABSTRACT. Experimental and numerical studies were performed to explore flow interactions between an incident shock wave and the transverse fuel injection from a slot in supersonic airstream, which is expected to occur in a scramjet combustor. Results showed that the characteristic length of the recirculation zone which plays a significant role in flame holding in a scramjet combustor increased as the incident shock wave was introduced downstream of the injection slot, whereas these values approached to a constant value as the incident shockwave was introduced upstream of the injection slot. The variations of the characteristic length with the location of incident shock wave measured based on wall static pressures were in good agreement with the PTV measurement preformed previously. The differences in wall static pressures in combustion and non-combustion cases clearly indicated that the flame was held in the recirculation zone downstream of the injection slot.

Keywords: *supersonic combustion, wall injection, shock wave, reattachment point*

INTRODUCTION

Scramjet is one of the key technologies to develop a hypersonic air-breathing propulsion system. In a scramjet combustor, it is expected that many shock waves are generated and they affect the flow field, especially fuel-air mixing region dramatically. It is, therefore, of importance to investigate the interaction between an incident shock wave and fuel injected flows to develop a controllable supersonic combustor. In our previous studies on supersonic combustion for a wall injection [1], it was found that flame is not held when an incident shock wave was introduced upstream of the fuel injection slot. It was also found that, on the other hand, when the incident shock wave was introduced downstream of the injection slot, flame holding was possible even at low total temperature of the supersonic airstream [1]. Particle Tracking Velocimetry (PTV) was also performed to measure the scale of the recirculation zone downstream of the injection slot to investigate the flame holding mechanism [2].
In the present study, wall static pressures were measured to evaluate the characteristic length of the recirculation zone and compared to the characteristics of the wall-static-pressure profiles obtained by an unsteady numerical simulation. The characteristic length was also compared to that obtained by PTV experiments and the effect of the incident shock wave on the flame holding was discussed.

EXPERIMENTAL SETUP

Experiments were conducted using the supersonic combustion wind tunnel at the Institute of Fluid Science, Tohoku University. This wind tunnel is a blow-down type which releases exhaust gases to atmosphere. A storage heater is equipped to increase total temperature of the airstream. Outlet diameter

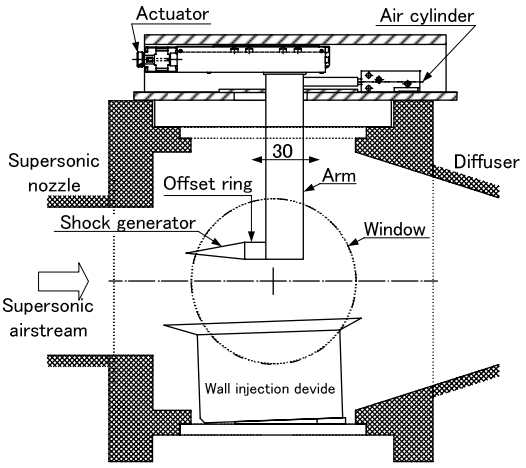

Figure 1. Schematic of the test section.

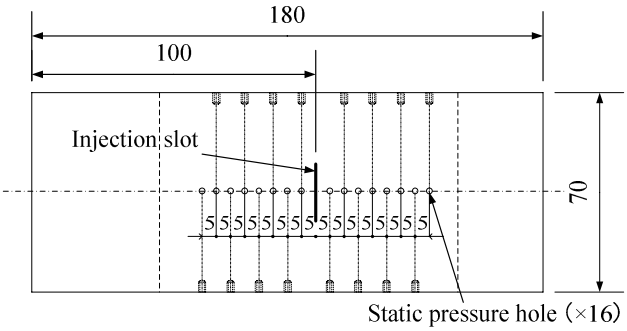

Figure 2. Drawing of the wall injection device.

of a supersonic nozzle exit is 135 mm and the test section is a semi-free-jet type. The Mach number was fixed at 2.5 in the present experiments.

A schematic of the test section is shown in Fig. 1. A wall injection device has a two-dimensional injection slot with a size of 0.5 mm × 20 mm and in total 16 holes to measure the wall static pressure as shown in Fig.2. Eight holes are lined up with 5 mm intervals both upstream and downstream of the injection slot. The diameters of the holes are 1 mm and the each hole is connected to a pressure sensor outside of the test section. A pre-burning chamber is located upstream of the fuel injection slot in the wall injection device for combustion experiments because the static temperature of the supersonic air-stream in this facility is lower than the auto-ignition temperature of hydrogen [1]. The injected gases for combustion experiment contain a large amount of unburned hydrogen at high temperature because the equivalence ratio of the gases supplied to the pre-burning chamber, ϕ, was sufficiently high ($\phi > 4$). In the case of non-combustion experiments, air was injected instead of the pre-burned hydrogen. Gas supplying tubes, pressure port, thermocouple, and electronic spark igniter were connected to the bottom of the pre-burning chamber. The wall injection device was installed into the test section with angle of +2 degrees in the direction of the supersonic airstream to prevent from boundary layer separation at the leading edge of the wall injection devise.

NUMERICAL METHOD

Two-dimensional compressive Reynolds Averaged Navier-Stokes (RANS) equations were used in the present study. These equations were solved using a finite volume method. The AUSM-DV method [3] for the convection terms and the MFGS method [4] for the time integral were used. For a turbulence model, the Wilcox's *k*-ω two-equation model [5] was employed.

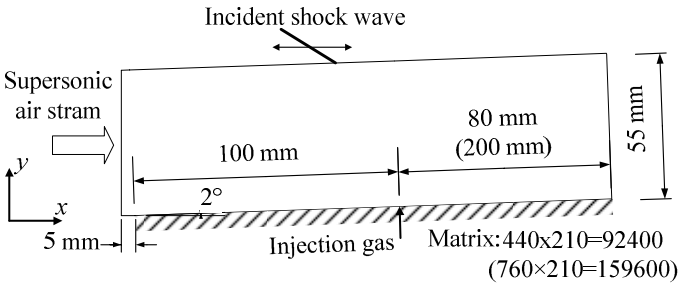

Figure 3. Schematic of the computational domain.

Figure 3 shows a schematic of the computational domain. Total width of wall is 180 mm and height of domain is 55 mm. It has 92,400 grid points in total and minimum grid interval near the wall is 10 μm. The Mach number, the total pressure, and the total temperature of the supersonic airstream were set to 2.5, 0.5 MPa and 673 K, respectively. The Mach number, the total pressure, and the total temperature of injected air conditions for non-combustion simulation were set to 1.0, 1.2 MPa and 300 K, respectively.

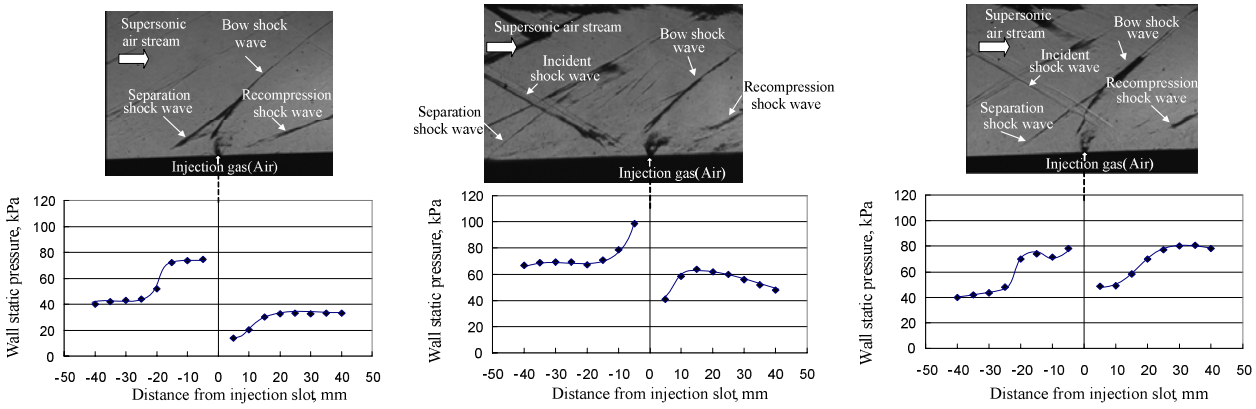
RESULTS AND DISCUSSION

Profiles of wall static pressures

Profiles of the wall static pressures with the distance from injection slot and the Schlieren images are shown in Fig. 4. Wall static pressures presented in the figure are time averaged values. Figure 4 (a), (b) and (c) are in the cases without an incident shock wave, with an incident shock wave introduced 9.2 mm upstream of the injection slot, with an incident shock wave introduced 20.5 mm downstream from the injection slot, respectively. The location of the incident shock wave, x_i, is defined as distance between the injection slot and the reaching point of the extrapolated line of the incident shock wave on the wall.

In the case of Fig. 4 (a), i.e., without incident shock wave, wall static pressures downstream of the injection slot are lower than 20 kPa and keep almost constant value (i.e., 35 kPa) after reattachment of the injected gas flow. This low pressure and low density condition might cause flameholding difficult. Upstream of the injection slot, meanwhile, the wall static pressures increases due to boundary layer separation and, from the point, an oblique shock wave is generated. The boundary layer separation of the airstream generates a recirculation zone between the separation point and the injection slot. The flow velocity inside the recirculation zone is lower than that of airstream.

In the case of Fig. 4 (b), i.e., x_i=-9.2 mm, wall static pressures behind the incident shock wave increases rapidly. Wall static pressures downstream of the shock wave are also higher than the case without incident shock wave (Fig.4 (a)). In this case, the separation point is located upstream of the measurement region, so that the pressure increase near the separation point could not be measured. The wall static pressures upstream of the injection slot are totally higher than those in other cases, and this conditions are advantageous for flameholding in terms of chemical reaction. In our previous study, however, flame-holding could not be attained in this condition [1]. The possible reason is that the injected hydrogen gas was not supplied enough for flameholding upstream as well as the static temperature of the supersonic airstream in the present test facility is not high.



(a) without incident shock wave (b) x_i = - 9.2 mm (c) x_i = 20.5 mm

Figure 4. Wall static pressure profiles and corresponding schlieren images depending on the location of incident shock waves, x_i. The injected gas is air and the total pressure of the injected air is 1.2 MPa.

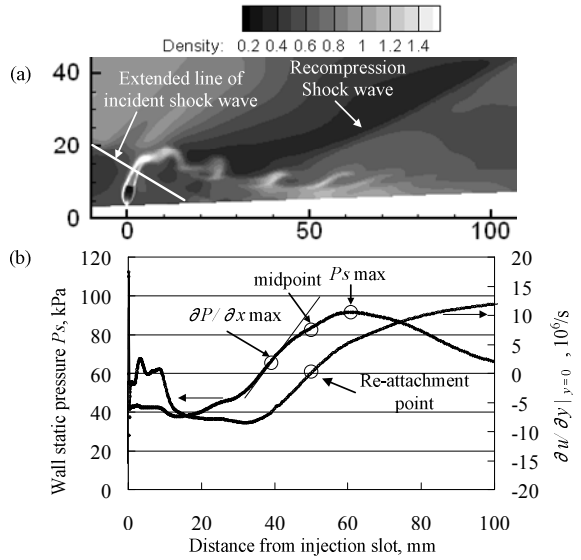


Figure 5. The method to define the characteristic length between the injection slot and the reattachment point using wall static pressure based on the unsteady numerical simulation: (a) contour of air density (x_i=15 mm); (b) relationship between time-averaged wall static pressures and $\partial u/\partial y$ at y=0.

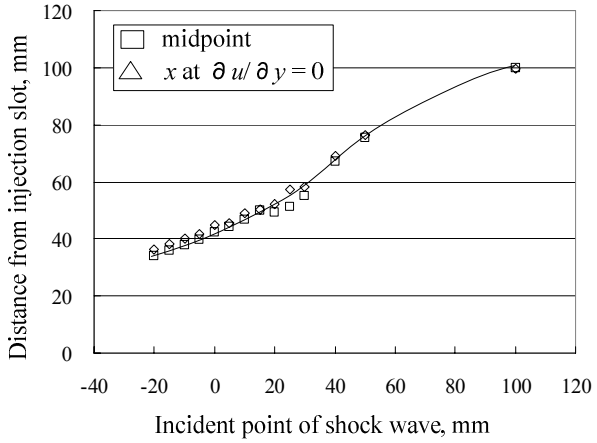

Figure 6. Relationship between the midpoint defined in Fig.5 and the point of ∂u/∂y=0 considered as reattachment point with the location of incident shock wave, x_i.

In the case of Fig. 4 (c), i.e., x_i=20.5 mm, when a shock wave was introduced downstream of the injection slot, wall static pressures downstream of the injection slot reached up to 80 kPa, which is the highest value in the present experiments. This is presumed to be one of the reasons why the flameholding was achieved in this condition [1]. Moreover, compared to the case of Fig. 4 (a), i.e., without incident shockwave, the separation point moved upstream. This result implies that the increase in the static pressure downstream of the injection slot also affects the static pressure upstream of the injection slot.

Figure 5(a) and (b) show instantaneous density profiles for x_i=15 mm and comparisons between the profiles of time averaged wall static pressure, P_s, and velocity gradient, ∂u/∂y at y=0, respectively, where u is the velocity component in the direction of airstream. Generally speaking, the reattachment point can be defined as the point where ∂u/∂y=0 at the wall, i.e., y=0. It is interesting to see that the midpoint between the maximum $\partial P_s/\partial x$ and the maximum P_s is well correspond to the reattachment

point, i.e., $\partial u/\partial y=0$. The increase in P_s downstream of the point is due to the recompression of the airstream where the recompression shock wave is formed and then P_s decreases again where the injected gas is accelerated near the wall. Therefore, it is reasonable to consider the reattachment point is located between $\partial P_s/\partial x$ point, i.e., the inflection point in P_s profile and the maximum P_s point.
To confirm how the midpoint corresponds to the reattachment point in other cases, variations of the midpoint and the reattachment point with locations of incident shock wave were plotted in Fig. 6. It is interesting to see that, regardless of the location of incident shock wave, the midpoint is in good agreement with the reattachment point. From these findings in the numerical simulations, in the present study, we have decided to determine the reattachment point from measured profiles of wall static pressures, that is, the midpoint is the reattachment point.
Measured discrete wall-static-pressure profiles were interpolated using a spline function, and then the midpoint was determined. In the case of the incident shock wave was introduced upstream of the injection slot, however, the profile of the wall static pressure does not have the inflection point of wall static pressure. Therefore, in those cases, the point of 5 mm downstream of the injection slot was assumed to be the inflection point of wall static pressure .

Comparison with the previous PTV measurements

Variations of the characteristic length with the location of incident shock wave measured using the above mentioned method are shown in Fig. 7. The results of PTV measurements reported previously [2] are also shown in the figure. Two cases of the injection pressure, 1.2 MPa and 1.6 MPa, are also compared there. When the incident shock wave was introduced to more than 10 mm downstream of the injection slot (x_i>10 mm), the characteristic length increased significantly. This means that the characteristic residence time becomes longer, thus the favourable condition for flameholding is realized. When the incident shock wave was introduced upstream of the injection slot, characteristic length does not change keeping a constant value of about 10 mm. These tendencies are in good agreement with the results of PTV measurements [2]. The difference between the characteristic length measured using wall static pressures and PTV measurements in the cases that the shock wave was introduced upstream of the injection slot seems to be due to the definition of the reattachment point because the inflection point in P_s profile could not be detected from measured wall static pressures and so it was assumed to be 5 mm downstream of the injection slot. These differences indicate that the point of maximum $\partial P_s/\partial x$ exists much closer to the injection slot. Figure 7 also shows interesting feature that the effect of the difference in total pressure of injection air is small in determination of the characteristic length.

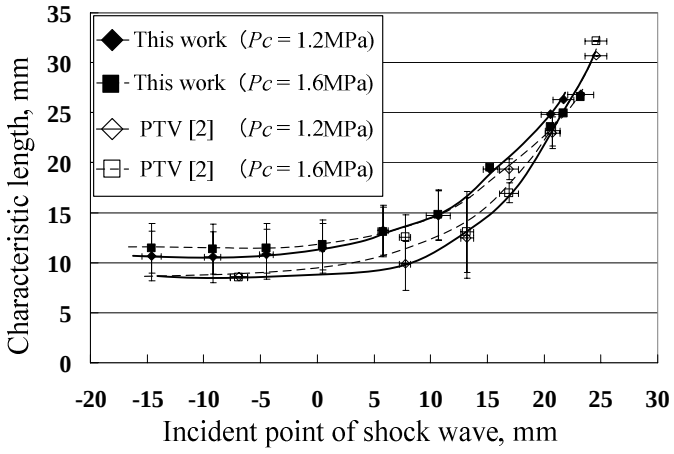

Figure 7. Variations of characteristic length with the location of incident shock wave.

Wall static pressure during combustion

Profiles of the wall static pressure were also measured during combustion. The experiments were conducted using the same procedure by Nakamura et al. [1], that is, the combustion experiments were performed moving the shock generator from downstream to upstream, thus the incident point of shock wave, x_i, moves after the supersonic wind tunnel started.

Figure 8 shows instantaneous profiles of wall static pressures during combustion. The initial location of incident shock wave is x_i=19.4 mm. The point of the maximum wall static pressure moves upstream as the location of incident shock wave, x_i, moves upstream. From comparison between the Schlieren images and wall static pressures, it was seen that the point of the maximum wall static pressure exists behind the recompression shock wave, being the same as the non-combustion cases. Just after flame extinction occurred, the wall static pressure downstream of the injection slot dropped rapidly. This transition of the wall static pressure indicates well that the flame is held in the recirculation zone downstream of the injection slot in the present experiment. The decrease in the wall static pressure after extinction moves the upstream separation point close to the injection slot, making the separation volume upstream of the injection slot smaller.

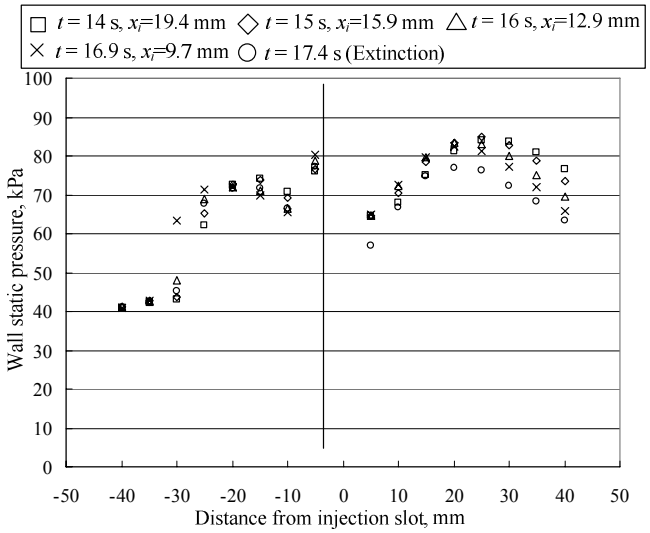

Figure 8. Variations of wall static pressures after the wind tunnel started in the case of combustion, where t is elapsed time. Flame was extinguished at t=17.4 s.

CONCLUSIONS

Experimental and numerical studies were performed to explore flow interactions between an incident shock wave and the transverse fuel injection from a slot in supersonic airstream in the cases of non-combustion and combustion. Based on the unsteady numerical simulations on the velocity profiles and wall static pressures, a method to determine the reattachment point of injected gas was proposed. The method could be applied to the experiments and a good agreement on the variations of the reattachment point between measured by wall static pressures and PTV measurements was obtained.

It was also confirmed that the characteristic length of the recirculation zone which plays a significant role in flame holding in supersonic airstream significantly increases as the incident shock wave was introduced downstream of the injection slot, whereas the length approaches to a constant value as the incident shockwave was introduced upstream of the injection slot. The change in the wall static pressures in combustion and non-combustion cases clearly indicated that the flame was held in the recirculation zone downstream of the injection slot.

ABSTRACT. A synthesis of a complete experimental campaign on transient aerothermal behaviour in a complex cavity is presented. Due to the high complexity of the configuration, a set of validation experiments are defined following a unitary models block approach. Measurements are adapted to quantify the transient heat transfer until the thermal equilibrium in each selected case by using a phase-average approach. Transient cycles are defined according to the thermal response of the systems. An accurate evaluation of the systematical experimental errors is also conducted.

Keywords: *validation experiments, transient heat transfer, engine core compartment, phase-average measurements*

INTRODUCTION

For aircraft engine manufacturers, the improvement of turbofan efficiency imposes constant technological innovations which imply important and complex aero-thermal and thermo-mechanical modifications. Thus the reliability of engine is directly linked with the optimisation of the thermal environment during all flight phases. However, a lack of knowledge on the heat evolution during high transient flight phases as take-off often leads to unnecessarily large design margins that increase cost, weight and inefficiency. In this context, they are widely involved in research for transient conjugate heat transfer problem and are especially interested in both the characterisation of heat exchange during the engine speed changes in several critical areas and the development of methods to simulate such coupled phenomena.
We propose here to describe the methodology developed during a complete experimental campaign defined by ONERA, in association with major French aeronautical industries. The goal of this important work is to characterize accurately the transient aero-thermal evolution in a turbofan engine core compartment configuration for a full engine cycle. This campaign will also allow constituting an accurate database useful to validate the numerical models developed jointly.
The by-pass engine core compartment configuration was selected due to its criticality (see figure 1). Localized between the IFS and the primary flow casing, this system is in the vicinity of the combustion chamber and high pressure turbine. The high heat transfer induces complex aero-thermal behaviour. Despite global air cooling coupled with dedicated ventilations which are taken directly from the cold fan flow, the thermal conditions could be severe in transient engine phases for the different critical items installed in this part of the nacelle as valves, ECS pipes, bleed ducts, electronic control systems or turbine casing.

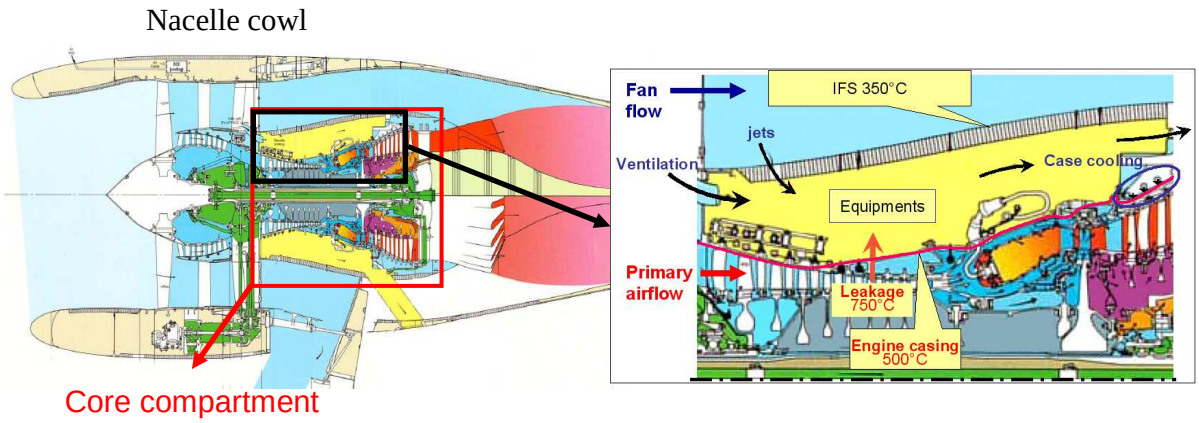

Figure 1. Nacelle core compartment – Aero-thermal behaviours

The definition of an experiment which models such complex and global aero-thermal problem, characterized by multi-physics phenomena with a high level of coupling, should follow the methodology defined by Oberkampf and Trucano [1]. They proposed to divide the system into several unitary models with simple geometries in order to separate each phenomenon following reference cases. At that point, correctly instrumented experiments are defined as accurate validation models. The figure 2 gives the decomposition of the nacelle core compartment aero-thermal configuration and the definition of an experimental campaign based on five different mock-ups to describe it particular aero-thermal behaviour.
In the following parts, we present two of them and discussed on the experimental methodology applied to study transient heat transfer.

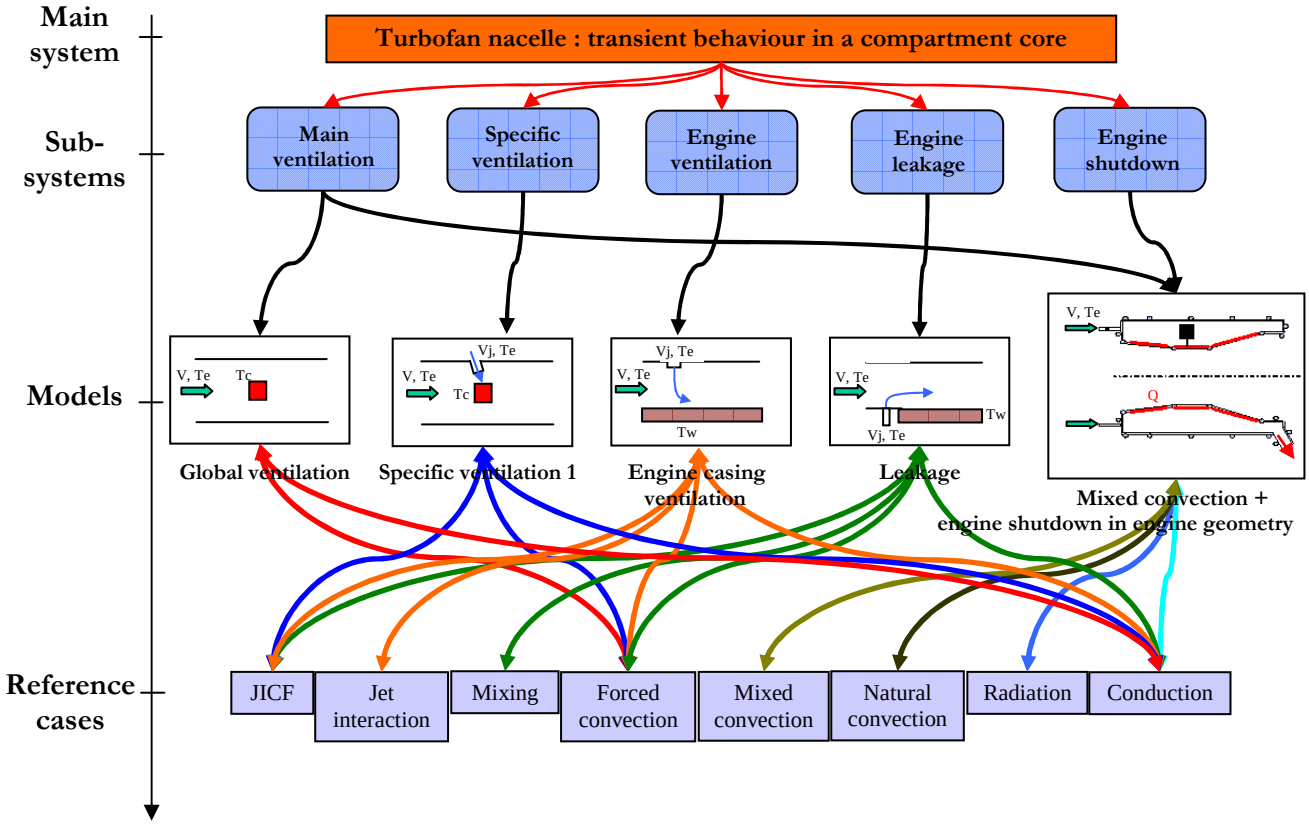

Figure 2. Decomposition of nacelle core compartment aero-thermal configuration in simplest models according to Oberkampf's block approach

DEFINITIONS OF EXPERIMENTS

Definition and experimental set-ups

"Engine casing ventilation" case. The case involves one or several vertical and cold jets discharging in a narrow channel cross flow at ambient temperature. They are in strong thermal interaction with a thick, opaque and homogenous flat plate heated on its back face at a constant temperature of 325 K as shown on figure 3(a). The target plate is made of a glass-ceramic Macor. This material is homogeneous, isotropic, and opaque for infrared radiation. But above all it allows the highest wall temperature evolution for our experimental conditions. The dimensions of jets and their positions above the target plate are defined to be representative of the engine real conditions. The mock-ups are integrated in an Eiffel wind tunnel with a test section 0.3 m high and 0.4 m wide. This kind of wind tunnel is well adapted for these experiments since there is no progressive heating of the flow. It produces a cross flow with a constant velocity. Moreover the temperature in the wind-tunnel room is controlled.

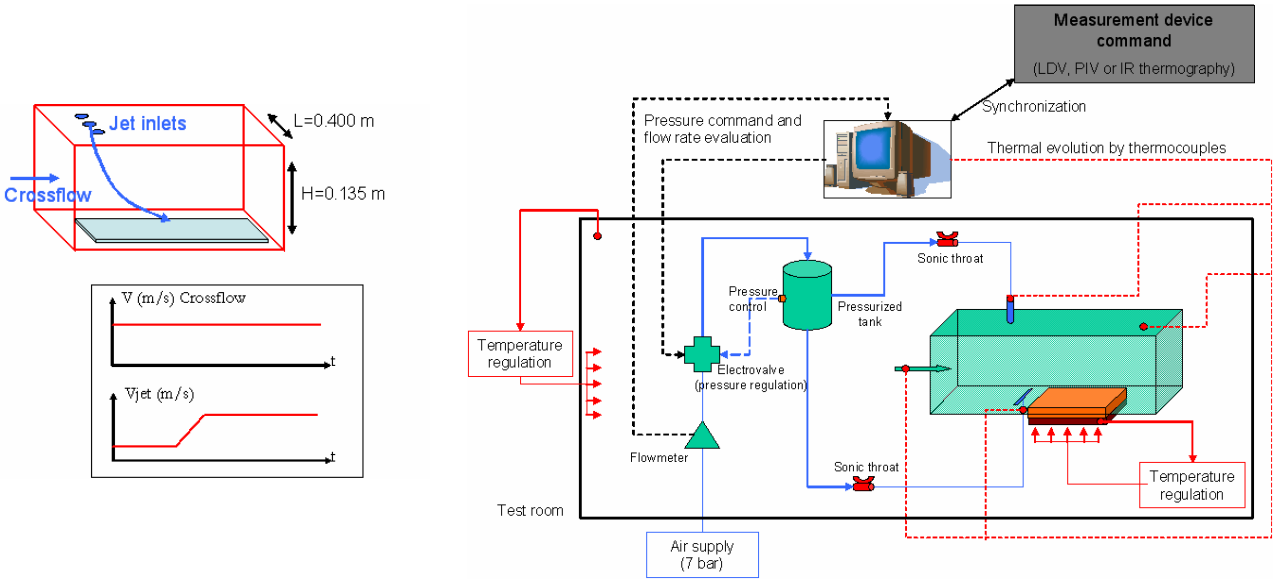

Figure 3. (a) Scheme of unsteady aerothermal validation experiment. (b) Experimental set-up and wind tunnel. Controls and regulations in the test cell

The geometric parameters as jet diameter d, relative position of jet and jet to impact side wall distance H are defined in order to respect similitude criteria. In particular, the ratio H/d is about 10 for an effective velocity ratio in the range from 6 to 7.5 with a main cross flow velocity of 4.2 m/s. The jet and cross flow temperatures are the same in order to avoid the phenomena of mixing and also simplify the validation. The thick flat plate (thickness e) is heated on its back side at constant uniform temperature T_e (with heating resistors controlled in temperature). The relative position of the jet always ensures an impact on the heated plate in the selected range of flow rates. The transient phase is based on the linear rising of jet velocity between two extreme values as shown on figure 3. Flow rate changes in 10s and each step is long enough to reach the thermal equilibrium for the heated plate. This flow rate evolution is well controlled and can be repeated a large number of times. An experimental set-up is developed to be compatible with phase-average measurements which need a complete synchronization between the test-section control computer and each acquisition device (see figure 3(b)). Moreover, for thermal measurements, this technique induces necessarily long time acquisitions. Besides all parameters have to be controlled and if necessary regulated, a complete characterization of the test-room is essential in particular in order to quantify experimental uncertainties. In this set-up, air which feed each jet comes from a controlled pressure

tank via a sonic throat. This solution allows the accurate control of jet velocity evolution with a fast proportional electro-valve. Moreover, jet nozzles are designed to ensure a rather uniform velocity on the whole jet exit surface. As both jet and main flow velocities are particularly critical variables, a flowmeter and a Pitot probe allow a permanent measure of them. In the same way, all temperatures (jet outlet, main flow, wind tunnel walls, glass-ceramic backside and test room) are acquired continuously.

"Convection in engine geometry" case. A simplified and modular half scale mock-up based on the CFM56-5C core compartment configuration is defined. It respects the form, the convective and turbulent flow specifications of the real configuration, but with temperature levels, heating power, mass flow rates, dimensions and cycle duration compatible with laboratory capacities. An illustration of the design is shown on figure 4.

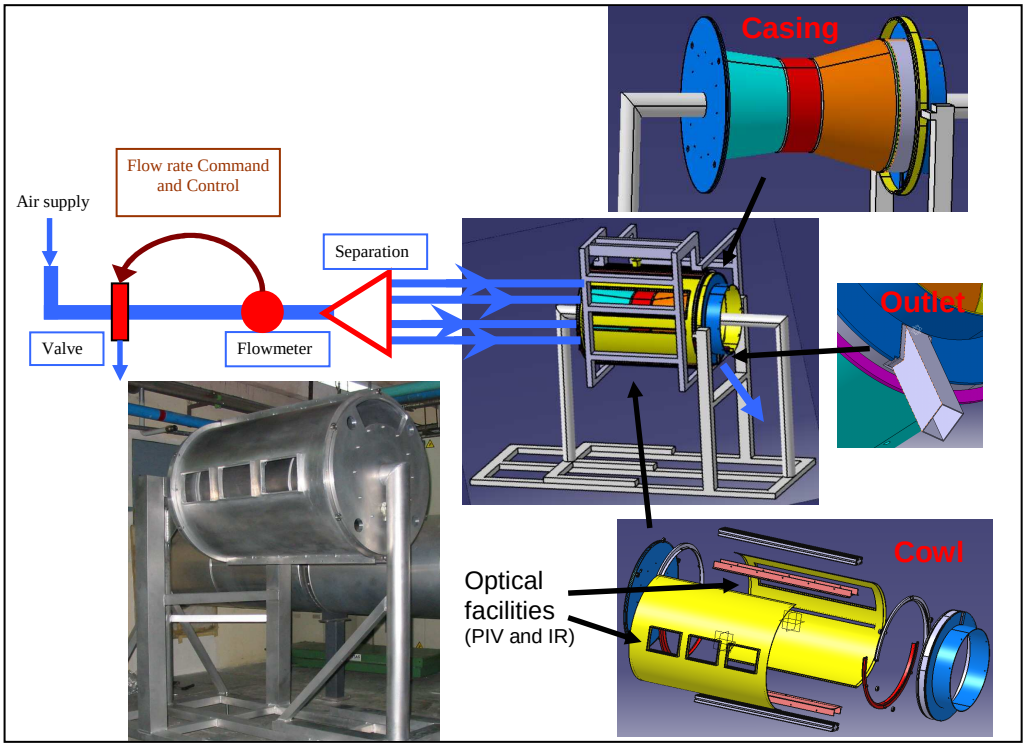

Figure 4. Nacelle core cavity set-up

It is made up with a cylindrical cowl with optical facilities built around a heated internal casing which model high pressure compressor, combustion chamber and high pressure turbine casings. By making a rotating cowl, the entire cavity is accessible by non intrusive optical measurement tools. Measurement localizations are referred with the angle of rotation (see figure 5). The entire cavity is either ventilated with four air inlets at ambient temperature (configuration C0) or not (natural convection configuration). For main ventilation studies, several items can be installed to generate realistic aero-thermal behaviour (configuration C1) as shown on figure 5(b).

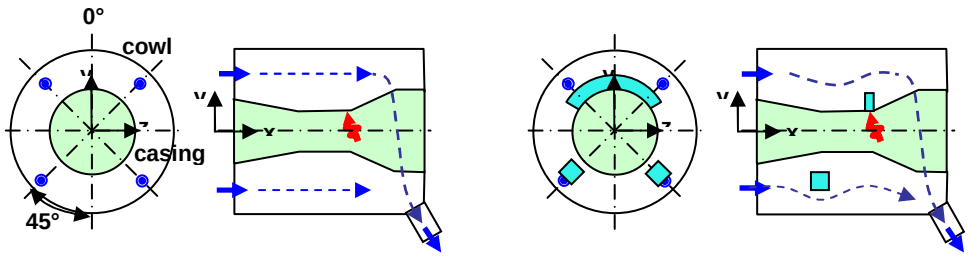

Figure 5. Configurations C0 (a) and C1 (b)

A dimensional analysis is made to select representative parameters as the ratio between internal casing radius and external IFS radius and either the Reynolds number (in the case of a forced convection configuration) or the Grashof number (in the case of natural convection configuration). Preliminary aerothermal calculations of the air flow and solid temperatures are done with stable mass flow rates and stable heating conductor surface flux on the inner wall of the casing. They allow imposing the more adequate powers in order to have the good wall temperatures, and the best materials to maximize thermal circumferential gradient (see table 1). The transient phase is based on the linear rising of inlet flow rate between GI and TO values in 8s (see figure 6).

Table 1
Typical temperatures for steady conditions

GROUND IDLE (GI)				TAKE OFF (TO)			
Mass Flow [g/s]	T1 [K]	T2 [K]	T3 [K]	Mass Flow [g/s]	T1 [K]	T2 [K]	T3 [K]
60	310	355	340	240	340	400	340

Phase-average measurements

In order to characterize dynamics and heat transfer during transient evolution, efficient techniques as PIV, LDV and infrared thermography are used. The measurements concern the flow velocity and turbulence, the heated plate wall temperature, and all the boundary conditions. For each configuration, steady dynamic and thermal conditions for both extreme flow rates are first quantified and the influence of operational conditions is estimated. In a second time, unsteady flow is measured with a phase-average approach to quantify the transient effects of either the test plate or the engine cavity casing.

PIV measurements. In each case, PIV measurements are performed with a 10 Hz double impulse YAG laser and a X-StreamVISION XS-5 camera coordinated by an IDT synchronizer. The post-processing software is IDT ProVision. Measurements are made in several axial and transverse planes through optical facilities and allow an accurate description of the flow topology. Mean fields are the result of an average based on several hundreds of image pairs validated by convergence study. The unsteady flow is measured with a phase-average approach on a number of cycles (as described on figure 2) consistent with steady measurements in order to quantify correctly the aero-thermal behavior. Length definition of cycles depends on both the configuration and the complexity of measurement process (see example on figure 6).

Infrared thermography measurements. Each test section is equipped with a ZnSe window which improves IR transmission. Infrared thermography measurements are realized with a Cedip Jade III LW camera with a 320*240 resolution. In parallel, several thermocouples follow the air temperature in jet and main flow and also on the test section wall temperature. They are used to quantify the wall temperature of all test section sides in order to check the adiabatic assumption and evaluate the radiative exchange error induced by using the Gebhart coefficient method. All these additional measurements are expected to quantify the systematic experimental errors.
In each case, the phase-average measurement is done with several cycles whose length is defined according to the evaluation of conduction characteristic time. For simple configurations, as jet impingement case, phase-average post-treatment is based on 350 acquired cycles with an acquisition frequency equal to 1 Hz. All the sequences are checked and validated in order to take into account the evolution of test-room conditions during the measurement. In this way, a criterion on the flow temperature is imposed and finally the phase-averaged post-treatment is done with less than 100 cycles of 660 s. However for the engine geometry mock-up, where transition conditions will be longer than in the simple cases (see figure 6), an other strategy is defined by using frame averaging in order to decrease the number of cycles. In our case, as the infrared camera is able to work at a frequency of 50 Hz, a 1Hz measurement is obtained by averaging 50 frames each second

in only one cycle. The accuracy of this approach is evaluated compared to the first method in the "engine casing ventilation" experiment and we obtain results quite consistent with an error lower than 0.3K.

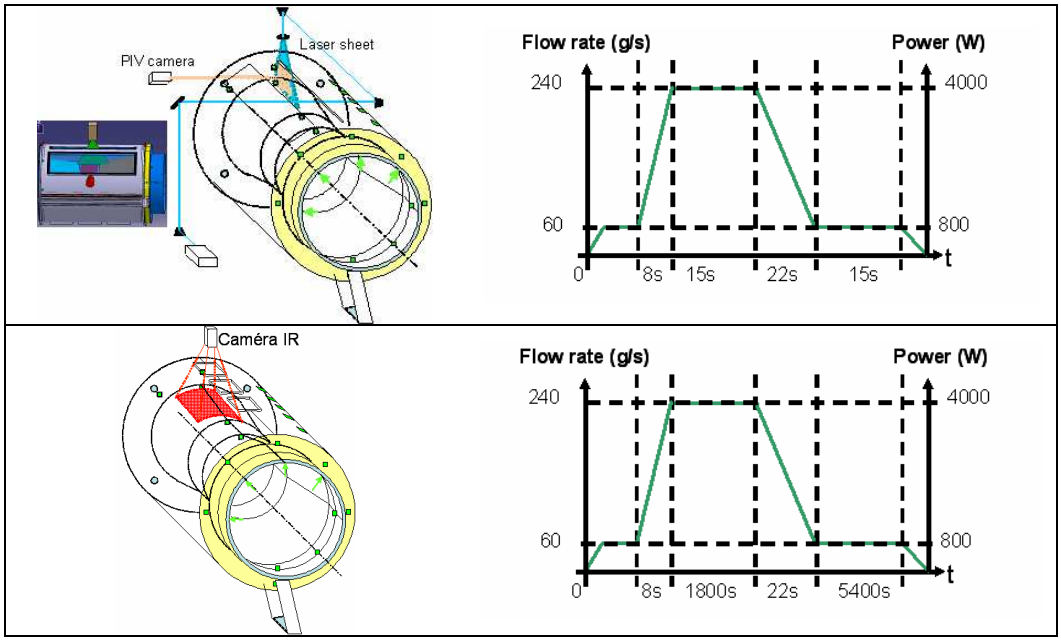

Figure 6. “Global ventilation” case – Adaptation of cycles for transient aerothermal measurements

RESULTS

“Engine casing ventilation” case – One jet in operation

The analyze of the main velocity field measured in the symmetrical plane for the both extreme flow shows the path and the impact of the jet on the heated plane with naturally an upstream position in the case of the higher flow rate. In both flow fields, the temperature profile looks quite symmetrical despite an accuracy of 0.8K for backside temperature condition. The impact of jet on the heated plate is detected and the impinging point on the material moves backward to the beginning of the material (from x=0.060 m to x=0.0 m), as confirmed by the study of the flow dynamics. In particular, for the higher flow rate condition, the decrease of the temperature is the result of the additional influence of the development of the boundary layer upstream and the jet impingement.

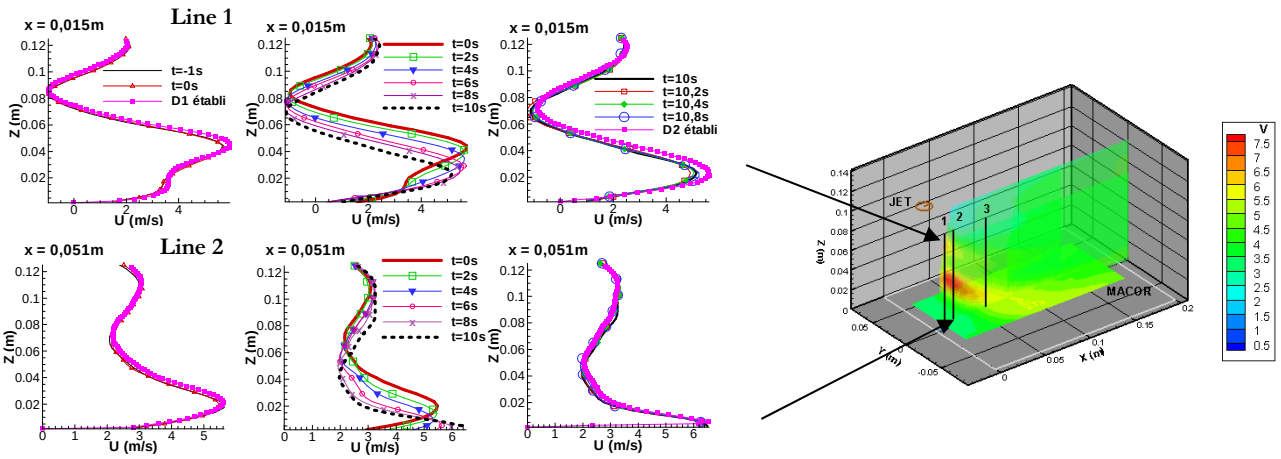

Figure 7. Main velocity field during transient evolution of jet flow rate

The maximum temperature difference between both extreme flow rates is about 8.8 K at x=0.014 m. The measurement statistic uncertainty is evaluated to be equal to 0.07 K. In the same way, the repeatability uncertainty due to the variation of measurement is less than 0.4 K. The velocity profile evolution during the unsteady period between -1s and 12s is shown on figure 7 according to two vertical lines localized in the symmetrical plane. First, axial velocity component profiles at the beginning (t=-1 to 0s) and at the end of the linear flow rate rising (t=10 to 10.8s) are compared to the steady case ones and show a good agreement (the maximal relative error is inferior to 8%).The velocity values at t=11.9s and t=9s are very similar, showing a fast transient evolution of velocities: we can consider that the dynamic equilibrium is reached instantaneously. During the flow rate linear evolution (t=0 to 10s), velocity profiles are given each 2s. The maximum of velocity induced by the jet is well detected and we can easily follow its vertical evolution during flow rate rising. As the jet speed increases, the impingement moves backward and strongly interacts with the boundary layer. Moreover the other influence of the jet is the deceleration of the higher part of the main flow due to an obstructing effect of the cross flow (velocity is from 2.6 to 4m/s, compared to the 4.2 m/s cross flow inlet).

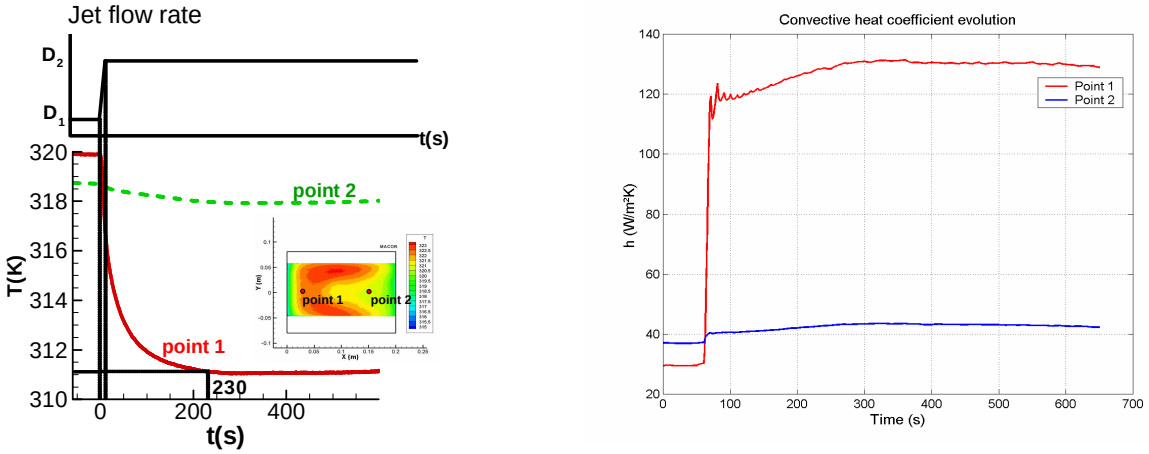

Figure 8. (a) Wall temperature evolution during transient experiment. (b) Convective heat coefficient evolution during transient experiment

The figure 8(a) shows the wall temperature at two distinct points during the transient phase. As the evolution of the flow field follows the jet flow rate increase, the convective conditions are quickly modified. Following the temperature evolution on point 1, which marks the impinging zone for the higher flow rate condition, the return to thermal equilibrium is reached in about 230 s. It is consistent with the theoretical estimation based on the conduction characteristic time (τ_c = 274 s). Moreover, the temperature fields obtained are used to evaluate the convective transfer coefficient during the transient phase (see figure 8(b)). This estimation is based on an inverse method developed in ONERA which resolve the heat conduction equation in the material with constant uniform temperature on rear face. It determines the heat flux evolution on front face (fluid – solid interface) to obtain the measured temperature evolution on this face.

“Convection in engine geometry” case

The figure 9 shows the main velocity field measured in axial planes for the both extreme flow and both configurations. The inlet jets in 45° and 135° are well detected. Between them, a large reverse flow appears in the entire cavity. The items involved in configuration C1 induce local modification of flow patterns. Based on thermal measurements, the resolution of an energetic balance in the cavity wall leads to convective heat coefficient evaluation (figure 10(a)). By following the evolution of the adimensional axial velocity defined with inlet value, the evolution of flow during transient phase is consistent and only items generate local dynamics evolution (see figure 10(b)).

CONCLUSIONS

In this paper, we present a methodology to experimentally describe the complex aerothermal behaviour of the nacelle core compartment during transient phases. Several simplified set-ups are defined to study each specific phenomenon (as cooling by air jet impact or global ventilation) which occurs in such complex system. The study of transient behaviours needs the adaptation of phase-average strategy. In each case, dynamics and wall temperature field characterizations are performed in order to highlight the strong link between the air flow and the wall temperature. These data are then used to evaluate the evolution of the heat coefficient during a transient phase. Specific post-processing is used in order to quantify measurements uncertainties and to evaluate corrections (as the closed cavity multi-reflection radiative heat transfer and its influence on the infrared measurement).

ABSTRACT. The flow in an axial compressor row is characterized by the presence of several secondary flow effects. When it occurs, the corner separation between the endwall and the blade in a compressor row dominates and is responsible for a large part of total pressure losses. It is well known that this separation is driven by the interaction between the cross flow on the endwall and the blade boundary layer. Hence, a promising way to improve axial compressors is to shape not only the blade but also the endwall in a three dimensional way in order to influence the cross flow. This paper presents a recently developed novel endwall design and its detailed experimental and numerical investigation of the resulting flow effects.
A non-axisymmetric endwall groove, which generates an aerodynamic separator, was designed by means of the 3D-RANS flow solver TRACE linked with an automated multiobjective optimizer. This aerodynamic separator interacts with the cross flow on the endwall, which leads to a significant loss reduction, load redistribution and reduction of recirculation.
Object of the investigation is a highly loaded compressor cascade which is described in detail with respect to its flow phenomena and physics. The measurements by means of 3-hole and 5-hole-probes as well as Laser-Two-Focus technique is carried out at the transonic cascade wind tunnel of the DLR in Cologne in order to detect the flow structure of the blocked endwall cross flow as well as the redistribution of the corner separation. Comparing the experimental and numerical data shows good agreement and allows a comprehensive view on the flow.
The endwall cross flow, caused by the pressure compensation between two adjacent blades is blocked and deflected by a vortex (aerodynamic separator), which is generated at the separation edge of the newly designed endwall contour. These results are obtained by oil-flow patterns as well as pressure distribution measurements on the endwall.
Concerning the cascade performance a considerable influence of the novel endwall design was observed. A significant loss reduction was achieved as well as an increase of the pressure ratio and the flow turning was detected. In summary, it can be stated that non-axisymmetric contoured endwalls have shown their potential for compressor improvement, thus they offer an additional design space for modern turbomachinery.

is essential in order to reduce CO_2 and NOX emissions. An improvement of compressor efficiency is directly linked with the possibility of influencing secondary flow effects in blade cascades. This correlation was already identified in the early 1950´s. Since that time and still ongoing systematic studies [1], [2], [3] have been performed in order to understand these flow phenomena.
A significant secondary flow effect in the vane row of an axial compressor is the corner separation, which is defined as the separation between the endwall and the vane, because this separation is responsible for a large part of the aerodynamic losses. The corner separation is caused by the interaction of the endwall cross flow and vane boundary layer during the concurrent presence of a pressure gradient in flow direction. Hence the research in the recent past has focused on influencing cross flow by endwall modifications. It has been shown by Corral and Gisbert [4] and Duden et.al [5] that the application of these modifications in form of non-axisymmetric contoured endwalls can be very successful in turbine stages. Concerning axial compressors Dorfner et.al. [6], Harvey and Offord [7], [8], as well as Iliopoulou et al. [9] have recently shown that it is possible to achieve such good results also for compressors. In order to continue the efforts in improving compressor performance, the DLR 3D-RANS flow solver TRACE [10] was used and linked with an in-house automated multiobjective optimization tool by Voss et al. [11] and extended by Dorfner [12] to design a numerically optimized endwall contour. The development of this novel non-axisymmetric endwall groove generating an aerodynamic separator and its influence on compressor cascade performance was first-time presented by Dorfner and Hergt et.al. [13], [14].
The objective of the present work was to measure the resulting flow structure in the highly loaded compressor cascade with contoured endwall in order to describe and analyse the flow phenomena in detail. Therefore, measurements in the transonic cascade wind tunnel of the DLR in Cologne [15] were carried out. In this process the investigation was focused on detailed measurements by means of 3-hole and 5-hole-probes as well as Laser-Two-Focus method within the cascade passage close to the endwall. Furthermore, experimental flow visualisation by means of oil streak pattern allows the detailed interpretation and description of the resulting flow phenomena. The experiments were carried out at the aerodynamic design point (ADP) of the cascade at $M_1 = 0.69$.

BASELINE CASCADE AND NOVEL ENDWALL DESIGN

The baseline configuration is a high-speed compressor cascade with CDA airfoils. Its consists of 6 blades with 70 mm chord and 186 mm blade span and has flat endwalls. This cascade enables tests at realistic flow conditions, e.g. Mach number, thus transferability to real turbomachines is possible to a certain extent. The aerodynamic design point of the datum cascade with inlet Mach number $M_1 = 0.7$ and inlet flow angle $\beta_1 = 134.8°$ was chosen for the tests. At these flow conditions the measured Mach number distribution at midspan as well as the blade profile is shown in Fig 1. Further cascade design parameters are the stagger angle $\beta_{st} = 109.9°$, the pitch to chord ratio $t/c = 0.75$ and the blade aspect ratio $h/c = 2.4$. The incoming endwall boundary layer thickness amounts to 18 mm on each wall which is equivalent to 22% of the blade span.
As described in the introduction, the interaction of the endwall cross flow and vane boundary layer during the concurrent presence of a pressure gradient in flow direction is responsible for the existence of corner separation. In order to prevent this separation a novel endwall design in form of a non-axisymmetric endwall groove has been developed in a previous study [12], [13]. This groove creates a vortex with its separation edge, which acts as an aerodynamic separator and prevents the endwall cross flow from interacting with the blade suction side boundary layer. Goal of the present investigation was to measure and visualize the resulting flow phenomena in order to improve the understanding of the aerodynamic separator and validate the numerical results. For the investigation a contoured endwall (CEW) cascade including the baseline blade profiles was constructed. A symmetrical, identical grooved endwall is attached to both sides of the blades in the cascade wind tunnel. Figure 2 shows the cascade blades with one attached contoured endwall (CEW).

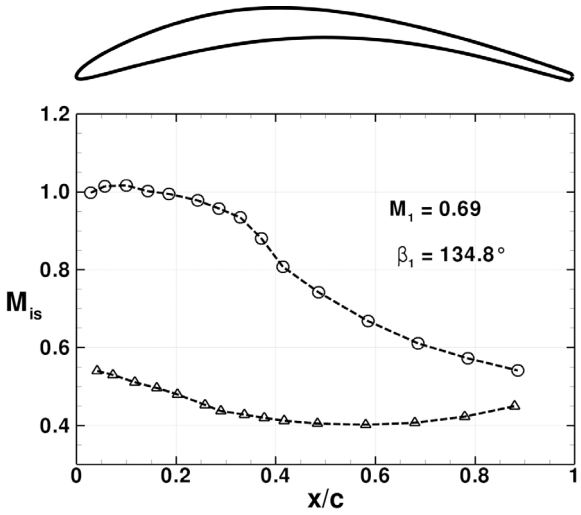

Figure 1: Profile (top) and measured Mach number distribution at midspan of the datum cascade

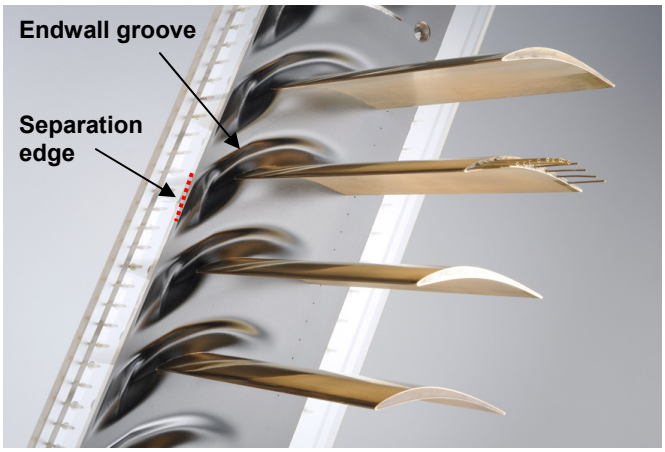

Figure 2: Cascade with non-axisymmetric endwall contouring

TEST FACILITY AND EXPERIMENTAL SETUP

The experiments were performed in the transonic cascade wind tunnel at the DLR in Cologne [15]. This tunnel is a closed loop, continuously running facility with a variable nozzle, an upper transonic wall, and a variable test section height. The air supply system enables an inlet Mach number range from 0.2 to 1.4 and a Mach number independent variation of the Reynolds number from 1×10^5 to 3×10^6. Figure 3 shows a cross section of the transonic cascade wind tunnel with the main inlet and outlet flow parameters.

For the present tests the blade chord Reynolds number was around 1×10^6. The inlet total temperature was about 300 K and the free stream turbulence level was around 0.6 percent. Two blades, in the center of the cascades, were instrumented at midspan on the pressure and suction side respectively.

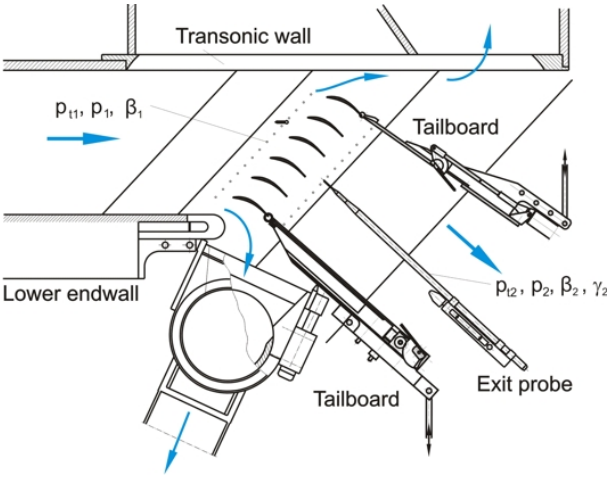

Figure 3: Cross section of the DLR transonic cascade wind tunnel

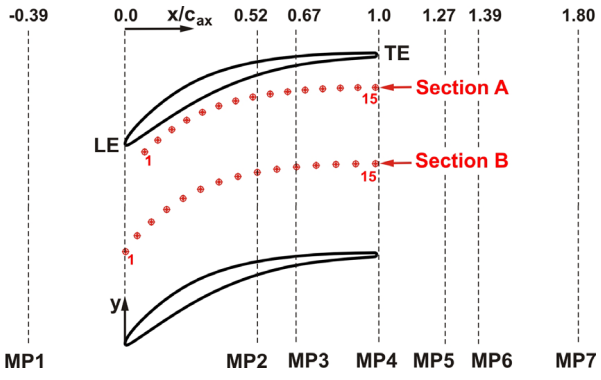

Figure 4: Location of pressure taps on the endwall (section A and B) and axial measurement planes (MP)

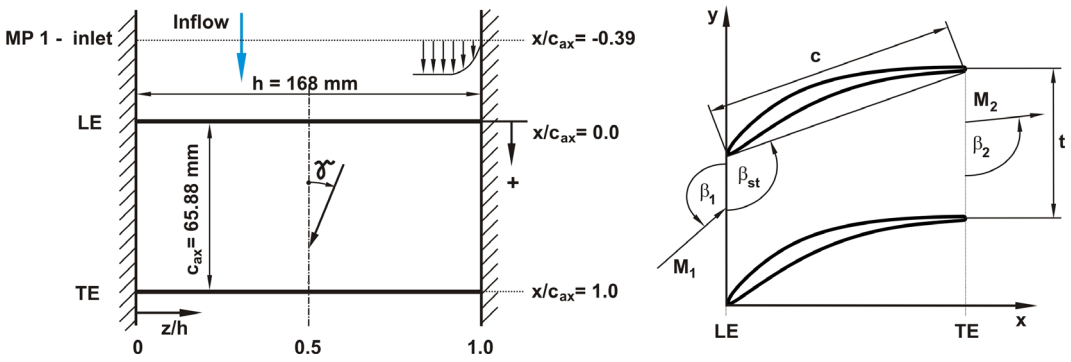

Figure 5: Cascade definition and parameter

Additionally, the spanwise flow symmetry in the datum cascade is verified by static taps on both endwalls near pressure and suction side. In order to verify spanwise flow symmetry in the CEW cascade, one blade in the center was instrumented at 10 percent and 90 percent span, since endwall instrumentation near suction side was impossible due to the contoured endwall. During the measurements of the datum and the CEW cascades, passage-to-passage flow periodicity was checked by traversing the wakes at midspan over the three middle passages as well as by measurement of the static pressure distribution across the inlet measurement plane (Fig. 5). Additionally, in the CEW cascade one blade passage was instrumented with 2 ×15 pressure taps, located as shown in Fig. 4 and denoted by section A and B. In this figure and in Fig. 5 also the measurement planes (MP1 to MP7) and cascade parameters and are given.
The test procedure is defined as follows: Generally, measurements were carried out at the ADP of the cascades with an inlet Mach number of 0.69 and included wake measurements with a combination of 3-hole and 5-hole probes at MP4, MP5, MP6 and MP7 in order to resolve the development of the wake against the axial distance and to indentify the losses. Additionally, 3-hole and 5-hole probe measurements were performed at MP2 and MP3 in order to resolve the development and effect of the aerodynamic separator on the endwall cross flow. These measurements are problematic due to the blockage of the pressure probes within the cascade. Hence, additional Laser Two Focus (L2F) [16] measurements were carried out at selective points in order to validate the pressure measurement. The one cascade endwall was flat and consists of acryl glass which allowed the optical accessibility for the tests. This means that the cascade endwall setup was asymmetric in this case, thus the cascade flow close to the endwalls was additionally checked. Thereby the flow close to the CEW endwall shows a good agreement with the results of the symmetric CEW cascade setup. The cascade loss measurements as well as the oil flow pattern were carried out with a symmetric cascade endwall setup.
Furthermore, the endwall pressure was measured at 2×15 pressure taps (Fig. 4) in order to validate the numerical results and to detect changes in the endwall pressure distribution due to the endwall groove. The estimated uncertainties of the test data at midspan are ± 0.2 deg for the inlet ant outlet flow angle as well as ± 0.002 for the midspan total pressure loss coefficient.

Numerical Setup

For comparison with the experimental results and in order to analyse the endwall flow in detail, steady numerical simulations with DLR's 3D-RANS flow solver TRACE, including k-*w* turbulence model, were carried out for both operating points at the measured inflow conditions. Concerning the convergence massflow as well as the global mean residual, which had to be less than $1x10^{-6}$, were checked. A fine multi-block grid of nearly 2 million nodes with an OCH topology was used in order to sufficiently resolve the blade and endwall boundary layer. Calculations with the fine grid as well as a coarse grid, in each case with and without wall functions, were carried out in order to check the grid independence. In the process the global values displayed very good agreement.

RESULTS AND DISCUSSION

The optimization and numerical results given by Dorfner et al. [12], [13] show that the novel endwall contour in form of a groove with a separation edge generates a vortex. This vortex acts as an aerodynamic separator and leads to a separation of the endwall cross flow above the endwall groove. Figure 6 shows the results of the 3-hole and 5-hole probe measurements in different axial cross sections (MP2 to MP7). These measured loss distributions illustrate the interaction of the aerodynamic separator with the endwall cross flow and the development of the loss wake behind the cascade. The measurement planes 2 and 3 range from y/t = 0.1 to 0.9 in which 0 and 1 represent the position of the trailing edges. In these planes a region with very high losses is visible close to the endwall (marked with I). Additionally, the rotational sense of the aerodynamic separator is marked on the planes for a better illustration. It shows that the endwall cross flow is prevented from interacting with the blade suction side boundary layer. The high loss region is detached from the blade suction side and results from the separation of the endwall cross flow above the groove. This is also illustrated in the measurement plane 4 directly behind the trailing edge. There, the high loss region caused by the corner separation is marked with III and the gap to the detached loss region is marked with II.

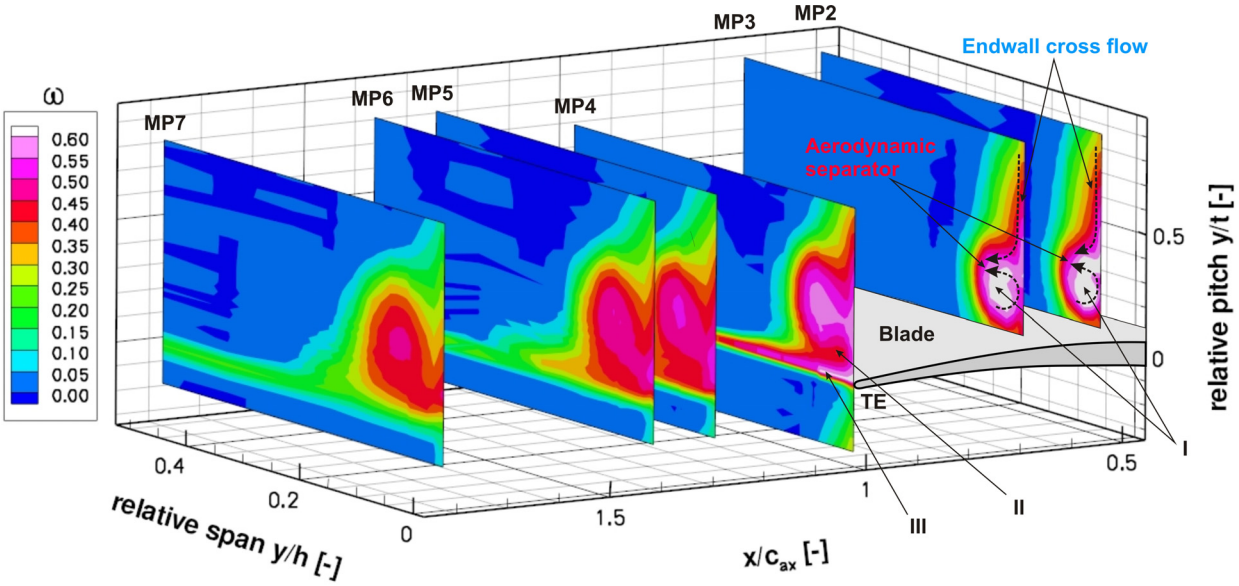

Figure 6: Measured total pressure loss distribution in different axial measurement planes.

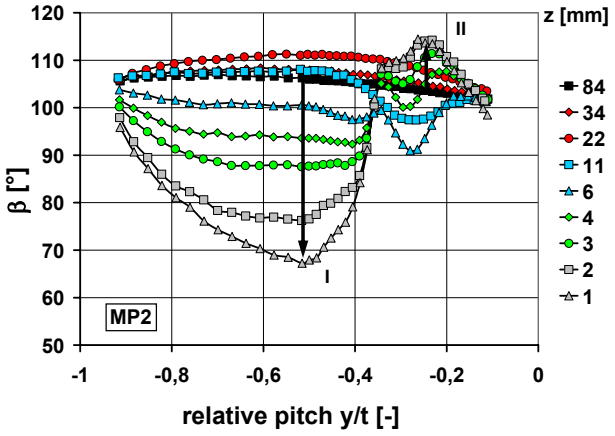

Figure 7: Measured pitchwise flow angle β distribution in MP2 at different spanwise positions

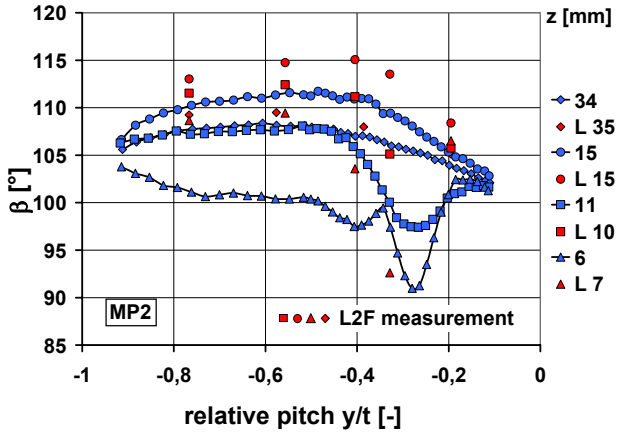

Figure 8: Comparison of measured pressure probe and L2F results for the flow angle β in MP2

Considering the wake behind the cascade it becomes apparent that the losses are not dominated by the corner separation. Close to the endwall the losses result from the kinetic losses induced by the aerodynamic separator. The pitchwise flow angle distributions which were measured in plane 2 and shown in Fig. 7 lead to the previous interpretations. Comparing the pitchwise flow angle distribution at midspan (z = 84 mm) and close to the endwall (z = 1 mm) the increase of overturning of the flow is observable. This overturning, marked I, represents the cross flow on the endwall above the groove. In the range of y/t = -0.1 to -0.4 an underturning is shown in Figure 7. The stepwise change of the flow angle close to the endwall at y/t = -0.4 compared to midspan can be explained by the interaction of the aerodynamic separator and the endwall cross flow. This interaction leads to the separation of the endwall boundary layer above the endwall groove at approximately y/t = -0.4.

In order to validate the pressure probe measurements within the cascade passage L2F measurements were carried out. Figure 8 shows a comparison of the results of the measurements. In this figure considerable differences are observable. At z = 34 mm the results show a good agreement, but towards the endwall the discrepancy increase. This results from uncertainty of the pressure measurement due to the blockage of the probes in the cascade passage as well as from the uncertainty of the L2F measurements caused by the light dispersion and high turbulence level close to the endwall, but the general tendency is comprehensible. Additionally, it has to be mentioned that the L2F measurements was not carried out at the same series of measurements. The oil flow pattern of Fig. 9 and Fig. 10 give an illustration of the flow path on the endwall of the datum and the CEW cascade.

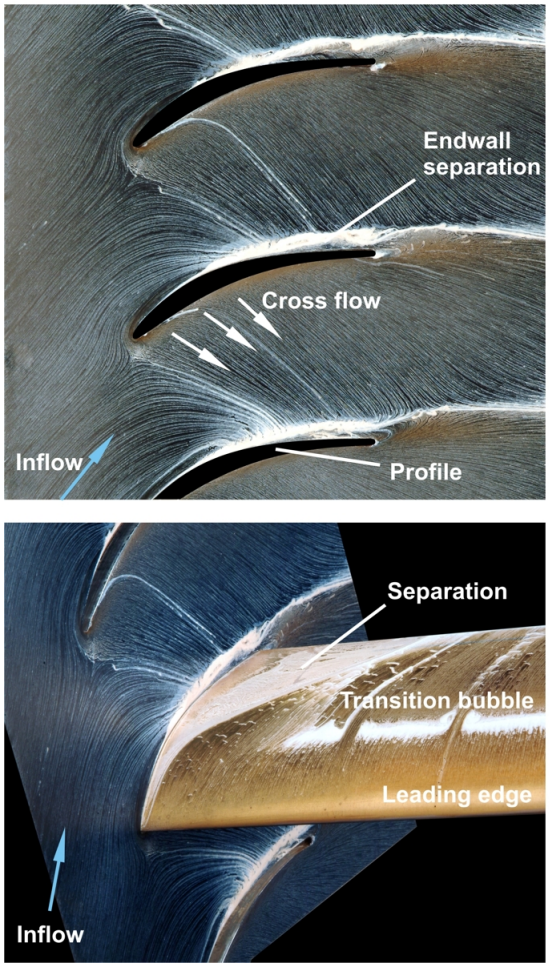

Figure 9: Oil-flow visualization on endwall (top) and blade suction side (bottom) datum cascade

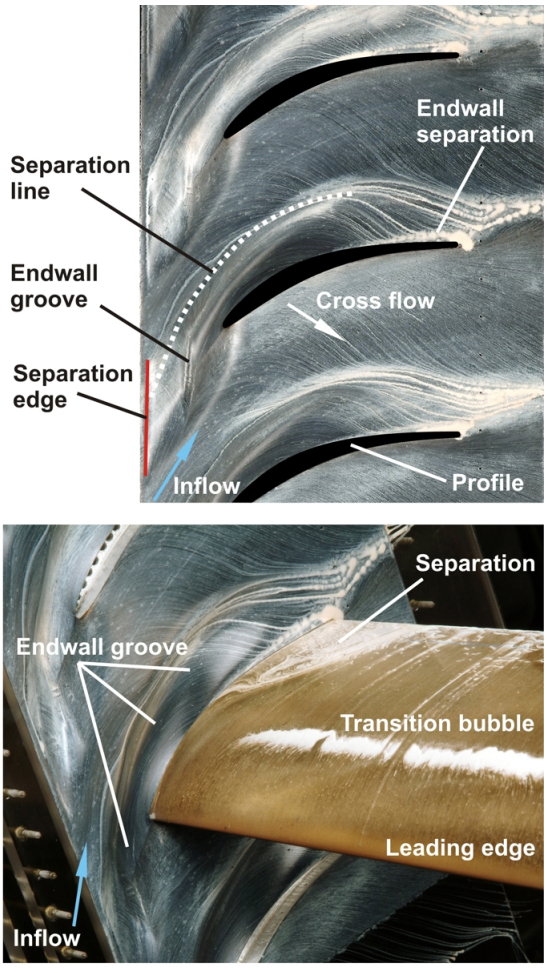

Figure 10: Oil-flow visualization on endwall (top) and blade suction side (bottom) CEW - cascade

In the case of the datum cascade low momentum fluid is forced towards the suction side corner, where this flow separates due to the high pressure gradient in flow direction. The typical flow pattern for these separations is visible in Fig. 9. The oil flow pattern of the CEW cascade with the endwall groove is shown in Fig. 10. In this figure the separation edge, where the vortex (aerodynamic separator) originates is visible. Furthermore the separation line above the Endwall is observable and it becomes apparent that the cross flow is blocked there. In addition the extension of the corner separation is significantly reduced for the CEW cascade in comparison with the datum cascade.

The changed flow patterns are also reflected in the static pressure distribution on the endwall as shown in Fig. 11, where the measurement plane 2 is marked by the dashed line at $x/c_{ax} = 0.52$. In this figure it is observable that the pressure distribution has generally changed. The pressure gradient between zone II and III is decreased as well as the curvature of the pressure profile in zone IV is smoothed, which leads to a pitchwise unloading of the endwall. The deflection of the flow within the endwall boundary layer is decreased in the case of contoured endwall. The change in pitchwise pressure gradient is also reflected in Fig. 12. It shows the comparison of the static pressure at endwall section A and B for the datum and the CEW cascade. The pressure difference or rather the driving force caused by the pressure gradient is decreased in zone II and III for the contoured endwall. It seems that the slight pressure change in zone I (Fig. 11 and Fig. 12) has no observable effect.

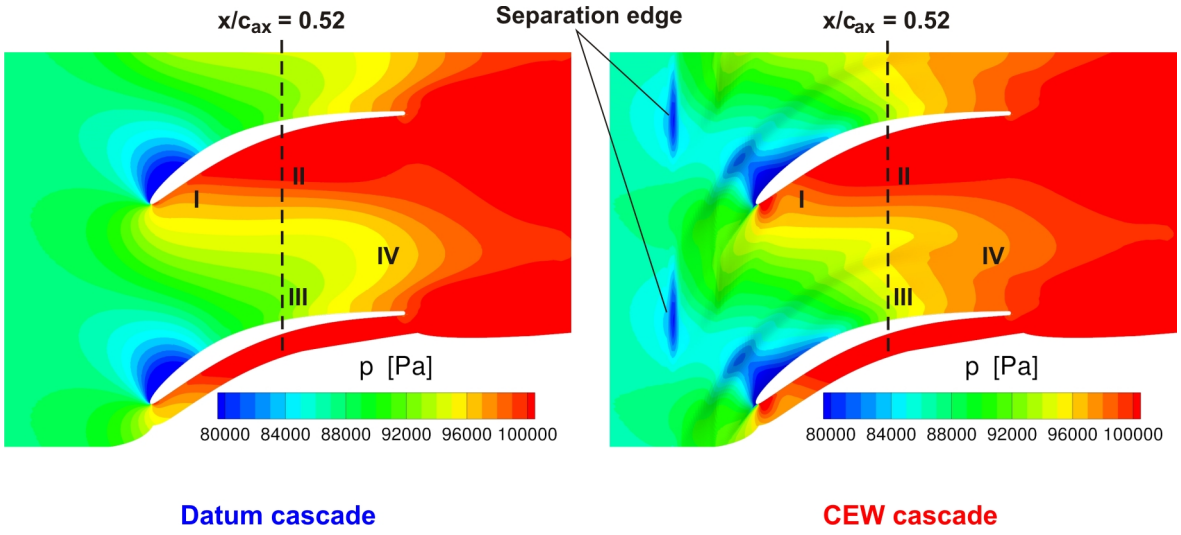

Figure 11: Numerical results of the static pressure distribution on the endwall of the datum and CEW cascade.

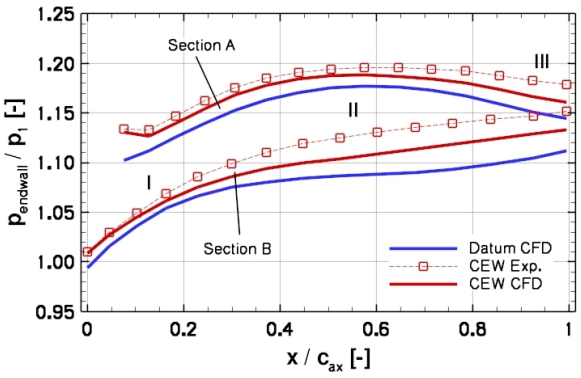

Figure 12: Measured and numerical results of the static pressure on endwall section A and B

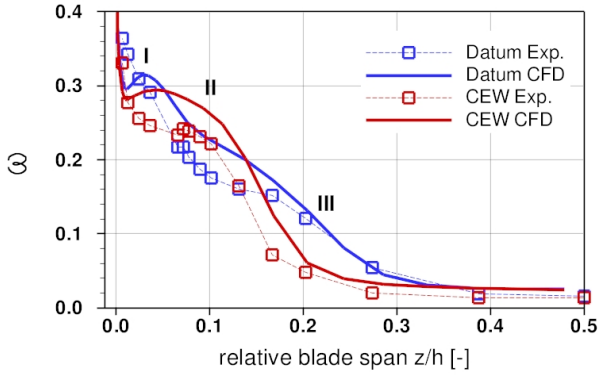

Figure 13: Measured and calculated spanwise loss distribution in MP6

Figure 13 shows the experimental and numerical results for the spanwise loss distribution (pitchwise averaged). This figure illustrates that the contoured endwall creates a redistribution and reduction of the losses near the endwall, whereas the losses at midspan (z/h = 0.5) remain unchanged. Between z/h = 0.15 and 0.3 (zone III in Fig. 12) as well as between the sidewall and 0.05 (zone I) the losses are decreased by a reduction of the corner separation. Due to the kinetic losses induced by the aerodynamic separator, a local slight loss increase is however observed in zone II of the Fig. 13. In summary a significant decrease of the total passage loss (mass averaged) is achieved in the range of 17 (Exp.) to 21 percent (CFD).

CONCLUSIONS

The flow phenomena of a novel numerically-optimized endwall contour have been investigated in detail in the presented paper. The experimental and numerical study deals with the influence of the developed aerodynamic separator on the endwall cross flow and the cascade loss behaviour.
Concerning the cross flow behaviour on the endwall it has been shown that the usual flow structure is significantly influenced by the aerodynamic separator, thus the strong interaction of low momentum endwall fluid with the suction side boundary layer and the resulting corner separation is considerably decreased.
Due to the decrease of the separation the losses are also significantly decreased. The separation is not completely suppressed by the aerodynamic separator, but the total passage loss is decreased around 20 percent at the aerodynamic design point of the cascade. In future, a detailed PIV study is going to be performed in order to resolve the vortex structure and the endwall separation of the cross flow.
In summary, non-axisymmetric contoured endwalls have shown their potential for compressor improvement and thus they offer an additional design space for modern turbomachinery and gas turbines.

THE EFFECT OF LEADING EDGE TUBERCLE GEOMETRY ON THE PERFORMANCE OF DIFFERENT AIRFOILS

K. L. Hansen, R. M. Kelso and B. B. Dally
School of Mechanical Engineering
University of Adelaide, Adelaide, Australia

ABSTRACT. Results are presented of an experimental investigation on the effects of modification to the leading edge geometry of two NACA airfoils with different aerodynamic characteristics. The modification was inspired by the humpback whale flipper, which has rounded tubercles on its leading edge resembling the shape of a sine curve. Force measurements on both modified and unmodified 2-D airfoils show that tubercles are more beneficial for the NACA 65-021 airfoil than the NACA 0021 airfoil. Also, for smaller amplitude tubercles, the modified NACA 65-021 airfoil outperforms its unmodified equivalent for most angles of attack. Hydrogen-bubble visualisation was used to identify characteristic features of the flow for airfoils with tubercles. It appears that the velocity behind the troughs is greater than behind the tubercles themselves at the leading edge. Downstream from the leading edge, the flow from behind the peaks seems to be entrained into this region, giving rise to the formation of stream-wise vortices.

Keywords: tubercles, passive flow control, airfoil performance, delayed stall, enhanced lift

INTRODUCTION

Tubercles are leading-edge, rounded protuberances that alter the flow-field around an airfoil. The presence of tubercles on the humpback whale flipper, for example, has been associated with the tight turning manoeuvres that it is required to make as part of its feeding ecology [1]. It has been postulated that tubercles give rise to the formation of stream-wise vortices, which enhance momentum exchange within the boundary layer [1]. This can lead to improvements in foil performance, such as delayed stall and higher maximum lift coefficient, allowing a smaller foil surface to be utilised [2]. Hence, drag at the cruise condition and weight of the wing can be reduced.

A numerical study by Watts & Fish [3], which compared a NACA 63_4-021 airfoil with sinusoidally-shaped tubercles to an unmodified airfoil, reported a 4.8% increase in lift, 10.9% reduction in induced drag, and 17.6% increase in lift-to-drag ratio (L/D) at a 10-degree angle of attack. It was concluded that tubercles have a negligible effect on drag at zero angle of attack but may incur an 11% increase in form drag at a 10-degree angle of attack.

An experimental investigation undertaken by Miklosovic *et al.* [4] compared the lift and drag of idealised scale models (NACA 0020) of the humpback whale flipper with and without tubercles. Their results showed 40% increase in the stall angle, 6% increase in the total maximum lift coefficient and a decrease in drag in the post-stall regime. The lift-to-drag ratio was larger for the airfoil with tubercles for all angles except $10° \leq \alpha \leq 12°$. Stein and Murray [5] conducted experiments

E-mail address: khansen@mecheng.adelaide.edu.au

for $0° \leq \alpha \leq 12°$, using a two-dimensional airfoil with sinusoidal tubercles having amplitude and spacing equal to the average values for the humpback whale. Their results revealed that the modified airfoil experiences reduced lift and increased drag compared to the unmodified airfoil. Another study by Murray *et al.* [6], found that aerodynamic performance of a 3D foil with tubercles could be improved by increasing the sweep angle.

An investigation by Johari *et al.* [7] compared the effect of changing the spacing and amplitude of sinusoidal tubercles on a nominally two-dimensional NACA 63_4-021 airfoil without sweep or taper. They concluded that airfoils with tubercles achieve a lower stall angle and lower maximum lift coefficient, $C_{L_{max}}$, than their unmodified equivalent, which is consistent with the findings in [5]. However, improvements were noted in the post-stall regime in which the airfoils with tubercles had lift coefficients as much as 50% greater than the unmodified airfoil [7]. They also found that the smallest amplitude and shortest wavelength tubercles performed best in terms of stall angle and $C_{L_{max}}$. It was also concluded that varying the amplitude has more effect on airfoil performance than changing the wavelength of the tubercles. Tuft experiments [7] showed that separation originates in the troughs between the tubercles and that the flow remains attached at the tubercle peaks. Despite indications of an earlier separation at lower angles of attack for airfoils with tubercles, at post-stall angles, the flow over the tubercle peaks was still attached when the flow over the unmodified airfoil had completely separated.

A dye visualisation study [8] of the same airfoils found that separation regions behind the troughs appear to be bi-periodic, in that adjacent troughs have the same pattern as their second neighbour. This behaviour was attributed to the fluctuating flow field at the trailing edge of the airfoil. The presence of tubercles creates span-wise flow as a result of the varying leading-edge sweep and this was reported to give rise to the formation of counter-rotating stream-wise vortices. Custodio [8] postulates that these counter-rotating vortices generate vortex lift similar to that observed on a delta wing. However, Nierop *et al.* [9] claim that it is not possible for the tubercles to act as vortex generators since the wavelength and amplitude are much larger that the boundary layer thickness. They propose the explanation that the greater downwash behind the tubercles compared to the troughs leads to a reduction in the effective angle of attack and thus delayed stall in this region.

The purpose of the experimental investigation reported here is to quantify the aerodynamic benefits of sinusoidal tubercles for two different airfoils at low Reynolds numbers. The airfoils investigated here have different chord-wise positions of maximum thickness and are designed for different flow regimes. The study also aims to examine the effect of the tubercle's amplitude and wavelength on the performance of the airfoil and to identify characteristic flow patterns for airfoils with tubercles.

EXPERIMENTAL PROCEDURE

Tubercle configurations were modelled for two types of airfoil: NACA 0021 and NACA 65-021. The airfoils were machined from aluminium and anodised in matte black to ensure optimum visualisation of hydrogen bubbles. All airfoils have a mean chord of $\bar{c}$ = 70mm and span of s = 495mm, giving a plan-form area of $S = 0.035\text{m}^2$. Sinusoidal tubercle configurations are illustrated in Figure 1 and the dimensions are summarised in Table 1. The values used here for amplitude and wavelength are close to estimates taken from data of an actual whale flipper [1]. Drag and lift forces for eight different airfoils were measured in a wind tunnel. Flow visualisation using the hydrogen-bubble technique was also performed to observe the flow field around the airfoil and to highlight flow separation regions and vortex formation.

Table 1
Tubercle configurations and adopted terminology

0021 airfoils		**65-021 airfoils**

Force measurements

Force experiments were undertaken in the open section of the wind tunnel at the University of Adelaide, which has a 0.5m square cross-section and a turbulence intensity of ~0.8%. Maximum blockage occurs at α = 30º and is calculated to be 7% and thus small enough to be ignored in this investigation. The free-stream velocity was measured using a Pitot tube and the sampling rate was 1000 Hz. The data were averaged over one minute and collected via a National Instruments USB-6008/6009 data acquisition device. The Reynolds number based on the free-stream velocity of U_∞ = 25m/s and mean chord length was 120,000. The working section was bolted to the exit of the wind tunnel (Figure 2) and the top of the airfoil was located very close (5mm) to the ceiling of the duct to minimise three-dimensional effects. The foundation of the load cell consisted of a heavy steel base-plate to inhibit the effects of floor vibration and a stiff frame to minimise vibrational disturbances generated by the airflow (Figure 3). These vibrations could potentially cause inaccuracies in the measurements. The angle of attack for the airfoil was set using a Vertex rotary table with an estimated uncertainty of ±0.2 degrees. Lift, drag and moment measurements were conducted using a 6-component load cell from JR3 with external digital electronics. This was fixed to a rotary table and rotated together with the airfoil. Care was taken to ensure the airfoil was mounted as accurately as possible with regard to the free-stream flow. System calibrations showed that the load cell accuracy is within ± 1%.

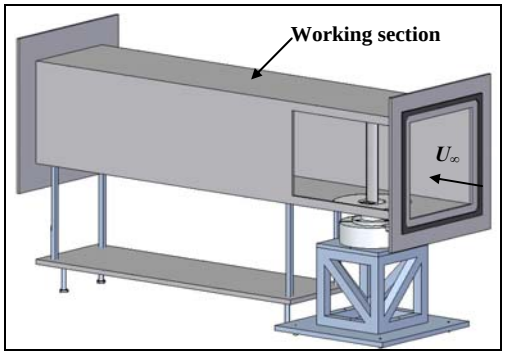

Figure 2. Sketch of experimental

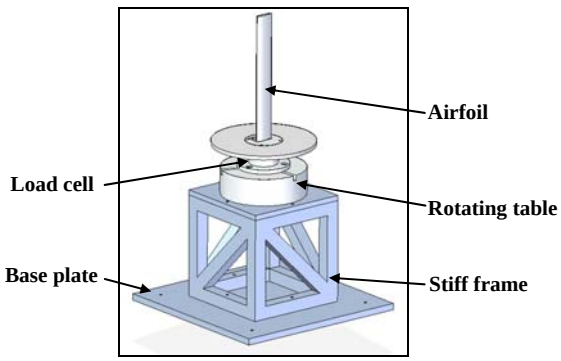

Figure 3. Load cell arrangement

The sampling period of the analogue-to-digital converter was 16ms, which ensured that at least 1000 samples were collected for each angle of attack. Due to the unsteady nature of the flow at post-stall angles, the number of collected samples was increased to 3000 for these cases.

Three sets of measurements were taken for each airfoil for the range of angles $-4° \leq \alpha \leq 30°$. The average results for the lift, drag and moment coefficients for the tested airfoils were then plotted and compared. The NACA 0021 and NACA 65-021 airfoils were analysed separately due to their different characteristics but the relative influence of the tubercles for the two airfoils was compared.

Hydrogen bubble visualisation

Hydrogen bubble visualisation was carried out in a 0.5m-square working section of a closed-return water channel of the University of Adelaide. The water tunnel velocity was selected to give optimum flow conditions for visualisation with the hydrogen bubble method. Thus velocities of U_∞= 70mm/s and 84mm/s were utilised, corresponding to Re = 4370 and 5250 respectively. A low current was passed through a sinusoidally-kinked platinum wire with diameter of 40μm, used to generate streak-lines. The flow was illuminated using a thin light sheet and digitally recorded via a SONY Mini-DV video camera, which was connected to a laptop computer. Footage was recorded from different orientations to highlight specific features. The side view shows the separation point; the top view shows variations in streak-line spacing alluding to local pressure and velocity variations and the angled top view enables identification of vortex structures. In all cases, the flow was visualised as close as possible to the mid-span location to minimise 3-D effects.

DATA ANALYSIS

For each airfoil, at each angle of attack (α), the chord-wise (F_C) and normal (F_N) forces were measured along with the moment about the span-wise axis, M_Z and converted to lift, drag and pitching moment. These were non-dimensionalised, giving the coefficients of lift and drag based on the dynamic pressure and plan-form area and pitching moment, based on the dynamic pressure, plan-form area and chord. Values of C_L, C_D and C_M for NACA 0021 are compared to published data [10]. Unfortunately, no data at the Re number of interest was found for the NACA 65-021 airfoil to compare with the results.

RESULTS

Force measurements

Lift coefficient (C_L). The lift coefficients are plotted against the angle of attack for the NACA 0021 airfoils in Figure 4. From the figure it is clear the airfoils with tubercles have lower C_{Lmax} values than the unmodified airfoil. However, the stall characteristics are much less abrupt. In comparison with

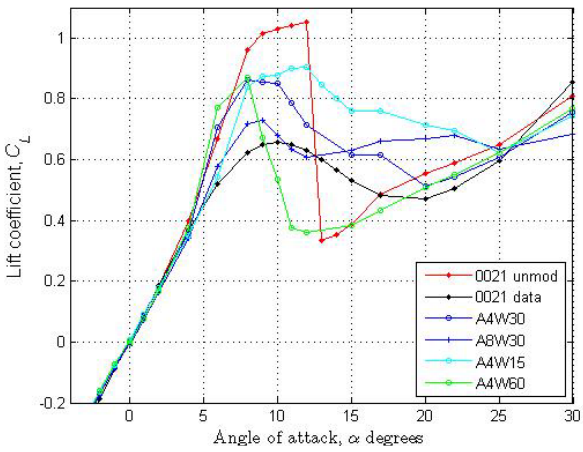

Figure 4. Lift Coefficient vs. Angle of Attack for NACA 0021

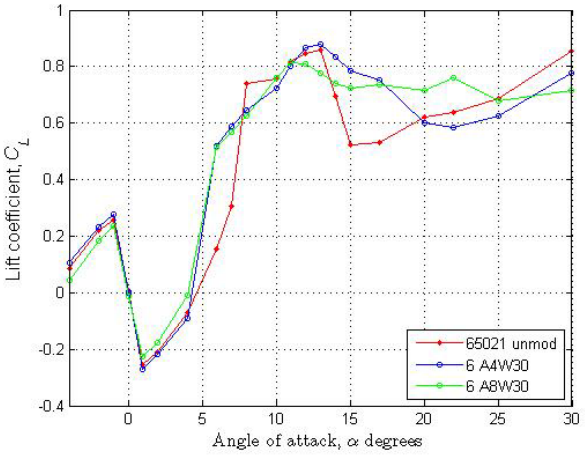

Figure 5. Lift Coefficient vs. Angle of Attack for NACA 65-021

the unmodified airfoil, the drop in C_L after stall (ΔC_L) is considerably less for the A8W30 airfoil with ΔC_L = 17% as opposed to ΔC_L = 68% for the unmodified airfoil. An interesting point is that there is a slight increase in the slope, $\partial C_L / \partial \alpha$ at around α = 4°, which is also evident in Miklosovic & Murray [11] and is perhaps a blockage effect.

Figure 5 indicates that the NACA 65-021 airfoils with tubercles achieve higher relative values of C_L for the majority of attack angles investigated in this study. Also, the lift characteristics are generally smoother for the modified airfoils. It can also be observed that for small angles of attack the NACA 65-021 airfoil generates a negative lift (for $0 < \alpha < 4$), which is attributed to an unexpected early separation of the laminar boundary layer on one side of the airfoil. This phenomenon is not observed, however, at larger angles of attack. This behaviour will be the subject of further investigation.

By increasing the amplitude of the tubercles, a smoother stall characteristic can be achieved but there is an associated penalty of a drop in $C_{L\,max}$ and a decrease in maximum stall angle. This can be seen in both Figure 4 and 5, where the post-stall C_L is higher for the A8W30 and 6 A8W30 airfoils in comparison to the A4W30 and 6 A4W30 airfoils. For both airfoils, the smaller amplitude tubercles achieve a larger C_{Lmax} and a higher maximum stall angle than the larger amplitude tubercles. It can be observed that the NACA 65-021 airfoil with smaller amplitude tubercles surpasses the unmodified airfoil in terms of performance, with its C_L value 3% and 17% higher for α = 13° and 14°, respectively. This indicates that there may be an optimum tubercle configuration for a particular airfoil and/or tubercles are more beneficial for certain airfoils.

It can be seen in Figure 4 that the wavelength of the tubercles noticeably influences the performance of the airfoil. As the wavelength is reduced, the stall angle increases and for the A4W15 airfoil, this angle is equal to that of the unmodified airfoil (i.e. α_{stall} = 12°). This result is in contradiction with other studies [7,9], which found that the varying the wavelength has negligible effects. In addition, the post-stall C_L is greater for the A4W15 airfoil compared to the other tubercle configurations, which illustrates that reducing the wavelength is beneficial for both the pre-stall and post-stall regimes. The effect of reducing the wavelength appears to be more advantageous than varying the amplitude, in terms of achieving both a higher $C_{L\,max}$ and favourable post-stall characteristics.

Drag coefficient (C_D). The results in Figures 6 and 7 indicate that at low angles of attack (i.e. $\alpha < 8°$), tubercles have a minimal effect on C_D for both airfoils. As the stall angle is approached, the tubercles act to increase the drag and thus reduce the extent of the drag bucket. At post-stall angles, tubercles achieve a favourable effect for all airfoils in terms of drag.

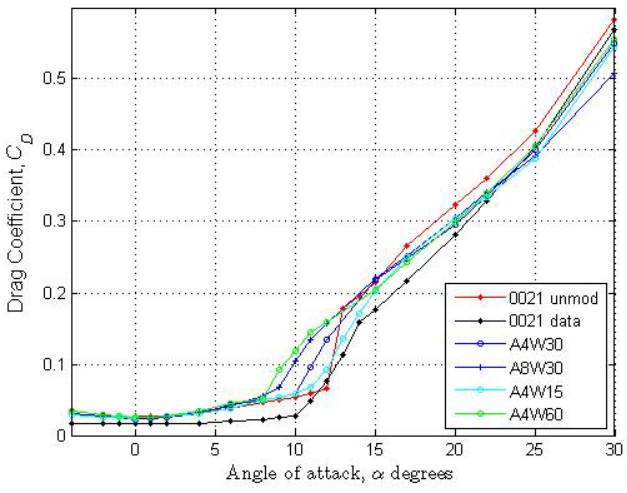

Figure 6. Drag Coefficient vs. Angle of Attack for NACA 0021

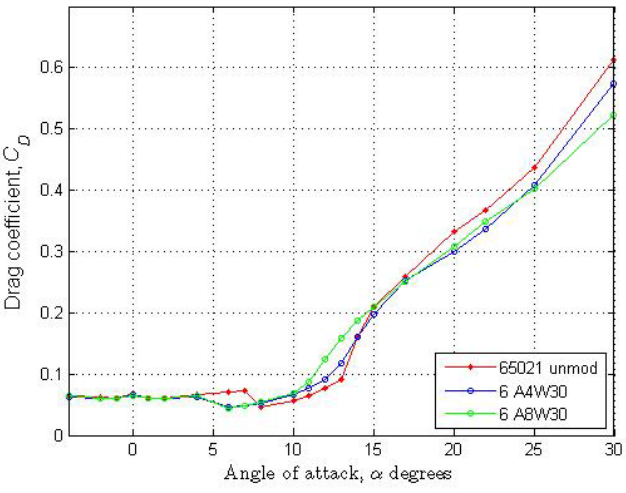

Figure 7. Drag Coefficient vs. Angle of Attack for NACA 65-021

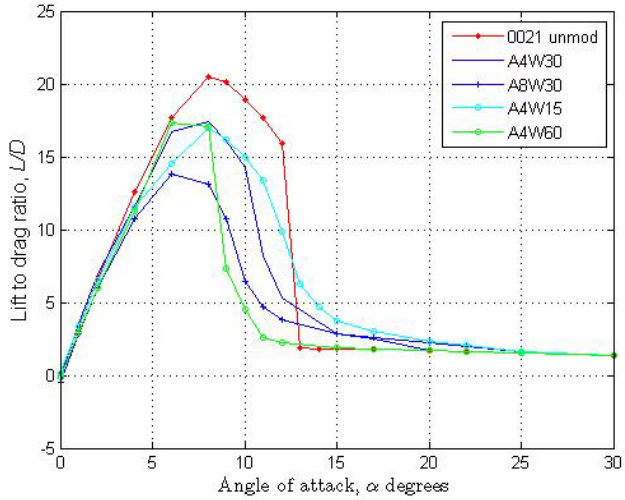

Figure 8. Lift-to-Drag Ratio vs. Angle of Attack for NACA 0021

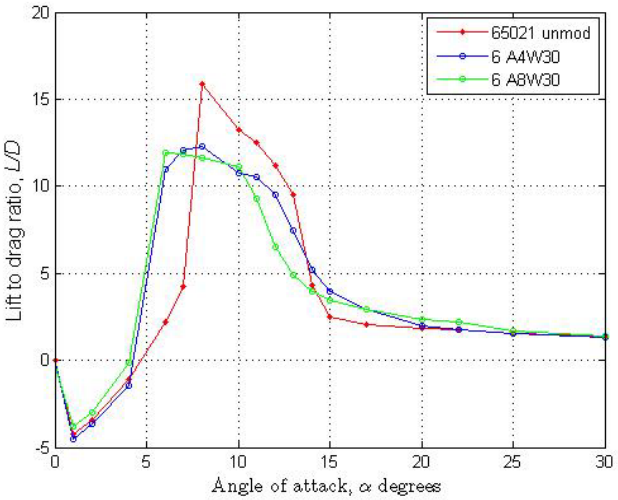

Figure 9. Lift-to-Drag Ratio vs. Angle of Attack for NACA 65-021

A lower drag is observed in the range 8º ≤ α ≤15º for the NACA 0021 airfoil having tubercles with smaller amplitude. For α < 8º, there is small difference in the drag characteristics and for α > 15º, the airfoil with larger tubercles exhibits a lower C_D. The NACA 65-021 airfoil shows a similar trend, although the range of lower C_D occurs at 8º≤ α ≤17º. Outside this range there is little difference in tubercle performance.

A comparison between tubercle wavelength configurations reveals that a smaller wavelength produces a significantly lower drag in the range 8º ≤ α ≤15º. In fact, for the angles excluding α = 10-12º, the A4W15 airfoil displays enhanced C_D performance when compared to the unmodified airfoil. At α > 15º, the larger wavelength configuration yields a slightly lower C_D.

Lift-to-drag *(L/D) ratio.* Figures 8 and 9 highlight the drag costs in producing lift, providing a measure of aerodynamic efficiency. It is observed that for both airfoils, incorporating tubercles gives a higher *L/D* ratio after stall. However, at lower angles of attack the unmodified airfoil is generally more efficient. The peak *L/D* ratio of 20.5 occurs at α = 8º for the unmodified NACA 0021 airfoil and it is 17% higher than the peak value for the A4W15, which represents the best tubercle configuration. After stall, the A4W15 airfoil demonstrates *L/D* ratios up to 70% higher than the unmodified airfoil.

For the NACA 65-021 airfoils, better *L/D* performance is noted in the range α < 8º and α > 14º for both airfoils with tubercles, compared to the unmodified airfoil. In general, smaller amplitude tubercles achieve a higher *L/D* than larger amplitude tubercles, especially in the range of 10º≤ α ≤15º. The peak *L/D* ratio for the unmodified airfoil of 15.9 also occurs at α = 8º, and is 23% higher than that for the 6 A4W30 airfoil. In the post-stall regime, the 6 A4W30 airfoil has *L/D* ratios up to 37% higher.

Pitching moment coefficient (C_M). The pitching moment coefficient, C_M relative to the quarter-chord position is plotted in Figures 10 and 11. The measured C_M displays more fluctuations than the data curve, however the overall trend is consistent. For small angles of attack (α < 4º), there is little difference in C_M between the unmodified airfoil and models with tubercles for the NACA 0021. At these angles, all airfoils experience a nose-up pitching moment.

Where as the unmodified airfoil drops to a negative C_M at α = 6º, the models with small wavelength or large amplitude tubercles remain positive. At stall, the unmodified airfoil rises to its maximum positive value but this rise is less pronounced for all airfoils with tubercles. In the post-stall region,

the majority of airfoils with tubercles have a less-negative C_M, which is an advantageous characteristic. Overall, changes in C_M are less abrupt for airfoils with tubercles.

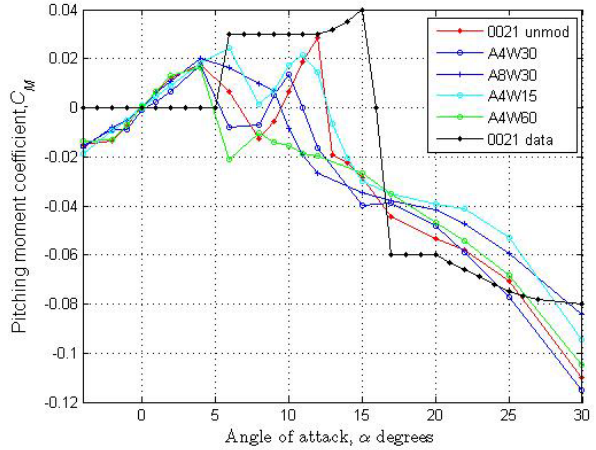

Figure 10. Pitching Moment Coefficient vs. Angle of Attack for NACA 0021

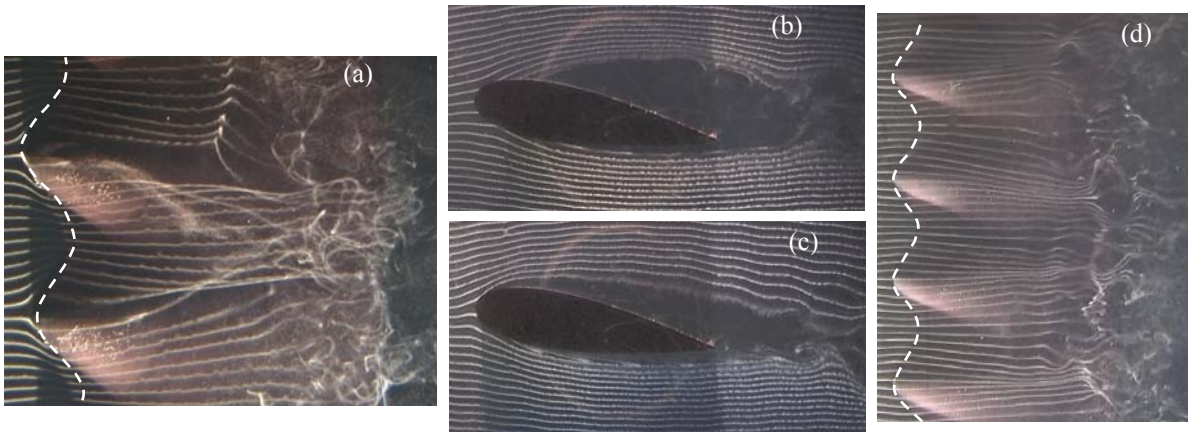

Figure 12. Hydrogen bubble visualisation (a) angled top view showing stream-wise vortices, (b) side view in plane of trough (c) side view in plane of peak and (d) top view depicting regions of acceleration. Dashed lines show the outline of the leading edge

Hydrogen bubble visualisation

Flow visualisation shows that stream-wise vortices form on either side of the troughs between tubercles, downstream of the leading edge (Figure 12(a)). It is also evident that the flow separates behind the tubercle troughs earlier than it separates behind the peaks. This can be seen in Figures 12(b) and 12(c), which show that the wake is wider behind the trough. Figures 12(a) and 12(d) suggests that the flow is accelerated in the troughs at the leading edge. This is indicated by the convergence of streak-lines in these regions. The influence of the stream-wise vortices can be seen in the convergence of streak-lines towards the tubercles. At the surface, the flow is expected to diverge away from the tubercles.

DISCUSSION

The mechanism by which tubercles alter the flow characteristics over airfoils is still not well understood. From the results presented here and also in [8] it is clear that tubercles give rise to the formation of stream-wise vortices. The acceleration of the flow in the troughs between tubercles is likely to lead to a region of low pressure in the troughs at the leading edge, which is consistent with [3]. The flow from behind the peaks seems to be entrained towards this apparent low-pressure region, giving rise to a pair of counter-rotating vortices behind each trough. It is unclear as to

whether these vortices induce a type of vortex lift as suggested in the literature [7,8,11] or if they increase the extent of flow attachment, thus delaying stall, through an augmented rate of momentum exchange within the boundary layer. According to Miklosovic *et al.* [11], the unsteadiness observed close to stall and in post-stall conditions showed signs of vortex-dominated flow. However, this was contradicted by the fact that the characteristic simultaneous increase of $C_{L\ max}$ and $C_{D\ min}$ did not occur [11]. It has been argued by van Nierop *et al.* [9] that it is implausible for tubercles to behave as vortex generators since their wavelength and amplitude are much larger than the boundary layer thickness and that instead, they alter the pressure distribution on the wing, increasing the extent of flow attachment. Despite this viewpoint, there seems to be a strong analogy between tubercles and counter-rotating vortex generators as described in [12].

In this study, it was observed that when the position of maximum thickness is further aft, increasing the extent of laminar flow, tubercles can be more beneficial. Since there is a more efficient exchange of momentum in a turbulent boundary layer [13], it is inferred that tubercles are more effective for a laminar boundary layer for which momentum exchange is poor. In regards to the smallest wavelength and amplitude being the most beneficial tubercle configuration, it is expected that associated stream-wise vortices are smaller, leading to a relatively lower form drag component. Additionally, since more vortices are generated per unit length of span for the smaller wavelength tubercles, this may result in greater momentum exchange.

CONCLUSIONS

The results for the NACA 0021 airfoil indicate that in the pre-stall regime there is marginal advantage in employing tubercles. At post-stall conditions, however, a large improvement in lift-to-drag ratio can be achieved and much smoother stall characteristics are observed. These results are consistent with results from [7]. The most beneficial configuration of the tubercles proves to be those with the smallest amplitude and narrowest wavelength. Results for the NACA 65-021 show that the position of maximum thickness has a noticeable effect on the performance of the tubercles. For this airfoil, tubercles maintain a higher lift-to-drag ratio for the majority of angles of attack, except near stall. For both airfoils, tubercles act to smooth out the pitching moment characteristics of the airfoil.

EXPERIMENTAL INVESTIGATION OF THE EFFECT OF HEAT TRANSFER ON PRESSURE DROP FOR A HEAT EXCHANGER FOR AERO ENGINE APPLICATIONS

C. Albanakis[1], D. Missirlis[1*], P. Storm[2], K. Yakinthos[1], A. Goulas[1]
[1]Laboratory of Fluid Mechanics & Turbomachinery, Department of Mechanical Engineering, Aristotle University of Thessaloniki, Egnatia street, 54124 Thessaloniki, Greece

ABSTRACT. The present work is investigating the effect of heat transfer on the pressure drop for a heat exchanger designed to be used in an aero engine installation. The main idea of this technology is based on the use of an alternative thermodynamic cycle. The heat exchanger consists of elliptic tubes placed in a 4-3-4 staggered arrangement and is operating as a heat recuperator aiming at the exploitation of the thermal energy of the turbine exhaust gas to pre-heat the compressor outlet air before combustion and thus, to decrease fuel consumption and pollutant emissions. The operation of the heat exchanger is characterized by two basic parameters, the pressure loss and the heat transfer taking place. The presence of the heat exchanger introduces a pressure drop in the flow field, which can significantly affect the downstream flow development and the effectiveness of the thermodynamic cycle of the installation. The pressure drop induced by the heat exchanger depends on geometry-related parameters, such as the geometry and the arrangement of the tubes, and to operation-related parameters, such as the flow inlet conditions and the heat transfer taking place. For the proper evaluation of the performance of the heat exchanger both of these parameters should be considered. For this reason a wide range of experimental measurements was carried out in a wind tunnel where a test section of the heat exchanger was installed. The presence of the hot gas was modelled with preheated air while for the heat transfer cold water was circulated inside the elliptic tubes. The experimental measurements were performed with the use of a 3-hole pressure probe and a Pitot-static tube, while for the air temperature measurements, a K-type thermocouple was used. For the water temperature measurements, a Platinum Resistance Thermometers PT100 thermocouple was used. Various sets of detailed experimental measurements were performed including also isothermal measurements in order to have a reference point for the pressure drop of the flow through the heat exchanger when no heat transfer was taking place. The experimental measurements showed that the pressure drop was directly affected by the mean temperature of the air flow through the heat exchanger.

Keywords: *heat transfer, pressure drop, heat exchanger, aero engine*

INTRODUCTION

Despite the fact that modern civil aero engines are of a high technological level, there are still demands of lower fuel consumption and reduced pollutant emissions. Consequently, it is necessary for engineers to investigate new concepts which can contribute to the optimization of the overall

operation of an aero engine. Towards this direction, MTU Aero Engines have developed the concept of the intercooled recuperative aero engine (IRA), as shown in Figure 1.

A detailed description of this technology can be found in the works of Broichhausen et al. [1], Wilfert and Masse [2] and in the MTU Aero Engine internet site [3]. The main idea in such a concept is the use of an alternative, but more efficient, thermodynamic cycle for aircraft engines, which is based on recuperation. For this reason a system of heat exchangers, operating as heat recuperators, is mounted at the exhaust nozzle of the aircraft engine so as to exploit part of the thermal energy of the exhaust gas of the aero engine and obtain a better combustion with less pollutant emissions.

Each one of the heat exchangers is constructed by special profiled tubes of elliptic geometry placed in a 4-3-4 staggered arrangement, in order to minimize the pressure drop, and consist of two manifold collector tubes, Figure 2. During engine operation, the flow from the high-pressure compressor (HPC) enters the upper tube from both sides and is distributed into the U-shaped profiled tubes, which are brazed into the manifold tubes and form the core of the heat exchanger. The preheated air is collected in the lower manifold tube and it is guided back to the combustion chamber. At the same time, the hot exhaust gas from the low-pressure turbine flows upwards through the heat exchanger elliptic tubes and its temperature is decreased while heating-up the air inside the elliptic tubes. Additional details of the heat exchanger geometry and of this technology can be found in the works of Missirlis et al. [4], Yakinthos et al. [5] and Albanakis et al. [6].

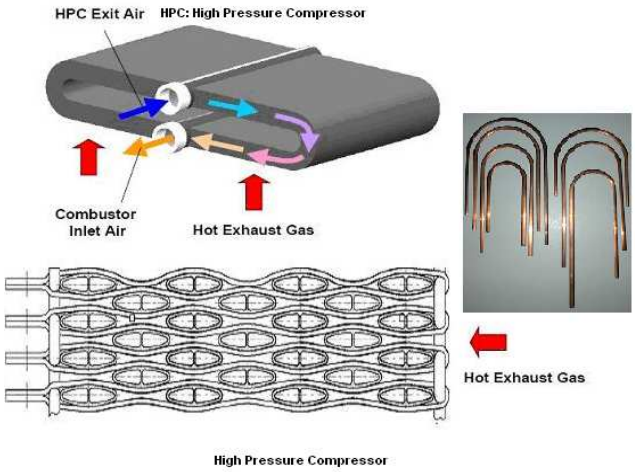

Figure 2. The heat exchanger and the U-shaped elliptic profiled tubes

EXPERIMENTAL SET-UP

To maximize the benefit of this technology it is necessary to investigate the hydraulic and thermal performance of these heat exchangers. For this reason, it was obligatory to carry out a wide range of experimental measurements sufficient enough to describe the operation of the heat exchanger. For the experimental measurements, a part of the heat exchanger corresponding to the straight part of the device was used as shown in Figure 3. The heat exchanger model was placed in a wind-tunnel with a rectangular cross-sectional area. Figures 3 and 4 show the test-rig with the heat-exchanger placed in the wind-tunnel. During the experimental measurements the hot gas has been generated with preheated air while, for the heat transfer, cold water was circulated inside the heat exchanger tubes. Additional details about the experimental setup can be found in the work of Albanakis et al. [6].

The measurement positions have been chosen to be 40mm upstream the model and 40mm downstream the model. The two positions were the same for both the velocity, pressure and temperature measurements. Additionally, in order to correlate the pressure drop between cases with and without heat transfer, two sets of pressure drop measurements have been carried-out, the first with no heat transfer (isothermal) and the second one with heat transfer (anisothermal).

The pressure drop measurements were performed with the use of a Pitot-static tube and a 3-hole pressure probe. The latter is capable of measuring total and static pressure, velocity and flow angle after a proper calibration. The probe consists of three small tubes, one central and two others which are placed in a symmetrical arrangement, as presented in Figure 5. Each of these tubes is capable of providing pressure values to a digital manometer attached to the probe. The final signal is transferred to a computer for further processing. The calibration procedure of the 3-hole probe is based on the suggestions of Gundogdu and Carpinlioglu [7], Morrison et al. [8] and it is similar to the one used in Missirlis et al. [4].

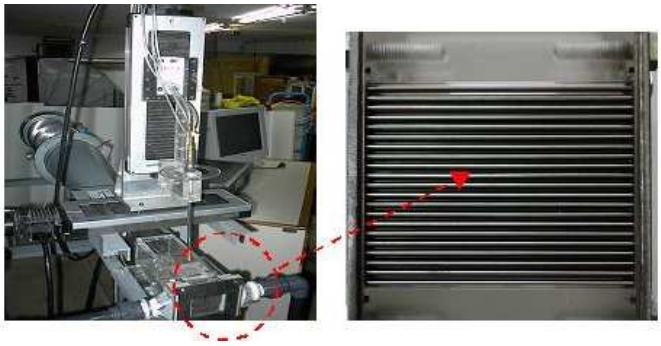

Figure 3. The test-rig with the heat exchanger

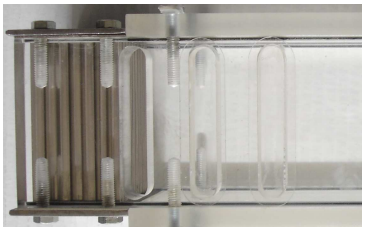

Figure 4. The test-rig with the heat exchanger

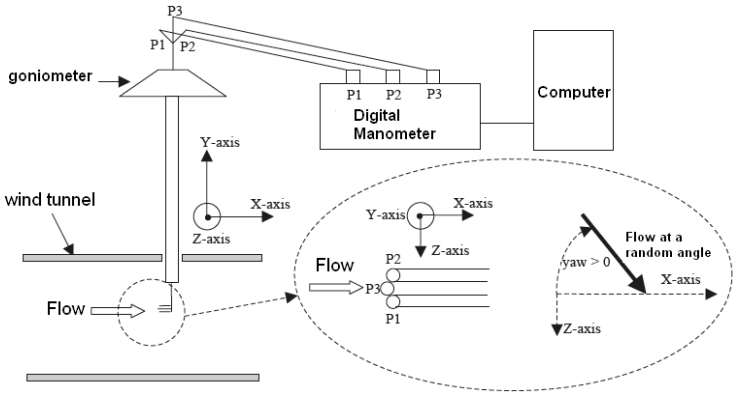

Figure 5. Diagram of the pressure probe operation

Regarding the calibration procedure, the side tubes P_1 and P_2 of the 3-hole pressure probe values will have equal values only when the tip of the probe is placed parallel to the local airflow direction. At this position, the pressure value of the center tube P_3 will be equal to the total pressure of the flow. This position is corresponding to the zero-degree position of the calibration. Thus, at the first step the probe is placed at airflow inside an empty wind tunnel and by changing the angle with the goniometer the zero-degree position is found and the P_1, P_2 and P_3 pressure values are recorded. From this position, the orientation of the probe is changed from +30 to -30 degrees (relatively to the zero-degree position) with a step of 5 degrees and each time the corresponding P_1, P_2 and P_3 values are recorded. Then, the following non-dimensional coefficients, as shown in equations (1), (2) and (3), are calculated for each angle.

$$Cp_{yaw} = (P_1 - P_2)/(P_3 - P_{ave}) \ , \quad P_{ave} = 0.5(P_1 + P_2) \tag{1}$$

$$Q_p = (P_3 - P_{ave})/(0.5\rho V^2) = (P_3 - P_{ave})/(P_{total} - P_{static}) \tag{2}$$

$$S_p = (P_{total} - P_3)/(P_3 - P_{ave}) \tag{3}$$

With the use of the measured values and polynomial curve fitting the functions of the coefficients towards the yaw angle are calculated as presented in Figure 6.

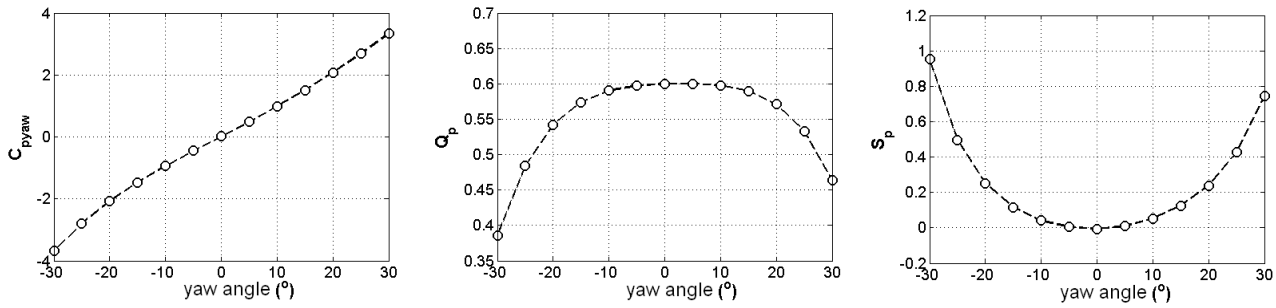

Figure 6. Plots Plots of the non-dimensionalized coefficients towards the flow angle

Hence, when the probe is placed in a random position inside a flow field in order to derive the total and static pressure, the yaw angle and the velocity components, the reverse procedure is followed. More specifically, since from a specific measurement the P_1, P_2 and P_3 pressure values are known, the C_{pyaw} can be easily calculated. In addition, from the curve fitting of the C_{pyaw} plot the yaw angle can be derived as a function of the C_{pyaw} and thus, the flow angle is also known. Furthermore, since the yaw angle is known, the Q_p and S_p coefficient can be calculated. At the final step, the values of the velocity, total and static pressure are calculated as presented in equations (4), (5) and (6) respectively:

$$V = \sqrt{\frac{P_3 - P_{ave}}{0.5\rho Q_p}} \tag{4}$$

$$P_{total} = S_p(P_3 - P_{ave}) + P_3 \tag{5}$$

$$P_{static} = P_{total} - \frac{1}{2}\rho V^2 \tag{6}$$

Regarding the air temperature measurements, a K-type thermocouple was used while for the water temperature measurements, a Platinum Resistance Thermometers PT100 thermocouple was used.

In order to ensure that the experimental measurements reflect the true average behavior of the heat exchanger it was necessary to proceed to a measurement step dependency study to determine the most appropriate measurement step size. After some preliminary measurements with different steps sizes at both measurement planes, it was decided to use a measurement step equal to 5 mm for the inlet and 2 mm for the outlet position since the use of these step values provided an accuracy corresponding to less than 1 Pa for the total and static pressure values and to approximately 0.01 m/s for the velocity magnitude.

MEASUREMENTS SET-UP AND RESULTS

The experimental measurements correspond to the following measurement sets:

- Isothermal measurements with T_{inlet}=T_{outlet}=20°C (293K)
- Isothermal measurements with T_{inlet}=T_{outlet}=40°C (313K)
- Isothermal measurements with T_{inlet}=T_{outlet}=60°C (333K)
- Isothermal measurements with T_{inlet}=T_{outlet}=80°C (353K)
- Anisothermal measurements with T_{inlet}=60°C and T_{outlet}=31°C (333K-304K), taking into account the heat transfer effect
- Anisothermal measurements with T_{inlet}=80°C and T_{outlet}=33°C (353K-306K), taking into account the heat transfer effect

The Reynolds number of the flow was defined by equation (7). For the experimental measurements of the present work, the corresponding Reynolds numbers were in the range of 3100 to 5500 which, based on suggestions of Umeda and Yang [9], are within the transitional regime.

$$\mathrm{Re} = \frac{u_{\max} D}{\nu} \tag{7}$$

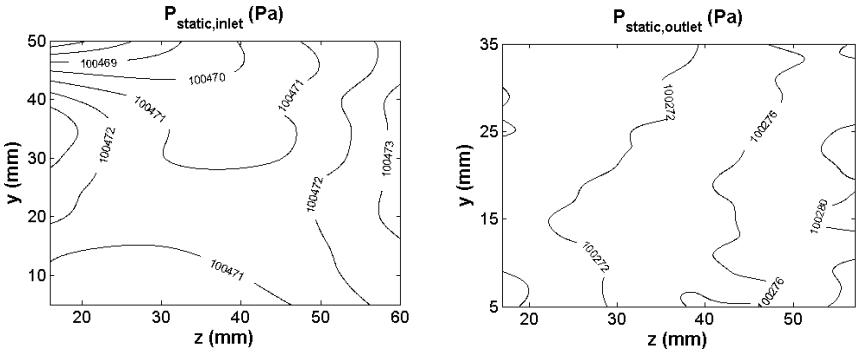
where,

$u_{\max}$: is the maximum velocity which is based on the minimum free area available for fluid flow $A_{\min}$

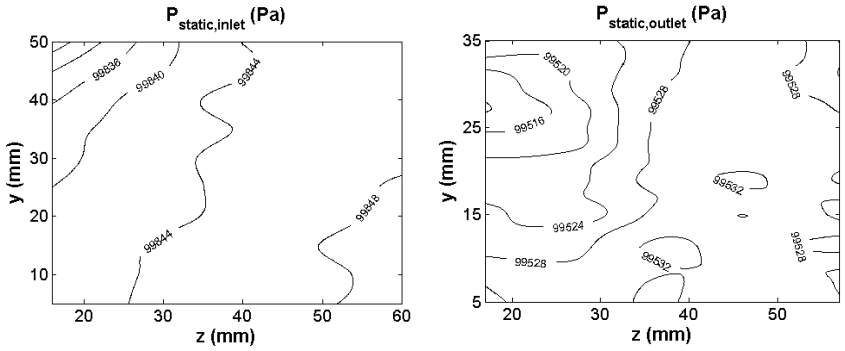
D : is the diameter of the equivalent circular tube with the same perimeter as the one of the elliptic tubes

ν : is the fluid kinematic viscosity

Typical plots of the static pressure measurements are presented in Figure 7. Figure 8 shows the static pressure drop per unit length for the isothermal cases, when the inlet air temperature takes values of 20°C, 40°C, 60°C and 80°C, together with the static pressure drop for the two anisothermal cases of T_{inlet}=60°C and T_{outlet}=31°C and of T_{inlet}=80°C and T_{outlet}=33°C. In the same figure the polynomial fitting curves are plotted which in all cases are best described by a second order polynomial curve. As it can be seen, the effect of the air temperature is clearly shown and a larger value of temperature leads to a larger pressure drop. This conclusion is valid also for the anisothermal measurements when an effective weighted temperature (e.g. average temperature) between the inlet and outlet is taken into consideration. Thus, the anisothermal case of T_{inlet}=80°C and T_{outlet}=33°C, which corresponds to average air flow temperature of 56.5°C, is placed in the static pressure drop plot of Figure 8 lower than the one of 60°C.



a) mass flow of $0.029\ kg/s$



b) mass flow of $0.037\ kg/s$

Figure 7. Inlet and outlet static pressure isolines for the isothermal measurements of 20°C

A very small deviation from this trend is met only for the anisothermal case of T_{inlet}=60°C and T_{outlet}=31°C, which corresponds to average air flow temperature of 45.5°C and which is placed almost exactly on the static pressure drop curve of the 40°C, even though under the same approach a higher pressure drop should be expected. Additionally, in order to correlate the pressure losses with the average air flow velocity inside the heat exchanger, which is related to the average temperature and density of the flow inside the heat exchanger, the results of the experimental measurements were reprocessed and are presented in Figure 9. As it can be seen, all experimental measurements follow the same second order polynomial curve. This indicates that the static pressure drop is strongly affected by the average velocity of the air flow inside the heat exchanger regardless of whether heat transfer takes place or not.

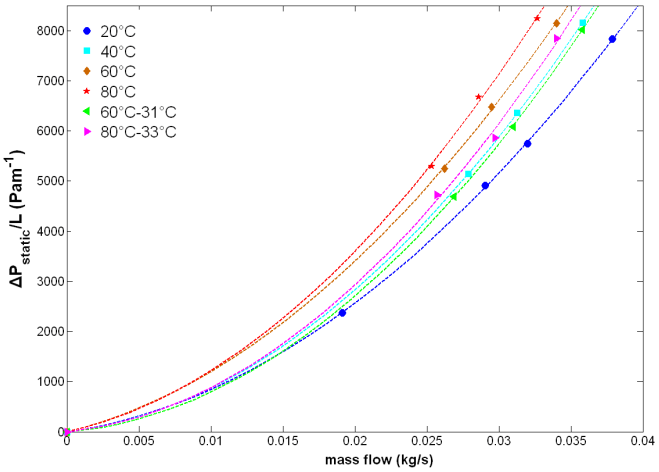


Figure 8. Comparison of the static pressure drop per unit length over mass flow for the isothermal and anisothermal cases

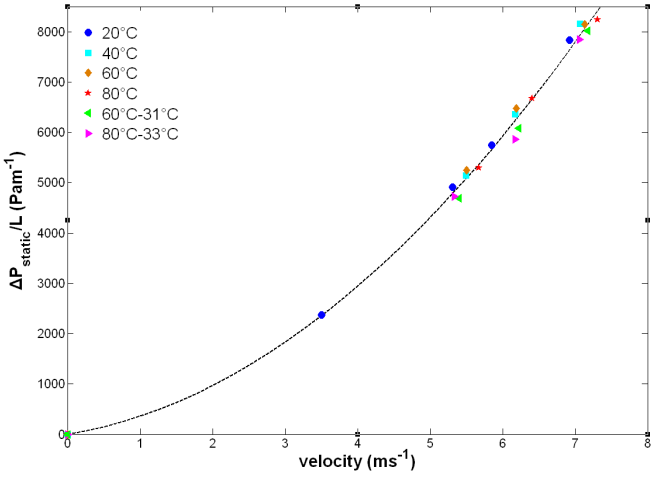

Figure 9. Static pressure drop over effective velocity

Consequently, since the correlation of the effective velocity with repect to pressure loss is known, it is relatively easy for the engineer to calculate the pressure losses due to the presence of the heat exchanger in the overall aero engine installation as long as the average air flow temperature can be estimated. The latter can be deduced from either the derivation of a Nusselt correlation from the

experimental anisothermal measurements or from a literature survey for similar setups (Kays and London [10], Zukauskas [11]).

CONCLUSIONS

In the present work, the performance of a heat exchanger designed for aero engines was investigated experimentally. The measurements show that the pressure drop is directly affected by the mean temperature of the air flowing through the heat exchanger. The static pressure drop could be described by a second order polynomial fitting curve and could be regarded as nearly independent of the inlet air temperature and heat transfer but strongly dependent on the average 'effective' velocity of the air flow inside the heat exchanger which is related to the average temperature and density of the flow inside the heat exchanger for the same mass flow at the inlet. Thus the measurements corresponding to the higher mean air flow temperature yield the higher pressure drop while the ones corresponding to the lower mean air flow temperature produce the lower pressure drop. Based on these conclusions a general pressure drop law can be derived which can sufficiently describe the pressure drop behaviour of the heat exchanger inside the aero engine installation.

ABSTRACT. The current paper presents a study on the effect of thermal boundary conditions on transient natural convection in an air filled rectangular enclosure. Experiments are carried out over a Grashof number range of 10^5-10^7 for an enclosure of aspect ratio of A = 0.25. The cavity is representative of an aircraft wing box resting on the apron where the top surface of the enclosure is exposed to solar loads. Experiments were carried out for the following three cases. In case one the top surface is heated to 100°C by means of a PID controlled heater mat, with conduction permitted through the side and bottom walls. For case two the top wall is again PID controlled, but an isothermal and constant temperature boundary condition was imposed on the bottom wall. Lastly for case three an isoflux boundary condition was imposed on the top wall, and again the bottom wall was isothermal and at constant temperature. Experimental methods employed included flow visualisation, particle image velocimetry and thermocouple measurements. Principal results indicate the existence of two counter acting flow circulations driven by the side wall, the flows were found to detach an adiabatic point adjacent to the side wall. The introduction of an isothermal bottom surface had the most effect on the flow structures, owing to elevated side wall temperatures. The interior air temperature distributions remained similar for each case.

Keywords: *natural convection, transient experiments, aircraft wing box compartment*

INTRODUCTION

Natural convection studies have received considerable attention over recent decades due to the broad range of engineering applications such as electronics cooling, solar collectors, nuclear reactors, fire research, pollution in lakes, chemical vapor deposition and ventilation in buildings. However, the application of aircraft compartment cooling has received little attention. This paper focuses on an aircraft wing box compartment subjected to solar loads directly on the upper wing surface. The aircraft is stationary on the apron for a time period relative to commercial aircraft turnaround time, and it is during this time that the aircraft experiences its most elevated temperatures. The wing box compartments are the location for many of the aircraft fuel tanks where heat generated is cooled by natural convection. With the replacement of traditional aircraft materials by advanced modern composite materials, a new thermal environment is introduced, where knowledge of such effects are desired. A transient experimental analysis of the natural convection behavior in a replica aluminum wing box heated only from above was carried out to deliver an in depth understanding of this phenomenon.

Review papers from Ostrach [1] and Catton [2] summarize the early enclosure natural convection investigations which proved to be the foundation of many of the studies to follow. Some of the most familiar and established studies on natural convection include those of Cormack *et al* [3, 4, 5], which also served as the basis for many of the early natural convection studies, particularly low aspect ratio studies. An abundance of studies on differentially heated cavities for various applications followed which included Ostrach [6] and Kimura and Bejan [7]. The first transient natural convection investigations include Patterson and Imberger's [8] scale analysis predictions of a low aspect ratio differentially heated cavity, and the closely related transient experimental analysis carried out by Yewell *et al* [9]. Ostrach [10] summarizes as extensively as possible the most relevant and significant studies of the early enclosure natural convection investigations era. The pertinent more recent studies on enclosure natural convection include investigations on the effect of varied boundary conditions on the fundamental natural convection fluid flow and heat transfer behavior. Das *et al* [11] studied a symmetrically side heated enclosure, Manca and Nardini [12] experimentally investigated an open ended cavity with a heated top wall and an unheated lower wall, where Anderozzi *et al* [13] carried out a similar numerical study. Other studies have focused on the effects wall boundary conditions such as conduction in the vertical walls [14] and the presence of non isothermal surfaces [15]. More relevant to the current study, Sadowski *et al* [16] experimentally investigated natural convection flow in an enclosure driven by a vertical wall with two separate uniform temperature sections of a vertical configuration, similarly Tscherry *et al* [17] investigated flow generated by colliding boundary layers along a vertical wall with two uniform temperature horizontal sections. Newport *et al* [18, 19] and Egan *et al* [20, 21] have carried out several in depth experimental and numerical studies relative to enclosure natural convection in aircraft compartments. Most relevant to the current study are the investigations carried out by Wu and Ching [22-24], where the effects of top wall temperatures on laminar natural convection in air filled cavities for varied aspect ratios was investigated.

The objectives of the current paper were to investigate the effects of varied thermal boundary conditions on the transient flow structures and temperature distributions in an air filled rectangular enclosure heated on the upper surface only. Experiments were carried out for the following three cases. For case one the top surface of the enclosure was heated to 100°C by means of a PID controlled heater mat, conduction through the side and bottom walls was permitted. For case two, wall conduction between the side and bottom walls was prohibited by placement of a rubber insulation material; forced convection cooling was also applied to the bottom surface resulting in an isothermal and constant temperature bottom surface at an average of 25°C. An isoflux boundary condition of 700 W/m^2 on the upper surface was then introduced for case three, the bottom surface is again isothermal and at constant temperature as per case two.

The paper is structured as follows. Details of the experimental set up and methods employed are described. The results from the analysis are presented on a case by case basis, and discussed comparatively. Flow visualization was employed to qualitatively investigate the transient evolution of the thermally induced flow structures. Particle image velocimetry was utilized to quantitatively measure the velocity fields to gain an understanding of the driving force behind the natural convection flow and thermocouple measurements delivered an insight into the transient wall and interior air temperature distributions. The conclusions are then offered upon closure.

EXPERIMENTATION

Thermocouple Measurements

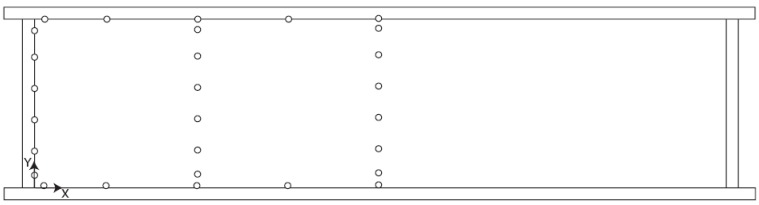

Figure 1. Test facility with thermocouple positions outlined

Experiments were conducted on an aluminium test facility as shown in Figure 1; the walls of the apparatus were made from 10 mm thick aluminium plates. The size of the apparatus was 620 mm (H) × 170 mm (L) × 620 mm (D). The interior enclosure size is 150 mm (H) × 600 mm (L) × 600 mm (D) yielding an aspect ratio of H/L = 0.25. The left and right side walls were made from 10 mm thick glass, thus allowing for optical access to view the flow structures within the enclosure. A 500W rubber heater mat was placed over the entire top surface area to achieve a boundary condition of 100°C. The test facility was insulated using 50mm fibre glass thermal insulation and the apparatus was placed on wooden slats to permit insulation of the bottom surface in case one, and the placement of a forced convection cooling mechanism for cases two and three. Dow Corning 340 Heat Sink Compound was applied at the end sections of each aluminium plate to minimize the thermal contact resistance and assist in conduction between each plate for case one, and only on the top end section for cases two and three. Thermocouples were used to record transient temperatures throughout the interior of the enclosure and on the inside wall surfaces. The thermocouples were mounted on a polycarbonate cross which was placed into the enclosure at a position of D=300mm. Surface measurements were recorded by fixing the thermocouples to the face of the respective surfaces using high temperature adhesive tape. K-type thermocouples were used for the measurements which were connected to an AGILENT data acquisition system. The thermocouples were calibrated using a LAUDA E100 thermocouple bath to an accuracy of ±0.5°C. The positions of the thermocouples are illustrated in Figure 1.

Particle Image velocimetry and Flow Visualisation

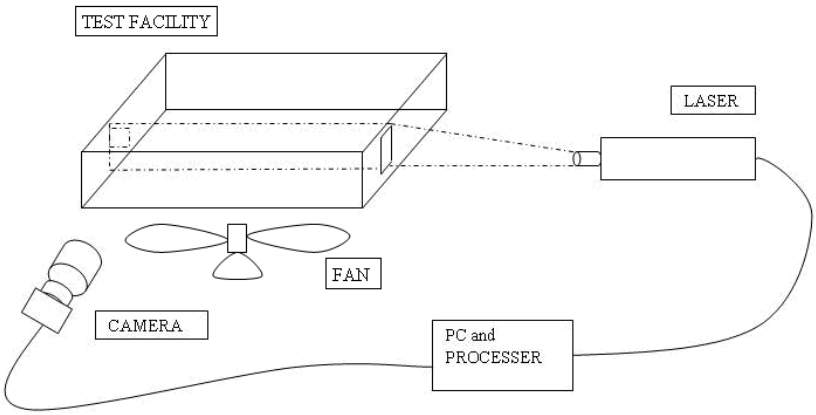

Figure 2. Experimental set up

Flow visualisation was employed to observe the flow structures from time zero to steady state temperature conditions. In the current experiments smoke was employed as a tracer fluid and entered the enclosure through a small opening in the left side glass panel. The illumination source used was a Nd:YAG laser of 532 nm wavelength. This produced a beam 2mm thick which entered the enclosure through a window in the rear aluminium panel as shown in Figure 2. The laser sheet illuminates the smoke particles revealing the natural convection flow structures. Flow visualisation images of size 115mm x 150mm (x × y) along the front wall were recorded using a 2 MP Power View CCD camera. Particle image velocimetry (PIV) was then employed to measure the instantaneous velocities of the particles. Images were processed using the TSI Insight 3G software. To ensure accurate measurements the resolution of the images was increased where the field of view was reduced to 58mm x 50mm. This was found to be sufficient to resolve the near wall velocity boundary layers which were recorded along the front vertical wall at heights of y = 130 mm, 85 mm and 30 mm.

RESULTS

This section is structured as follows. First the initial observations based on the measured transient Grashof numbers, boundary conditions and interior temperature distributions are discussed and defined. The results are then presented in order of case where the observed transient flow structures, measured velocity profiles and wall and interior air temperature distributions are discussed comparatively.

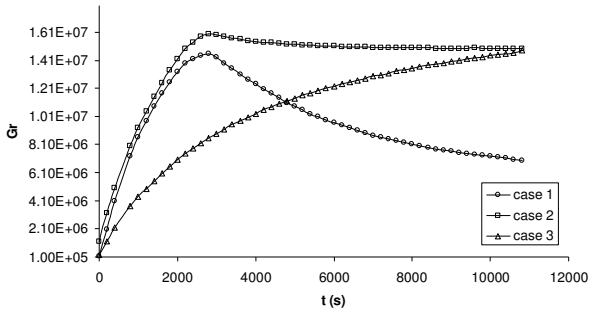

Figure 3. Transient Grashof number for cases 1-3

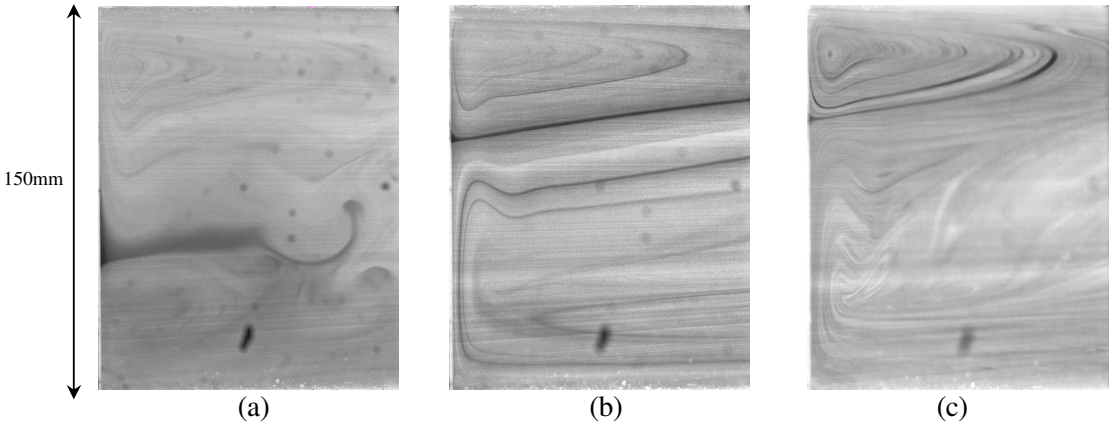
Experiments were carried out over the laminar Grashof range of 10^5-10^7 as shown in Figure 3. For case one the top surface was heated by means of a PID controlled heater mat, the time taken to reach the desired boundary condition of 100°C was 45 minutes (2700 seconds), conduction was permitted through the bottom surface hence reducing the temperature gradient relative to the height of the enclosure, where a gradual reduction in Grashof number was observed. For case two an isothermal and constant bottom surface temperature was introduced allowing the Grashof number to remain constant from 45 minutes onward. In case three a constant heat flux boundary condition was imposed on the top wall giving a Grashof number equal to that in case two at a steady state time of 180 minutes (10800 seconds).

The fluid flow and heat transfer was observed to be symmetrical about the vertical centreline of the enclosure where the vertical walls were found to be the main driving force behind the natural convection flow. The flow visualisation images presented in Figure 4 are representative of the flow structures adjacent to the front vertical wall. A degree of non isothermality was present on both the top and bottom surfaces. For the purpose of data analysis an averaged temperature surface boundary condition was calculated. The dimensionless local temperature is denoted by $T^* = (T_L-T_B)/(T_T-T_B)$ and is calculated based on the top and bottom surface temperatures at each transient instant, the dimensionless vertical height is denoted by $y^* = y/H$ and the corresponding horizontal position by $x^* = x/L$.

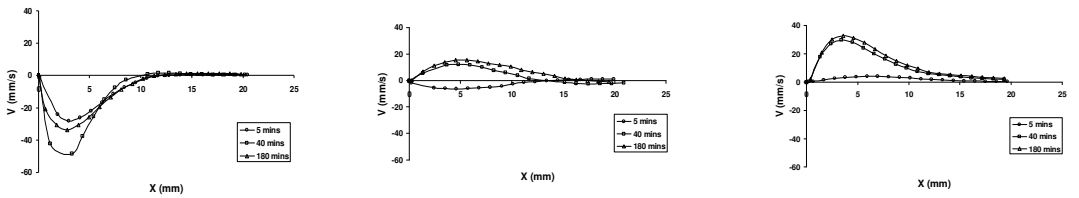
Case One



(a) (b) (c)

Figure 4. Flow Visualisation Images at (a) 5 (b) 45 and (c) 180 minutes

The transient flow structures for case one are shown in Figure 4. At 5 minutes the flow was observed to initiate from the centre of the heated top surface and act towards the cooler vertical side wall, the flow then proceeds to descend along the vertical wall where a definite detachment of the flow was observed. The fluid then becomes entrained in the natural convective circulation current completing the counter clockwise circulation evident in the upper left hand side of the enclosure. Below the point of detachment the air was observed to be almost stationary at this early transient stage as the fluid in this region of the enclosure is not exposed to any significant temperature gradient. At 45 minutes as shown in Figure 4 (b), the top surface is at 100°C, the flow structures are developed and the presence of two counter acting circulations along the vertical wall is clearly evident. In the upper region of the cavity the flow structures are the same as those observed at 5 minutes, however in the lower region of the cavity an upward flow has now developed opposing the downward fluid motion yielding a clockwise circulation in the lower region of the cavity. The detachment point of the flow has also increased in height compared to Figure 4 (a). The point of detachment is the exact location where the surface and fluid temperature in the immediate vicinity adjacent to the vertical wall are equal. Conduction through the vertical wall therefore becomes significantly influential in determining the exact location of the detachment point. At 180 minutes, on arrival of steady state, the only notable difference between the flow structures at 45 minutes is a further increase in the detachment point height suggesting that the transient conduction through the side wall has a significant effect on the adjacent natural convection circulations.

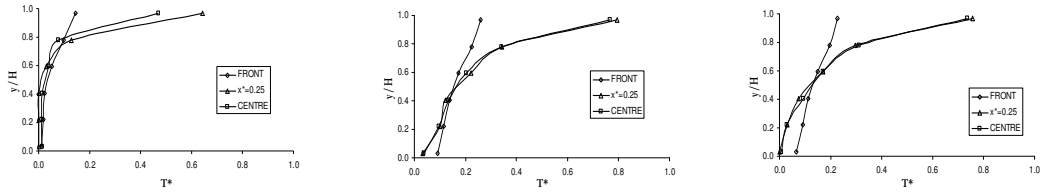


(a) (b) (c)

Figure 5. Velocity Profiles at (a) y=130mm (y*=0.86) (b) 85mm (y*=0.56) (c) 20mm (y*=0.13)

A quantitative insight into the fluid velocity and direction along the vertical wall was gained by particle image velocimetry measurements as shown in Figure 5. At a position of y = 130mm the fluid, at all times, is at a higher temperature than the vertical wall and hence is subjected to a negative buoyancy force as it is cooled and flows down towards the base of the compartment. The fluid velocity was

observed to increase from a minimum of -28 mm/s at 5 minutes to a maximum of -48 mm/s at 45 minutes which coincided with the top wall reaching 100°C. The velocity at 180 minutes then reduces to -33 mm/s due to the now constant top wall boundary condition and also the increased side wall temperature owing to the prolonged period of heating time from 45 minutes to steady state. The interaction between the wall and adjacent fluid temperature is further highlighted as influential in determining the fluid flow direction at this point. At a position of y = 85 mm a reversal of flow direction was observed, at 5 minutes a weak downward acting flow of -6 mm/s was overturned to an upward flow of 12 mm/s at 45 minutes which gradually increased marginally to 15 mm/s at 180 minutes. It is noted that at y = 20 mm the fluid flow is consistently acting upward where the velocity magnitudes are larger than at y = 85 mm. In the lower region of the cavity the side wall acts as a heating mechanism to the adjacent cooler fluid yielding the upward fluid motion, a decrease in velocity magnitude was observed at y = 85 mm due to the opposing force of the downward acting fluid in the upper region of the cavity where the side wall acts as a cooling mechanism to the adjacent warmer fluid in the vicinity of the heated top wall. The opposing flows meet at the adiabatic detachment point of zero velocity where they then act towards the core region of the enclosure and complete their respective circulations as observed previously.



(a) (b) (c)

Figure 6. Temperature Distributions at (a) 5 (b) 45 and (c) 180 minutes

From analysis of Figure 5 an understanding of the transient flow structures has been gained. Shown in Figure 6 are measurements of the front vertical wall and the interior air temperature distributions at the vertical centreline and at x* = 0.25. At a time of 5 minutes and at y* > 0.75, the initial flow direction within the enclosure, is determined at an early stage as shown in Figure 6 (a). At just 5 minutes the interior air temperatures were found to be larger than that of the side wall indicating that the upper section of the wall acts as a cooling mechanism to the adjacent fluid yielding the downward acting flow. A small temperature gradient in the enclosure at y* < 0.45 was observed agreeing with previous flow visualisation images indicating only minor activity in the lower region of the enclosure at this time. At 45 minutes the presence of the two opposing heat transfer mechanisms is evident. The front wall temperature is lower than the fluid temperature at y* > 0.45 where the downward motion was previously observed and at y* < 0.45 the wall temperature is higher than the adjacent fluid where the previous upward motion was observed. The point at y* = 0.45 is deemed to be the location of the adiabatic detachment point. At 180 minutes similar behaviour was observed, however the detachment point has increased in height to y* = 0.55 again agreeing with the previously observed flow structures where the flow physics remained similar with only a small increase in detachment height being the notable difference. The detachment point was observed to be higher than y* = 0.45-0.55 in the flow visualisation images. Higher resolution temperature measurements in the immediate vicinity of the vertical front wall may permit a more accurate representation of the exact transient detachment locations; however the correct fundamental fluid flow and heat transfer behaviour concerning the enclosure as an entirety is sufficiently achieved.

Case Two

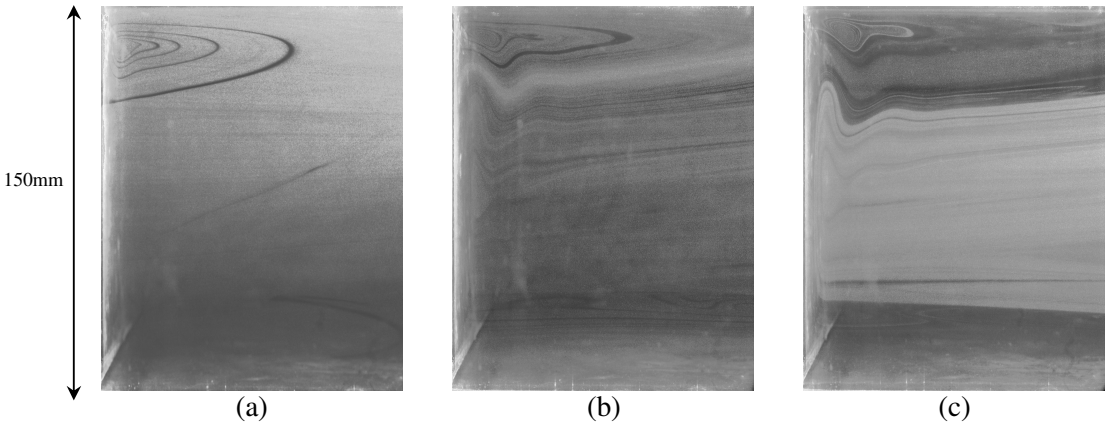


Figure 7. Flow Visualisation Images at (a) 5 (b) 45 and (c) 180 minutes

For case two the top surface remains heated to 100°C by means of PID control; however an isothermal and constant temperature bottom surface is introduced inhibiting conduction from the side walls to the bottom wall and the addition of forced convection cooling on the exterior of the bottom surface. The effect of such alteration of the boundary conditions on the evolved flow structures is illustrated in Figure 7. At 5 minutes the fundamental flow physics remains similar as in case one, with the notable difference being significant increase in the detachment point height along the vertical wall. As seen previously the front wall temperature is highly influential on the developed flow structures, therefore a higher detachment point indicates a higher wall temperature where the effect of a cooling mechanism on the warm fluid in the upper region of the cavity is reduced. Based on the flow visualisation observations it is suggested that reducing conduction from the side wall to the bottom wall induces elevated local side wall temperatures which effectively increase the adiabatic detachment point between the solid wall and the adjacent fluid. At 45 minutes the flow structures reveal a dominant clockwise acting circulation adjacent to the side wall where the detachment point is in close proximity to the heated top wall. The downward motion and counter clockwise circulation is still present but less prominent and less effective as acting as a cooling mechanism on the warm fluid in this region. Upon arrival of steady state at 180 minutes the downward fluid motion has been lessened to a zone of recirculation in the most upper part of the enclosure adjacent to the side wall, where the upward fluid motion dominates the flow adjacent to the vertical side wall.

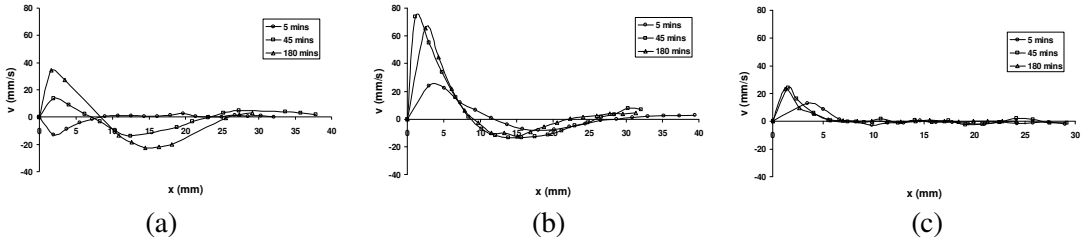

Figure 8. Velocity Profiles at (a) y=130mm (y*=0.86) (b) 85mm (y*=0.56) (c) 20mm (y*=0.13)

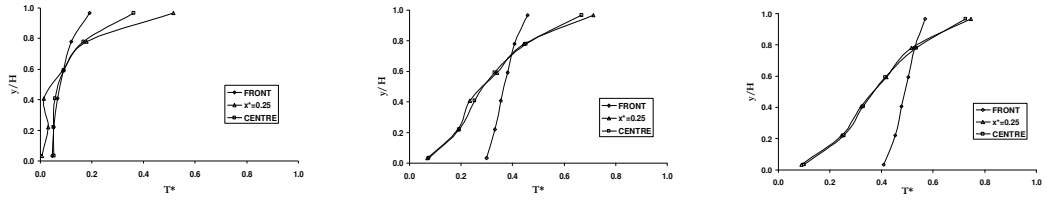
The experimentally measured velocity profiles at the side wall for case two are shown in Figure 8. At 5 minutes and at a location of y = 130 mm, the fluid is cooled by the vertical wall and has a velocity of -14 mm/s compared to -28 mm/s at the same position for case one. The reduction in velocity suggests a reduction in temperature gradient between the vertical sidewall and the adjacent fluid where the effect of the wall as a cooling mechanism has been reduced at this early transient stage. At 45 minutes and

180 minutes the fluid flow direction has been reversed with velocities of 13 mm/s and 34 mm/s recorded. At y = 85 mm the flow direction is again acting upward at all times, the minimum velocity of 26 mm/s occurring at 5 minutes and the maximum of 75 mm/s at 45 minutes. The fluid velocity then reduces to 65 mm/s at this location once reaching 180 minutes. The reduction in velocity is proportional to the imposed top wall boundary condition where the PID output is at 100% until the top surface reaches 100°C at 45 minutes, the output then reduces maintaining the desired constant temperature boundary condition until the arrival of steady state at 180 minutes. At the same position in case one, the velocity magnitudes were observed to be lower at all times, the elevated side wall temperatures observed in case two induce a higher temperature gradient between the side wall and the adjacent fluid which leads to higher velocity magnitudes in case two. At y = 20mm the flow was again found to be acting upward at each transient stage from a minimum of 13 mm/s at 5 minutes to 24 mm/s and 23 mm/s at 45 and 180 minutes.

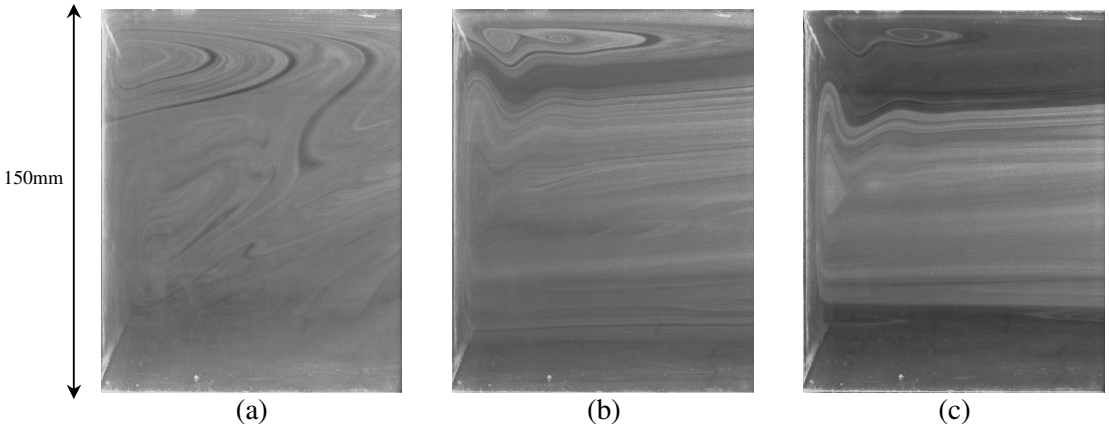


(a) (b) (c)

Figure 9. Temperature Distributions at (a) 5 (b) 45 and (c) 180 minutes

Shown in Figure 9, at 5 minutes the front surface temperature was observed to be at a maximum of T*=0.2, higher than in case one at a maximum of T*=0.15 at the same time. The previous fluid flow observations and velocity measurements are supported where an increase in detachment height from y* = 0.45 in case one at 5 minutes to y* = 0.6 in case two at 5 minutes was observed, owing to the increased front wall temperature. For case two, at 45 minutes the detachment height has increased to y* = 0.7 and again increases to y* = 0.8 at 180 minutes. The similarity in the trends between the interior temperature distributions at 45 minutes and 180 minutes for cases one and two also agrees with the previously observed similar flow structures. The only notable difference in each case is the small increase in the detachment height from 45 minutes to 180 minutes.

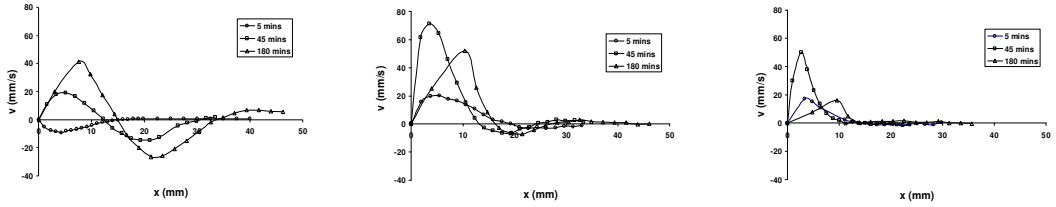
Case Three



(a) (b) (c)

Figure 10. Flow Visualisation Images at (a) 5 (b) 45 and (c) 180 minutes

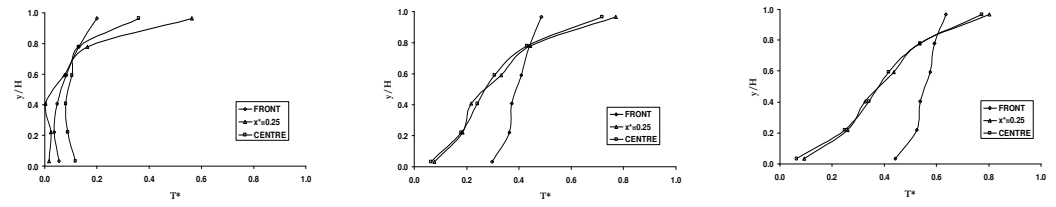
For case three a constant heat flux boundary condition of 700 W/m2 was imposed on the top wall, where the bottom surface is identical to that of case two, remaining isothermal and at constant temperature. It was observed that the flow physics between the three cases remains very similar, where the detachment point varies, dependant on the adjacent side wall temperature. For cases two and three the transient flow structures revealed a distinct similarity as shown in Figure 10. At five minutes the downward acting flow is present where the detachment points occur at approximately the same location, the flow then acts towards the core region where it becomes entrained and completes the counter clockwise circulation in the upper region of the enclosure. In the lower region of the enclosure the initial development of the upward acting flow occurs. At 45 and 180 minutes the flow structures for case three are fully developed and exhibit the same flow behaviour as that of case two where the increase of the detachment point is the only difference. This indicates that for different top surface boundary conditions, the temperature gradients in the enclosure are proportional inducing the same transient flow structures.



(a) (b) (c)

Figure 11. Velocity Profiles at (a) y=130mm (y*=0.86) (b) 85mm (y*=0.56) (c) 20mm (y*=0.13)

The transient velocity profiles measured for case three exhibit similar behaviour to that of case two as shown in Figure 11. At y = 130 mm the flow was observed to initially act downward at 5 minutes, where at 45 and 180 minutes the flow direction is then reversed as the side wall temperature and detachment height increase. The velocity was seen to gradually increase from a velocity of 18 mm/s at 45 minutes and 41 mm/s at 180 minutes. The transition was observed to be gradual for case three. For the PID controlled top surfaces of case one and case two a fluctuation was observed where the maximum velocity occurred at 45 minutes when the 100°C boundary condition was achieved. The velocity magnitudes indicate that the temperature gradient between the top surface and the adjacent side walls for case one and two were found to be at a maximum at 45 minutes, whereas for the isoflux case three the evolution was observed to gradual. At the positions of y = 85 mm and y = 20 mm the fluid adjacent to the side wall was observed to flow towards the top surface at all times recorded. The maximum velocity magnitudes at these locations occurred at 45 minutes and were observed to decrease on approach to steady state; a possible reason for this is that the side wall heats faster resulting in arrival at the thermal capacitance limit of the solid wall before the interior air. Therefore after 45 minutes the air continues heating at a faster rate than that of the adjacent solid wall which resulted in a decrease in the velocity magnitudes.



(a) (b) (c)

Figure 12. Temperature Distributions at (a) 5 (b) 45 and (c) 180 minutes

Figure 12 depicts the temperature distribution for case three; again the only notable difference is the increase in detachment height, again supporting the previously observed transient flow structures. The temperature distributions for case three exhibit the same heat transfer and flow physics as cases one and two.

For cases one to three, it was observed that the transient interior air temperatures trends are similar for each case. The front surface temperatures for cases two and three were observed to be higher than case one, resulting in the change in flow structures and the higher detachment point.

CONCLUSIONS

- An understanding of the fundamental heat transfer process and flow physics for an air filled enclosure heated from above only has been gained. The flow is fundamentally vertical about the vertical centreline where the side walls were observed to be the main driving force behind the flow. Two counter acting circulations existed adjacent to the side wall where the opposing flows detach at an adiabatic point along the side wall once the solid and fluid temperatures are equal.
- The effect of thermal boundary conditions on the flow structures and temperature distributions have been investigated. The flow physics and temperature distributions were shown to obey the same fundamental physics for each of the cases analysed.
- The introduction of an isothermal bottom surface was deemed to have the most significant effect on the induced flow structures, the local side wall temperatures were observed to increase effectively increasing the detachment point along the vertical wall.
- The elevated side wall temperatures reduced the cooling effect on the warm fluid in upper region of the enclosure. The counter clockwise acting circulation was reduced, where the dominant flow was the clockwise acting circulation acting from the lower region of the enclosure.

ABSTRACT. The unsteady flow field behind an oscillating airfoil, below and beyond static stall condition, has been investigated in a low speed wind tunnel by means of hot-wire anemometer. The airfoil was an EPPLER 361 oscillating in a pitching motion about the half chord axis at reduced frequency of 0.182. The amplitude of oscillation was 8 deg. To assess effect of mean incidence angle, the mean incidence of oscillation was varied 0-10 deg. Streamwise mean velocity profiles and turbulence intensity profiles at 0.25 chord distance behind trailing edge of airfoil were investigated. When the maximum dynamic angle of attack was below the static stall angle of attack, weak effects on the wake were found by increasing mean angle of attack. Instead, for higher angles of attack strong unsteady effects were appeared on the wake. Furthermore, variations of momentum deficit coefficients were discussed.

INTRODUCTION

In recent years considerable research has been conducted into the problem of unsteady aerodynamic of an oscillating airfoil, especially problem of airfoil stall. Most of the previous investigations were directed to unsteady wing loading and dynamic stall process, as reviewed by McCroskey [1]. Dynamic stall phenomenon appears on helicopters rotor blades, rapidly maneuvering aircraft, wind turbine and even insect wings. In many cases dynamic stall becomes the primary limiting factor in the performance of the associated vehicle or structure [2]. The mechanism of dynamic stall was first identified on helicopters. The importance of unsteady aerodynamics was considered by Harris and Pruyen [3] when helicopter designs were unable to predict the performance of high speed helicopters using conventional aerodynamics. Tolouei et al [4] investigated experimentally the unsteady pressure distribution over an EPPLER 361 airfoil. They found that pressure coefficients in the low angle of attack range showed little overshoot when compared with the static values, while for the large angle of attack cases the differences were significant. They considered that the large overshoot in the dynamic pressure coefficient for the high angle of attack case is probably due to the existence of the stable dynamic vortex, which is created near the leading edge and moves downstream. Mani et al [5] measured Surface static pressure distribution on the upper and lower sides of the model, during the oscillating motion. It was found that reduced frequency had strong effects on the pressure distribution, near the leading edge of the airfoil.

There are many practical situations where unsteady wakes are involved. The wake-blade interaction in turbo machinery flows is one example. Relatively scant attention has been given to the study of

oscillating wakes. Satyanarayana [6] measured unsteady wakes of airfoils and cascades under a sinusoidally varying gust flow. Time-mean and time-dependent wake profiles at low frequency behind the airfoil were reported in his work, and the distinctions between these were discussed. Panda and Zaman [7] studied the wake of a similar airfoil at mean angles of attack above the static stall angle by use of hot wire anemometry and flow visualization. They saw that in addition to the familiar dynamic stall vortex (DSV), an intense vortex of opposite sign originates from the trailing edge just when the DSV is shed. These two vortices take the shape of the cross section of a large mushroom. They also measure the vorticity flux shed into the wake and compute the circulatory part of the lift coefficient by means of Kutta-Joukowski theorem. Koochesfahani [8] studied experimentally the vortical flow patterns in the wake of a NACA0012 airfoil pitching at small amplitudes and showed that the oscillation wave form has an important effect in the vortical pattern shapes and mean velocity profiles in the wake. He found that there is a critical value for the oscillation frequency that the usual velocity defect profiles in the wake changes to excessive momentum similar to a jet flow and the airfoil produces trust force. Also, he showed that in special cases mean velocity profiles have two peak of velocity defect, that this is symptom of a double-wake structure. Recently, an experimental measurement of unsteady wake behind a sinusoidally unsteady airfoil was performed by Mani et al [9]. They were shown that the angle of attack and reduced frequency are the most important parameters which influence on the velocity profiles. Also, they found that the influence of angle of attack on the velocity profiles is to increase the momentum deficit and wake thickness.

The primary purpose of the present study is to investigate the characteristics of unsteady wake of an airfoil oscillating sinusoidally in pitch, below, near and beyond static stall condition. The airfoil was an EPPLER 361. The velocity in the wake was measured by means of hot-wire anemometer. The airfoil was given at different mean incidence angles, and the resulting wakes were investigated to understand the effects of them.

EXPERIMENTAL SETUP

The experiments were conducted in a TE-44/C PLINT low speed wind tunnel of Amirkabir University of Technology (AUT) having a rectangular test section of 0.45m×0.45m×1.2m. An airfoil of Eppler-361 profile was mounted horizontally in test section. The chord of the airfoil was 0.145 m, and the aspect ratio was 3.0. The gap between the airfoil and the side wall was 1 mm. The ratio of the chord length to the height of the test section was 1:3. Figure 1 shows a view of the airfoil in test section.

Figure 1. A view of airfoil in test section

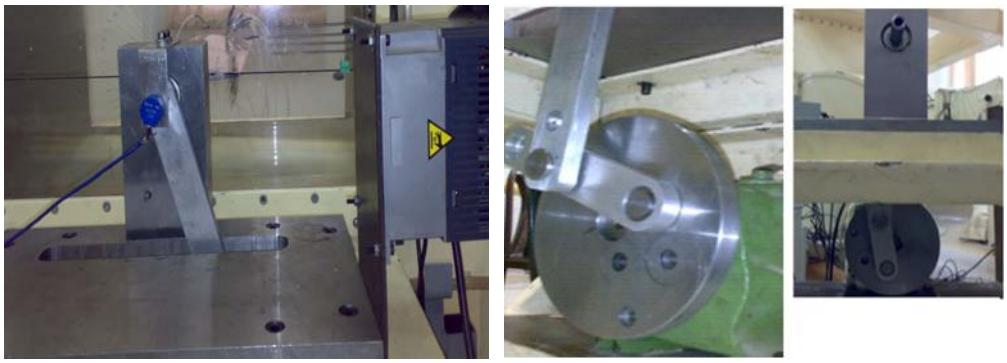

Figure 2. Views of oscillation system

Pitching oscillation about the half-chord axis was provided by a crank-connecting rod mechanism, driven by a variable-speed ac motor. Figure 2 shows the pictures of oscillation mechanism. The instantaneous angle of attack (dynamic angle), α , can be expressed as:

$$\alpha = \alpha_0 + A\sin 2\pi ft \tag{1}$$

Throughout the test, the oscillation amplitude was 8 deg. The mean incidence angles of attack were given four values of 0, 2.5, 5 and 10 deg. Therefore, during the test, instantaneous angle of attack of airfoil was varied from -8 to 18 degrees. It should be note that the static stall angle of this airfoil was about 12.5 °. The value of reduced frequency *k*, define as $k = 2\pi fC / 2U_\infty$, was considered about k =0.182. The tunnel speed and the frequency of oscillation were set at U_∞ =5 m/s and f =2 Hz, respectively. The corresponding Reynolds number, based on the chord length, was 50000.

A constant temperature hot-wire anemometer (CTAs) was employed for the velocity measurements. The hot-wire probes were mounted on a support in the center plane of the test section behind the airfoil as shown in Fig. 3. Each sensor of probe was made of tungsten and the diameter of sensor was about 5μm.The overheat ratio and DC offset voltage for each hot-wire sensor carefully adjusted such that each sensor nearly the same operating conditions. Data were acquired and processed by a 12 bit 16 channel A/D converter board capable of sample rates up to 200 kHz.

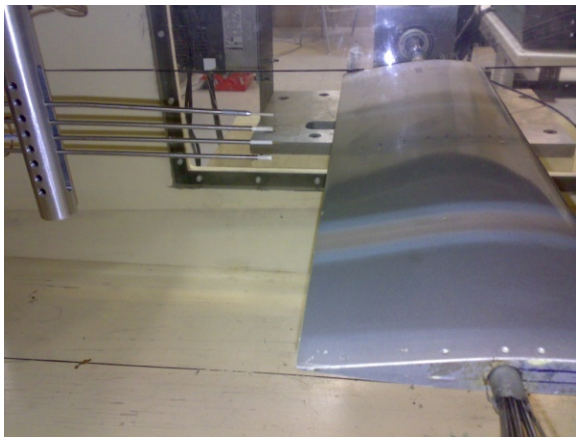

Figure 3. Model and hot-wire sensors

DATA ACQUISITION AND REDUCTION

A potentiometer model LT-M-0200-S was used to initiate data sampling. It was connected to the oscillation mechanism and its output voltage was synchronized with the CTA outputs. A personal computer (P4) with a 16 channel A/D converter board also processed the data. Data was taken, at a given probes location. Measurements were carried out for one downstream station. The vertical traverse was restricted from *Y/C*= -0.63 to +0.63 moved by every 50 mm for the measurements. The ensemble averaging procedure that has been adopted in the present experiment, where the samples in each bin are statistically independent because they were collected during different cycles, avoids statistical bios, as observed by lyn et al [10]. Statistical uncertainty in mean and r.m.s velocities depends on the number of sampled data, turbulence intensity and confidence level. For the present experiment, considering a typical value of 2000 sampled data, a confidence level of 95% and a local turbulence intensity of 30%, uncertainties of ±4% and ±5% are expected for the mean and r.m.s velocities, respectively.

EXPERIMENAL RESULTS AND DISCUSSION

The results of the investigation will be described in three main subsections. First, the effect of mean incidence angle on the wake will be studied while airfoil oscillates quite below static angle of attack ($\alpha < 12.5^{\circ}$). Then, the results will be investigated while maximum angle of attack is near static angle of attack. Finally, the wake will be studied when maximum angle of attack is quite beyond static angle of attack.

Maximum angle of attack below static stall

In this subsection, the results are obtained at two mean angles of 0° and 2.5° for oscillation amplitude of A=8°. The amplitude and mean angles of attack are selected such that during one oscillation cycle, the model would oscillate quite below static angle of attack.

Mean velocity profile. Figure 4 illustrates the mean velocity profiles at aforementioned mean angles. This figure shows very low increasing of velocity defect when mean incidence angle becomes larger.

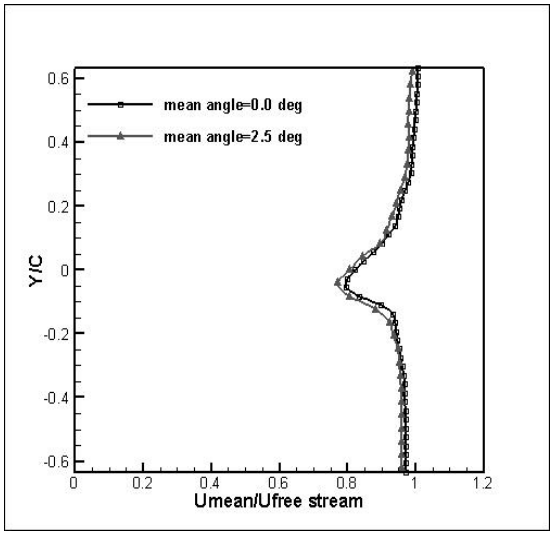

Figure 4. Mean velocity profiles at α_0=0° and 2.5°

Momentum deficit coefficient. The momentum deficit coefficients at aforementioned mean angles are obtained. It should be mention that the mean velocity profiles are used to estimate the momentum deficit on the airfoil [8]. The values of C_f for two mean angles of 0° and 2.5° are estimated about 0.13550 and 0.14235, respectively. It is found that momentum deficit coefficient increases only about 4.81 percent with increasing mean incidence angle.

R.M.S. velocity profile. Figures 5 shows the r.m.s. streamwise velocity profiles at two mean incidence angles at phase angle of 180°. Small differences are found in two profiles. Both profiles have well defined double peak structure at the same phase angle, and the position of each peak is very close for both mean angles.

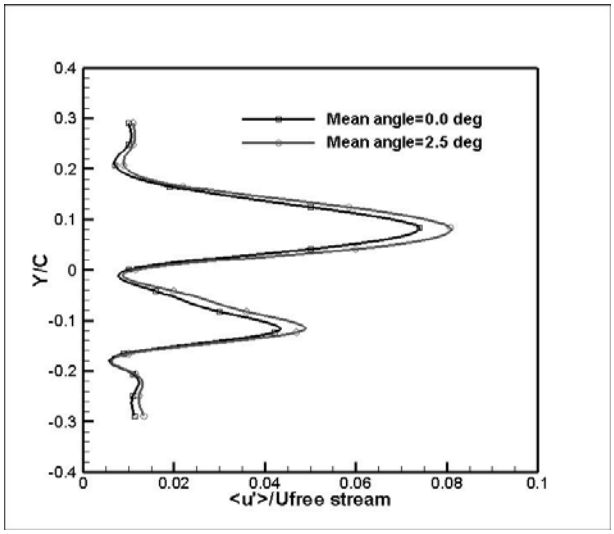

Figure 5. R.M.S. velocity profiles at α_0=0° and 2.5°, Phase ($2\pi ft$) =180°

The all above results totally confirm no particular effects on the wake profiles with increasing mean angle of attack. When airfoil oscillates below static stall angle of attack, flow remains attached throughout the oscillation cycle on the airfoil surface and vortices form the wake with arranged mutation. Therefore, the wake keeps almost the same structure in all angles below static stall.

Maximum angle of attack near static stall

In order to compare profiles, when maximum angle of attack exceeds static angle of attack slightly, mean angles of attack are set at 2.5° and 5° at oscillation amplitude A=8° , Fig. 5. In this case, airfoil could oscillate below static angle of attack at α_0 =2.5° and nearly beyond static angle of attack at α_0 =5°, respectively.

Mean velocity profile. The mean velocity profiles at two mean angles of 2.5° and 5° are plotted in Fig. 6. It is seen that the profiles are considerably different from each other. As seen in Fig. 6, the velocity defect and wake thickness increase with mean angle.

Momentum deficit coefficient. The momentum deficit coefficient for mean angle of 5° is obtained and is compared with the mean angle of attack of 2.5°. The value of C_f at α_0 =5° is estimated about 0.17372. The momentum deficit coefficient at the case of 5° increases about 18 percent against case of 2.5°. This increasing of momentum deficit coefficient is more considerable than previous case.

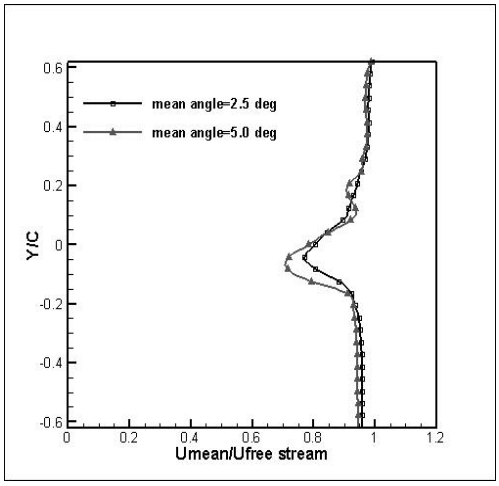

Figure 6. Mean velocity profiles at α_0=2.5° and 5°

R.M.S. velocity profile. Figures 7 shows the r.m.s. streamwise velocity profiles at two aforementioned mean incidence angles at phase angle of 180°. The manifest variations in turbulence intensities, especially in peaks of profiles and positions of them are observed as mean angle becomes larger.

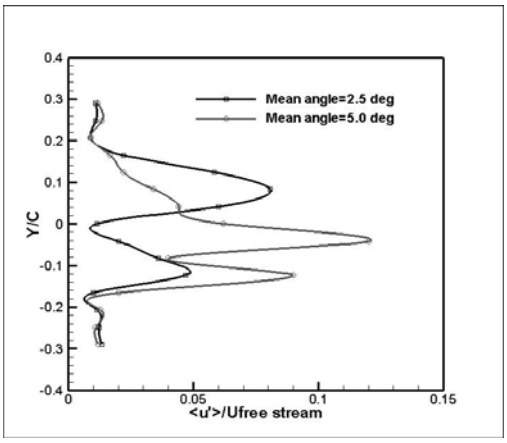

Figure 7. R.M.S. velocity profiles at α_0=2.5° and 5°, Phase ($2\pi ft$) =180°

All results in above subsection show the considerable variation in the wake as maximum angle of attack passes static angle of attack slightly. When airfoil exceeds static stall angle, flow reversal occurs in boundary layer. This eventuates that formed vortices in the wake become larger with irregular mutation.

Maximum angle of attack beyond static stall

Finally, mean angles of attack are selected such that the maximum angle of attack is quite beyond static angle of attack.

Mean velocity profile. Figure 8 shows a great increasing of the wake thickness and velocity defect with mean incidence angle. when the mean angle of attack is 10 °, a very broad region of large velocity defect and wake thickness is noted, which is absent for the cases of 0°, 2.5 °or 5 °.

Momentum deficit coefficient. The momentum deficit coefficient for the mean angle of 10° is estimated about 0.23469. It is found that momentum deficit coefficient increases surprisingly about 26 percent in comparison with the mean angle of 5°. This increasing of momentum deficit coefficient is very considerable than last cases. In fact, this shows the more decreasing of momentum around airfoil when maximum angle of attack is quite beyond static angle of attack.

R.M.S. velocity profile. Figure 9 illustrates the r.m.s. streamwise velocity profiles at two mean angles of 5 ° and 10°. It is seen that turbulence intensities in all positions for mean angle of 10 º in the wake increase excessively. Also, the double peaks structure of turbulence profiles disappears at mean angle of 10 º. This huge variation in turbulence structure in the wake indicates occurrence of a recent phenomenon.

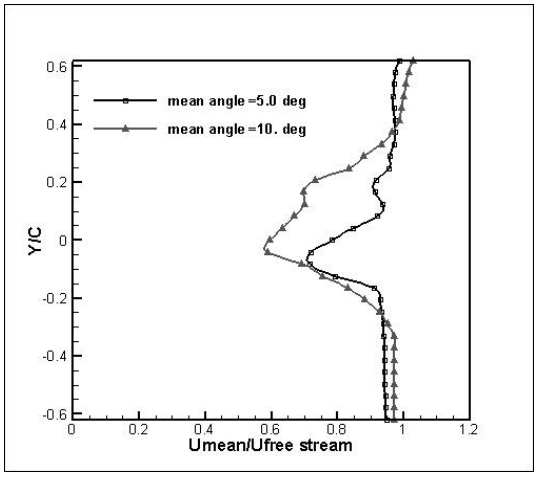

Figure 8. Mean velocity profiles at α_0=5° and 10°

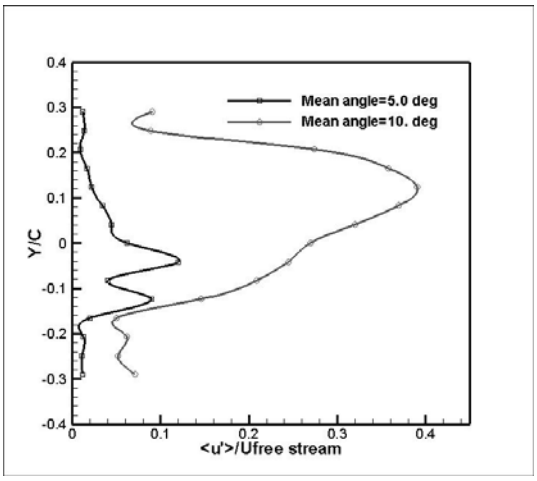

Figure 9. R.M.S. velocity profiles at α_0=5° and 10° Phase ($2\pi ft$) =180°

Above observations are evidences of a large region of separated flow on the airfoil surface or dynamic stall during the motion at α_0=10°. This huge separation causes that airfoil surface vortex goes into the wake and a sudden growth on vortices size, wake thickness and turbulence intensity appears.

CONCLUSIONS

The unsteady wakes developed behind an EPPLER 361 oscillating airfoil were characterized by using hot-wire anemometer. The results of the present investigation have revealed the different effects of changing mean angle on the wake profiles and momentum deficit coefficients. When maximum angle of attack was below the static angle, weak effects of mean angle increasing were observed. This is due to attached flow on the airfoil surface. The considerable effects were appeared after static angle whereas larger vortices formed the wake. A huge growth of wake thickness, turbulence intensity and momentum deficit were considered after special mean angle of attack to be result of large separation on the airfoil surface.

ABSTRACT. An experimental investigation was carried out to study the behaviour of the flow field in the wake of an oscillating airfoil in a subsonic wind tunnel. The airfoil was given the harmonic pitching motion about the half chord axis at various oscillation frequencies. The oscillation amplitudes were 8 and 10 deg, and the mean angle of attack was set at 2.5 deg. To assess the effect of Reynolds number, the measurements were performed at 3 different Reynolds numbers of 50000,100000 and 200000. Streamwise mean velocity profiles and turbulence intensity profiles were investigated at several vertically aligned points behind the airfoil at one-quarter chord downstream distance from trailing edge. The results revealed that with increasing oscillation frequency, the wake thickness and turbulence intensity decreased. Besides, it was found that increasing oscillation amplitude caused more increasing of the wake thickness, velocity defect and turbulence intensity in the wake. Furthermore, as an extension of the studying, an estimation of the momentum deficit coefficient was obtained.

INTRODUCTION

The unsteady aerodynamic theory of oscillating airfoils has received considerable attention in past years. The classical unsteady aerodynamic theory of oscillating airfoils was developed as a result of interest in aircraft flutter problems by Theodorsen [1]. Later, Lighthill [2] extended this theory using propulsion modeling of certain spaces of aquatic animal, birds and insects. In comparison with the many theoretical and numerical studies that have been devoted to the subject of oscillating airfoil, quite a few experimental results appear to be available. Experimental unsteady aerodynamic researches have very important role in both understanding the essential physics of the problem and validating the results from the computational studies. Most of the previous investigations were directed to unsteady wing loading and dynamic stall process, as reviewed by McCroskey [3]. Recently, Tolouei et al [4] investigated experimentally the unsteady pressure distribution over an EPPLER 361 airfoil. They found that pressure coefficients in the low angle of attack range showed little overshoot when compared with the static values, while for the large angle of attack cases the differences were significant. They considered that the large overshoot in the dynamic pressure coefficient for the high angle of attack case is probably due to the existence of the stable dynamic vortex, which is created near the leading edge and moves downstream. Soltani et al [5] showed that by increasing the oscillation frequency, the motion of the airfoil could not adjusted the free-stream flow, and the hysteresis loop of pressure coefficient will change into straight line. In addition in high angles of attack the hysteresis loop grows, so that preventing wing stall and increasing the lift. But this is just applied to smaller speeds. Ajalli et al [6] showed that at different amplitudes for

unsteady airfoil, the hysteresis loops in the pressure data were both clockwise and counter clockwise when plotted against the equivalent angle of attack. It was found that heaving amplitudes had strong effects in pressure distribution, near the leading edge of the airfoil. Mani et al [7] measured Surface static pressure distribution on the upper and lower sides of the model, during the oscillating motion. It was found that reduced frequency had strong effects on the pressure distribution, near the leading edge of the airfoil.
In spite of less attention about studying the characteristic of the wake in comparison with the measuring the force on oscillating airfoils, several important researches have been conducted into the problem of downstream wake. Satyanarayana [8] measured unsteady wakes of airfoils and cascades under a sinusoidally varying gust flow. Time-mean and time-dependent wake profiles at low frequency behind the airfoil were reported in his work, and the distinctions between these were discussed. Koochesfahani [9] studied experimentally the vortical flow patterns in the wake of a NACA0012 airfoil pitching at small amplitudes and showed that the oscillation wave form has an important effect in the vortical pattern shapes and mean velocity profiles in the wake. He found that there is a critical value for the oscillation frequency that the usual velocity defect profiles in the wake changes to excessive momentum similar to a jet flow and the airfoil produces trust force. Also, he showed that in special cases mean velocity profiles have two peak of velocity defect, that this is symptom of a double-wake structure. Recently, an experimental measurement of unsteady wake behind a sinusoidally unsteady airfoil was performed by Mani et al [10]. They were shown that the angle of attack and reduced frequency are the most important parameters which influence on the velocity profiles. Also, they found that the influence of angle of attack on the velocity profiles is to increase the momentum deficit and wake thickness.

The objectives of the present study are to examine the unsteady wake of an airfoil oscillating sinusoidally in pitch at various conditions. The airfoil was EPPLER-361. The velocity in the wake was measured using the hot-wire anemometer. The airfoil was given at different oscillation frequencies, Reynolds numbers and oscillation amplitudes, and the resulting wakes (mean velocity profiles) were measured to understand the effects of them.

EXPERIMENTAL FACILITY

The experiments were conducted in the subsonic wind tunnel. The tunnel was of closed return type and had a test section of 0.457 m × 0.457 m × 1.2 m. The nozzle contraction of the tunnel was about 7.31, and the turbulence intensity was less than 0.1% in the test section. Figure 1 shows a view of the wind tunnel.

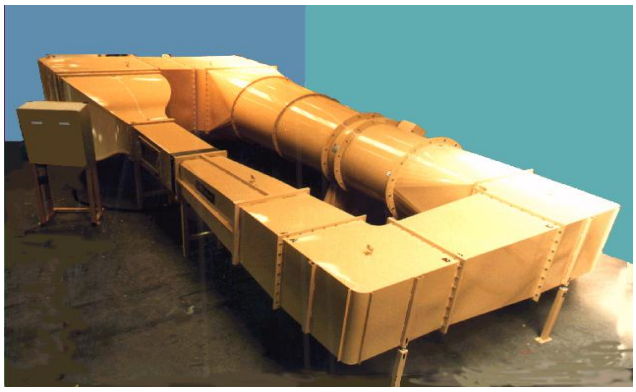

Figure 1. A schematic of wind tunnel

Figure 2. Views of oscillation system

An EPPLER 361 airfoil, with Chord of 0.145 m and a span of 0.45 m was used in the investigations. An especially oscillation mechanism capable of pitching the model at various amplitudes, mean angles of attack and oscillation frequencies was used in the present experiment. The pitch rotation axis was fixed at the wing half chord. Figure 2 shows the picture of oscillation mechanism. A constant temperature hot-wire anemometer (CTAs) was employed for the velocity measurements. The hot-wire probes were mounted on a support in the center plane of the test section behind the airfoil as shown in Fig 3. The traverse mechanism was used to shift sensors. The vertical traverse was restricted from *Y/C*= -0.63 to +0.63 moved by every 50 mm for the measurements.

EXPERIMENTAL PROCEDURE

The motion of the airfoil was sinusoidally pitching oscillation. The dynamic angle of attack, α, can be expressed as:

$$\alpha = \alpha_0 + A\sin 2\pi ft$$

During the test, the oscillation amplitudes were 8 deg and 10 deg, and the mean angle of attack was set at 2.5 deg. The values of oscillation frequency, *f*, were considered about f =1, 2 and 3 Hz. The free stream velocities were set at U_∞=5, 10 and 20 m/s and the corresponding Reynolds numbers were 50000, 100000 and 200000.

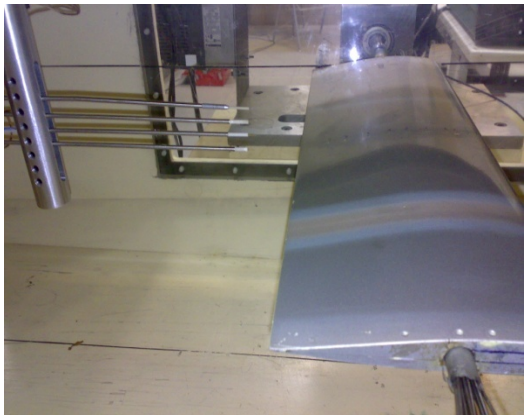

Figure 3. Model and hot-wire sensors

MEASURMENT ACCURACY

Comprehensive reviews of errors in hot-wire measurements and guidelines to evaluate them were given by Bruun [11]. For the present experiment, several works have been done to decrease errors. Hot-wire's sensors have been calibrated by wind tunnel before and after each experiment in order to minimize errors of variation of sensor's temperature. The ensemble averaging procedure that has been adopted in the present experiment, where the samples in each bin are statistically independent because they were collected during different cycles, avoids statistical bios, as observed by lyn et al [12]. Statistical uncertainty in mean and r.m.s velocities depends on the number of sampled data, turbulence intensity and confidence level. For the present experiment, considering a typical value of 2000 sampled data, a confidence level of 95% and a local turbulence intensity of 30%, uncertainties of ±4% and ±5% are expected for the mean and r.m.s velocities, respectively.

EXPERIMENTAL RESULTS AND DISCUSSION

Mean velocity profile

In this subsection, the results are described by streamwise mean velocity profiles in the wake. It is necessary to mention that streamwise mean velocity and vertical distance are non-dimensioned by free stream velocity and airfoil chord, respectively.

Effect of oscillation frequency. The mean velocity profiles at frequencies of f =1, f =2 and f =3 Hz for oscillation amplitude of A=8° and Reynolds of Re =50000 are plotted in Fig. 4. This Figure illustrates that the broadness of profiles or wake thickness becomes smaller slightly, when the oscillation frequency increases.

Effect of oscillation amplitude. Figure 5 illustrates the profiles at two oscillation amplitudes of 8° and 10° for frequency of f =2 Hz and Reynolds of Re =50000. It is seen that at case of 10 degree, the velocity defect and broadness of profile increases.

Effect of Reynolds number. To reveal the effect of Reynolds number on the wake of an oscillating airfoil, mean velocity profiles are plotted at 3 Reynolds numbers of Re =50000, Re =100000 and Re=200000 in Fig. 6. In this case, the oscillation amplitude and oscillation frequency are A=8° and f =2 Hz, respectively. This Figure shows that with increasing Reynolds number, velocity defect and wake thickness decrease.

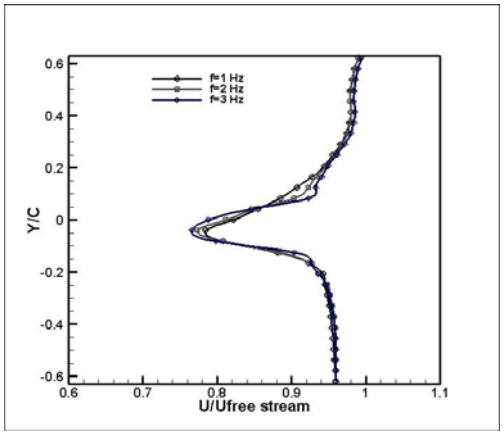

Figure 4. Mean velocity profiles at different frequencies

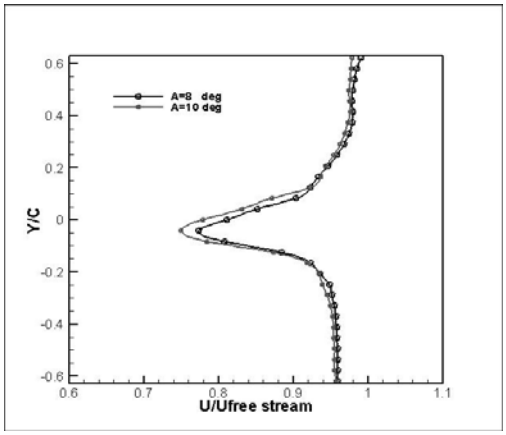

Figure 5. Mean velocity profiles at different amplitudes

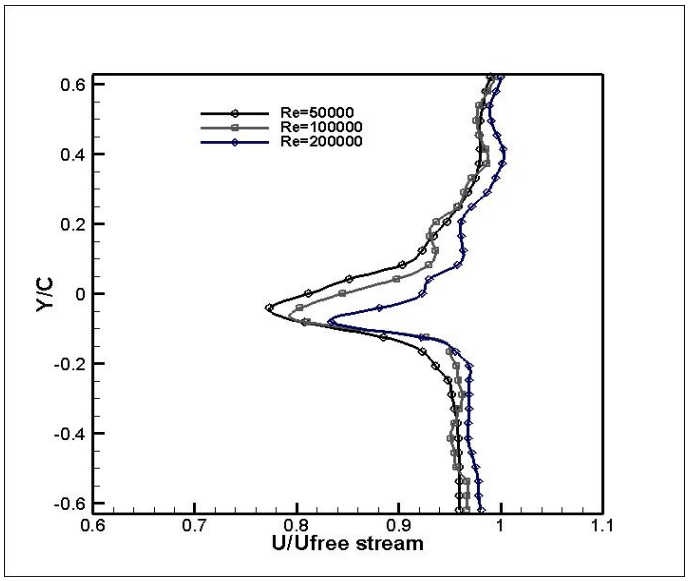

Figure 6. Mean velocity profiles at different Reynolds numbers

Momentum deficit coefficient

The mean velocity profile can be used to estimate the momentum deficit on the airfoil [9]. With usual normalization of the force with freestream dynamic head and the airfoil chord, the momentum deficit is given by

$$C_f = 2/C\int_{-\infty}^{\infty} U/U_\infty(1-U/U_\infty) \tag{2}$$

where the contribution due to the fluctuating quantities and the pressure term have been neglected.

Effect of oscillation frequency. Variation of momentum deficit coefficient with reduced frequency is depicted in Fig. 7. In this case, A =8° and Re =50000. This figure shows the considerable decreasing in momentum deficit coefficient with frequency. This demonstrates very important role of oscillation frequency that increasing frequency is the one of the most important factors to reduce momentum deficit and achieving thrust.

Effect of oscillation amplitude. Momentum deficit coefficients are compared for two different amplitudes in Fig. 8. In this case, f =2 Hz and Re =50000. It is found that, for the case of 10 degree, the momentum deficit coefficient increases about 10 percent against case of 8 degree. This demonstrates the considerable increasing of momentum deficit around airfoil with increasing oscillation amplitude.

Effect of Reynolds number. To assess the effect of Reynolds number on the Momentum deficit for the present oscillating airfoil, momentum deficit coefficients are compared at 3 Reynolds numbers, Fig. 9. In this case, the oscillation amplitude and oscillation frequency are A=8° and f =2 Hz, respectively. Figure 9 shows that with increasing Reynolds number, momentum deficit coefficient decreases.

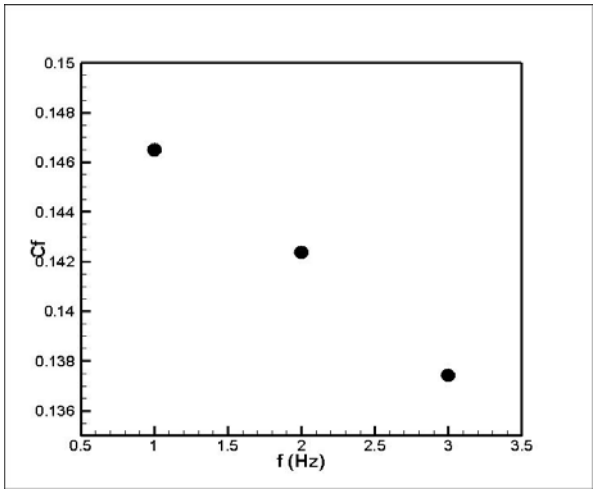

Figure 7. Variations of momentum deficit coefficients with frequencies

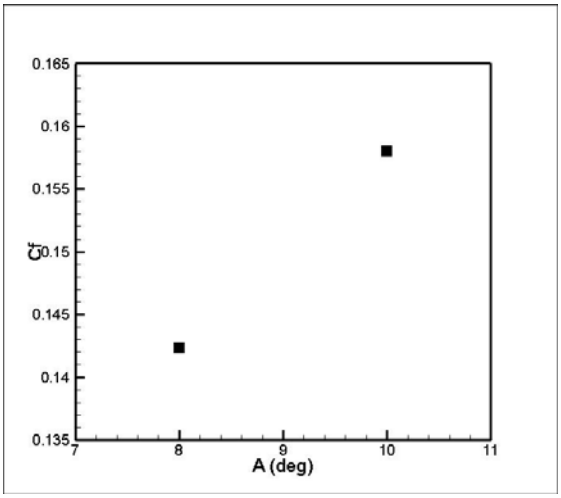

Figure 8. Variations of momentum deficit coefficients with amplitudes

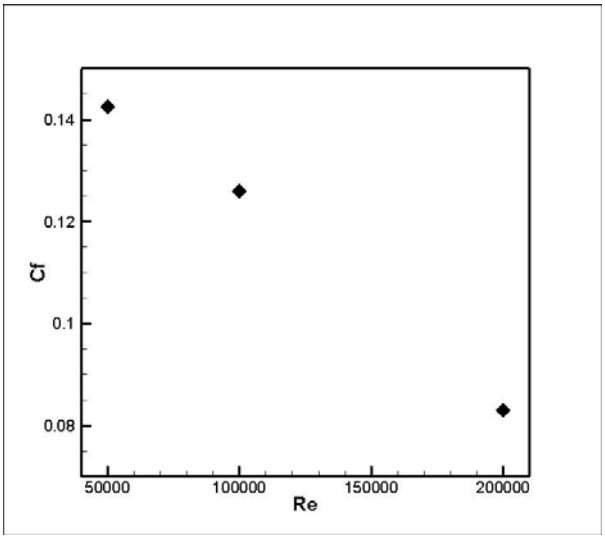

Figure 9. Variations of momentum velocity deficit coefficients with Reynolds numbers

R.M.S. velocity profile

In order to better identification and discussion of flow field in the wake, r.m.s. streamwise velocity profiles are obtained. It should be mention that r.m.s. streamwise velocity is $\sqrt{u'^2}/U_\infty$.

Effect of oscillation frequency. Figures 10 and 11 show r.m.s. streamwise velocity profiles at two different frequencies at two phase angles of 0° and 180°, respectively. In these cases, A=8° and Re =50000. The considerable differences in the pick of profiles and positions of them at f =1 Hz indicate the importance of history and state of fluid motion. It is clear from figures that with increasing frequency, profiles tend to have same behaviour. In fact, increasing frequency reduces history of fluid motion. These figures illustrate that the wake becomes less turbulent as the frequency increases. Increasing the rate of oscillating causes more stability in boundary layer and the rate of vortex formation is reduced around airfoil. This is due to delay in vortex initiation with increasing pitch rate. Therefore, vortices in the wake become smaller and wake thickness decreases.

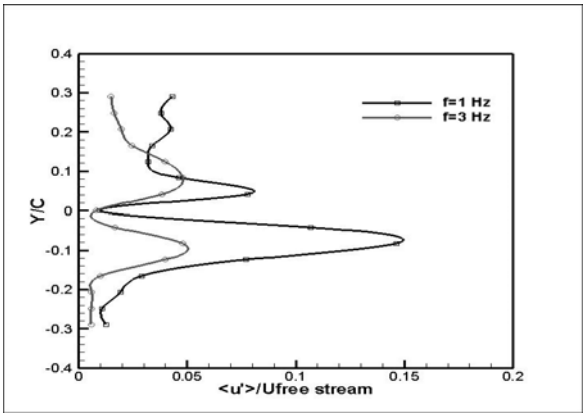

Figure 10. Streamwise r.m.s. velocity profiles Phase ($2\pi ft$) =0°

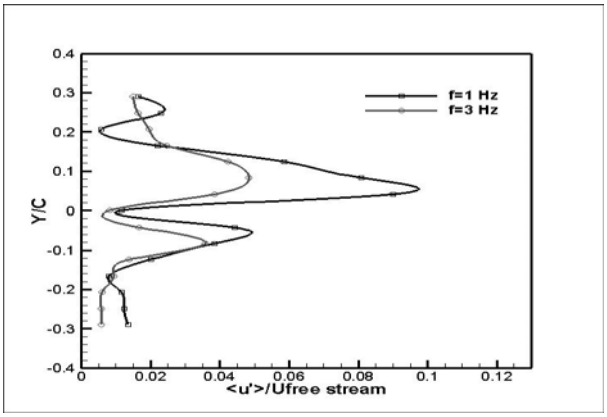

Figure 11. Streamwise r.m.s. velocity profiles Phase ($2\pi ft$) =180°

Effect of oscillation amplitude Figures 12 and 13 illustrate r.m.s. streamwise velocity profiles at two different amplitudes at two phase angles of 0° and 180°, respectively. In these cases, f =1 Hz and Re =50000. It is seen that in both figures with increasing oscillation amplitude, turbulence intensities in the wake increase. Increasing oscillation amplitude initiates vortex development earlier in the oscillating cycle and formed vortices in the wake become larger. So, it causes wake thickness and turbulence intensity increase.

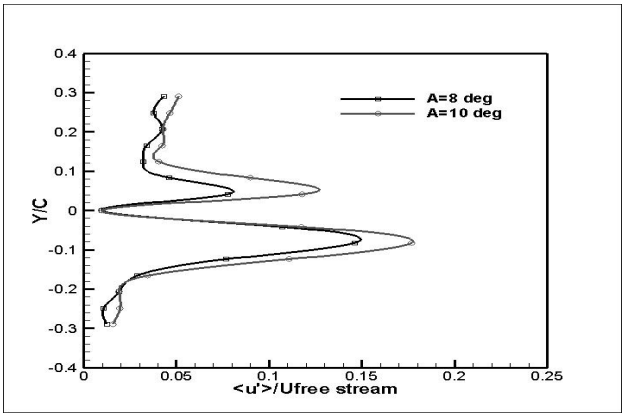

Figure 12. Streamwise r.m.s. velocity profiles Phase ($2\pi ft$) =0°

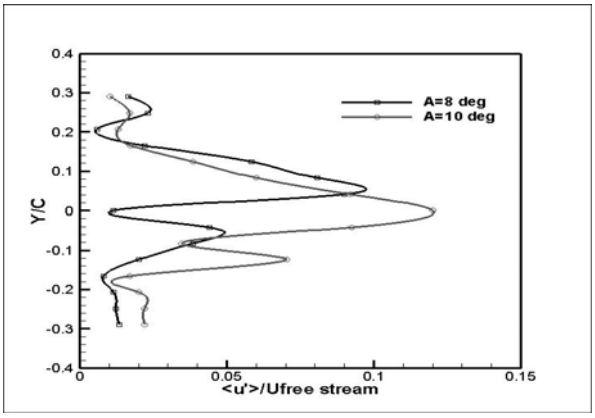

Figure 13. Streamwise r.m.s. velocity profiles Phase ($2\pi ft$) =180°

CONCLUSIONS

The mean velocity profiles, momentum deficit coefficients and r.m.s velocity profiles in the wake of an oscillating airfoil have been experimentally investigated, and the results have been revealed several interesting features. Increasing oscillation amplitude increased momentum deficit, wake thickness and turbulence intensity because of earlier vortex development in the oscillating cycle and formation of larger vortices in the wake. It was found that oscillation frequency has important role to reduce momentum velocity deficit and wake thickness due to delay in vortex initiation. Also, the results showed that with increasing Reynolds number, velocity defect and momentum deficit decreased.

NOMENCLATURE

A	Oscillation Amplitude (degree)
C	Airfoil Chord (m)

ABSTRACT. A feedback control experiment is conducted for flow past an oscillating square cylinder using PIV and HWA. The interest here is towards active control of the flow field that is likely to result in drag reduction at intermediate Reynolds numbers. Additionally, the dynamics of the flow phenomena for a square cylinder with oscillations in the direction of the incoming flow is also of interest. Experiments have been conducted at a Reynolds number of 175. The feedback loop consists of the hotwire probe, phase shifter available in labVIEW, a power amplifier and electromagnetic actuators. The detailed flow field has been investigated using PIV. Flow visualization images are also captured using laser light sheet and a CCD camera. The flow field has been investigated in terms of instantaneous as well as time-averaged velocity fields. The instantaneous flow field shows suppression of vortex shedding and reduction in velocity fluctuations in the presence of feedback. The periodic structure is disrupted in the presence of the feedback signal. The time averaged flow field shows the reduction in the size of the recirculation region with both open loop and feedback when compared to flow past a stationary cylinder.

INTRODUCTION

Control of bluff body wakes is of fundamental interest as well as practical significance. Flow control can be employed to reduce the intensity of the wake in order to eliminate flow induced oscillation and reduce drag experienced by the object. A variety of control techniques have been proposed. These are classified as active and passive control strategies. In passive control, the flow geometry is altered and there is no external addition of energy. In active control, momentum is transferred over a portion of the boundary and net energy is transferred to the fluid. Active control can be classified as open and closed loop. A closed loop active control system uses actuators driven by external energy sources through a feedback signal collected from the flow field.

The choice of the transfer function connecting the velocity/pressure signal and the one driving the actuator is crucial for the effectiveness of a feedback signal (Zhang et al. 2005). For objects that are set in motion by the unsteady forces, literature shows that a control system will best perform when a combination of flow field information and body motion is used for control (Ikemoto et al. 2001). Tao et al. (1996) reported a feedback experiment with a hotwire probe wherein flow visualization was conducted using a dye injection technique for flow past a circular cylinder. The flow visualization images clearly showed complete suppression and enhancement for various feedback conditions. Roussopoulos (1993) studied feedback control of vortex shedding for flow past a circular cylinder at an intermediate Reynolds number using flow visualization and hotwire technique and was able to increase the critical Reynolds number of the onset of vortex shedding. A loudspeaker was used as an actuator and the hotwire sensor as control. The wake

unsteadiness could be controlled for up to 10 times the critical Reynolds number. Zhang et al. (2003, 2004) studied the control mechanism of vortex shedding for a spring loaded square cylinder whose top surface was perturbed using a piezo actuator. Both closed loop and open loop studies showed a reduction in the time-averaged drag coefficient. The open loop system can suppress vortex shedding only if it is outside the synchronization range. Within the synchronization range the open loop control enhances vortex shedding and hence, the structural vibration. On the other hand, the feedback signal from the flow suppresses vortex shedding by adjusting the phase of the forcing signal. Thus, the study revealed that closed loop control was more advantageous when compared to the open loop system. Wolfe and Ziada (2003) studied the effect of feedback control on vortex shedding from two tandem cylinders in cross-flow. Feedback control was applied for resonant and non resonant cases downstream of the cylinder. A synthetic jet was induced upstream through a narrow slit using a loudspeaker. The response of the downstream cylinder could be reduced up to 70% in the resonant and 75% for non-resonant experiments. Zhang et al. (2005) studied flow past a stationary cylinder with a perturbation of its top surface at a Reynolds number of 7400. The authors used closed loop control with PID controller to perturb the surface using piezo-ceramic actuators. The study showed that when the surface perturbation and the force due to vortex shedding are in opposed phase, there is a weakening of vortex shedding and a reduction in the fluctuating forces.

CONTROL SCHEME AND EXPERIMENTAL DETAILS

The present investigation is an experimental study wherein wake characteristics of an oscillating prismatic cylinder are obtained using particle image velocimetry (PIV). A low speed vertical test cell has been used for generating the base flow. The cylinder is square in cross-section and is mounted horizontally with its axis perpendicular to the flow direction. The cylinder is driven in a direction parallel to the incoming flow by electromagnetic actuators. The frequency of oscillation is determined by using a single wire hot-wire anemometer that detects wake unsteadiness. The details of the experimental setup are described in Dutta et al. (2007). The flow field is characterized in terms of time averaged as well as instantaneous quantities such as velocity vectors, rms velocity, vorticity contours center-line recovery of velocity. The time-averaged velocity vectors are used to determine the drag coefficient acting on the cylinder. The goal of the study is to explore conditions under which the cylinder experiences lower drag and its correlation to the vorticity field. The data analysis procedures are identical to those reported in Dutta et al.(2007).

The PIV system (*Oxford Lasers*, UK) used in the study consists of a double pulsed Nd :YAG laser (λ= 532 nm) of 15 mJ/pulse power, a Peltier-cooled 12 bit CDD camera with a frame speed of 8 Hz, a synchronizer, frame grabber and a dual processor PC. The CCD consists of an array of 1280×1024 pixels. The field of view for PIV measurements is 40×35 mm. In experiments the oil particle size was around 2-3 μm while the pixel size was 6.7 μm. The size of the particle image on the pixel array was estimated as 14-15 μm from a histogram distribution of light intensity over an interrogation spot. The velocity vectors are calculated from particle traces by the cross-correlation method. The interrogation size is 16×16 pixels and 5561 velocity vectors are obtained with a spatial resolution of 0.5 mm for velocity. The cylinder motion is generated by mounting the prism over two electromagnetic shakers (*Spanktronics*, India). The shaker frequency and amplitude are adjustable through a control unit that is interfaced to a PC. The PC also receives signals from a hot-wire probe and the control strategy is implemented in a *Labview* environment. Flow visualization is carried out using light sheet of the laser and the CCD camera that accompanies PIV measurements, but with a reduced particle number density. Time averages are calculated by working with an image sequence comprising 200 frames.

Experiments were conducted in the following manner. A hotwire probe was placed at $\boldsymbol{x/d}$ =5 downstream and $\boldsymbol{y/d}$=1.2 from the cylinder centre. A long hotwire signal (60000 points) sampled at 1000 values per second was collected in the near wake of a stationary cylinder. This data was subsequently used for generating the feedback signal for the oscillating of the cylinder. The signal was low-passed filtered at a cut off frequency of 100 Hz to remove the high frequency components.

The signal was amplified to the level acceptable to the actuator. A phase shift was given to the filtered signal before sending it to the actuator. By placing the time series of the filtered and amplified signal in a loop, it was possible to run the experiment for a long period of time. The schematic layout of the feedback circuit is shown in Figure 1(b). Results discussed below are for a phase shift of 180^o. The amplitude of oscillation is practically constant in the oscillation experiments with and without feedback.

UNCERTAINTY AND VALIDATION

The seeding of flow with oil particles, calibration, light sheet reflection, and image digitization affect PIV measurement. Room temperature and calibration affect the hotwire measurement. For the particle size utilized and the range of frequency in the wake, a slip velocity error of 0.3-0.5 % relative to the instantaneous local velocity is expected. In the present experiments, the effect of introducing particles is examined by conducting experiments at a fixed Reynolds number by varying the size of the cylinder and air speed. The streamline plot and the dimensionless size of the recirculation region were found to be identical. The *x* and *y* velocity profiles from the PIV measurements matched hotwire measurement very well in the far wake. From repeated measurements the uncertainty in drag coefficient measurement was estimated to be within 3-4 %.

Figure 1(a). Photograph of the setup

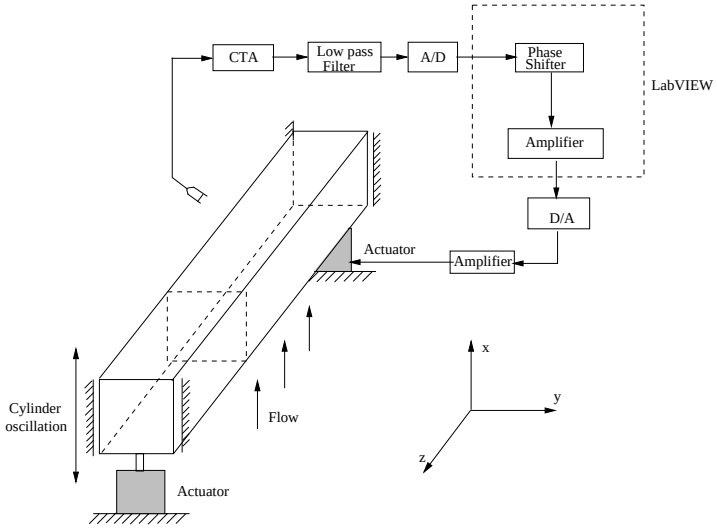

Figure 1(b). Schematic diagram of the feedback circuit

RESULTS AND DISCUSSIONS

Flow patterns are presented in terms of the time-averaged and instantaneous quantities recorded from experiments. Figure 2 shows the streamwise velocity signal as a function of time for stationary and oscillating cylinders, the latter with feedback. With feedback, the magnitude of velocity fluctuation is seen to be substantially reduced. Further, the spectral characteristics of the signal are also seen to be affected.

Table 1 presents the drag coefficient value for stationary and oscillating cylinders with and without feedback. Drag coefficient reported here arises from the combined effect of momentum deficit and time-averaged turbulent stresses at the outflow plane of the wake. It has been determined as a time-averaged quantity from a PIV data set of 200 images. The drag coefficient has been determined from the profiles of velocity and velocity fluctuations across the entire test cell at a streamwise location of $\boldsymbol{x}$=10.

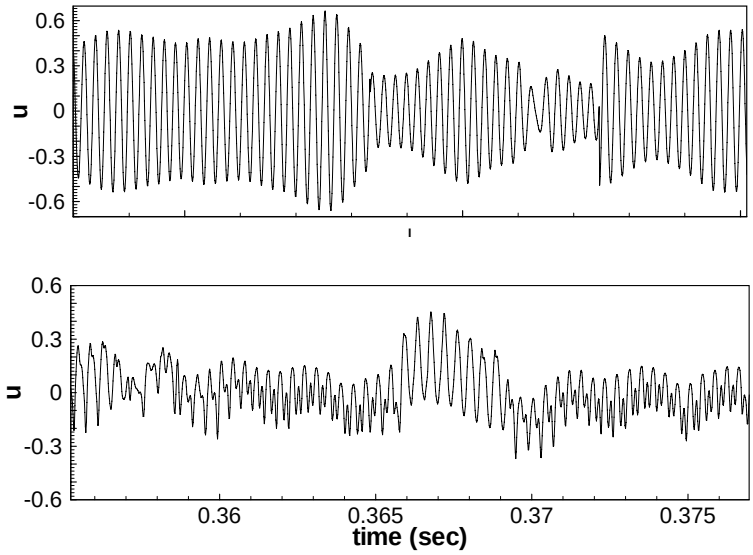

Figure 2. Typical time histories of the streamwise velocity component with (lower trace) and without (upper trace) perturbation. Time scales for the two traces are identical. Re=175.

The drag coefficient has been calculated from the extended formula

$$C_D = 2\int_{-\infty}^{\infty} \tfrac{u}{U}(1-\tfrac{u}{U})dy + 2\int_{-\infty}^{\infty} (\frac{\overline{v'^2} - \overline{u'^2}}{U^2})dy$$

The first term is the momentum deficit of the time-averaged flow field and the second term is the contribution of the turbulent fluctuations. In all experiments, the second term was found to be 10-15 % of the total drag.

TABLE 1

Drag coefficient (C_D) value for Stationary and Oscillating Cylinder (open loop and closed loop) at Re=175.

Cylinder motion	Stationary	Forced oscillations	With feedback
Drag coefficient (C_D)	1.42 ±3%	1.31±4%	1.35±4%

Figure **3** shows the time-averaged velocity vectors for stationary and oscillating cylinders, with and without feedback. From the figure it is seen that the near wake velocity is strongly affected by cylinder motion. The size of the velocity deficit zone (in blue) reduces in the presence of cylinder oscillation. The recirculation zone is quite small for the open loop system. With feedback, the size of the recirculation zone increases when compared to open loop oscillation. The size of the recirculation zone is related to base pressure and hence related to drag coefficient. Thus, for the choice of parameters, feedback does not appear to have a beneficial effect in diminishing the time-averaged drag coefficient beyond the value for forced oscillations. A similar conclusion was arrived at by Zhang et al. (2004). The proper choice of the feedback parameters is thus, crucial.

Figure 4 shows the time-averaged and fluctuating velocity components in the wake for three cases: when the cylinder is stationary, oscillatory and oscillations are with feedback. Measurements at the location x=**4** are reported.

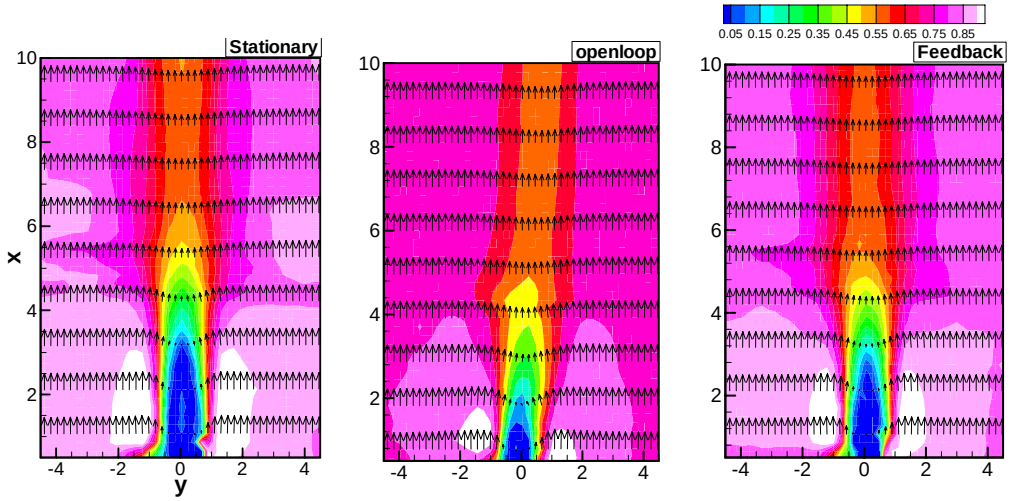

Figure 3. Time-averaged velocity vectors for stationary and oscillating cylinder (with and without feedback) at Re=175. The flooded contours represent the absolute velocity magnitude.

The mean velocity deficit is higher for the stationary cylinder when compared to the perturbed. The velocity deficit for the closed loop experiment is higher when compared to forced oscillations. The velocity deficit is a second measure of the time-averaged drag coefficient along with the wake size of the base region.

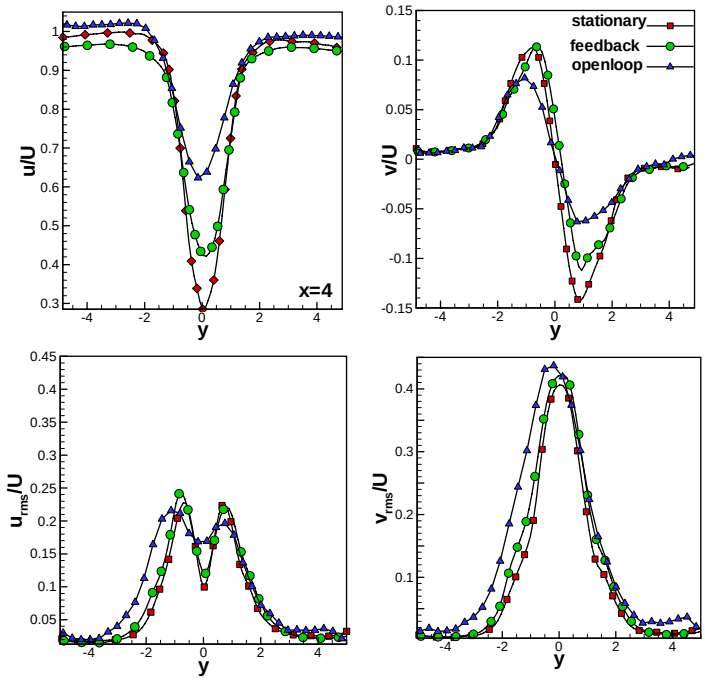

Figure 4. Comparison of time-averaged velocities $\boldsymbol{u}$ and $\boldsymbol{v}$, velocity fluctuations $\boldsymbol{u}_{\text{rms}}$ and $\boldsymbol{v}_{\text{rms}}$ for stationary and oscillating cylinders (with and without feedback) at a downstream location of $\boldsymbol{x}$ =4, Re=175.

Thus, for the present set of parameters, the control function (namely a phase shift of 180^{o}) is seen to be ineffective in reducing the time-averaged drag coefficient beyond what is seen for forced oscillations. In contrast, it is shown later from instantaneous flow visualization images (Figure 8) that vortex shedding is weakened with feedback.

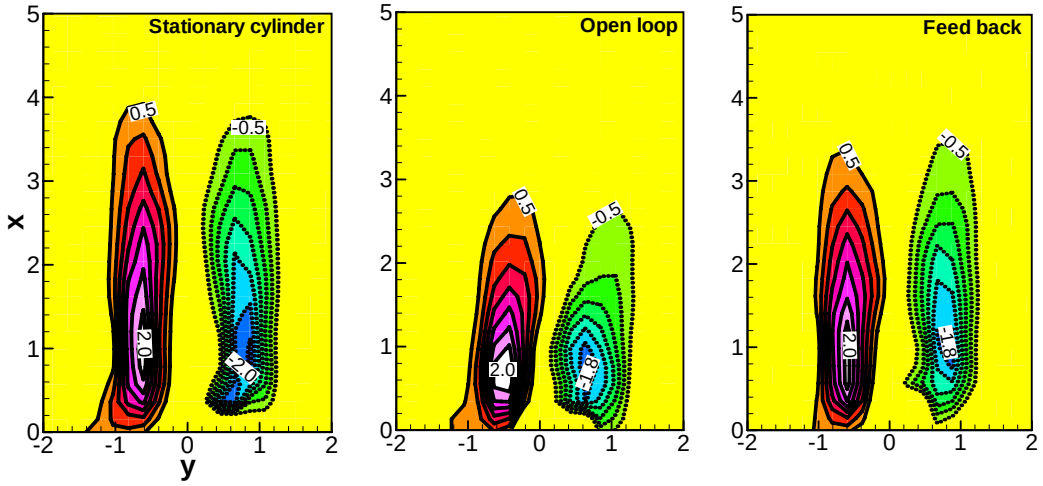

Figure 5. Time-averaged vorticity contours for stationary and oscillating cylinder (with and without feedback) at Re=175.

The strength of the velocity fluctuations diminish, as seen from the time traces of the velocity signal (Figure 2). The magnitudes of u_{rms} and v_{rms} were measured to be nearly equal for experiments with and without feedback, but smaller than for a wake of a stationary cylinder.

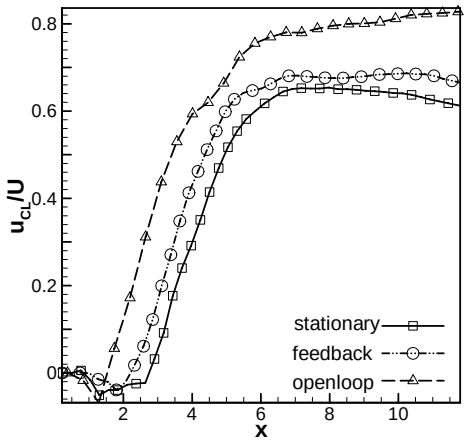

Figure 6. Centerline recovery of streamwise velocity for stationary and oscillating cylinder (with and without feedback at Re=175.

Figure 5 compares the dimensionless time-averaged spanwise (ω_z) vorticity contours for a stationary cylinder against open loop and feedback controlled oscillations. For the open loop, the vortices move close to the cylinder and the concentration of vortices near the cylinder increases. The concentration of the maximum vorticity zone in the near field region confirms the reduction in the size of the recirculation zone, Figure 3**.** With feedback control, the concentration near the cylinder marginally decreases, indicating that feedback negates some of the beneficial aspects of forced oscillations.

Figure 6 shows the centerline recovery of streamwise velocity for stationary and oscillating cylinders, with and without feedback. The centerline velocity dips to a minimum and then increases as fluid is entrained from the region outside the wake. The average centreline velocity is lower inside the recirculation zone, where the transverse velocity is high. The recovery is faster in the near field region and reaches an asymptotic value at around x =7. The rate of velocity recovery is seen to be high for the open loop system when compared to the stationary and feedback control experiments.

Figure 7 shows the instantaneous contours of spanwise vorticity for stationary and oscillating cylinders (with and without feed back) at selected instants of time. Positive vorticity corresponds to clockwise rotation and is indicated by solid lines whereas the negative spanwise vorticity corresponds to counter clockwise rotation and is indicated by dashed lines. When there is no perturbation, the vortices display the pattern of a Karman vortex street. With forced perturbation, the vortices get distorted. The vortices are shed much closer to the cylinder and the longitudinal spacing of the vortices decreases. With feedback controlled oscillations, the periodic structure is disrupted. Experiments showed that the structure thus generated is not continuous and has intermittency.

Figure 8 shows particle traces for stationary and the oscillation experiments for flow past a square cylinder. The top row shows a sequence of three instantaneous images for a stationary cylinder. Pure Karman vortex shedding flow pattern is seen from the images. The shedding mechanism is different for an oscillating cylinder when compared to the stationary. With oscillation at the vortex shedding frequency, vortex shedding is governed by the amplitude of oscillation of the cylinder. Vortices are shed from very near the cylinder. With the application of feedback to the actuator, vortex shedding is fully distorted and the wake size significantly reduces. This pattern was not continuously seen with feedback. Intermittently the vortex shedding such as that for a stationary cylinder was also seen.

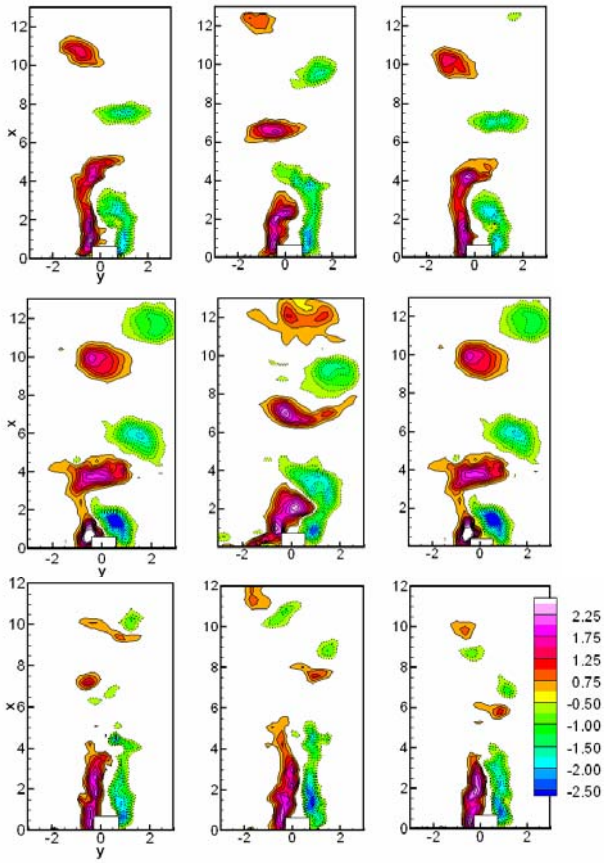

Figure7. Instantaneous spanwise vorticity contours for a stationary cylinder (top), oscillating cylinder without feedback (middle) and cylinder with feedback (bottom) cylinder at Re=175.

CONCLUSIONS

The flow field in the wake of a cylinder oscillated using feedback control was investigated in terms of instantaneous as well as time-averaged data. In the feedback mode, the cylinder was fed an 180^{o} phase shifted signal with respect to the velocity signal in the near wake. The instantaneous flow field showed suppression of vortex shedding and reduction in velocity fluctuations with feedback. The time averaged flow field showed a smaller recirculation region both with open loop and feedback when compared to a stationary cylinder. Keeping amplitude and frequency fixed, the time-

averaged wake size was seen to increase with feedback. However, the instantaneous velocity fluctuations were seen to be damped.

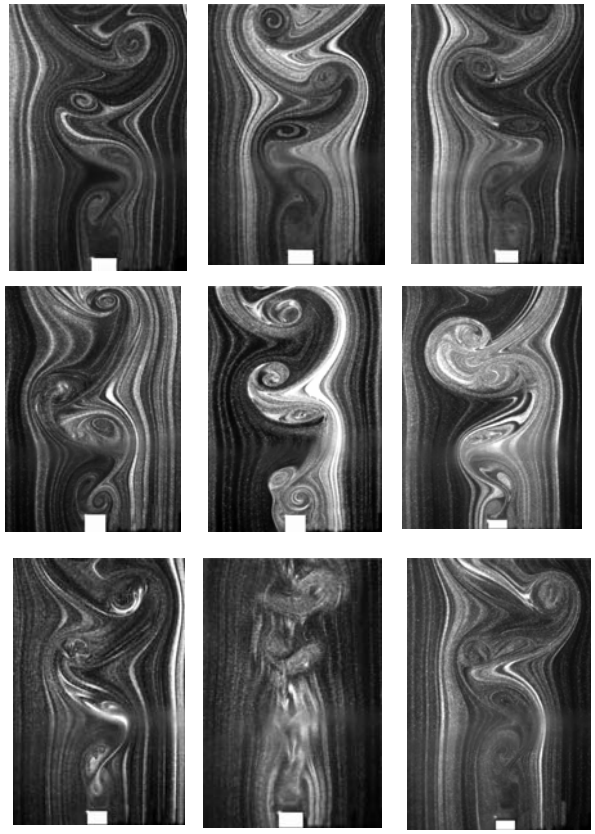

Figure 8. Flow visualization images for stationary (top row), open loop (middle row) and closed loop oscillation (bottom row). Images are phase matched.

Computational Methodology

DEVELOPMENT OF A SCALABLE 3-D GEOMETRIC MODEL FOR CFD FLOW SIMULATION OF SHAFT KILNS

Z. Xu*, H. Woche, and E. Specht
Institute of Fluid Dynamics and Thermodynamics, Otto von Guericke University Magdeburg, Magdeburg, Germany

ABSTRACT. The knowledge of temperature distribution and radial gas mixing plays a very important role in design of shaft kilns, yet is poorly understood. This is due to the geometric complexity and the movement of the lumpy processed material, which make it impossible to measure the main parameters, such as temperature, gas components, and velocity etc. The purpose of this study is to develop a three-dimensional geometric model that can be applied by computational fluid dynamics (CFD) to visualize the full flow structure in the important zone of the kilns. It is shown that tetra-based packed arrangement is suitable for model with spheres. The jet behaviour is independent of the loading height after expanding into a packed tube, so that 4 layers of particles up the burner system are assumed to be enough for modelling. A 9-layer wall segment model is developed finally and used for CFD simulation successfully. This geometric model has proved to be scalable and computationally less expensive.
Keywords: *Shaft kilns, CFD, packed bed, geometric model, flow simulation*

INTRODUCTION

Shaft kilns have wide use in industry, from the calcination of limestone, refractory material (magnesite, dolomite, corundum) to mineral wool manufacturing etc. The normal shaft kiln, basically a packed bed reactor, works on a very simple principle. The raw material is fed in at the top of the kiln and the product is withdrawn from the bottom. Heat to calcine the material is introduced roughly in the middle of the kiln through gas heating systems. The design of these systems, however, may fail to provide optimum combustion of gas in the calcining zone (injection zone) due to the significant influences of the processed material on the gas permeability. This results in decreased quality of products, reduced productivity, and low thermal efficiency [1]. The optimization is usually very empirical and costly because the industrial shaft kilns are large and complicated systems. Comparing with investigation in experimental manner, mathematical modelling is much more efficient. In fact, modelling has aided the design and operation of shaft kilns over the years. Many works have appeared in the literature [1-5]. But most of these studies are based on thermal balance and material balance of the kilns, whereas the knowledge on the in-kiln phenomena especially on the radial gas distribution and mixing is not sufficient. As demands on system performance increase, model needs to be able to give the radial distribution of the fluid in detail in order to acquire thorough knowledge of the problems, for instance, to localize regions of deficient heating or overheating. Computational fluid dynamics (CFD) is one of the critical "enabling technologies" for achieving this. It allows engineers to predict and design the desired fluid dynamics in geometrically complicated equipment [6-8].
Nowadays, none of the researchers attempted the CFD simulation of shaft kilns due to complex geometry definition, extremely computational cost, and limitations in computational power as well. The related studies are flow simulation in packed bed reactors using CFD approach. These works

reviewed by Dixon et al. [9-10], however, mainly focus on studying gas flowing through packed tubes which have a very low tube-to-particle diameter ratio (N), e. g. N=4.
The first step, also the most critical, in CFD simulation is geometric modelling. Correct definition of the geometry provides a more realistic scenario for simulation, and the technique used for constructing the geometry will ensure the feasibility of generating a mesh good enough to capture the full phenomena involved in the problem. Therefore, this work aims to develop a less expensive geometric model which can be used for simulating the flow structures in the industrial-scale shaft kilns by using CFD. With this intention, a geometry having a tube-to-particle diameter ratio of 20 was developed step by step in this paper. Simulations were carried out based on the geometry to demonstrate the viability of using CFD as a design tool for shaft kilns. Geometry and grid generation were executed by using Gambit 2.3.16, and all numerical simulations were performed with the commercial CFD code FLUENT6.2.16 on HP-Proliant-DL585 server (4×DualOperon885-2600MHz 32GB Memory).

DEVELOPMENT OF THE GEOMETRIC MODEL

Simplifications

For the first stage, the process and the characteristics of the kilns and processed materials were simplified, as clarified by the following:

(1) Fixed bed. In practice, the solid phase is moving downwards the kiln. But considering that the velocity is extremely slow, e.g. about 10 m/day in lime production, the bed is defined to be fixed.
(2) Regular packed Spheres. Due to the complicated packing structure in the shaft kilns, processed material granules are assumed to have uniform spherical geometry.
(3) No heat transfer between gas and solid. Heat transfer between two phases is complicated to simulate. To solve this process, the resolution near the wall should be fine enough, which will result in a prohibitively high computation cost. Therefore, no solid computation domain exists in the model.

Packed arrangement

To create the geometry, the first step is to select a proper packed arrangement. For regular packing, the packed arrangements are determined by three basic types of sphere cluster. According to the spatial structure of each sphere cluster, they are named tetra-based arrangement, hexa-based arrangement, and octo-based arrangement respectively.

Hexa-based arrangement. A hexa-based sphere cluster is formed by eight spheres with centres at the apexes of a cube, shown in Figure 1. Arrangement, constructed by this element structure, has a very simple structure and can be easily created. As can be seen in Figure 1, particles are piled up linearly. But it's also obvious that, channelling problem tends to occur with this geometry, which can lead to a non-representative flow pattern. The void fraction of this arrangement is about 0.48.

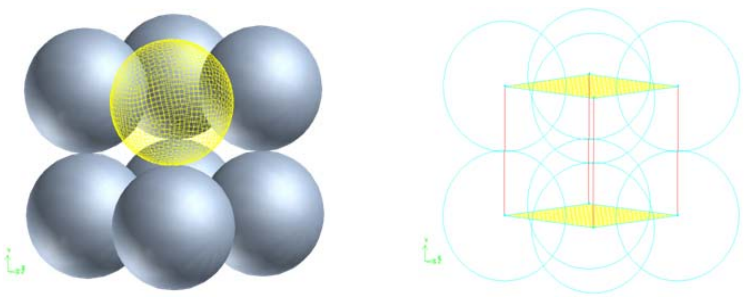

Figure 1. A single hexa-based sphere cluster

Octa-based arrangement. Figure 2 depicts an octa-based sphere cluster, which is constituted by six spheres with centres at the apexes of an octahedron. This arrangement has the same void fraction as the hexa-based structure, about 0.48. Comparing with the octa-space configuration, this structure is relatively complicated and more sensible for modelling. But channelling problem cannot be avoided taking place completely if gas flows in certain directions, indicated by the arrows in Figure 2. For normal shaft kilns, as being known, there is cooling air flowing axially from the bottom to the top and concurrently radial fuel injections from circumference. Therefore, this packed arrangement is not practicle as well.

Tetra-based arrangement. Apparently, a tetra-based structure consists of four particles with centres at the apexes of a tetrahedron. Figure 3 shows a single tetra-based sphere cluster. Comparing with the other arrangements, this configuration is more spatially stable and compact. Besides, channelling problem can be prevented by properly stacking the clusters, which gives this arrangement a big advantage. However, the densely structure also leads to a low void fraction, say, about 0.26 [11]. Given that that the normal porosity of the packed material in shaft kilns is around 0.4, the particle is shrunk to a certain extent to get a bigger void fraction. Consequently, there are no real "contacts" between particles in the model, and of course this will influence the flow pattern somewhat especially on the heat transfer mechanism. When heat transfer is considered in modelling, the geometrical arrangement should be carefully designed.

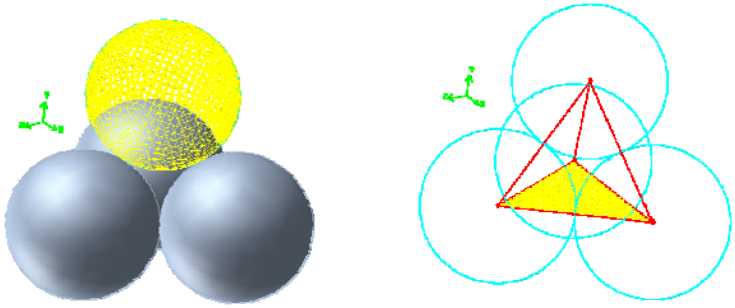

Figure 3. A single tetra-based sphere cluster

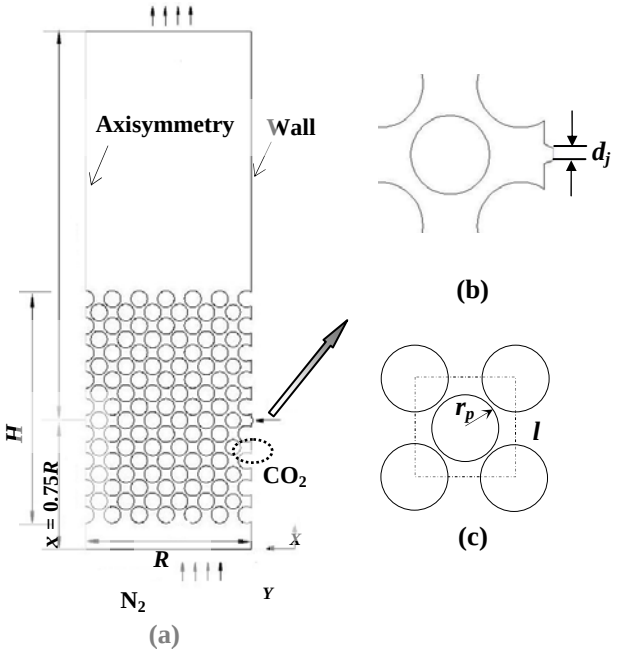

Figure 4. 2-D simulation geometry: (a) schematic of the geometry, (b) close view of the slot injector, (c) packed arrangement

Particle loading height

As mentioned in the introduction, the calcining zone is where engineers are interested in. To visualize the flow fields in this region is therefore the primary aim of CFD simulation. But one very important question in modelling is what the loading height (*H*) is needed to obtain results that are representative. In the industry, the shaft kiln can be up to 30 meters high. The tremendous number of particles will definitely make the computation prohibitive. In order to gain the effect of loading height on the behaviour of the fuel injector, simulations based on 2-D models were performed. Figure 4 shows the geometry, which consists of a half perpendicular plane of a packed tube (R=1.0 *m*), subtracted by circles corresponding to packed particles (d_p=100 *mm*), and inlets of N_2 and CO_2 corresponding to the cooling flow and fuel jet flow respectively. The particle loading height was created to 1.5 *m* and 4 *m* for study.

Figure 5 and Figure 6 show the temperature contours and mass fraction of CO_2 along the cross-section at x=0.75 *m* within the two packed tube. As can be noted, there is no obvious difference between the two cases, which indicates that the behaviour of the jet flow is independent of the loading height. Chukin et al. [12] once experimentally studied the effect of bed height on the gas distribution in a packed bed with jet flow from the bottom. After fifty experiments being performed, a conclusion was drawn that, after the gas jet finished expanding into the bed, increases or decreases of bed would not affect the gas-flow distribution within it.

The experimental data also showed that stabilization in the gas-flow distribution over the bed cross section began even at a height of ~15 *mm*. In other words, the height for jet expanding is about three to four layers in terms of the particle size (d_p=4.6-6.0 *mm*). As can be seen in Figure 5, the expansion of the CO_2 jet is diminishing after through 4 layers, which is in well agreement with the experiment. In contrast with jet from bottom, however, for the cases with circumferential jets the stabilization height depends on the injector-to-particle diameter ratio as well. Apparently, if the ratio is much great than 1, the results will be definitely not validate. Therefore, 4 layers up the burner system are assumed to be enough for modelling when the main focus is on the fuel injection zone and the burner-to-particle diameter ratio is around or less than 1.

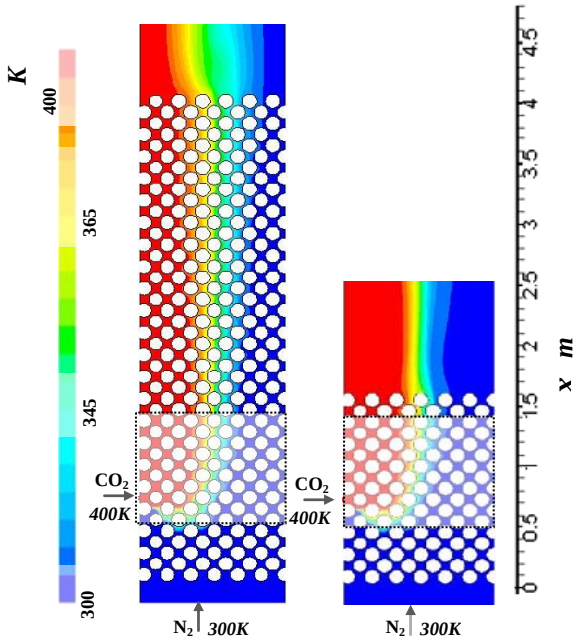

Figure 5. Temperature contours comparison V_{CO_2}/V_{N_2}= 4, v_{N_2}=0.5 *m/s*

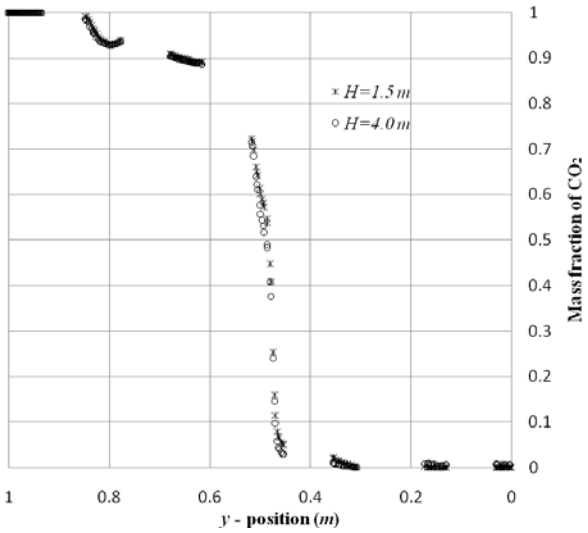

Figure 6. Mass fraction of CO_2 along the cross-section at *x*=0.75 *m*

Wall segment strategy

According to the study presented above, the height of the model can be reduced dramatically. Even with a low height, however, the particle number is still huge if the full cross-section of a kiln is to be modelled. Fortunately, shaft kilns usually have many burners which divided it into several periodic sections. Therefore the geometric model can be further reduced to a small wall segment by taking advantage of the flow symmetry. This strategy (WS model) has been widely used for CFD flow simulation of packed bed [13-15].

A shaft kiln with 12 circumferential burners is depicted in Figure 7, in which planes 1 through 4 indicate two sorts of symmetric or periodic faces. Figure 8 shows one of the 30° WS model for CFD simulation. The wall is subtracted by particles to avoid near-wall effect in this stage.

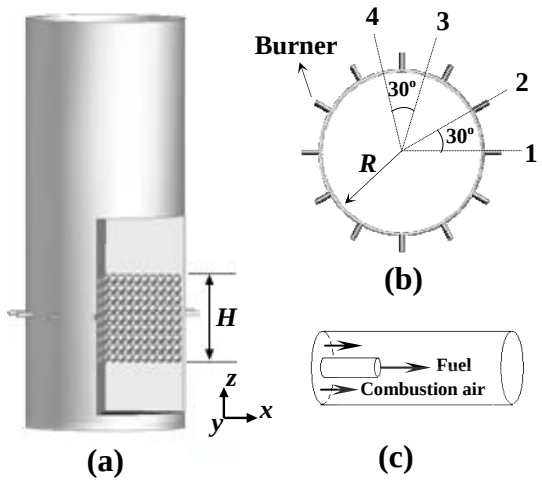

Figure 7. A scheme of shaft kiln (calcining zone): (a) front view, (b) top view, (c) close-up of burner

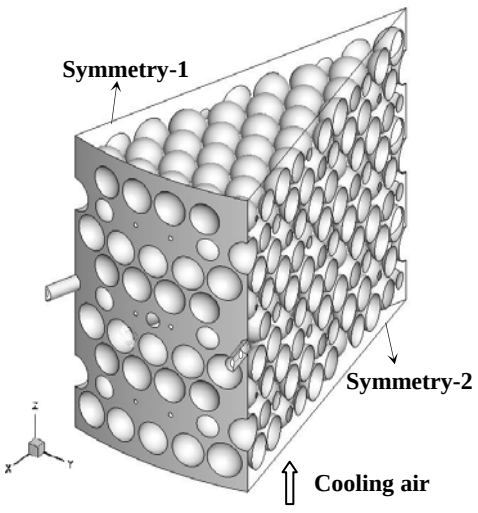

Figure 8. A WS model for simulation

Mesh design

Mesh is another essential parameter in CFD modelling. Theoretically, finer the mesh size, more accurate the solution is. However, it can lead to extremely high computational requirements as well. Therefore, a compromise has to be with respect to accuracy and computation cost. A graded mesh was created after the grid independence study. The mesh was designed with special attention paid on the small gaps between particles. Figure 9 shows the non-uniform surface mesh on the spheres. As can be noted, grid is finer in the small gaps and becomes coarser in the larger void area. The resulting mesh contains totally about 3,104,000 cells.

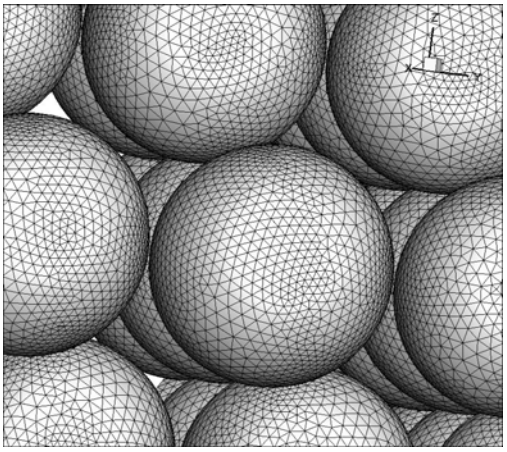

Figure 9. Graded mesh design on the surface of particles

CFD SIMULATION

In this section, some simulations and results based on the developed geometric model will be presented. So far, however, the simulations were carried out just to test the application of CFD approach on flow modelling of shaft kilns while with no intention to compute a real case. Thus the operating parameters defined in the simulation did not follow the industry production conditions.

Models and boundary conditions

The fluid was taken to be incompressible flow. The standard k-ε turbulence model and species transport model were employed to calculate combustion with methane and air as the fuel and oxidant. First-order upwind schemes were selected to compute the field variables. The pressure-velocity coupling algorithm was the SIMPLE scheme. Some geometric details and boundary conditions are listed in Table 1.

Table 1
Geometry dimension and boundary conditions

Inlet	D_h (m)	Velocity (m/s)	Temperature (K)
Fuel	0.02	60	315
Combustion air	0.04	40	315
Cooling air	2.0	0.34	600

In the table, D_h is hydraulic diameter and velocity is superficial velocity.

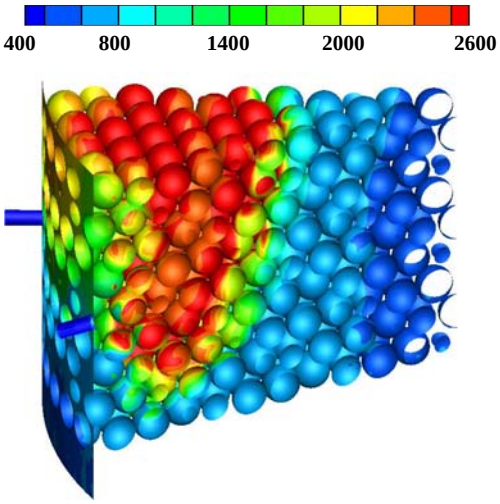

Figure 10. Temperature contours on the particles surface with combustion

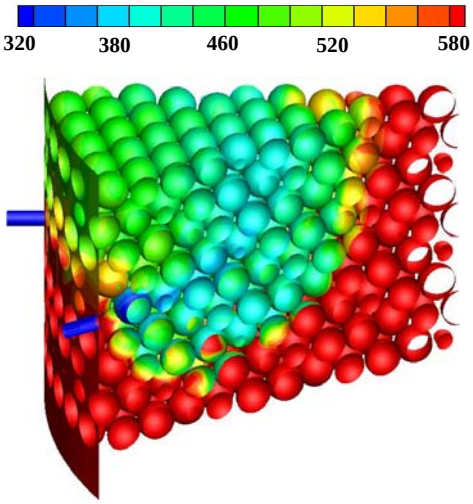

Figure 11. Temperature contours on the particles surface without combustion

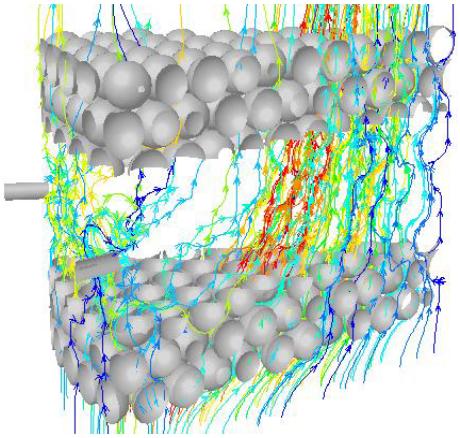

Figure 12. Path lines from the cooling-air inlet with combustion

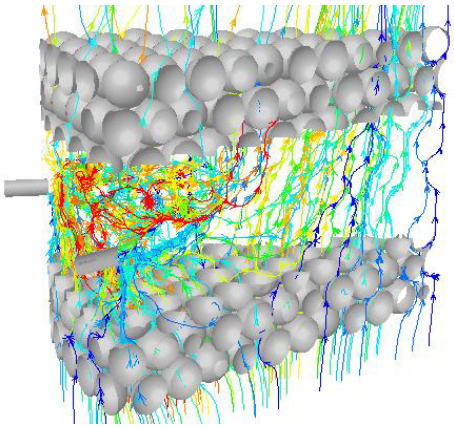

Figure 13. Path lines from the cooling-air inlet without combustion

Simulation results and postprocessing

Simulations were carried out initially to check the effect of combustion modelling on the computational time demand and the radial gas distribution. In one case, the gaseous fuel was ignited successfully by patching a high temperature, whereas in the other, simulation was performed with "cold-flow" (without reactions).

The results are presented in the form of temperature contour and path line plots to illustrate the qualitative features of temperature distribution and insight of the flow pattern, shown in Figure 10 to Figure 13. As expected, combustion modelling takes more iteration to obtain a converged solution due to the strong impact of the reaction on the flow pattern. Surprisingly, however, combustion does not improve the radial mixing. On the contrary, the mixing is worse in the combustion case. The explanation is beyond the present work. However, all the observations discussed above demonstrate that CFD modelling can provide highly detailed information on the in-kiln phenomena. The challenge for the future is to improve the model, including the shape of particles, the structure of packing and correspondingly the mesh design etc., to gain the knowledge that is accurate enough for design purposes.

SUMMARY

A scalable 3-D geometric model for simulating the flow in a shaft kiln has been developed in this paper. The model is reduced by taking advantage of the flow symmetry and the independence of jet behaviour on the loading height. This makes a great contribution to decrease the computational cost, and thereby the model can be scaled up for larger shaft kilns. To develop other packed arrangement, even a random structure, is the logically expansion of the present work. With verification and model improvement, computational fluid dynamics is expected to be a useful design tool for industrial shaft kilns.

COMBINED EXPERIMENTAL AND NUMERICAL CHARACTERIZATION OF HEAT TRANSFER IN HERMETIC RECIPROCATING COMPRESSORS

T. Dutra, C. J. Deschamps*
Federal University of Santa Catarina, Florianopolis, Brazil

ABSTRACT. A combined experimental and numerical study is developed to characterize heat transfer in the shell of a hermetic reciprocating compressor adopted for household refrigeration, under actual operating conditions. For the first time, measurements of heat flux are carried out in several regions of the shell surface and validated through energy balances and numerical simulation. The results indicate the effect of lubricating oil as an agent in the heat transfer process. Additionally, local heat transfer coefficients inside the compressor are seen to be virtually not affected by the condensing and evaporating temperatures, which is a convenient aspect for numerical modelling.

Keywords: *heat flux measurement, hermetic compressor, heat transfer modelling.*

INTRODUCTION

In reciprocating compressors adopted for household refrigeration, great part of the energy used to compress the gas is converted into heat. If such an amount of heat is not sufficiently removed from the compressor internal ambient, its thermodynamic efficiency is greatly affected by gas superheating associated with heat transfer in the suction system. Heat transfer that takes place throughout the suction system walls is a function of gas temperature inside the compressor shell, which is a result of heat dissipated by heat sources, such as the compression chamber.

According to [1], gas superheating corresponds to 49% of the overall thermodynamic loss in small reciprocating compressors. Several attempts have been directed to provide a better understanding of heat transfer inside the compressor and, as a consequence, alternatives to reduce superheating. However, thermal analysis of compressors is a difficult task due to its geometric complexity, which does not allow simple modeling approaches. Moreover, the oil inside the compressor acts as a lubricating agent for bearings and also as a mean to directly transfer heat from the compressor kit to the shell. In order to find alternatives to reduce superheating losses, it is of fundamental importance the understanding of all relevant heat transfer phenomena acting on the gas during its path from the suction line up to the compression chamber.

A number of numerical models have been proposed in the literature to predict heat transfer in reciprocating compressors. Some of these models [2-3] are based on integral formulations, in which mass and energy balances are applied to a number control volumes specified in the compressor domain. The output data is the temperature level in each control volume. Other studies are based on differential formulations for the whole domain, including heat transfer in the compressor components and in the gas, but with a great computational cost [4]. Finally, a third group of methodologies [5, 6] combine integral and differential formulations in the form of a hybrid model.

Heat transfer in reciprocating compressors has also been experimentally investigated [7, 8]. In such works, thermocouples are usually employed to measure the gas temperature in positions strategically chosen so as to evaluate heat transfer in different components through energy balances. However, thermocouples are not suitable when a more detailed analysis is required, such as the local characterization of heat exchange between the gas and surfaces.

This paper is concerned with an experimental investigation aimed at characterizing heat transfer in a small reciprocating compressor under actual operating conditions. Measurements are carried out in several regions of the compressor shell and validated by means of results from energy balances and numerical simulations. Additionally, data for heat flux and temperature are combined to obtain local heat transfer coefficients in some positions of the shell.

EXPERIMENTAL PROCEDURE

The internal and external surfaces of a hermetic reciprocating compressor shell were instrumented with heat flux sensors (HFS) and thermocouples. The internal surface was divided into eleven regions, whereas ten regions were used for the external surface, as can be seen on Figure 1. Each region was characterized by one HFS, with the exception of regions *i2* and *i3*, where two sensors were adopted instead. On the other hand, heat flux at the external regions *e6* and *e7* were evaluated from an analytical solution available for fins [9]. Most HFS's employed in the present work are provided with a thermocouple to measure also its surface temperature, with the exception of a different type of HFS needed at region *i11*.

A HFS is built from thermocouples in a serial association. The voltage output of a thermopile, E, is a function of the thermoelectric sensitivity of the materials, S_T, the number of thermocouple junctions, N, and the temperature difference between the HFS surfaces, ΔT, i.e. $E = N S_T \Delta T$. On the other hand, the one-dimensional steady-state heat flux perpendicular to the HFS surfaces, q'', depends on the HFS thermal conductivity, k, the HFS thickness, t, and the temperature difference between its surfaces ($q'' = k \Delta T / t$). Thus, by combining the aforementioned equations, one obtains a linear relation between heat flux and the voltage output ($q'' = E / S$), where S ($= N S_T t / k$) is the sensitivity of the HFS. The value of S is usually provided by the sensor manufacturer, but can also be obtained from a calibration procedure. In this study, some HFS's were calibrated and no difference higher than 10% was observed in relation to the values of S specified by the manufacturer. For this reason, the latter were considered in the measurements.

The instrumentation of HFS's on the internal surface of a compressor shell is not a simple task, due to the high temperature levels inside the compressor and the presence of lubricating oil. To circumvent such difficulties, an epoxy-adhesive was adopted to attach the HFS to the surfaces. Moreover, their wires were carefully positioned inside the compressor, as illustrated in Figure 2(a), so as to minimize changes in the lubricating oil flow path. This is a very important aspect, because the lubricating oil affects the heat transfer process inside the compressor. Figure 2(b) presents a three-dimensional schematic view of the compressor, with the identification of some of its main components, including an oil pump. As can be seen, the oil is stored at the carter in the lower region of the compressor shell and taken to the upper parts by centrifugal action of an oil pump.

Several thermocouples were also instrumented in the compressor internal ambient, in order to establish a suitable reference temperature, T_∞, to estimates the local heat transfer coefficient, h, in each region, i.e.:

$$h = \frac{q''}{T_S - T_\infty} \tag{1}$$

where T_S is the sensor surface temperature. It should be mentioned that in most regions inside the compressor there is a thin film of oil covering the surface, as illustrated in Figure 3. Therefore, since the reference temperature, T_∞, is measured in the gas, the heat transfer coefficient h should be in fact regarded as a global heat transfer coefficient. For the shell external surface there is no such an issue and the usual interpretation for the heat transfer coefficient holds.

RESULTS AND DISCUSSIONS

A reciprocating compressor operating with R134a was selected for the analysis, being submitted to two operating conditions, represented by two pairs of evaporation and condensation temperatures: (-23.3ºC/40.5ºC) and (-10.0ºC/90.0ºC). All tests were conducted in a calorimeter facility following refrigerating conditions established by standards. The uncertainties associated with measurements taken with the calorimeter are $\pm$ 2% for mass flow rate and power consumption. Further details of the experimental facility can be found in [9]. The compressor was tested five times for each operating condition. Results for heat flux, temperature and heat transfer coefficient are presented with an uncertainty bar corresponding to a 95% confidence limit.

Validation of experimental results

The heat transfer rate rejected through the compressor shell, $\dot{Q}_C$, can be evaluated by summing up the contributions of local heat flux measured in each of the regions depicted in Figure 1. Hence,

$$\dot{Q}_C = \sum_{i=1}^{n} q''_i \, A_i \tag{2}$$

where q''_i is the local heat flux on the *i*-nth region of the shell surface with an area equal to A_i. Values of A_i needed in equation (2) are obtained from a CAD model.

The heat rejected through the compressor shell, $\dot{Q}_C$, can also be obtained from an energy balance applied to the compressor itself:

$$\dot{W}_C = \dot{m}\left(h_{DIS} - h_{SUC}\right) + \dot{Q}_C \tag{3}$$

where $\dot{W}_C$ is the compressor power consumption, $\dot{m}$ is the refrigerant mass flow rate and h_{SUC} and h_{DIS} are the refrigerant specific enthalpies at suction and discharge lines, respectively. The power consumption is measured with a power meter and the specific enthalpies are determined from measurements of temperature and pressure at suction and discharge lines. As Figure 4 shows, there is a satisfactory agreement between results for $\dot{Q}_C$ obtained from measurements, equation (2), and from the energy balance, equation (3). The larger deviation occurs for the value measured at external surface, which is approximately 15% higher than that returned from the energy balance.

It should be mentioned a number of uncertainty sources in the measurements, associated with the following aspects: i) accuracy of the heat flux sensor; ii) compressor instrumentation process; iii) contribution of thermal radiation; iv) selection of representative regions to quantify the total heat transfer rate through equation (2). As far as the heat flux sensor is concerned, the manufacturer specifies an accuracy of 5%. On the other hand, random errors associated with instrumentation were treated by repeating five times each test condition and then applying a 95% confidence limit to the average value. Thermal radiation is also an issue since there is a difficulty to characterize the emissivity of surfaces, especially inside the compressor where oil is present on almost all surfaces. Yet, for the external surface, infrared thermography was combined with thermocouples to quantify the emissivity. Finally, the number of regions in which HFS are assembled must enough to properly discretize the heat transfer that takes place on both surfaces of the compressor shell, as given by equation (2). Therefore, for the purpose of energy balance, measurement of heat transfer is not a trivial task since one should have information about the thermal field before installing the heat flux sensors. Naturally, if the aim is to obtain only local values for heat transfer, then this issue is not relevant. Considering all the aforementioned difficulties, the level of agreement between estimates for $\dot{Q}_C$ obtained from equations (2) and (3) are considered acceptable.

Local heat transfer analysis

Figures 5 and 6 show experimental results prepared to analyse the heat transfer process at the internal surface of the compressor shell. From Figure 5, one can clearly notice the presence of high flux rates at the border of the shell cover (*i9*, *i10*, *i11*) and region *i6*. This is so for regions *i9*, *i10* and *i11* because, after leaving the pump, the oil hits against the cover surface, forming an impinging jet in the form of volute that enhances heat transfer there. Moreover, heat transfer is increased in region *i6* by oil spatter, which is much more intense than in the opposite side *i7*. Figure 2(b) provides a schematic view of the oil spatter that takes place in the upper region of the compressor. As can be seen, some components inside the compressor, such as the discharge muffler and the bundy pipe, act as baffles, avoiding oil spatters on region *i7* with the same intensity as it occurs on *i6*.

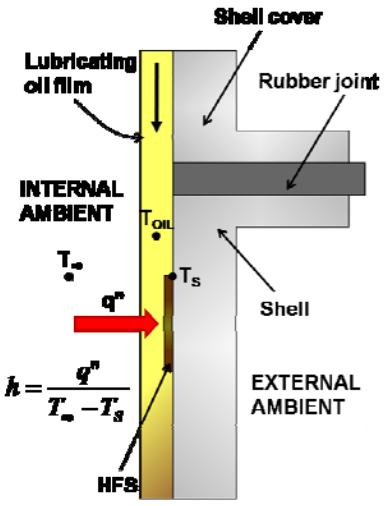

Figure 3. Lubricating oil film on the shell internal surface.

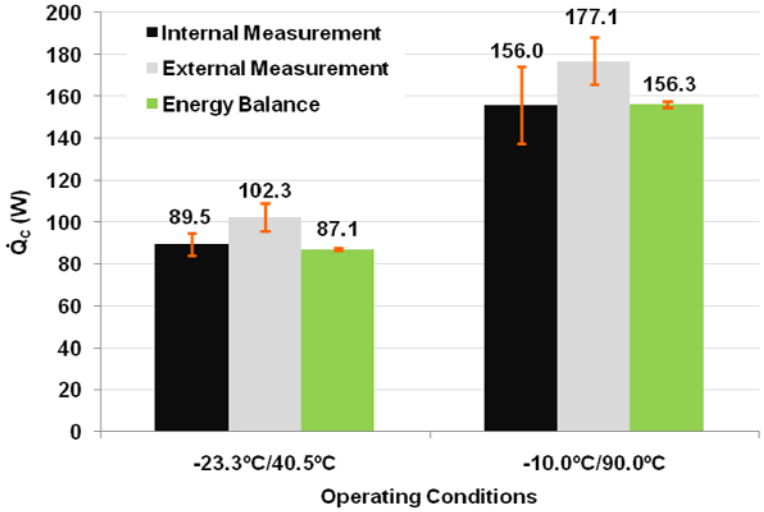

Figure 4. Compressor heat transfer rate at different operating conditions.

Figure 5(b) shows high values of heat transfer coefficients on surfaces *i9*, *i10* and *i6*, confirming the previously explained effect of the oil. For region *i11*, the heat transfer coefficient was not evaluated because, as already mentioned, the HFS installed there had no capability for temperature measurement. The results show that when the compressor operating condition is changed from -23.3ºC/40.5ºC to -10.0ºC/90.0ºC, there is an increase in the levels of heat transfer and temperature, although heat transfer coefficients remain almost constant. Therefore, such an increase in heat transfer can be attributed mainly to a shift in the compressor thermal profile, as one can verify by comparing Figures 6(a) and 6(b).

Turning the attention to the external surface, Figure 7 indicates a high intensity heat flux at regions *e2*, *e4*, *e5* and *e9*, mainly associated with higher heat transfer coefficients, as shown in Figure 8. Such regions belong to the compressor side that was exposed to the air flow stream from a fan installed inside the compartment in which the compressor is tested. The adoption of such a fan is a requirement of standards for compressor testing, which specifies that levels of temperature and air velocity inside the compartment must be controlled.

Although it is observed significant differences between local heat fluxes on the external and internal surfaces, heat flux levels on external surface are also increased when condition -23.3ºC/40.5ºC is changed to -10.0ºC/90.0ºC. This increase in the heat flux level is related to a temperature profile shift

on the external surface, as also verified for the internal surface, and for this reason the heat transfer coefficient virtually does not change.

Figure 8. Difference between the temperatures in the air and on shell external surfaces: (a) -23.3ºC/40.5ºC; (b) -10.0ºC/90.0ºC.

Numerical simulation

Heat conduction in the compressor shell was simulated with the commercial code FLUENT 6.3 [10], which adopts a finite volume methodology to discretize the governing equations. Boundary conditions of local convective heat transfer coefficient and ambient temperature were prescribed for both the internal and external surfaces, with reference to the experimental data. The three-dimensional geometry of the compressor shell was prepared and made available from CAD software. Two computational grids were tested for assessment of truncation errors, one with 1.3 x 10^6 and other with 2.7 x 10^6 volumes. Results for temperature [ºC] obtained with each grid were in an agreement within 1% in the whole domain and, therefore, the numerical solution was considered to be representative of the heat conduction equation.

Figure 9 shows a comparison between results for temperature field on the external surface of the compressor shell provided by the numerical prediction and measured with infrared thermography combined with thermocouples. Good agreement is seen between the experimental and numerical results, with a typical deviation of 2%. The greatest difference was found at the base plate, corresponding to approximately 5%. The level of agreement seen in Figure 9 provides further evidence about the measurement accuracy.

CONCLUSIONS

An experimental investigation of heat transfer in the shell of a small reciprocating compressor has been reported. It was identified a number of factors that can negatively affect the measurements. The experimental data were validated with reference to results obtained from energy balances and numerical simulations. Heat flux sensors and thermocouples allowed the characterization of local heat transfer in several regions of the external and internal surfaces. The results showed a great effect of the lubricating oil in the heat transfer process. On the other hand, it was observed that local heat transfer coefficients are insensitive to the compressor operating conditions. This is an interesting aspect that makes it easy to characterize boundary conditions for numerical modelling of heat transfer in compressors. The experimental procedure presented in this paper was not available in the literature and, therefore, represents a valuable contribution for the analysis of superheating in compressors. The work will be extended to include measurements for other components of the compressor, such as suction and discharge mufflers, electrical motor and cylinder.

ACKNOWLEDGEMENTS

This study forms part of a joint technical-scientific program of the Federal University of Santa Catarina and EMBRACO. Support from FINEP (Federal Agency of Research and Projects Financing) and CAPES (Coordination for the Improvement of High Level Personnel) is also acknowledged.

ABSTRACT. A multiscale modeling approach is presented for multiphase flow phenomena featuring a thin-film bounding two phases. A Micro Scale Solver predicts the thin film dynamics, influenced by an antagonistic Van der Waals force and a stabilizing repulsive force, which is mapped onto a Macro Scale Solver through a multiscale coupling. Numerical experiments of thin-film slug flow in a micro-pipe demonstrate that the key to capture multiscale phenomena lies in the accurate modelling of the microscale parameters. Faitful results are obtained with the multiscale treatment for the modelling of slug flow with a 10.4 nm thin-film, where pure computational multi-fluid dynamics is deficient.
Keywords: *Multiscale coupling, two-phase flow, numerical simulations, Level Set method.*

INTRODUCTION

Typical microfluidics examples involving multiscale phenomena are flows with moving contact lines, boiling, droplet/bubble coalescence and break-up, ect. To accurately capture their physical behaviour it is crucial to describe the interaction between the different, macroscopic and microscopic length scales of these flows. This poses challenges on theoreticians as well as modellers since these phenomena are not often based on one theoretical framework. Molecular dynamics (MD) theory could capture effects on both the macro- and micro-scale, but large-scale molecular dynamics simulations are today not accessible due to excessive computational time. Macroscopic continuum theory does permit large-scale computations, but lack in capturing intermolecular effects at microscale. We propose in the present paper a multiscale modelling approach for multiphase flow phenomena featuring a microscopic thin-film that separates two phases. A multiscale coupling is introduced, linking a microscopic thin-film model including intermolecular forces and a continuum model describing the large-scale multiphase flow motions. The developed multiscale simulation platform is based on two solvers: a Sub-Grid-Scale (SGS) Mirco Scale Solver (MiSS) for the thin-film dynamics, and a Macro Scale Solver (MaSS) for the modelling of the macroscopic multiphase flow characteristics. The models are based on two different theoretical frameworks and are well documented in the literature; namely the Long Wave Theory and the Navier Stokes equations with a Level Set interface tracking formulation. Numerical experiments of thin-film slug flow are presented with the modelling of a 10.4 nm film.

Two-phase slug flow have features that makes it suitable to optimize heat and mass transport in channels and capillaries, and are for these purposes studied here. This flow regime is indeed attractive for numerous applications in biomedical engineering and micro-system technology. Between the interface of the elongated drops or bubbles and the channel surface a thin bounding liquid film is formed, and its existence is the determining factor for controlling the heat and mass transfer in the flow. In cases of high heat flux, of gas-liquid slug flow, a rupture of the thin-film could generate a rapid temperature increase in the solid, referred to as a *dry-out* phenomenon.

Slug flow in small channels has been subject of investigations since the pioneering work of Bretherton [4] and Taylor [1]. Based on hydrodynamic theory Bretherton related the liquid film thickness (h_b), between the channel surface and the bubble interface, to the Capillary (Ca) number, using $h_b = 0.83 * Ca^{2/3}$. $Ca = (\mu_l U_B)/\sigma$, where μ_l is the film viscosity, U_B is the bubble speed and σ is the surface tension coefficient. The capillary number expresses the relative importance of the surface tension force to the viscous force in the flow. Bretherton's correlation has recently been modified [1], based on the experimental results of Taylor [1], in order to account for a larger range of Ca-number flows. These continuum models seemingly only holds as long as Ca is greater than $\sim 10^{-3}$. For lower Ca numbers, these models fail to correctly estimate the film height. Bretherton pointed out that a disjoining pressure (from non-hydrodynamic forces) could be the cause of deviation from physical observations and the proposed correlation. This is an early evidence of the influence of intermolecular forces on the film in slug flow. The availability of various experimental [4, 15, 17] and numerical investigations [6, 10] on slug flow in small channels, does not give any qualitative information concerning the film height for low Ca-number slug flows. For this flow regime the length scale of the film (h) is well separated from the characteristic length scale (L) of the phenomena, where $h \ll L$. As the film height becomes close to 100nm, the validity of the continuum theory starts to lack a theoretical justification and a molecular dynamics description is needed to adequately describe the physical phenomena.

MODELING FRAMEWORK OF THE MACRO SCALE SOLVER (MaSS)

The interface tracking method

The theoretical framework of the MaSS is based on a single fluid formalism of the Navier Stokes equations for an incompressible interfacial two-phase flow,

$$\nabla \cdot \mathbf{u} = 0, \tag{1}$$

$$\rho(\phi)(\partial_t \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u}) = -\nabla p + \nabla \cdot (\mu(\phi)(\nabla \mathbf{u} + (\nabla \mathbf{u})^T) + \delta \mathbf{F}_s, \tag{2}$$

$\delta \mathbf{F}_s = \sigma \mathrm{K} \cdot \mathbf{n} = \sigma \mathrm{K} \cdot \nabla \phi / |\nabla \phi|$ is the surface tension force acting on the interface δ_s with a curvature K and a normal **n**, here using the continuum surface force model by Brackbill et al. [3]. The Level Set method [16] is applied to track the evolution of the interface in time by solving an additional scalar advection equation, defined by

$$\partial_t \phi + \mathbf{u} \cdot \nabla \phi = 0, \tag{3}$$

where ϕ stands for the signed distance function to the interface, where $\phi=0$. The ϕ-function separates the two different phases with $\phi>0$ indicating the liquid phase and $\phi<0$ indicating the gas phase. To avoid distortion of the Level Set function as it is advected in time, a re-initialization procedure is solved in accordance with the method proposed by Sussman et al. [16].

The method as implemented in the CMFD solver TransAT (developed at ASCOMP Gmbh), which is based on the finite volume method and applied as the MaSS, has proven to be successful for many multiphase flow phenomena [6, 10]. Nevertheless, the method can be deficient for other flows, producing unphysical results without a sub-grid-scale multi-physics treatment of thin-films. This alleviate the DNS dilemma, since resolving all relevant length scales would generate a prohibitive computational costs due to the spatial and temporal resolution requirements (Δt, $\Delta x \sim 10^{-9}$).

MODELING FRAMEWORK OF THE MICRO SCALE SOLVER (MiSS)

A mechanistic thin-film model

The mathematical formulation of the MiSS is based on the Long Wave Theory (LWT), which is deduced by an asymptotical reduction of the Navier Stokes equations [14]. The LWT, with the modelling of molecular long- and short-range forces, has shown to correctly describe the microscopic thin-film morphology on a flat plate dominated by intermolecular forces [2]. This recent validation of the theory, through matching experimental results, makes it suitable as a theoretical framework for the Sub-Grid-Scale (SGS) modelling of thin films, influenced by intermolecular forces. In the present

work we confine ourselves to the treatment of relatively "thick" films (>10 nm), where also the LWT is valid. The Knudsen (Kn) number is often applied as measure to distinguish the continuum from the molecular flow field representation, Kn=λ/L. It is defined as the ratio of the molecular length scale (λ) (the mean free path) to the characteristic macroscopic length scale (L). For films larger than 10nm the Kn number regime between continuum mechanics and slip-flow applies, alleviating the need of a no-slip condition at the wall.

The long wave evolution equation describes the spatio-temporal evolution of a thin liquid film on a solid surface under the influence of intermolecular interactions [18]:

$$\mu\partial_t h(z,t) - \frac{1}{3}\partial_x\left[h(z,t)^3\partial_x(\Phi - \sigma\partial_x^2 h(z,t))\right] = 0, \tag{4}$$

representing three different phenomena in play; a pseudo-viscous force μh(z,t), the excess intermolecular force $\partial_x(h(z,t)^3\partial_x(\Phi))$ and the surface tension force $\partial_x(h(z,t)^3\sigma\partial^2{}_x h(z,t))$. The relative magnitude of the different terms controls the dynamics of the film. In Eq. 4 h is the film height, Φ represents the intermolecular interaction, μ and σ are the dynamic viscosity and the surface tension coefficient. The surface tension force acts as a stabilizing force of the film. The influence of the excess intermolecular forces have two contributions the antagonistic attractive Van der Waals force, and a stabilizing repulsive force. A Mie potential [8] is typically introduced in the thin-film equation for the modelling of the intermolecular interaction. The long range attractive Van der Waals potential $A/(12\pi h(z,t)^3)$ is modelled in concordance with Jain and Ruckstein [9]. The short range stabilizing repulsive potential $-B/h(z,t)^4$ is based on the analysis of Oron [13]. This results in a 3-4 intermolecular potential rather than the more frequently used 3-9 potential:

$$V'(h) = \Phi = \frac{A}{12\pi\cdot h(z,t)^3} - \frac{B}{h(z,t)^4}, \tag{5}$$

where A is the Hamaker constant and B is the repulsive forces coefficient. The Hamaker constant is a material property that controls the interaction force acting between two interfaces or an interface and a solid surface. Its sign determines if the Van der Waals interaction acting on the film is either attractive (positive A) or repulsive (negative A). A rigor modelling of the Hamaker constant is still an open question to be solved and beyond the scope of the present work. The application of the 3-4 potential circumvents the need for a transition region between the films large ridges and its stable minimum height in the pseudo-wetting scenario [13]. To ensure a correct order of magnitude of the retarding coefficient B, we use the measured value from Becker et al. [2] in the 4-potential: $B_B=6.3*10^{-76}Jm^6$. Although the materials here differ form the ones in the experiments of Becker et al. [2], the same coefficient in the 4-potential gives $B=nB_B^{3/8}= 8B_B^{3/8}$. n is a numerical parameter introduced in order to obtain a larger transition region for the pseudo wetting between stable flat films and the rupture regime.

The Sub-Grid-Scale (SGS) MiSS is based on the thin-film Eq. 4. Due to the stiff nature of the time dependent partial differential equation with higher order derivatives (4^{th} order), special care needs to be taken in the numerical solution method. The thin-film equation has been solved in MatLab by a finite difference method with a 4^{th} order stencil for the spatial derivatives. A Gear method was applied for the time marching [12], which is known to be optimal for the treatment of stiff problems. The code was validated against previously published results for the thin-film equation with the inclusion of the intermolecular Van der Waals potential (Burelbach et al. [5]).

MULTISCALE COUPLING METHODOLOGY

The application of the multiscale coupling between the MaSS and MiSS is motivated by two factors. First, such a coupling enables us to numerically investigate multi-physics phenomena taking place on different length and time scales, which does not lie in one theoretical framework. The virtue behind the multiscale methodology is the ability to model the microscale tendencies, which are captured, and then mapped onto the macroscale solution. As we will show below, this is the key to correctly capture the

flow of certain multi-physics phenomena. Secondly, the multiscale coupling seeks to obtain a high computational efficiency with the strict requirement that is [7]; *computational cost with a multiscale method << computational cost with pure micro solver*. This is obtained here by decoupling the two solvers in the multiscale coupling approach by exploiting the separation of both temporal and spatial length scales; the MiSS converges toward a steady-state solution, within one MaSS time step. As a result the MaSS is not restricted by the time step applied in the MiSS, $\Delta t_{MiSS} << \Delta t_{MaSS}$. A scheme of the multiscale coupling methodology is shown in Fig. 1. First, we check if the macroscale formulation would fail in the present model for physical phenomena with characteristic length scales less than ~100nm. This is done by checking whether the near wall cell is <200nm. If a multiscale treatment is not needed, which means that Δx_{wall}>200nm and no dry-out, pure macro scale simulations would apply. Should this not be true, a multiscale treatment is needed and some macroscale parameters are transferred from the MaSS to the MiSS. The parameters are the near wall mesh resolution, the unstable wave number, the film viscosity and the surface tension coefficient.

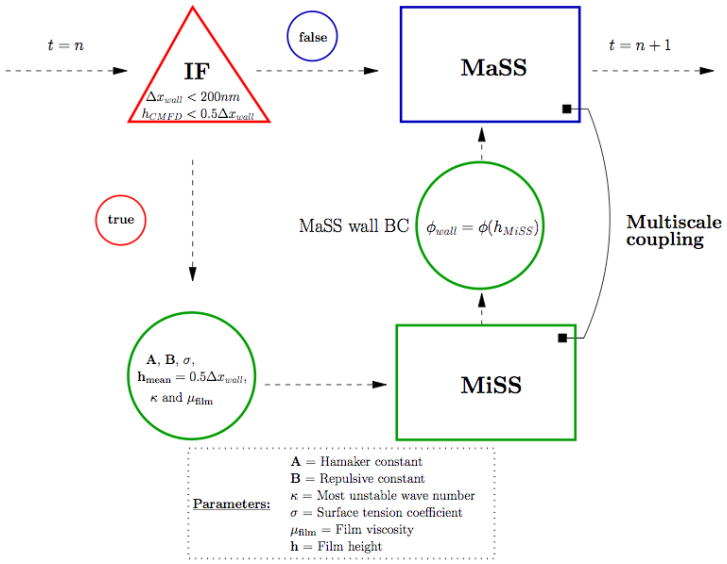

Figure. 1. Schematic description of the multiscale simulation platform.

The main feature with the multiscale coupling methodology is to substantially reduce computation time, without the sacrifice of key physics. For this purpose, MiSS computations are not performed at every time step. The minimum film height is extracted from a thin-film stability map pre-computed with the MiSS, based on variations in the Hamaker constant (all other parameters are kept constant), see Fig. 2. The microscale film height h, is mapped onto the macroscale flow field through a boundary condition applied in the MaSS, $\phi_{wall} = \phi(h_{MiSS})$. This is performed in the computations by the Level Set ϕ function, which locally represents the film height in the wall-normal direction of the near wall cell.

Thin-film stability map based in the Hamaker constant

Fig. 2 shows the thin-film stability map predicted by the MiSS, and is based on the Hamaker constant and the minimum film height. The film has a viscosity μ_s=0.002Pa*s and a surface tension coefficient σ=0.1Nm. Initially, the film has a long-wave disturbance

$$h(z,t) = h_{mean} \cdot (1 + \cos(\kappa^2 z / \pi)), \quad (6)$$

where κ is the most unstable wave number and the fastest growing linear mode [14], and h_{mean} is half of the near wall cell size, h_{mean} =83nm. The thin-film equation is solved in a spatial domain of z= h_{mean} [-π/κ, π/κ], with periodic boundary conditions at the edge of the domain. The thin-film equation is solved in Cartesian coordinates.

The MiSS, depending on the magnitude of the Hamaker constant, predicted three different film regimes. The typical thin-film morphology for these regimes is shown in Fig. 2. For A>9*10^{-19}J the

film is stable and flattens, meaning that the attractive intermolecular forces are not large enough compared with stabilizing (repulsive- and surface tension-) forces. In this case, the film will lubricate the pipe surface. The second pseudo-wetting regime was observed for $9*10^{-19}$J <A< $1.6*10^{-19}$J; see Fig. 2. In the pseudo-wetting scenario, the attractive forces accelerate the film towards the solid surface, and as it approaches its equilibrium minimum film height, the repulsive forces grow and decelerate the film motion. The film finally obtains its equilibrium configuration, with a flat region with the minimum film height that is bounded by large ridges; see centre of Fig. 2. In both the stable and pseudo-wetting regime, a stable minimum film height is obtained.

For the regime A>$1.6*10^{-19}$J, the minimum film height becomes less than 10nm, and the LWT starts to loose its validity. A transition region between thin films that can be described within the LWT and a molecular dynamics theory, is illustrated in Fig. 2 (right part). By further increasing the Hamaker constant, the unstable film rupture regime is reached, which would result in a *dry-out* condition. The right part in Fig. 2 describes the typical film shape as it ruptures. In this scenario, the film accelerates towards the surface due to the strong antagonistic attractive forces. The repulsive and surface tension forces do not manage to stabilize the film, which finally leads to a film rupture. At the point-of-rupture the thin-film equation diverges ($h \rightarrow 0$) and the LWT is no more justifiable, which implies that the exact time of rupture and film shape cannot be extracted with fidelity. Nonetheless, the important resulting micro scale information like: stable minimum film height or film rupture, are extracted from the thin-film stability map and coupled to the macro scale solver through a boundary condition on the pipe surface. For cases where the film ruptures, a contact line would be formed at the solid surface. The treatment and modelling of moving contact lines is assumed to be an important aspect in dry-out conditions; it is although not a subject in the present work.

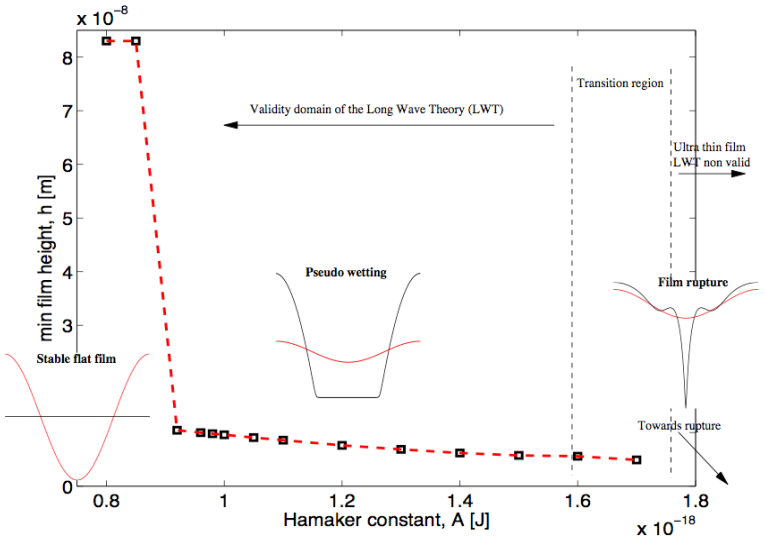

Figure. 2. Thin-film stability map based on Hamaker constant and min film height, $\Phi=A/(12\pi h^3) - B/h^4$.

MULTISCALE SIMULATION PLATFORM

Simulation setup and boundary conditions

Two-dimensional axis-symmetric simulations of a liquid-liquid slug flow in a pipe with D=10μm diameter have been performed. The simulation setup is shown in Fig. 3 with the boundary conditions. The outer annulus is feeding silicone oil with viscosity μ_s=0.002Pa*s and density ρ_s=950kg/m^3, and the small concentric pipe is feeding water with viscosity μ_w=0.001Pa*s and density ρ_w=998kg/m^3. The two phases have a surface tension coefficient of σ=0.1Nm, and with a Hamaker constant A=$9*10^{-19}$J, and a repulsive coefficient B=$8.3*10^{-23}$Jm. The simulations were performed on an equidistant mesh, with 60 cells over the pipe diameter, giving a mesh spacing $\Delta z=\Delta r$=168nm. These parameters give a prediction in the MiSS of a minimum film height of 10.4 nm, so that a thin oil film should sustain

between the pipe surface and the droplets. The inlet velocity for the silicone oil is set to U_s= 0.11m/s and for water U_w = 0.066m/s. We make the assumption that at t=0 the flow is not fully developed and that entrance edge effects can be ignored. Gravitational effects have been neglected in accordance with the limit derived by Bretherton [4]. The convergence criteria were set to 10^{-4}, and a dynamic time stepping scheme has been applied based on the Courant-Friedrich-Leavy (CFL) number with CFL_{max}=0.3 and CFL_{max}=0.1. A monotonic upwind scheme Hybrid Linear/Parabolic Approximation (HLPA) has been applied for the momentum equations with a Weighted Essential Non-Oscillatory (WENO) scheme for the Level Set function. A Strongly Implicit Procedure (SIP) solver [11] by Stone is used to solve the system of linear matrices. A first-order Euler scheme has been applied for the time integration and the pressure-velocity is decoupled with a Semi-Implicit Method for Pressure-Linked Equations (SIMPLE) [11].

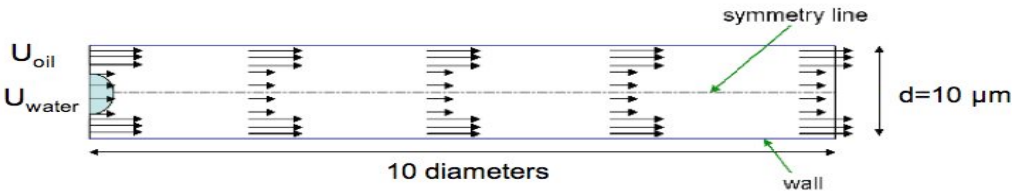

Figure. 3. Simulation setup and boundary conditions.

RESULTS

Comparison between CMFD and Multiscale simulation

The water and oil flow through the two inlets and new interfacial area is formed with the shape of a thumb (Fig. 4). At some point, there is an incipience of an interfacial disturbance that grows in time to finally result in the formation of a droplet. Droplets are in the present simulations generated with a nearly constant frequency. A more thorough description of the droplet formation and propagation can be found in the paper by Lakehal et al. [10].

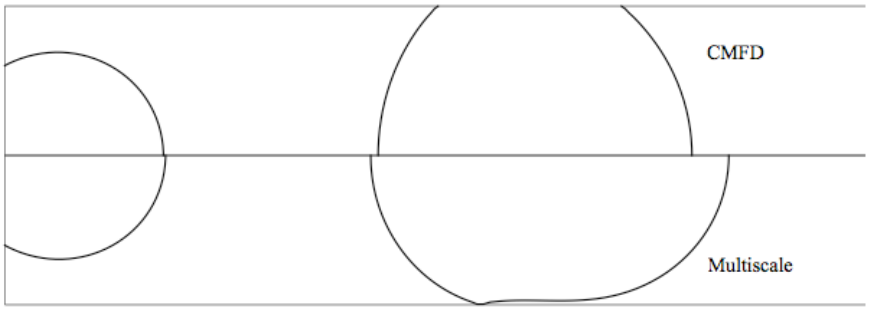

Fig. 4. Comparison of the two-phase flow predicted with pure CMFD (upper) and the multiscale simulation platform (lower), represented by the iso-contour of the zero level set function at t=398 µs.

Fig. 4 shows the multiphase flow characteristics in a section of the pipe that is corresponding to a length of three diameters. The upper subfigure is the prediction from the CMFD simulation and the lower subfigure is the prediction from the multiscale simulation platform. To the left of Fig. 4 one can observe the two inlets feeding water and oil, noticing that the interface has a nearly spherical shape due to the dominating capillary force. The upper subfigure shows the multiphase flow prediction with CMFD, a few instances after the first droplet has been formed. The droplet does not immediately wet the wall, but as it travels downstream it relaxes to its equilibrium shape, and the film between the surface and interface is thinned. This leads to a loss of the numerical accuracy of the thin-film. As it becomes less than half of the near wall cell size $h<0.5\Delta x_{wall}$, the droplet wets the pipe surface (see Fig. 4). As the interface comes in contact with the pipe surface, two contact lines are formed (see Fig. 4). In the present simulation an equilibrium contact angle formed between the tangent of the interface and the pipe surface of 140° has been introduced as a boundary condition. This event is characterized as a numerical dry-out since a wetting film should sustain. Further, as the film ruptures the droplet looses its

characteristic shape resulting in a change in the droplet curvature at its front and rear. By comparing the CMFD result with the multiscale simulation, we notice clearly that the film rupture process induces a mass loss in the droplet (Fig. 4). The lower subfigure in Fig. 4 shows a very different droplet shape, predicted with the multiscale simulation approach. As the droplets interface approaches the pipe surface, the film height is predicted by the MiSS and the imposed as a boundary condition for the MaSS simulation. The microscopic thin-film in the present case has a minimum film height of 10.4 nm. The re-initialization of the level-set function gives a smooth transition between the minimum film height and the outer macroscopic droplet shape. The multiscale simulation captures the wetting film and it conserves the droplet size. Comparing the droplet shape using CMFD and multiscale, with the experimental results of Sarrazin [15], reveals that the multiscale treatment provides a more faithful picture than pure CMFD, notice that these experiments were performed with slightly different non-dimensional numbers and channel size.

Although the multiscale coupling gives more physically realizable results, there are some weakness points that need to be emphasized. The coupling does in its present state generate spurious pressure and velocities in the narrow vicinity of the thin-film treatment zone. This directly affects the ability to meet a low convergence criterion ($<10^{-4}$), which is also difficult to control. The main reason for the production of spurious pressure and velocities is the way the film has been mapped onto the MaSS. In order to limit such numerical deficiencies, a mass and momentum balance needs to be introduced at the film through a rigorous coupling between the two solvers. The CMFD simulation produces also velocities that are not smooth at the contact lines.

Comparison of resolved MaSS thin-film and Multiscale simulation

Fig. 5 shows a comparison between a resolved CMFD simulation (upper subfigure) and a multiscale simulation on a coarse mesh (lower subfigure). The two simulations have strikingly similar predictions of the flow characteristics, with slight difference in the droplet size caused by a different pinch-off time and location. A higher mesh resolution subsequently reduces the numerical width of the interface, which is an important factor for coalescence predictions. Fig. 5 shows evidence of the different break-up scenarios, as the interface at the inlet in the multiscale simulation propagates further downstream than the resolved CMFD, at the same time. The CMFD result predict quite well the droplet shape on a fine mesh, although at the expense of an increased computational cost. The thin-film between the interface and the pipe surface is in the present simulation captured within one cell only. In order to fully resolve such a flow phenomenon the film should be resolved with approximately 10 cells, which is an absolute minimum in order to capture a laminar flow profile. This would increase the computational costs rather drastically. The key-point is although that pure CMFD lacks a theoretical sound thin-film prediction.

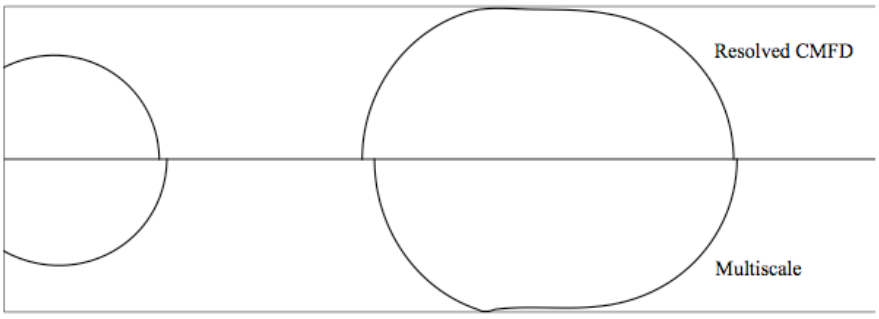

Figure. 5. Comparison of the flow characteristics predicted with CMFD on a fine mesh and the multiscale simulation on a coarser mesh, lines denote the iso-contour of the zero level set function at t=398μs.

CONCLUSION

In the present paper we have presented a multiscale modelling approach for interfacial flow phenomena endowed with a microscopic thin-film separating the two phases. A multiscale coupling is introduced between a Micro Scale Solver, which simulates the resulting thin-film dynamics, and a Macro Scale Solver for the macroscopic two-phase flow. The minimum thin-film height is seen as a sub-grid-scale variable that can evolve freely on the macro scale field through a wall boundary condition, without restricting the macroscopic time marching. This enables an efficient prediction of this class flow phenomena featuring complex physics without a unifying theoretical framework. A pure continuum model, in this case a CMFD method, will even in a direct numerical simulation lack a theoretical justification as intermolecular forces will be govern the phenomenon. A practical example of slug flow in a micro pipe has been presented, with the successful modelling of a 10.4 nm bounding thin-film formed between the slugs interface and the pipe surface. The numerical dry-out generated with CMFD on a coarse grid is an example of an unphysical solution. The multiscale simulation compares well with a resolved CMFD simulation. The multiscale simulation result also compare well with the droplet shape seen in the experiments by Sarrazin [15]. The presented computational capabilities are crucial in order to predict, inter-phase heat and mass transfer processes in micro channels that contains a two-phase flow.

RECONSTRUCTION OF THE HEAT TRANSFER COEFFICIENT FOR IMPINGEMENT HEAT EXCHANGE

A. Ryfa[1*], R. Bialecki[1,]
[1]Institute of Thermal Technology at Silesian University of Technology, Gliwice, Poland

ABSTRACT. The paper presents an application of the inverse technique for the heat transfer coefficient (HTC) retrieval for the single phase impingement heat exchange. Such heat transfer method involves a jet flow of fluid from nozzle to a target. A high velocity of the jet causes the destruction of the boundary layer at the targeted surface what leads to a very intensive heat transfer. The method presented here retrieves the HTC directly from the temperature measurements at the opposite side of the targeted object. In order to provide a sufficient amount of input data for the inverse procedure the thermal camera is involved in measurements. It allows distinguishing a large number of measurement points for every time instance. The superposition principle is used to decompose a searched boundary condition to a sum of known linear components multiplied by unknown coefficients. The difficulties that arise from non-linear dependency of the temperature on the HTC are bypassed by application of the definition of the convective boundary condition together with using the fact that the HTC is constant in time. The developed technique was used to retrieve the HTC for the air jet impingement heating on a flat surface.

Keywords: *heat transfer coefficient, inverse analysis, impingement, thermography*

INTRODUCTION

Jet impingement [1] technique consists in directing a jet flow from a nozzle to a target, typically a solid surface. The momentum of the jet destroys the boundary layer at the surface, leading to intensive heat exchange. The efficiency of this heat transfer arrangement makes jet impingement a popular method of intensive cooling and heating. Drying of textile or paper, cooling of electronic packages, cooling of slabs in steel industry, car or aircraft engines cooling are just few examples of applications of the jet impingement technique encountered in industry.
A straightforward technique of modelling jet impingement heat exchange is to apply the CFD analysis coupled with the heat conduction analysis in solid. However, especially for multiphase problems, this technique is both inaccurate and numerically very intensive. Thus, convective boundary condition, where heat transfer coefficient plays the central role, is frequently used in engineering practice. A convenient feature of the HTC is that while transient temperature and heat flux fields on the boundary may vary rapidly, HTC defined as their ratio remains often practically constant. Inverse analysis [2] applied to retrieving the convective heat condition is therefore an attractive alternative to coupled CFD simulations. The inconvenience of using inverse analysis is that it requires experiments in order to determine the value of HTC.
Standard inverse technique relies on separate evaluation of the temperature and heat flux distribution on the impinged surface [3]. The idea is to adjust the response of a heat conduction model in the solid to the measured temperatures. The free parameters in this optimization process are the coefficients describing the spatial and temporal distribution of boundary temperature and

E-mail address: arkadiusz.ryfa@polsl.pl

heat flux on the surface impinged by the jet. Once the temperature and heat flux distributions are retrieved, the HTC distribution is evaluated from its definition, as a ratio of heat flux and temperature excess. The disadvantage of this approach is that the resulting distribution of the HTC is irregular, as both the temperature and heat flux may vary independently. The proposed method produces the spatial distribution of the HTC directly from transient temperature measurements. The paper is a follow up of our earlier work [3] where an implicit technique has been employed.

DEVELOPED METHOD

The HTC depends nonlinearly on the temperature and thus the inverse problem of retrieving HTC is nonlinear as well. Due to this fact the superposition principle cannot be applied directly. However, application of the definition of the convective boundary condition (1) allows overcoming this difficulty.

$$h = \frac{q}{T_f - T} \tag{1}$$

where T_f is bulk temperature of the fluid. The typical inverse procedures apply the Robin condition after the heat flux and boundary temperatures are retrieved. This method called indirect is explained in details in [3]. It requires solving of the optimization problem twice and allows on independent variation of the temperature and the heat flux. It leads, in the presence of the measurement errors, to solution that differs from the correct one. This paper concerns on the second possibility, which is the explicit method. The method allows obtaining spatial distribution of the HTC for impingement cooling solving the optimization problem only once. It uses a fact that the HTC for impingement cooling is constant in time and applies the convective boundary condition directly to the minimized objective function.

Lest take the boundary Γ of the domain Ω and divide it into two parts. On the first part Γ_R the heat flux is unknown. On the remaining portion of the boundary Γ_E, the BC's are known. The temperature at arbitrary point $\mathbf{r}_i$ is expressed as:

$$T(\mathbf{r}_i) = T_E(\mathbf{r}_i) + T_R(\mathbf{r}_i) \tag{2}$$

where the T_E is the temperature field corresponding to the zero flux prescribed at Γ_R and the BC on Γ_E and the internal heat generation unchanged. The second temperature field T_R corresponds to homogeneous BC's on Γ_E and real heat flux on Γ_R which is unknown. This flux is expressed as a linear combination of known trial functions N_j.

$$q_R(\mathbf{r}_i) = \sum_{j=1}^{J} q_j N_j \tag{3}$$

The trial functions are analog to shape functions arising in FEM and BEM techniques [3]. Each of them is associated with a certain spatial location that is decided by the user. It provides the necessary method flexibility and allows using any knowledge about the process for which the HTC is retrieved. From the linearity of the problem, it can be immediately seen that for a selected set of points $\mathbf{r}_{i:}$ $i=1,2,...N$

$$T(\mathbf{r}_i) = T_E(\mathbf{r}_i) + \sum_{j=1}^{J} q_j \Theta_j(\mathbf{r}_i),\ i = 1,2,...N \tag{4}$$

where Θ_j is a temperature field obtained assuming that the heat flux on Γ_R is just the trial function N_j. Equation (4) can be rewritten in a matrix form

$$\mathbf{T} = \mathbf{T}_E + \mathbf{J}\mathbf{q} \tag{5}$$

In the case under consideration, the sensitivity coefficient is the derivative of the temperature at a given point, with respect to the unknown parameter

$$j_{ki} = \frac{\partial T(\mathbf{r}_i)}{\partial q_k} \tag{6}$$

The sensitivity coefficients are just the entries of the matrix **J** being the auxiliary temperatures $\Theta_k(\mathbf{r}_i)$ entering equation (4). As the retrieved heat flux depends on the time, the temporal domain must also be discretized. Assume that the limits of the time steps used to approximate the temporal variation of the heat flux are denoted as $t_0, t_1,\ldots,t_k, t_{k+1}, t_U$ with u standing for the index of the time step while U the total number of thereof. The estimated heat flux distribution can then be expressed as a product of space and time dependent functions

$$q_R(\mathbf{r}_i,t) = \sum_{j=1}^{J}\sum_{u=1}^{U} q_j^u N_j(\mathbf{r}_i) M_u(t) \tag{7}$$

where M is a known trial function depending solely on time and q^u_j is unknown parameter describing the temporal and spatial distribution of the heat flux on Γ_R. Let the subscript p be associated with a pair of spatial trial function j and temporal trial function u as $p = u(U\text{-}1) + j$. Additionally, to simplify the notation let the $Q_p(\mathbf{r},t) = N_j(\mathbf{r})M_u(t)$. Using this notation, equation (7) can be rewritten in more compact form as:

$$q_P(\mathbf{r}_i,t) = \sum_{p=1}^{P} q_P Q_p(\mathbf{r}_i,t) \tag{8}$$

Analog to equation (4), the temperature at any point and time instant can be written as

$$T(\mathbf{r}_i,t) = T_E(\mathbf{r}_i,t) + \sum_{p=1}^{P} q_p \Theta_p(\mathbf{r}_i,t) \tag{9}$$

In the case under consideration, where the HTC is constant in time it is enough to employ only one time step. It causes that only two temporal values of heat flux and temperature are searched for each spatial location associated with trial functions. If the temperature at the boundary Γ_r has to be determined instead of the heat flux, the procedure is completely analogous. The problem remains linear and the only change is that in equations (3-9) the temperature T is used instead of the heat flux q.

The unknown coefficients are determined from least square fit of the model and the measurements

$$\min\phi = \sum_{i=1}^{I} [\hat{T} - T_{\mathrm{mod}}(T_{p1},\ldots T_{pJ}, T_{k1},\ldots T_{kJ})]^2 \tag{10}$$

To retrieve the HTC directly, the residuals for both heat flux and temperature parts have to be added (11). As the HTC is constant for a whole considered time the heat fluxes are then removed

$$\min\phi = \sum_{i=1}^{I} [\hat{T} - T_{\mathrm{mod}}(T_{p1},\ldots T_{pJ}, T_{k1},\ldots T_{kJ})]^2 + \sum_{i=1}^{I} [\hat{T} - T_{\mathrm{mod}}(q_{p1},\ldots q_{pJ}, q_{k1},\ldots q_{kJ})]^2 \tag{11}$$

from the optimization formula by applying the definition of the Robin (12) boundary condition what leads to its final form (13).

$$h_i = \frac{q_{ip}}{T_f - T_{ip}} = \frac{q_{ik}}{T_f - T_{ik}} \tag{12}$$

$$\min \phi = \sum_{i=1}^{I} [\hat{T} - T_{\mathrm{mod}}(T_{p1},...T_{pJ},T_{k1},...T_{kJ})]^2 + \sum_{i=1}^{I} [\hat{T} - T_{\mathrm{mod}}(h_1,...h_J T_{p1},...T_{pJ},T_{k1},...T_{kJ})]^2 \tag{13}$$

This optimization problem (13) can be solved by applying one of the available nonlinear programming procedures. In this case it was recast into a solution of a set of nonlinear equations by resorting to the necessary conditions for minimum. The result led to a set of *J* algebraic equations of *J* unknowns. Due to the aforementioned ill posedness of the problem, the solution of this set is very sensitive to input data errors. Here, the optimization was solved using modified Levenberg-Marquardt technique, which was originally developed for non linear systems and therefore it improves the stability of the solution in the presence of the measurement errors. The sensitivity coefficients i.e. the temperatures $\Theta_k(\mathbf{r}_i)$ entering equation (4) can be obtained using any available analytical or numerical methods. It is, however convenient to use numerical solution due to its universality with respect to domain shape and automation possibilities. Due to those advantages, in the case at hand the sensitivity matrix entries were calculated using a commercial FEM code MSC.Marc.

RECONSTRUCTION PROCEDURE

Experimental rig

The developed technique was used to retrieve the HTC for the air jet impingement heating on a flat surface. The test rig is presented in Figure 1. The compressed air is heated up by a heater to 50^{o}C.

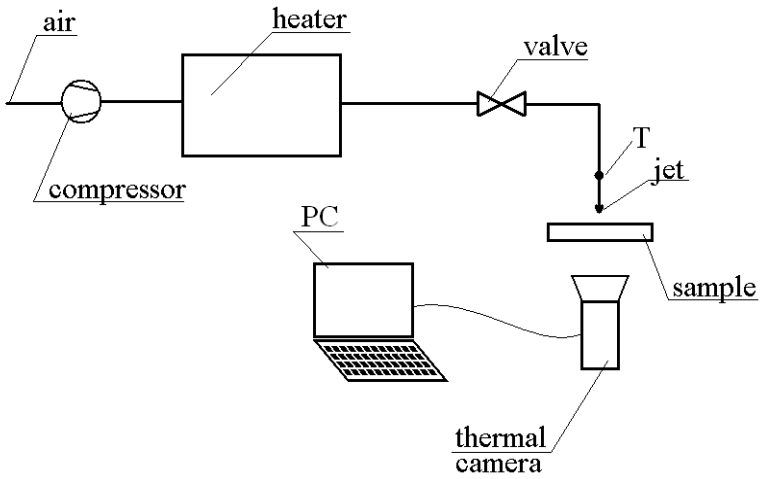

Figure 1. The test rig.

After constant air parameters are reached, the valve is opened and the air flows through nozzle towards the sample. The heated object is a steel cylinder of 60 mm diameter and 5 mm thickness. When the hot air impinges the front surface the sample starts heating up. The temperature measurements are taken with the SC-2000 thermal camera at the back surface of the sample. The images are picked up every 0.2 second. The influence of the nozzle diameter on the jet heating efficiency was tested by use of jets of diameters *d* equal respectively to 5, 6 and 7mm. For each nozzle the measurements lasts until the temperature field at the back of the sample does not change. However, for the inverse procedure only the initial part of the measurements, with the strongest temperature variation is taken. It improves stability and reduces the influence of the temperature errors on the solution. The thermography measurement technique offers a possibility of treating

each pixel of the registered thermal-image as a temperature sensor. For the applied grid resolution and measurement time it produced a set of nearly 2700 equations for determining the spatial distribution of the HTC.

Inverse procedure

The HTC is retrieved by two spatial trial functions of compact support (Figure 2). The description of such functions involves the definition of the sub domains where they do not vanish. In the problem at hand two domains have been defined. The central one is limited by a coaxial circle of a 25mm diameter with the centre at the impingement point, while second covers remaining portion of

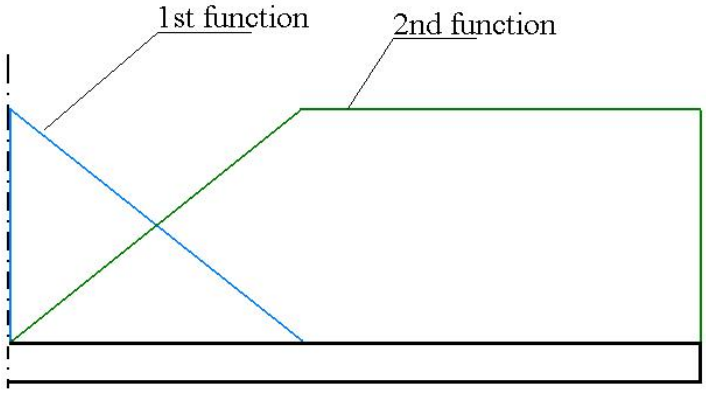

Figure 2. Functions used for HTC retrieval.

the object. The linear trial function is prescribed in the first zone, to retrieve the peak value of the HTC. In the second zone constant in space function is used, as the variation of the retrieved parameters is expected to be very low. It needs to be stressed, that the choice of the approximating functions is crucial for the results. On one hand a selected set of trial functions should produce a highly accuracy approximation of the retrieved function. The purpose is to obtain an accurate reproduction of searched film coefficient. On the other hand, reducing the number of unknowns generally improves the conditioning of the inverse problem. Thus, the number of trial functions used in the approximation of the reconstructed function should be low. Additionally, to reduce the ill posedness of the inverse problem, the trail functions should filter out the high frequency noise. Polynomial functions of low order, such as used in this case constant and linear functions are very suitable for this purpose.

RESULTS

The HTC was reconstructed for three different nozzle diameters between 5 and 7 mm and two nozzle-to-sample distances equal to 15mm and 18mm. The results are presented in Figures 3 and 4. The results show that the highest value of the HTC is at the impingement point. Then it gradually decreases when increasing radial distance. The minimal value is reached in the second zone of the impinged surface. The minimal HTC value is at the level of 10-15% of the peak one. Therefore the choice of constant trial function in that zone is justified because the possible spatial variation can be neglected. With the increase of the nozzle diameter the peak value of the HTC decreases. The radial decrease of the HTC is steeper while the minimal value increases significantly. It means that smaller nozzle can heat up more intensively the impingement region while surrounding area is less heated than for larger nozzle. Other factor with the significant impact on the heat exchange efficiency is the nozzle-to-sample distance (Figure 4). Increasing this distance decreases the peak HTC value of about 10-15%. It comes together with increase of the minimal HTC of value about 20-40%.

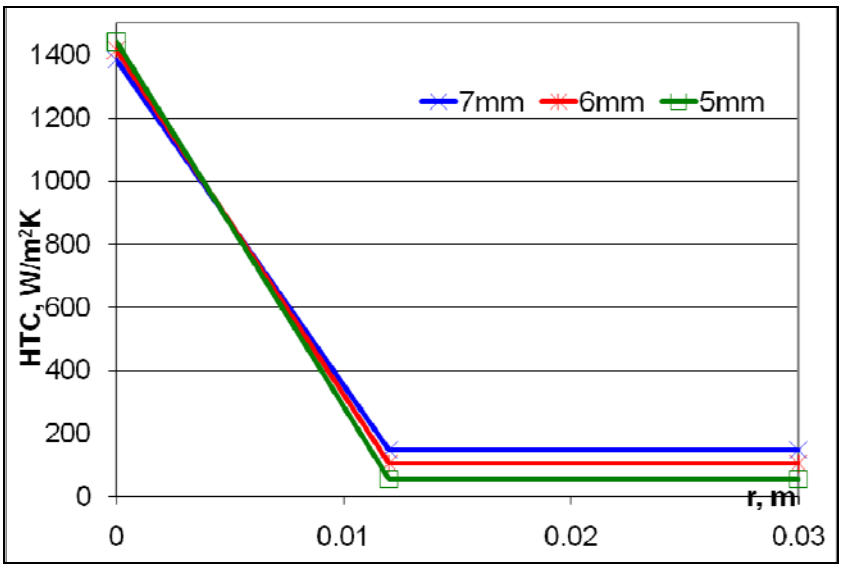

Figure 3. Retrieved HTC for different nozzle diameters.

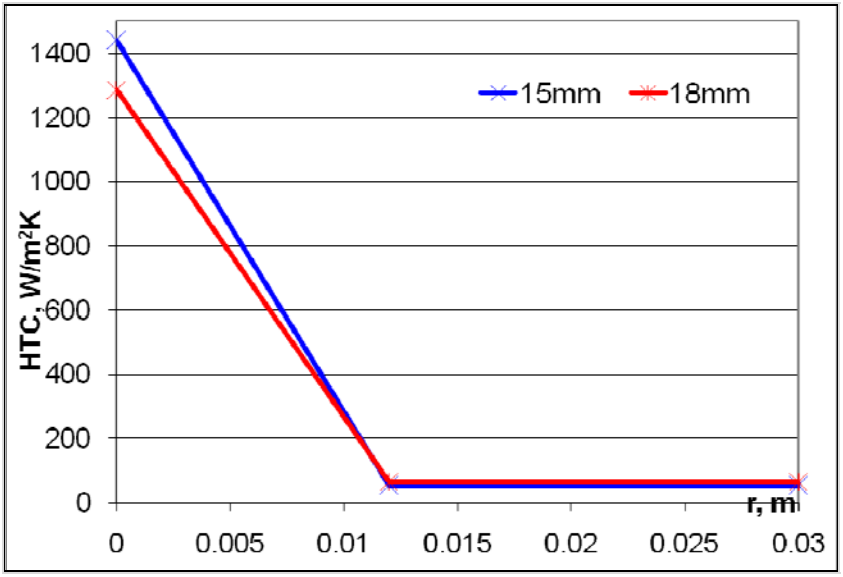

Figure 4. The influence of the nozzle-to-sample distance on the HTC for 5mm nozzle.

To verify the accuracy of the inverse procedure obtained values of the HTC were used as an input boundary condition in a direct heat conduction case called *check run*. The temperatures obtained from solution of this direct case were compared, with the measured temperatures $\hat{T}$. The quality of solution was then judged by mean temperature difference (14) calculated for all points at all time instances. The comparison is presented in Table 1.

$$\Delta = \frac{\sqrt{\sum_{i=1}^{I} (\hat{T} - T_{DIR})^2}}{I} \tag{14}$$

Additionally the measured temperatures at several locations, distributed at different distances from the impingement point were compared with those obtained from *check run* (Figure 5).

Table 1
Mean temperature difference between experiment and inverse analysis

nozzle (mm)	nozzle-to-surface distance (mm)	
	15	18
5	0.24	0.34
6	0.34	0.25
7	0.37	0.42

For all measurement series, the mean temperature difference is small. It means that the temperature field obtained from the *check run* is very similar to the one from measurement. It leads to conclusion that the retrieved convective boundary condition is also in good accordance with the actual one. The temperature time history for two points is presented in Figure 5. One of those points

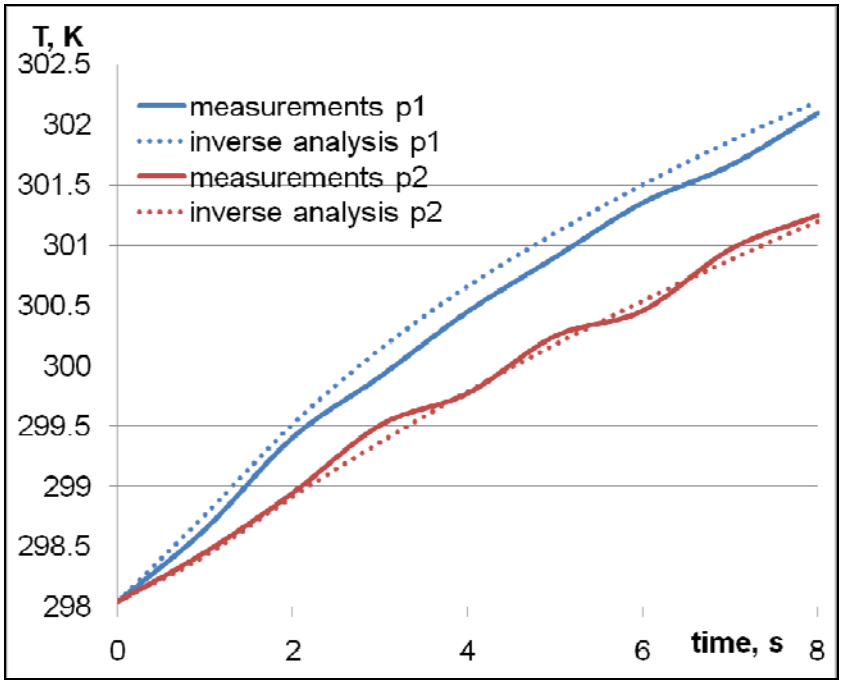

Figure 5. Comparison between measured and temperatures from model for 5mm jet.

lays in the impingement point, while second one 10mm from it. Both solid lines (measurements) show some minor oscillations that are most probably caused by radiation reflected from the measured surface. For both points there is a good agreement between measured and calculated temperature.

CONCLUSIONS

The results show that the proposed method is suitable for retrieving the spatial distribution of the HTC for the impingement phenomenon. The applied linear and constant trial functions are able to reproduce general shape and magnitude of HTC with good accuracy. Low temperature differences obtained from the comparison procedure proved correctness of main assumption of the method i.e. constancy of the HTC in time. The results proved that the inverse procedure is stable if only some precautions are taken. The main point here is to limit the number of the estimated degrees of

freedom to the necessary minimum. The by-products of the analysis are the smoothed sensitivity coefficients which are very helpful at the stage of planning the experiments. Values of those coefficients show the best places where the temperature sensors should be placed. The inverse problems are ill-posed what means the errors in input data are amplified during the solution procedure what often leads to instability of the solution. Simple trial functions used in the developed method filter out the high frequency errors and decrease influence of ill-conditioning on the solution.

EXPERIMENTAL VALIDATION OF THE NUMERICAL MODEL OF THE HEAT TRANSFER COEFFICIENT CALCULATION FOR A CROSS FLOW HEAT EXCHANGERS

T. Bury*, J. Składzień, A. Sachajdak
Silesian University of Technology, Gliwice, Poland

ABSTRACT. The paper deals with the thermal analysis of a ribbed cross-flow heat exchanger of a gas-liquid type with non-uniform flow of the agents. The form and scope of the air inflow to the exchanger have been investigated on a special measuring rig. The results became the basis for elaboration of a computer code for thermal-hydraulic analyses of such type heat exchangers. The initial validation of this code has shown some differences between experimental and numerical results. The heat transfer coefficient at the gas side has been indicated as a possible reason of the recorded discrepancies. An enlarged model of the recurrent element of the heat exchanger under consideration has been built and mounted on an additional test station in order to check the numerical procedure responsible for determination of this parameter. A comparison of the experimental and numerical results shows satisfactory compliance. The numerical results are a little bit underestimated, but the relative differences of compared parameters are rather small. According to the results of analyses one may conclude that the CFD based numerical model accurately portrays the real phenomena.

Keywords: *cross-flow heat exchangers, heat transfer coefficient, numerical simulations, CFD, infra-red thermography*

INTRODUCTION

Among the currently applied heat exchangers with extended surface of the heat transfer the most important meaning have the plate exchangers (with the mixed current) and the ribbed cross-flow heat exchangers, which core has the form of a bunch of pipes with flat plate ribs. Small size, low weight and a high efficiency determine the strong position of such devices. A compact ribbed heat exchangers are commonly used in thermal technique, refrigeration, air-conditioning and automotive industry.

The paper presents a part of the research project related to thermal analysis of a ribbed cross-flow heat exchanger of a gas-liquid type with non-uniform flow of the agents. One of the most important parameters describing such heat exchangers is the heat transfer coefficient at the gas side. A variety of constructions being applied causes significant problems with determination of this coefficient. The problem is additionally complicated by a non-uniform flow of a gas. The last issue has been investigated in detail on a special test station in the Institute of Thermal Technology of the Silesian University of Technology [1]. The scope and form of this inequality have been measured on the test station shown in Fig. 1. The main element of the measuring system is a thermoanemometric sensor installed onto a measuring probe which shifting is controlled by a computer. It allows to determine velocity and temperature fields of the air at the exchanger inlet and outlet. The measurements

E-mail address: Tomasz.Bury@polsl.pl

results have then became the basis for elaboration of the numerical model of the considered exchanger.

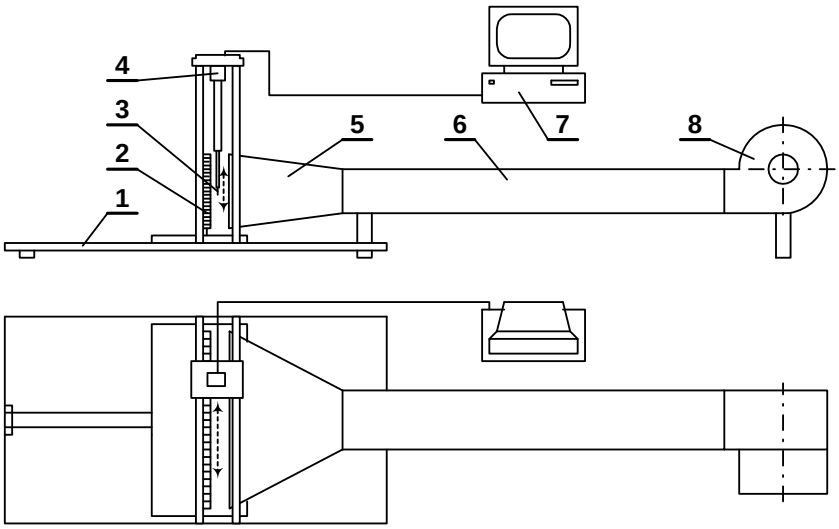

Figure 1. Test station - the air supply module (1 – support plate, 2 – heat exchanger, 3 – thermoanemometric sensor, 4 – measuring probe, 5 – diffuser, 6 – channel, 7 – control computer, 8 – fan)

The measurement within framework of [1] were performed without presence of a hot medium and the initial arrangement of the test station did not allow for validation of the computer code. It became possible after modernization of the experimental rig and installation of the hot water supply module – see Fig. 2. The validation procedure was performed by means of comparison of the experimental and numerical results. The total heat flux transported in the heat exchanger is the main compared parameter and it is the basis for evaluation of the code. A significant differences have been recorded between experimental and numerical data after the initial validation of the model [2]. A minor changes have been put into the code and the validation procedure was then repeated with usage of the infra-red thermography measurements results also [3]. The last stage of the research was the sensitivity analysis [4]. This analysis has shown that the heat transfer coefficient from ribbed surfaces to a gas may be a reason for recorded discrepancies between numerical and experimental results.

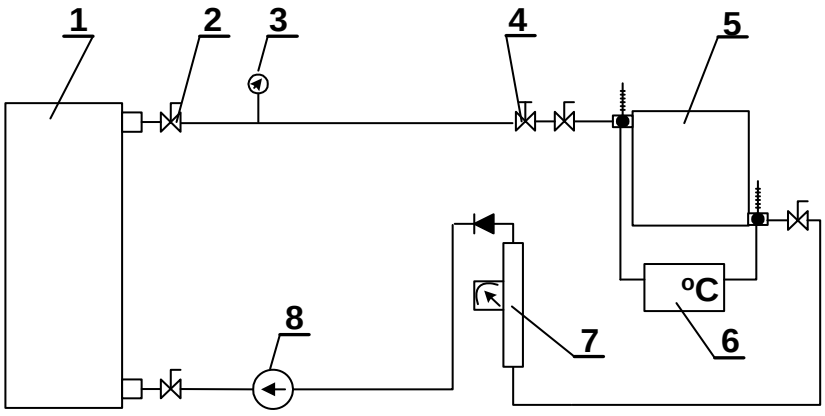

Figure 2. Test station – the water supply module (1 – electric heater, 2 – cut-out valve, 3 – manometer, 4 – control valve, 5 – heat exchanger, 6 – water temperature measuring system, 7 – flow meter, 8 – pump)

An enlarged special model of a fragment of the considered exchanger has been built in order to check the numerical procedure responsible for determination of the heat transfer coefficient from the ribs to the gas [5]. The verification of this procedure is the main aim of the investigations. The numerical model of the system under consideration is a part of the mentioned laboratory stand and contains the flow channel with the ribs. All the performed simulations have been realized using the measured air flux and the electric heaters surfaces temperature as the boundary conditions.

EXPERIMENTAL ANALYSIS

Test rig for investigations of the heat transfer conditions on a plate rib surface

The model consists of four plate ribs with respective pipe sections. Two electric heaters simulate the hot water flow inside the pipes. This model is placed in a flow channel with an observation window and it is cooled by the forced air flow (see Figure 2). The air flux and temperatures at the inlet and outlet are measured by thermocouples. The infra-red thermography technique is used for measurement of the temperature field on the surface of the first rib. Several thermocouples are also installed for measuring the temperature on the other ribs surfaces.
Two parameters have been set as independent during experiments: the temperature of the pipe internal wall and the air flow rate. Following parameters have been recorded during measurements:

- the air volumetric flow rate,
- the air temperature at the inlet and outlet of the ribs section,
- the electric heater surface temperature (assumed after as the pipe inner surface temperature)
- temperatures on the ribs surface in the measuring points,
- temperature distribution on the surface of the first rib.

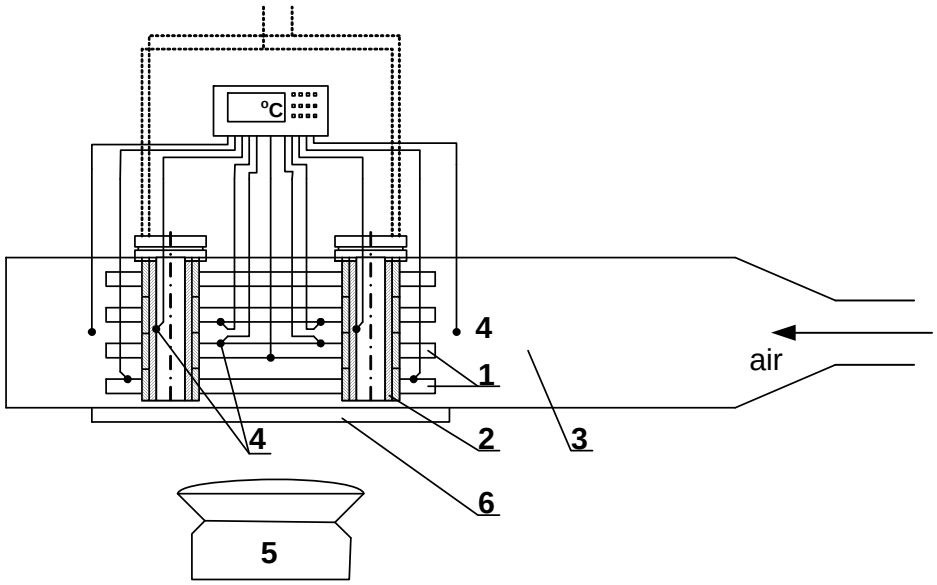

Figure 2. Simplified sketch of the test station (1 - ribs and pipe models, 2 - electric heaters, 3 - flow channel, 4 - thermocouples, 5 - infra-red camera, 6 - speculum)

Experimental results

Twenty five experiments have been realized in total (signed MS-1 to MS-25 respectively) during basic measurements. These experiment have been divided onto five measuring series differing with the set temperature of the electric heaters (from 50 to 90 degrees Celsius with ten degree step). Table 1 presents experimental results for two selected series. These results concerning two given

temperatures of the electric heaters surfaces (50ºC and 90ºC). This temperature are measured independently for each heat and is signed as t_{g1} and t_{g2} in Table 1. The air volumetric flow rate V_{air} has changed from 25m^3/h up to 45 m^3/h. The electric power N_g consumed by the heaters and the inlet and outlet air temperatures ($t_{air,in}$ and $t_{air,out}$ respectively) are also presented in Table 1.

Table 1
Selected experimental results

Experiment No.	V_{air} m^3/h	t_{g1} ^{o}C	t_{g2} ^{o}C	N_g W	$t_{air,in}$ ^{o}C	$t_{air,out}$ ^{o}C
MS-1	25.3	49.5	50.2	116.5	24.0	37.5
MS-2	30.1	49.2	50.6	122.6	24.0	35.9
MS-3	35.0	49.6	50.4	128.0	24.4	34.8
MS-4	40.3	49.1	50.5	132.4	24.5	33.4
MS-5	44.9	49.7	50.4	137.1	22.9	31.1
MS-21	25.3	93,7	90.4	192.0	23.9	44.8
MS-22	30.1	89.5	90.6	196.5	24.0	42.9
MS-23	34.9	90.8	90.5	200.5	24.0	40.7
MS-24	40.2	89.3	89.6	207.0	24.0	39.2
MS-25	45.1	89.7	90.6	215.8	24.5	38.3

The infra-red thermographic temperature distributions on the first rib surface are the main experimental results. Such a distribution for one of the measuring series is presented in Fig. 3.

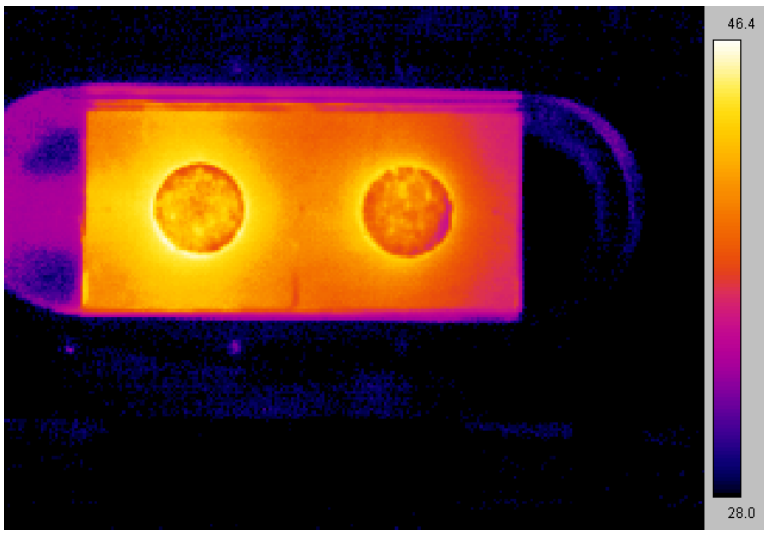

Figure 3. Sample infrared thermographic picture of the first rib surface – experiment MS-1

NUMERICAL SIMULATIONS

The geometry of the model has been created using Gambit preprocessor and it is shown in Figure 4 as well as the boundary conditions types. The numerical grid counts over 550 thousands of tetrahedral cells. Turbulence models tests have shown that the standard k-ε model gives the best results. All the performed simulations have been realized using the measured air flow rates and the

electric heaters surfaces temperature as the boundary conditions. A steady state conditions were assumed during computations.

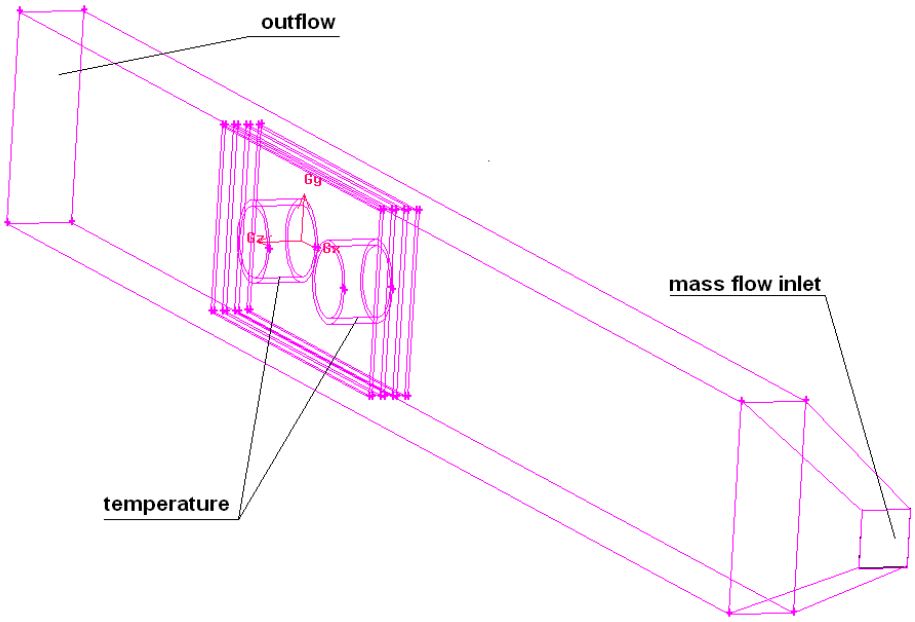

Figure 4. Geometry of the numerical model of the test rig and boundary conditions types

The CFD analysis gives the possibility to view fields of the most important parameters in different cross sections of the object under consideration. The air velocity distribution is shown in Fig. 5. The cross section plane is parallel to the flow direction and it crosses the second rib. One may note that the air inflow to the ribs section is quite well unified.

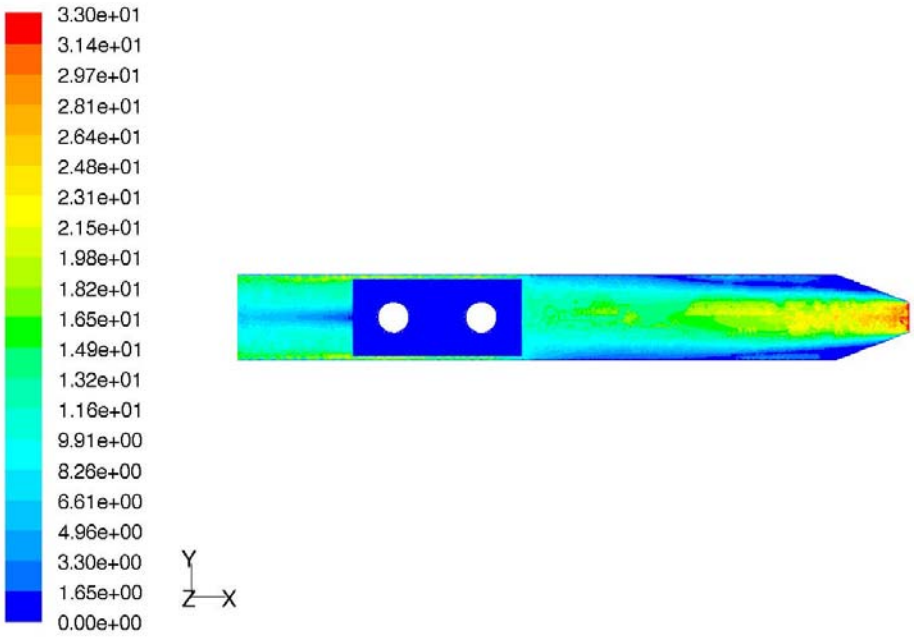

Figure 5. Distribution of the air velocity in the flow channel, m/s – calculations for experiment MS-1

The most interesting numerical results are the temperature distributions on the first rib surface, as well as the experimental results. These distributions may be next compared with the infra-red

thermography measurements. The sample first rib surface temperature field for experiment MS-1 is presented in Fig. 6.

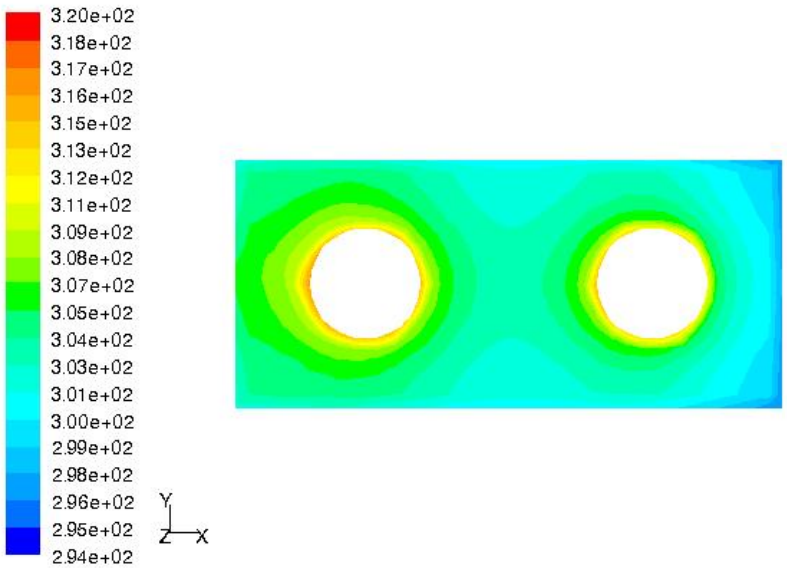

Figure 6. Temperature field on the first rib surface, K – calculations for experiment MS-1

COMPARATIVE ANALYSIS

The main goal of the analysis is to evaluate the numerical CFD model used for computations of the heat transfer coefficient at the gas side of the considered heat exchanger. A simple comparison of measured and computed temperatures for two analysed experiments is presented in Table 2. The subscripts at the temperature given in Table 2 mean the numbers of the thermocouples. The first three thermocouples are placed on the first rib visible surface and are also used for calibration of the infra-red camera. The calculated surface temperature values are a little bit underestimated, as well as the air outlet temperature. The last parameter is computed as the area weighted average value for the cross section placed 2 cm next to the ribs section.

Table 2
Sample comparison of experimental and numerical data for the rib temperature

		t_1, °C	t_2, °C	t_3, °C	t_4, °C	t_5, °C	t_6, °C	t_7, °C	$t_{air,out}$, °C
MS-4	Measurement	40,4	41,5	34,5	43,9	39,8	40,6	33,9	33,4
	Simulation	40,1	40,9	33,8	43,5	39,4	39,9	33,3	32,9
MS-22	Measurement	56,2	57,7	48,0	61,1	55,4	56,5	47,2	42,9
	Simulation	55,5	56,2	47,1	60,5	54,6	55,1	46,3	41,3

The most interesting is comparison of the temperature field for the first rib surface (see Figures 7 and 8). Due to a different colour scales a direct comparison is somewhat difficult.

The next step in the analysis was the computation and comparison of the total heat flow rate transported from the ribbed surface to the flowing air. The results for measuring series MS-1 to MS-5 are presented in Table 3. The total heat flux has been calculated twice based on the air enthalpy raise:

- considering the measured values of the volumetric air flow and its temperature measured at the inlet and outlet of the ribs section (Q_{air} in Table 3),
- taking into account the computed values of the mentioned parameters (Q_{Fluent} in Table 3).

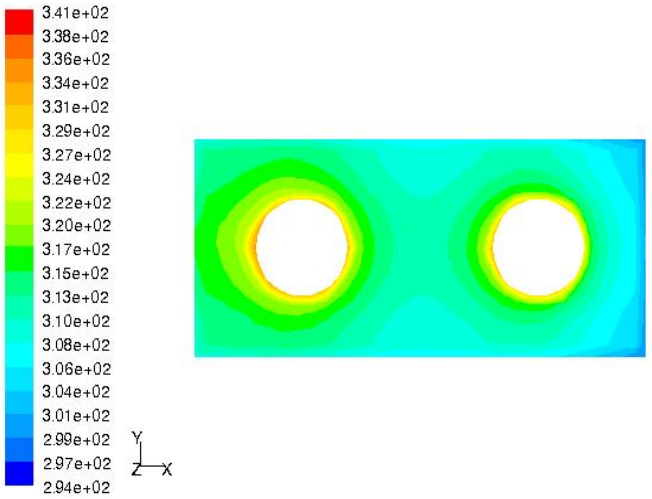

Figure 7. Calculated temperature field of the first rib surface for experiment MS-4

Table 3
Comparison of experimental and computational data – heat flow rates

Measurement No.	**N_g W**	**Q_{air} W**	**Q_{Fluent} W**	**δ_{Qair} %**	**$\delta_{QFluent}$ %**
MS-1	116.5	111.8	104.5	4.03%	10.30%
MS-2	122.6	117.2	109.9	4.40%	10.36%
MS-3	128.0	119.0	111.7	7.03%	12.73%
MS-4	132.4	117.2	109.9	11.48%	16.99%
MS-5	137.1	120.9	113.6	11.82%	17.14%
MS-21	192.0	173.1	165.8	9.84%	13.65%
MS-22	196.5	186.2	178.9	5.24%	8.96%
MS-23	200.5	190.7	183.4	4.89%	8.53%
MS-24	207.0	200.0	192.7	3.38%	6.91%
MS-25	215.8	203.3	196.0	5.79%	9.18%

The relative differences (δ_Q) between experimental and numerical results have been calculated. The heat flow rates calculated based on the measured values, as it can be seen, is lower than the measured values of the electric power of the heaters. The obvious reason of this situation are the heat losses through the rear wall of the flow channel. The differences between experimental and computational heat flow rates calculated as the CFD results reach up to 18% for some cases, but the average difference is somewhat over 10%.

CONCLUSIONS

The main aim of the performed research has been to investigate if the numerical model of the recurrent fragment of the exchanger under consideration may be a useful and reliable tool for determination of the heat transfer coefficient at the gas side. The simple comparison of the experimental and numerical data shows satisfactory compliance of results. The numerical results are mostly a little bit underestimated, but the relative differences of compared parameters do not exceed 18%.

According to the results of analyses it may be noted that the CFD based numerical model portrays the physical phenomena with satisfying accuracy. A probable reason of the recorded discrepancies are some simplifications in the numerical model geometry and neglecting of the radiative heat transport.

MECHANISMS OF BUBBLE FRAGMENTATION IN FLASHING FLOWS

O. Ivashniov, M. Ivashneva*
MV Lomonosov State University, Moscow, Russia

ABSTRACT. The model of boiling flow considering bubbles break-up possibility was used to simulate the depressurization of a high-pressure vessel. The results of numerical experiment were in good agreement with that of a physical one and reveal the role of bubble fragmentation in the flow dynamics. The break-up induced by a centrifugal acceleration of the interfacial surface under a rapid bubble growth is the reason of the pressure rise and its maintenance at the level intermediate between the pressure of saturation and atmospheric one at the wave stage of efflux. The bubble fragmentation induced by the difference in phase velocities is 'responsible' for an explosive evaporation in moving front at the main stage of efflux.

Keywords: *flashing, fragmentation, bubble, boiling, intensification*

INTRODUCTION

In a normally working nuclear reactor the hot water is under high pressure. If there is damage water starts to flow out at a high speed. Owing to the drop of pressure this efflux is accompanied by boiling. To create a safety system a model for boiling liquid flow is necessary that comply with experimental data. The full-scale experiments are expensive and the models having a minimal number of non-physical coefficients are of special interest in the sight of physical experiments substitution by numerical ones. The opening of a high-pressure tube may considered to be a simplest model of reactor damage. This process simulation by the models of boiling flow based on the equations of conservation is given in [1]. The model considering the boiling to be equilibrium has no non-physical coefficients at all and the boiling centers number is chosen in the model permitting the liquid temperature to differ from that of vapor. According to the experiment (Figure 1), on the vessel opening, the pressure keeps a certain level which is lower than the pressure of saturation and falls down in the wave moving towards the closed tube side. The equilibrium model does not model the intermediate level keeping (it predicts the pressure fall up to the pressure of saturation) and the non-equilibrium model does not simulate boiling fronts predicting monotonous pressure diminution. The application of the last model for nozzle flows simulation [2] shows that the number of boiling centers must be chosen three orders of magnitude greater than that which gives the best correspondence for depressurization simulation. This difference and the fact that the numbers of centers are too great to be of physical reasoning: 10^6-10^9per liquid kilogram, gives the idea that the number is not a constant but a function determined by the bubble fragmentation. The results of the numerical modeling of high-pressure vessel depressurization using the boiling flow model which considers bubble fragmentation are presented in the paper.

BUBBLE FRAGMENTATION INDUCED BY THE DIFFERENCE IN PHASE VELOCITIES

For simulation there were used experimental results of Edwards & O'Brien [3]. A 4m-length tube with 7.5 cm internal diameter was initially occupied by hot water with temperature T_0=515 K. The pressure in the tube, P_0=7 MPa, was twice the pressure of saturation and water did not boil. The

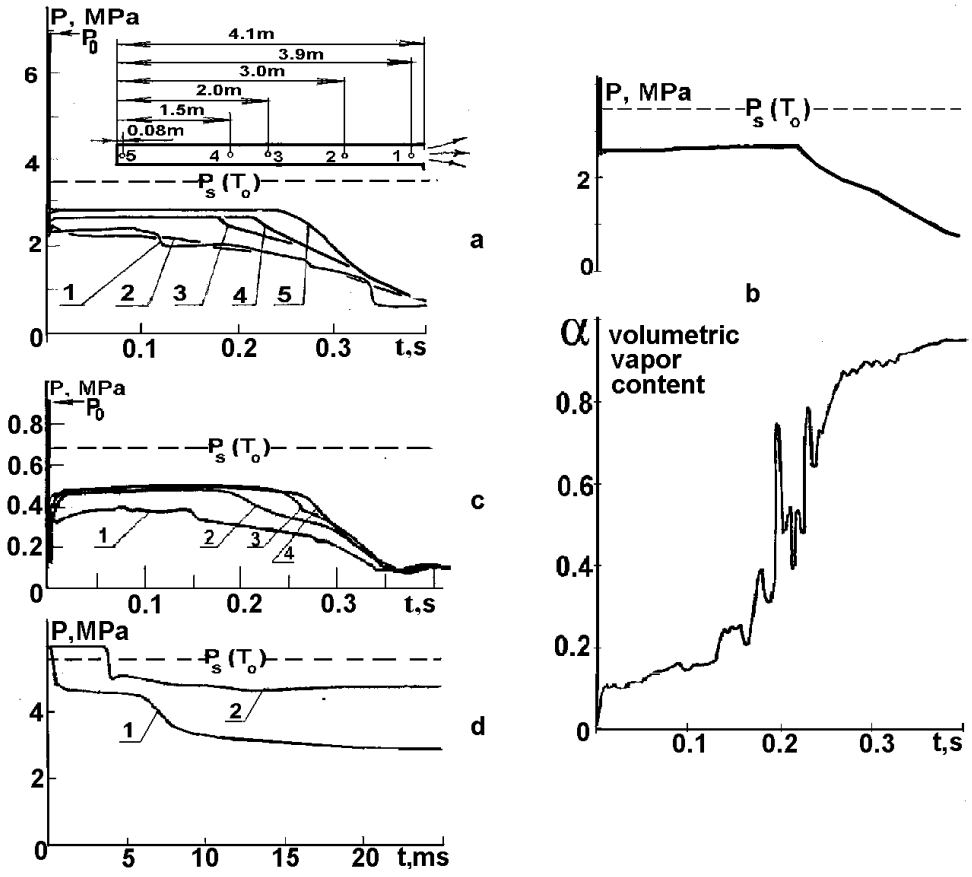

Figure 1. The experiments on high-pressure vessel depressurization. The experiment of Edwards & O'Brien (1970): (a) pressure oscillograms at five tube cross-section locations shown in the insert, (b) versus time curves for the pressure P and volumetric vapour content α in the 4th cross-section. The results of one from the experiments of Winters & Merte (1979) on the depressurization of the tube occupied with dichlorodifluoromethane (c). Pressure oscillograms at cross-sections located 6.3, 0.428, 0.792 and 1.156 m distant from the opened side (the curves 1-4). The experiments of Isaev (1980) on boiling CO_2 efflux (d). Pressure oscillograms at the tube cross-section 12 and 32 cm distant from an opened side (the curves 1 and 2).

right-hand end of the tube was closed with a glass disc. On destroying the disc the liquid efflux started. The pressure oscillograms measured at five tube cross-sections are shown by solid lines in the Figure 1(a). At the 4th point the volumetric vapour fraction was additionally measured (Figure 1(b)). It is seen than a uniform pressure 2.7 MPa which was less than the pressure of saturation was settled at points 3, 4, 5 practically at once after the vessel opening (i.e. in a short time of 3 ms necessary for the wave moving with a speed of sound in a pure liquid to travel the length of the channel). The pressure remained constant for a long time: only after 0.2 s did it start to decrease rapidly at the 3-rd point, and then at the 4-th and 5-th one. The front of pressure reduction was moving with the speed of only 12 m/s (Figure 1(a)). Decompression was accompanied by a large increase in the volumetric vapour content (Figure 1(b)).

We supposed that an explosive evaporation may be caused by the bubble fragmentation which being multiple resulted in a quick and effective increase in the interfacial surface. The model considering bubble fragmentation due to Kelvin-Helmholtz instability was constructed. It is the model of boiling flow of Nigmatulin and Soplenkovu [4] with the only exception that it 'allows' the change

in the bubble concentration. The model consists of the laws for conservation for the mixture mass, momentum and energy, vapor mass and the equation for the bubble number balance.

$$\frac{\partial \rho}{\partial t}+\frac{\partial(\rho u)}{\partial x}=0 \qquad \frac{\partial(\rho u)}{\partial t}+\frac{\partial\left(\rho u^2+P\right)}{\partial x}=-\xi\frac{\rho|u|u}{2D} \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho\left(i-\frac{P}{\rho}+\frac{u^2}{2}\right)\right)+\frac{\partial}{\partial x}\left(\rho u\left(i+\frac{u^2}{2}\right)\right)=0 \tag{2}$$

$$\frac{\partial\left(\rho_g\alpha\right)}{\partial t}+\frac{\partial\left(\rho_g\alpha u\right)}{\partial x}=jn \tag{3}$$

The intensity of the liquid evaporation into a bubble j is determined from the automodel solution of the problem about a heat growth of a vapor bubble in approximated form [7].

$$j=2\pi D_l a\rho_l \,\mathrm{Ja}\,\mathrm{Nu} \qquad \mathrm{Nu}=2+\left(\frac{6\,\mathrm{Ja}}{\pi}\right)^{2/3}+\frac{12\,\mathrm{Ja}}{\pi} \qquad \mathrm{Ja}=\frac{c_l\rho_l\left(T_l-T_s\right)}{\rho_g h} \tag{4}$$

where Ja is the Jakob number, $T_s(P)$ and T_l are the liquid temperatures on the bubble surface and in the distance from the bubble. Besides (4), the set of equations (1-3) is closed by the equations of state for liquid and vapor phases and by the caloric equation for the liquid.

There introduced the equation for bubble number balance. Phase by-passing is determined from the balance equation for the forces acting the bubble (the inertia of a bubble itself is neglected).

$$\frac{dc}{dt}=\psi \qquad f_A+f_m+f_\mu=0 \tag{5}$$

$$f_A=\rho_l\frac{4}{3}\pi a^3\frac{du}{dt} \qquad f_\mu=-\rho_l\frac{c_\mu}{2}\pi a^3\left|u_g-u\right|\left(u_g-u\right) \tag{6}$$

$$f_m=-\rho_l\frac{2}{3}\pi a^3\left(\frac{d_g u_g}{dt}-\frac{du}{dt}\right)-\frac{\rho_l}{2}\left(u_g-u\right)\frac{d_g}{dt}\left(\frac{4}{3}\pi a^3\right) \tag{7}$$

$$\mathrm{Re}\le 10.9: \quad c_\mu=\frac{16}{\mathrm{Re}}$$

$$10.9<\mathrm{Re}\le 1000: \quad c_\mu=\frac{48}{\mathrm{Re}}\left(1-\frac{2.2}{\sqrt{\mathrm{Re}}}\right) \quad \mathrm{Re}=2a\rho_l\frac{\left|u_g-u\right|}{\mu}$$

$$\mathrm{Re}>1000: \quad c_\mu=4.466\cdot 10^{-2}$$

The intensity of the bubble fragmentation is defined by a relax ratio.

$$\psi=\frac{c^*-c}{\tau^*} \tag{8}$$

c^* is the number of bubbles which would appear in the case of instantaneous break-up, τ^* is the character time of fragmentation. The parameters c^* and τ^* are determined from the solution of the problem about the growth of small indignations of a plane interfacial surface flowing round by the liquid. A dispersion analysis gives the law of the versus time dependence of the amplitude of a sine-shaped perturbation of the length λ:

$$\xi=K\exp\left[h\cdot t-\mathrm{i}\frac{2\pi}{\lambda}x\right] \qquad h(\lambda)=\pm\sqrt{\frac{4\pi^2}{\lambda^2}\frac{\rho_g\left(u_g-u_l\right)}{\rho_l}-\frac{8\pi^3}{\lambda^3}\frac{\sigma}{\rho_l}}$$

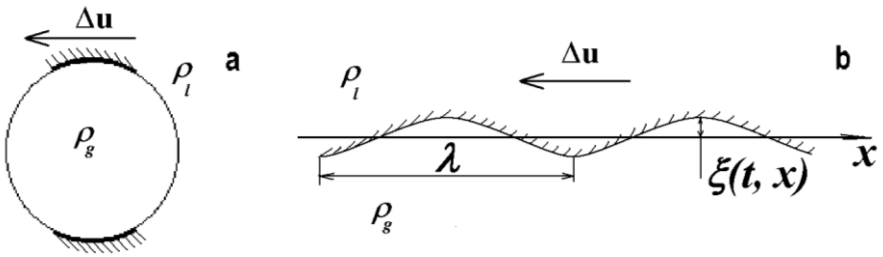

Figure 2. The schemes for the bubble break-up (a) and for the indignation development (b).

Considering a bubble to fragment by the wave with the fastest growing amplitude λ^* which cannot exceed the bubble diameter, $\lambda^* \le 2a$ [7], we obtain the criterion for the stability of the bubble overflowing by the liquid and the estimation for its critical value We^*.

$$\lambda^* = \frac{3\pi\sigma}{\rho_g\left(u_g - u_l\right)^2} \qquad We = \frac{2a\rho_g\left(u_g - u_l\right)^2}{\sigma} \qquad We^* = 3\pi$$

The number of bubble fragments, c^*/c, is estimated as the ratio of the bubble diameter to the length of the wave with the fastest growing amplitude The characteristic time of a bubble fragmentation is estimated as the time of e-fold growth of a harmonic perturbation of the length λ^*.

$$\frac{c^*}{c} = \frac{2a}{\lambda^*} = \frac{We}{We^*} \qquad \tau^* \approx \frac{1}{h\left(\lambda^*\right)} = \sqrt{\frac{\rho_l a^3}{\sigma}\left(\frac{We}{We^*}\right)^3}$$

The model has two free parameters: the initial number of boiling centers and the critical meaning of Weber number. The best correspondence to the experiment is achieved with their meanings: c_0=0.4 10^6kg^{-1}and We^*=1. The calculative parameters distribution within 0.1, 0.2 and 0.3 seconds since the vessel opening are shown in the Figure 3. The explosive evaporation in boiling fronts is repeated in a numerical experiment on high- pressure vessel depressurization.

The flow consists of three zones. The first one is between a closed tube side and the wave front. The concentration of bubbles and the liquid overheats are homogeneous over this zone (Figure 3, c,d) and the intensity of the mixture expansion due to boiling is homogeneous as well. Along the zone, the velocity is increasing according to a linear low from 0 to 10 m/s (Figure 3,f). The acceleration is about 100 m/s^2. The pressure gradient corresponding to such acceleration is approximately 0.1 MPa and is not noticeable versus the pressure level, 3 MPa. In the second zone, the parameters changes sharply. The number of bubbles is increasing by 6 orders of magnitude (Figure 3,c). A sharp increase in the interfacial surface due to multiple bubble fragmentation intensifies the boiling and the vapor content is increasing from 0.2 up to 0.8 (Figure 3,b). The temperatures of liquid and vapor equalize (Figure 3,d). The third zone is a zone of an equilibrium boiling, a centered wave of rarefaction.

Boiling fronts were observed in the experiments under the other initial water parameters [3] and with the other fluids [6, 7] as well (Figure 1,c,d). An explosive boiling in moving fronts is, thus, a specific feature of high-pressure vessel depressurization that is in agreement with its explanation from dynamic flow characteristics seen from the numerical experiment. The difference in phase velocities which is maximal at the channel exit causes a multiple bubble fragmentation following by a sudden increase in the interfacial area and a quick lost of liquid heat energy due to evaporation.

The evaporation results in the increase in the pressure, flow velocity and the conditions for the bubble fragmentation are created upstream. The wave travels transforming the potential energy of overheated liquid into the kinetic energy of flow.

The possibility of bubble fragmentation in speed flows agree with the data of Yamamoto et al., 2007.

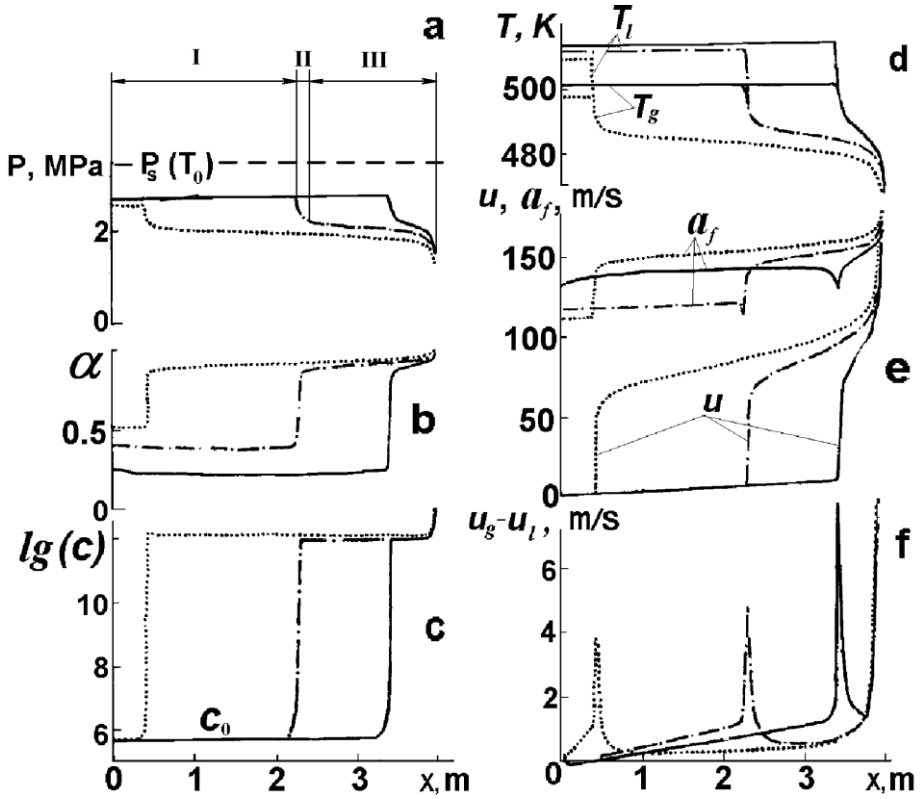

Figure 3. The boiling fronts under high-pressure vessel opening. Versus channel length distributions of the pressure (a), volumetric vapor content (b), the bubble number per mixture unit (c), liquid and vapor temperatures (d), the flow velocity and the frozen speed of sound (e), the difference in phase velocities (f) within 0.1, 0,2 and 0.3 ms since the depressurization (solid, dash and dotted lines, respectively).

Investigating the boiling flow structure at slow and pre-flashing regimes under the same volumetric vapor content [8] he found out that the vapor phase was significantly more dispersed under high-speed flow regimes.

FRAGMENTATION INDUCED BY RADIAL ACCELERATIONS OF BUBBLE SURFACE

In the Figure 1(a,c) the pressure behavior at the wave stage of depressurization looks like an instantaneous drop up to 2.7 MPa. Micro-scale pressure oscillogram fixed in the same experiment of Edvards & O'Brien (Figure 4,left, solid line) shows that it drops lower with a subsequent rising to this level. The bubble number chosen to simulate the pressure level is about a million per liquid kilogram. The liquid with such concentration of centers must not be clear that is not the case and we may suppose that this number is not 'initial'. The bubble number has time to increase within the wave stage of efflux. The reason of the increase is supposed to be the same as the increase in the number of boiling centers at the main stage of efflux, the bubble fragmentation. Within the time interval the pressure rise occurs the bubbles of a zero radius can only grow up to the dimensions of 0.1 mm in diameter. Neither of known schemes for bubble fragmentation (due to Kelvin-Helmholtz instability on the lateral surfaces of the bubble, the destabilization of head and tail surfaces induced by the flow acceleration) 'permits' the fragmentation of such small bubbles.

We have proposed that the development of the instability of the bubble surface may be caused by radial accelerations in the liquid surrounding the bubble (Figure 4,a).When the bubble acceleration is positive, $a > 0$, there is a negative pressure gradient in the surrounding liquid: the pressure decreases with a distance from the bubble center. The situation is qualitatively similar to that when a heavier liquid above a lighter one. They only differ in the forces that induce the pressure gradient.

It is reasonable to characterize the proposed type of instability by the Bond number as well, substituting the gravity for the inertia.

$$Bo = \frac{4a^2 \rho_l \dot{\omega}_a}{\sigma}, \qquad \dot{\omega}_a = \frac{d\omega_a}{dt}, \tag{9}$$

Constructing the fragmentation scheme we will use (as we do for the fragmentation scheme due to Kelvin-Hemholtz instability) the results of the solution of the problem about the growth of small perturbations of a flat interfacial surface under the action of the body force of $\dot{\omega}_a$ density (Birkhoff, 1960). A dispersion analysis gives the law of the versus time dependence of the amplitude of a sine-shaped perturbation of the length λ:

$$\delta = \delta_0 \exp\left[I\, t - \mathrm{i} \frac{2\pi}{\lambda} x \right] \qquad I(\lambda) = \sqrt{\frac{2\pi}{\lambda}\dot{\omega}_a - \frac{8\pi^3}{\lambda^3}\frac{\sigma}{\rho_l}}, \qquad \mathrm{i}^2 = -1$$

From the conditions $dI/d\lambda = 0$ and $d^2 I/d\lambda^2 < 0$, we find the length of the wave with the fastest growing amplitude:

$$\lambda^* = \sqrt{\frac{12\pi^2\sigma}{\rho_l}}$$

Supposing a bubble to break-up by the waves with the length λ^* which cannot exceed the bubble diameter, $\lambda \le 2a$ (Nigmatulin, 1989), we obtain the expression for the Bond number (9), the estimation for its critical value, $Bo^* = 4\pi^2$, the characteristic time of a bubble fragmentation and

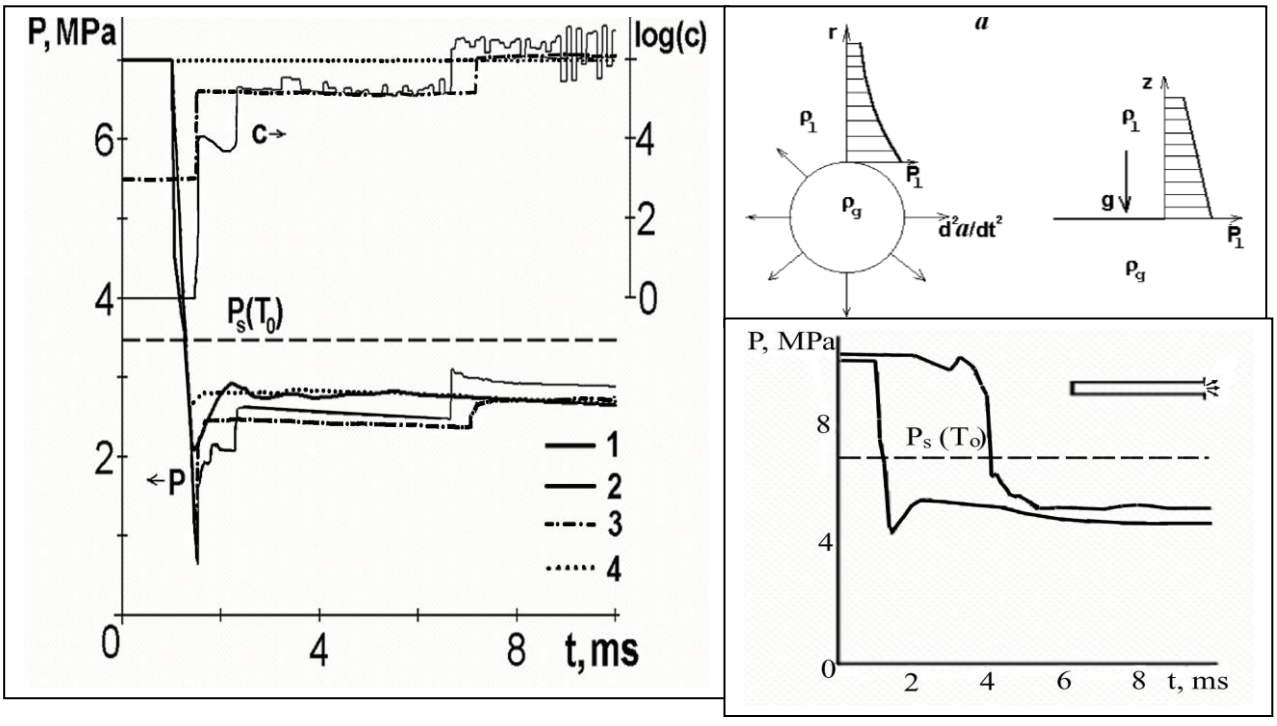

Figure 4 The scheme of the development of the bubble surface instability (a). Left-hand, small-scale pressure and bubble number oscillograms in cross-section 1.1 m from the open vessel end: 1, experiment; 2-4, calculations with the advanced model for different c_0 values: 1, 10^3, 10^6/kg. Right-hand bottom, versus time experimental pressure dependences: the tube of 7.5 cm diameter (left), 10.3 MPa, 559 K (Edwards and O'Brien, 1970); the tube diameter is 1.27 cm (right), 10.3 MPa, 563 K (Lienhard et al, 1978).

the number of bubble fragments.

$$\tau^* = \sqrt{\frac{\rho_l a^3}{\sigma}}\left(\frac{\mathrm{Bo}^*}{\mathrm{Bo}}\right)^{3/4} \qquad \frac{c^*}{c} = \frac{2a}{\lambda^*} \approx \sqrt{\frac{\mathrm{Bo}}{\mathrm{Bo}^*}}. \tag{10}$$

Within the framework of the homobaric model, we will calculate the radial acceleration of the phase interface from the equation for a bubble mass balance $dm_g/dt=j$, rewritten it in the form:

$$a\omega_a + \frac{1}{3}a^2\frac{\dot{P}}{P} = \frac{D_l}{2}\mathrm{Ja}\,\mathrm{Nu} \tag{11}$$

Differentiating (11) with respect to time gives:

$$a\dot{\omega}_a = \frac{D_l}{2}\left[\left(\mathrm{Nu}+\mathrm{Ja}\frac{d\,\mathrm{Nu}}{d\,\mathrm{Ja}}\right)\frac{d\,\mathrm{Ja}}{dt} - \frac{2}{3}\mathrm{Ja}\,\mathrm{Nu}\frac{\dot{P}}{P}\right] - \omega_a^2 - \frac{a^2\ddot{P}}{3P} + \frac{5a^2\dot{P}^2}{9P^2} \tag{12}$$

$$\frac{d\,\mathrm{Ja}}{dt} = -\frac{jn(i_g - i_l)}{\rho_g h(1-\alpha)} - \frac{c_l\rho_l}{\rho_g h}\left(\frac{T_l - T_s}{P} + \frac{dT_s}{dP}\right)\dot{P} \qquad \dot{P} = \frac{dP}{dt}, \quad \ddot{P} = \frac{d^2P}{dt^2}$$

$\dot{P}$, $\ddot{P}$ are substantial time derivatives of the pressure. These derivatives are expressed via time derivatives of specific volume with the equation of the mixture state. The equation below (where a_f is a 'frozen' speed of sound in the mixture) is derived from the equations of mass balance for mixture and vapor and state equations for liquid and vapor.

$$\frac{dP}{dt} = \rho^2 a_f^2\left(-\frac{dV}{dt} + 2\pi D_l a\,\mathrm{Ja}\,\mathrm{Nu}\,c\right) \qquad a_f = \left(\frac{\rho\rho_l(1-\alpha)}{\beta^2} + \frac{\rho\alpha}{P}\right)^{-1/2} \tag{13}$$

After differentiating (13) with respect to time, we obtain

$$\frac{d^2P}{dt^2} = \rho^2 a_f^2\left\{-\frac{d^2V}{dt^2} - \left(jc - \frac{2\chi}{P}\dot{P}\right)\frac{\dot{P}}{\rho_g P} + 2\pi D_l c\left[\omega_a\,\mathrm{Ja}\,\mathrm{Nu} + a\left(\mathrm{Nu}+\mathrm{Ja}\frac{d\,\mathrm{Nu}}{d\,\mathrm{Ja}}\right)\dot{\mathrm{Ja}}\right]\right\} \tag{14}$$

Using balance equations for the mixture mass and momentum (1) we may express the first and second substantial time derivatives of the specific mixture volume, $V = 1/\rho$, in term of the derivatives with respect to coordinate. For the parameter distribution known, time derivatives may, thus, be calculated for each time instant/step.

$$\frac{dV}{dt} = V\frac{\partial u}{\partial x}, \qquad \frac{d^2V}{dt^2} = V\left[\left(\frac{\partial u}{\partial x}\right)^2 - \frac{\partial}{\partial x}\left(V\frac{\partial P}{\partial x}\right)\right]$$

Thus all the parameters for Bond number estimation may be obtained with the equations (11)-(14).

Using the model version considering the possibility of bubble fragmentation caused by radial accelerations the wave stage of depressurization has been studied numerically. The vessel dimensions and the water parameters are taken from the same experiment of Edvards & O'Brien (1970): P_0=7 MPa, T_0=515 K. The no-flow condition is specified at the left-hand end of the channel. At the right-hand side, the pressure attains the atmospheric value within τ =0.256ms, and remains constant afterwards.

Calculated oscillograms for the pressure and bubble number in the cross-sections 3 m spaced from the closed vessel end for different initial concentrations of boiling centers and Bo^*=300 are plotted on the same graph in the Figure 4,left. It is seen that the pressure curves obtained for the meanings of initial centers concentration 1, $10^3$and 10^6 kg^{-1} approaches the same level (corresponding to that obtained in the experiment shown by a thick solid curve) in a few milliseconds. The 'behavior' of the bubble concentration is similar: with no dependence on the initial bubble number tasked the bubble concentration approaches the level 10^6 kg^{-1}.

This numerical experiment explains the contradiction in the mode of boiling centers induction revealed from the analysis of the experimental data. The pressure curves measured for the depressurization of a thin and thick tube (Figure 4,right) coincide in the 'steady' level installed at the wave stage. That means that the intensity of boiling does not depend on the area of the wall surface per liquid volume and may be a ground of the opinion that the bubbled appear in all the volume. However the experiments on the boiling in low-gravity [10] and in the drop isolated from the walls [11] do not show volume-induced bubbles. We may adopt the bubble concentrations tasked in numerical experiment to be the concentration of wall-induced bubbles. We see that the bubbles fragment until their concentration reaches the same level. The reason is that that the waves induced by fragmentation and caused the further fragmentation 'require' certain energy to spread [12]. Liquid energy 'wasted' on evaporation is proportional to the bubble concentration through the interfacial area. Since the limit concentration when the fragmentation is ceases does not depend on the initial one the system 'does not remember' the number of wall-induced bubbles that gives the impression that the bubbles are induced in the volume. The break-up of bubbles explains the boiling-up in the nozzles with a sharp entrance edge [4]. The coefficient of the stream narrowing shows the liquid to be pure and that permits to conclude that the liquid boils up in the absence of walls. A few bubbles appear on the walls does not influence on the liquid pureness and due to break-up their number increase in orders resulting in intensive boiling.

CONCLUSIONS

The model of boiling flow based on the equations of conservation which considers bubbles break-up possibility was used to study the depressurization of a high-pressure vessel. In numerical experiment we obtained the boiling non-equilibriumity with the pressure keeping a certain level at the wave stage and its sudden diminution in a moving front at the main stage of efflux that was in good agreement with the physical experiment. The numerical simulation of the high-pressure vessel depressurization has shown bubbles fragmentation to be an important mechanism of interfacial surface formation specific for flashing flows. A multiple bubble fragmentation induced by the accelerated movement of the surface of rapidly expanded bubble is a reason of the volume-type boiling up after the pressure drop.The bubble break-up induces by the difference in phase velocities is 'responsible' for an explosive evaporation in boiling fronts.

NOMENCLATURE

NUMERICAL FLOW ANALYSIS FOR SETTLING POND DESIGN

D.K. Lee[1,*], Y.J. Kim[1,] and Y.D. Jo[1]
[1]Korea Institute of Geoscience & Mineral Resources (KIGAM), Daejeon, Korea Republic

ABSTRACT. Numerical flow analysis for settling pond design has been conducted to investigate the optimal flow characteristics, including the inflow rate and the shape and depth of a settling pond. Total area and maximum depth of the pond is 500 m^2 and 3 m respectively. We define retention time, retention time ratio, homogeneity index and inflow exchange efficiency for choosing the optimal conditions. As a result of this study, the optimum flow rate and width:length of the pond were found to be under 15 ℓ/sec and 1:5, respectively.

Keywords: *settling pond, inflow age, retention time*

INTRODCUTION

Iron exists in the ferrous form within the country's mine workings. Upon exposure to the surface the ferrous iron oxidizes to become ferric iron, a hydrolysis reaction which causes the precipitation of ferric hydroxide, these particles fall from the solution and join together to form a thick substance that coats the pond. A settling pond stores mine drainage within a given period for leading the precipitation of ferric hydroxide in mine drainage, so that remediation of contaminated effluents can be accomplished. The key to design of a settling pond is to ensure that the retention time of mine drainage in a pond is sufficiently long that iron precipitates will settle out effectively. In past retention time recommendations for such purposes have ranged from as little as 8 hours to more than 72 hours. It has revealed the existence of a relatively robust linear relationship between the percentage reduction in the influent iron concentration and nominal hydraulic retention time (Parker, 2003). In the UK Coal industry, basic water treatment design guidance for engineers was provided by NCB (1982). Total pond volume and flow rate are often designed on the basis of 48 hours retention time (Laine and Jarvis, 2003) and 100 m^2 of pond surface area for every liter/sec of drainage. The length to width ratio should be within the range 2:1 to 5:1 (NCB, 1982). The depth of the pond is usually set at around 3 m to to prevent re-suspension of settled particles due to wind (PIRAMID Consortium, 2003). The theoretical maximum concentration of ferrous iron that can be oxidized in a single aeration cascade is 50 mg/l. But practical experience suggests that 30 mg/l ferrous iron is a more realistic figure (NCB, 1982). For discharges with in excess of 30 mg/l it will be necessary to have a series of aeration cascades, with settling ponds in between. Until now, the nominal hydraulic retention time calculated simply as the ratio of the volume of mine drainage stored in a pond to the flow rate is used for design of a settling pond. The flow distribution characteristics in a pond varies as shape and depth of a pond and flow rate of mine drainage so that more sophisticated techniques such as application of the physics represented by Navier-Stokes equation are needed.

MUMERICAL METHODS

Concept of inflow age

The concept 'air age' in the field of air conditioning was introduced to estimate the retention time of the inflow mine drainage. The air age means the time that the inflow air as shown in Figure 1 moves down to the point P and the retention time means the time that air flows down to the outlet. Fluid of this study is not air but mine drainage, thus the air age was renamed as 'inflow age' and used.

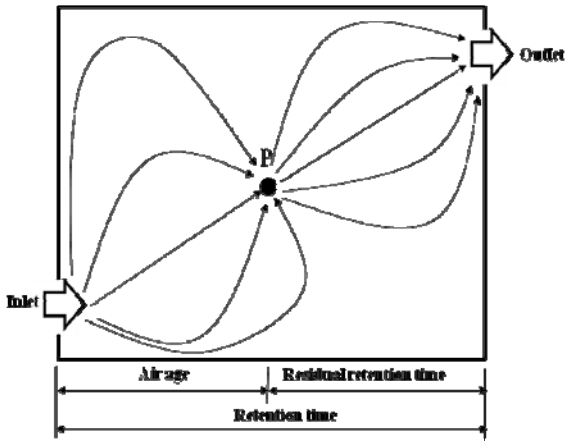

Figure 1. The concept of air age.

Suggestions of the estimating indices for settling pond design

Retention time

Retention time means the time needs that the inflow mine drainage from the entrance reaches to exit and is defined in this study as the areal average inflow age using the result of computational analysis.

Retention time ratio

Retention time ratio is a guideline showing how long does the inflow mine drainage stay in the pond and is defined as the ratio of nominal retention time to the retention time.

Homogeneity Index

Homogeneity index is defined as the value of the average retention time of the route with the minimum staying time from the entrance to the exit divided by the volume average retention time. The homogeneity index closer to 1 indicates that the distribution of the retention time has better homogeneous.

Inflow Exchange Efficiency

Inflow exchange efficiency is defined as the ratio of mean retention time and inflow exchange. Inflow exchange efficiency means the shortest time to take for the pond to be exchanged with the fresh inflow mine drainage and is defined as the ratio of the average retention time to the inflow exchange time.

Cases setting of a settling pond

A schematic of a settling pond is shown in Figure 2. Dimensions of inlet and outlet of the pond are the same as 0.3 m × 0.3 m. Area of the pond is 500 m^2 in all cases. Flow rate at inlet is determined on the basis of 100 m^2 of pond surface area for every liter/sec of mine drainage by NCB(1982). Table 1 gives all cases on flow rate and shape and depth of a settling pond.

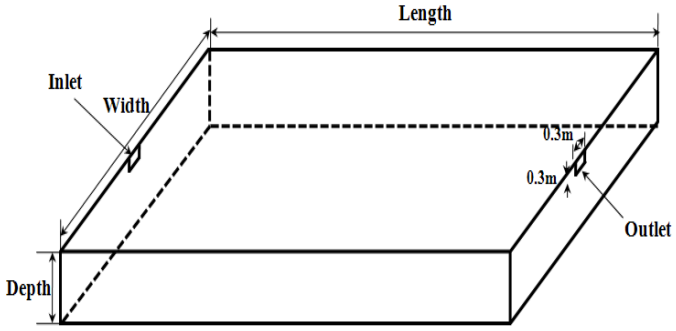

Figure 2. Schematic of a settling pond

Table 1. Cases of settling pond.

Case	Width:length	Flow rate(ℓ/sec)	Length(m)	Width(m)	Depth(m)

Mesh construction

In the case that if both sides on the basis of the symmetric plane have the same shape and flow conditions, the analysis has been made only for half. The meshes were more denser at near inlet and outlet and the grid sizes were increased gradually as closer to the middle of the pond.

Numerical analysis method

Computational analyses were performed for the three governing equations as continuity equation, momentum equation and turbulent dissipation equation to predict the flow distribution, retention time and estimating indices in 3-dimensional settling pond. In this study, the flow rate in the settling pond was very low but the k-ε turbulent model was used in consideration of the sudden change in the velocity at the inflow part.

RESULTS AND DISCUSSION

Flow characteristics by the flow rate at inlet

Figure 3 shows the distributions of the velocity and the inflow age of the mine drainage in the pond according to the inflow rate. As shown in the figure, the velocity in the pond was generally increased by increase in the inflow rate and the distributions of the velocity at the mine drainage

inlet and outlet were symmetry with same trends. On the other hand, stagnant areas with relatively low velocity were formed at the corners of rectangular ponds. In most cases, the smallest inflow age could be seen along the straight line from the inlet to the outlet, while the farther from the straight line the higher age of inflow to be achieved. Especially because the corners of the rectangular ponds are the stagnant areas, the ages of inflow in this area are relatively quite high.

Figure 3. Distributions of velocity and inflow age according to inflow rate in settling ponds.

Case	inflow rate (ℓ/sec)	Velocity distribution	velocity (m/sec)	inflow age distribution	inflow age (hr)
1	1				2	5				
3	10				
4	15				
5	20				

Figure 4(a) represents the relationship between the flow rate and the volumetric average velocity in the pond. The figure indicates that the volumetric average velocity and the flow rate are in proportional. Figure 4(b) shows the retention time verse the different flow rates for cases 1 to 5 with the depth of 3 m. It was found that the flow rate is in inversely proportional to the retention time in the figure. Figure 4(c) shows that the ratio of the retention time at the outlet to the nominal retention time. It was confirmed that the retention time increased as the flow rate increased.

The homogeneity index and the exchange efficiency versus the flow rate are presented in Figure 4(d) and Figure 4(e), respectively. It can be seen in the figure that the homogeneity index and the exchange efficiency nearly kept constant up to the flow rate of 15 ℓ/sec and was decreased from the flow rate of 20 ℓ/sec. It could be considered that the homogeneous index and the inflow exchange efficiency decreases as flow rate increase more than 15 ℓ/sec in the settling pond.

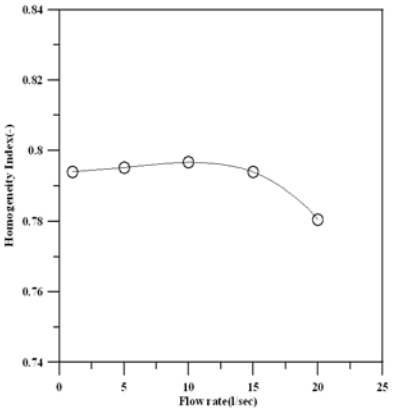
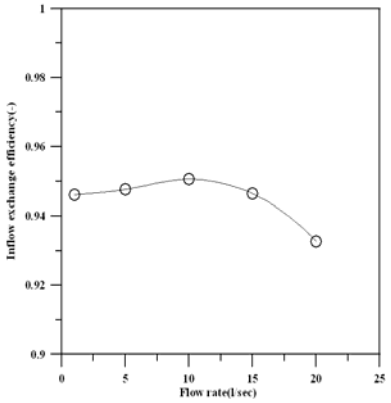
(c) Retention time ration



(d) Homogeneity index



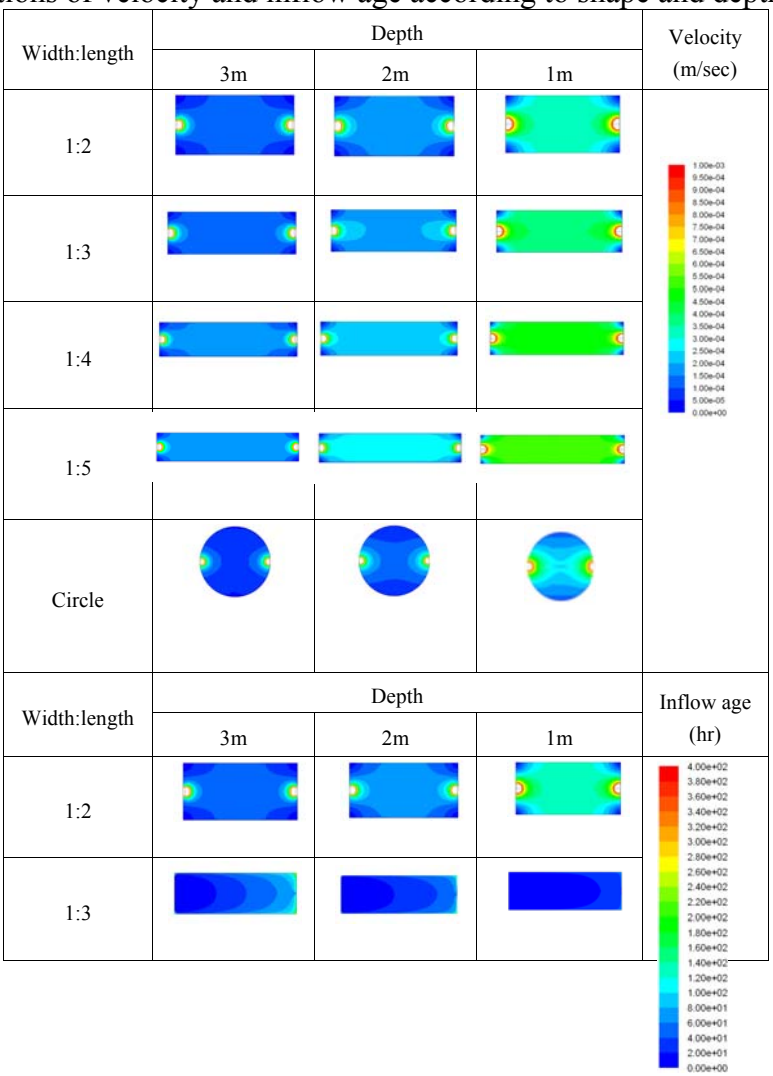
(e) Inflow exchange efficiency

Figure 4. Flow characteristics by inflow rate in a settling pond.

Flow characteristics by the shape of settling ponds

Figure 5 demonstrates the distributions of the velocity and the inflow age in the settling ponds with different shapes when the mine drainage inflows under the same condition with 5 ℓ/sec of flow rate in a settling pond with 500 m^2 of surface area. As the ratio of the length to the width is increased, the area of the stagnant region around the corners decreases and the velocity near the central region increases gradually. In the case that the settling pond has round-shape, the velocity is relatively lower than in the rectangular pond. For the distribution of the inflow age, as the ratio of the length to the width increases, a homogeneous distribution along the direction to outlet was found. However, if the settling pond is round shape, the inflow age is high along the both sides and it was found that the stagnant area is increased.

Figure 5. Distributions of velocity and inflow age according to shape and depth of settling ponds.



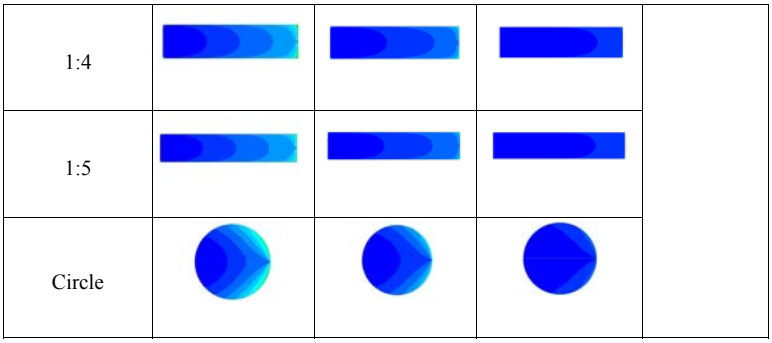


Figure 6(a) shows the relationship between shape of the pond and the volumetric average velocity. By increasing the ratio of length/width and also decreasing the depth as shown in the figure, the volumetric average velocity increased. It should be noted that the depth of the pond gave bigger effect than the ratio of length and width of the pond. However, the volumetric average velocity in the round pond was smaller than in the rectangular pond. Figure 6(b) represents the change of the retention time for the shape of the pond. As shown in the figure 6(b), if the depth of the pond in rectangular shape was constant, the retention time was not changed regardless the length/width ratio of the pond, while the retention time in the round pond was little higher than in the rectangular one. Therefore it was found out that there is no effect of the length/width ratio in the retention time in the rectangular pond. The retention time ratio for the different pond shapes were demonstrated in Figure 6(c). From the figure, it was found that the retention time ratio, except with 1 m of depth, decreased with the following sequence; the round-shaped pond, the rectangular ponds with the width:length of 1:2, 1:3, 1:4 and 1:5. The homogeneity index for the different pond shapes were shown in Figure 6(d). The smallest homogeneity index at the round pond and the increase in the homogeneity index by increase in the length/width ratio of the rectangular pond were found out from the figure. In Figure 6(e), the relationship between the shape of the pond and the inflow exchange efficiency was presented. As seen in the figure, the inflow exchange efficiency was increased as the length/ width ratio of the rectangular pond was increased. For the rectangular pond, the efficiency became to be lowest at the pond with the length/width ratio of 1:2 and became to be highest at the pond with the ratio of 1:5. On the other hand, for round pond the inflow exchange efficiency was lowest at the pond with 1 m of depth.

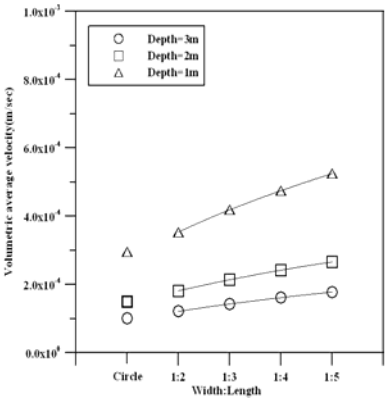
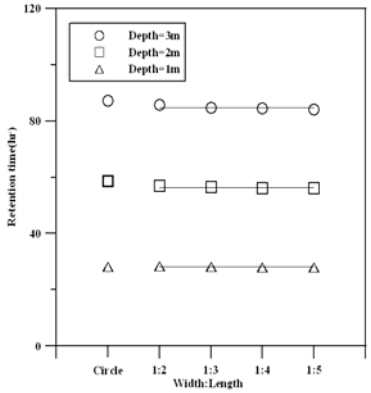
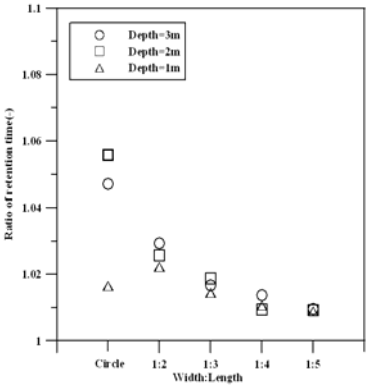


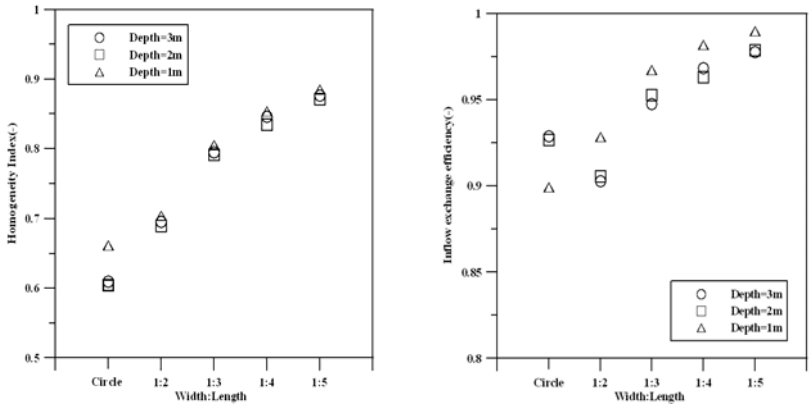
(a) Volumetric average velocity



(b) Retention time



(c) Retention time ratio



(d) Homogeneity index (e) Inflow exchange efficiency

Figure 6. Flow characteristics by shapes of settling ponds.

Flow characteristics by the depth of a settling pond

Figure 5 shows the distributions of the velocity and the age of inflow for the different depths when the mine drainage inflows under the same condition with the flow rate of 5 ℓ/sec in 500 m^2 of the pond area. As shown in the figure, for all of the pond shapes as the depth of the pond increased, the average velocity in the pond was rapidly decreased in the same inflow rate. Especially, when the depth of the pond increased in the rectangular pond, it was found that the range of stagnant region was expanded around the corner parts. The inflow age increased by increasing the depth of the pond as well, and the inflow age gave a high value at the stagnant region. Figure 7(a) represents the relationship of the volumetric average velocity and the depth for the different pond shapes. For the all cases in the figure, the volumetric average velocity decreased as the depth increased. In Figure 7(b), the relationship of the retention time to the depth for different pond shapes was demonstrated. The retention time was linearly proportional to the depth of the settling pond. For the rectangular ponds, similar linear relationships to the retention time regardless the shape of the pond was presented while for the round pond, the retention time was little higher than in the rectangular pond. Figure 7(c) gives the retention time ratio for the depth of different ponds. In the rectangular ponds with the width:length of 1:5, 1:4 and 1:3, the retention time ratio did not changed by the depth, but in the pond with the width:length of 1:2, the retention time ratio was slightly increased by the increase of the depth. However, in the round pond the retention time ratio showed a parabolic trend for the retention time ratio as the depth increased. The homogeneity index for the depth of different shaped ponds was illustrated in Figure 7(d). The homogeneity index has almost same values for all cases in the rectangular ponds, but in the round pond it gives the biggest value when the depth is 1 m and the homogeneity index tends to decrease as the depth increases. Figure 7(e) shows that the relationship of the inflow exchange efficiency to the depth for different pond shapes. The inflow exchange efficiency was decreased by increasing the depth of the rectangular settling pond. It was interesting to have an almost same efficiency value for the ponds with 2 m and 3 m of depths while the inflow exchange efficiency increment was higher for the pond with smaller length/width ratio of the rectangular pond. For the round pond, there was a trend that the inflow exchange efficiency increased as the depth increased.

CONCLUSIONS

1) To estimate the retention time for settling pond design a computational analysis method was proposed using the concept of the inflow age And, the retention time, the stagnant level, the distribution level and the exchange level of the mine drainage in a settling pond were also proposed by defining the concept of retention time, retention time ratio, homogeneity index and inflow exchange efficiency, respectively. Therefore, the basis to find out the optimum conditions needed for designing a settling pond was established.

2) The flow characteristics for the flow rate in the rectangular pond with the area of 500 m^2, the width:length of 1:3 and the depth of 3 m were analyzed. It was confirmed that the maximum proper inflow rate is 15 ℓ/sec by analyzing the estimating indices suggested for settling pond design.

3) The retention time was identical regardless of the shape of the settling pond, and as the length become larger than the width, the stagnant level get lowered, more homogeneous distribution get appeared and therefore it is more appropriate as an settling pond. However, the round pond was revealed to be the worst settling pond.

4) To predict the depth of the pond or the time that the sediments in the pond need to be cleaned, the relation between the retention time and the depth of the rectangular pond was proposed on figure. The effect on the retention time ratio and the homogeneity index was negligible and only the inflow exchange efficiency tended to be decreased by increasing the depth.

ABSTRACT. We describe behaviour of the air-coal mixture using the Navier-Stokes equations for gas and particle phases, accompanied by a turbulence model. The undergoing chemical reactions are described by the Arrhenian kinetics. We also consider the heat transfer via conduction and radiation. Moreover we use improved turbulence-chemistry interactions for reaction terms. The system of PDEs is discretized using the finite volume method (FVM) and an advection upstream splitting method as the Riemann solver. The resulting ODEs are solved using the 4th-order Runge-Kutta method. Sample simulation results for typical power production levels are presented.

Keywords: *Turbulence, heat transfer, combustion, NO_x*

INTRODUCTION

Our main motivation of the combustion model research is its use for design of the combustion chamber geometry and other important parameters needed for the boiler operation. In this paper we compare experimental and simulated values of the temperature fields and present other simulated properties of a boiler, mainly NO production. Production of the nitrogen oxides, which strongly depends on the temperature distribution, can be controlled by intelligent distribution of fuel and oxygen into the burners. Because the experiments on a real device are prohibitively cumbersome and expensive, in extreme cases even hazardous, the only way to test the behaviour of the furnace is mathematical modelling.

An industrial pulverized coal furnace is basically a vertical channel with square cross-section. The dimensions are determined by the power generation requirements from the order of meters to tens of meters. In the case we model, the furnace has 35 meters in height and 7 meters in width and depth. Power production of such a furnace is about 90 MW, and the furnace coupled with a steam generator is capable of producing about 100 tons of pressurized superheated steam per hour.

In the bottom of the channel walls, there are several burners, jets where the mixture of the air and coal powder is injected. The mixture then flows up and burns, while it transfers some of the combustion heat to the walls containing the water pipes.

At the top, the heated flue gas continues to flow to the superheater channel where further heat exchange occurs, and this has already been covered by [3].Our main concern is now modelling of the processes in the area, where the coal gets burnt and nitric oxides are produced. We numerically investigated influence of different setups of the burners on the production of NO and total heat production and utilization by the boiler walls. We also compared numerical results with experimentally measured values from real coal power plant.

$$-q_c = \nabla \cdot (\lambda \nabla T), \quad q_r = \nabla \cdot \left(cT^3 \nabla T\right), \quad q_s = -A(T_{\text{gas}} - T_{\text{wall}}) - B(T_{\text{gas}}^4 - T_{\text{wall}}^4)$$

Figure 1. Navier-Stokes equations

MATHEMATICAL MODEL

The mathematical model of combustion is based on the Navier-Stokes equations for a mixture of multiple components where the coal particles are treated as one of the phases. Unlike e.g. in [2], where the gas particles are treated separately and use separate equations of momentum, we chose to use this approach, as it simplifies the model especially when dealing with turbulence, and also removes several empirical relations and constants.

Currently, the following components of the mixture are considered:

- chemical compounds engaged in major thermal and fuel NO reactions (nitrogen, oxygen, nitric oxide, hydrogen cyanide, ammonia, carbon dioxide and water
- char and volatile part of the coal particle

The gas phase is described by the equations which can be seen from Figure 1.

The particle mass change rate is currently described by the one-step Arrhenian kinetics, which is used separately for the char and volatile coal components - combustion of the volatiles is more rapid than combustion of the char

$$\frac{dm}{dt} = -Am^a \left[O_2\right]^b \exp\left(\frac{\Delta E}{\overline{R}T}\right) \tag{1}$$

These equations are accompanied by the equation of state, as usual

$$p = (\gamma - 1)\rho\left(u - \frac{1}{2}u^2\right) \tag{2}$$

For the turbulence modelling, we use the standard $k-\varepsilon$ model, which describes the evolution of turbulence using two equations (see Figure 2).

SIMPLIFIED MODEL OF NO CHEMISTRY

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_j}(\rho k u_j) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + G_k - \rho\epsilon$$

$$\frac{\partial}{\partial t}(\rho\epsilon) + \frac{\partial}{\partial x_j}(\rho\epsilon u_j) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\epsilon}\right)\frac{\partial \epsilon}{\partial x_j}\right] + C_{1\epsilon}\frac{\epsilon}{k}G_k - C_{2\epsilon}\rho\frac{\epsilon^2}{k}$$

$$S_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right), \quad G_k = \mu_t S^2, \quad S = (2S_{jl}S_{jl})^{1/2}$$

$$C_{1\epsilon} = 1.44, \quad C_{2\epsilon} = 1.92, \quad \sigma_k = 1.0, \quad \sigma_\epsilon = 1.3, \quad \mathrm{Sc}_t = 0.7$$

Figure 2. Turbulence model

This model has been developed to approximately describe the amounts of NO emissions leaving a coal combustion furnace. The real mechanism of coal flue gas production seems to be very complicated, so that just the most important phenomena and reaction paths were considered to provide maximum possibility of using this model in real-time control and operation systems.
There are two major processes attributing to the total NO. The former is known as Thermal NO or Zeldovich and simply consists of oxidation of atmospheric nitrogen at high temperature conditions. The latter is called Fuel NO and describes NO creation from nitrogen, which is chemically bounded in coal fuel. Fuel NO is usually the major source of NO emissions, when the thermal way is suppressed. These are the only mechanisms involved, although a few more could be considered (such as Prompt NO (Fenimore) or Nitrous oxide intermediate mechanisms).

Thermal NO
Thermal NO generation mechanism attributes only at high temperature conditions and is represented by a set of three equations, introduced by Zeldovich [4] and extended by Bowman [5]

$$\begin{aligned} O + N_2 &\overset{k_1}{\leftrightarrow} N + NO \\ N + O_2 &\overset{k_2}{\leftrightarrow} O + NO \\ N + OH &\overset{k_3}{\leftrightarrow} H + NO \end{aligned} \tag{3}$$

All these reactions are considered to be reversible. Rate constants can be found in [8].
In order to compute the NO concentration, concentrations of nitrogen radical, oxygen radical and hydroxyl radical must be known. It is useful to assume that N is in a quasi-steady state according to its nearly immediate conservation after creation. In fact, this N radical formation is the rate limiting factor for thermal NO production, due to extremely high activation energy of nitrogen molecule, which is caused by a triple bond between two nitrogen atoms. Hence, the NO formation rate can be stated as

$$\frac{d[NO]}{dt} = 2k_{+1}[O][N_2]\frac{1 - \dfrac{k_{-1}k_{-2}[NO]^2}{k_{+1}[N_2]k_{+2}[O_2]}}{1 + \dfrac{k_{-1}[NO]}{k_{+2}[O_2] + k_{+3}[OH]}} \tag{4}$$

Under certain conditions, the oxygen molecule splits and recombines cyclically

$$O_2 \overset{K_1}{\leftrightarrow} O + O \tag{5}$$

which can be profitably described by following partial equilibrium approach [6]

$$[O] = K_1 [O_2]^{1/2} T^{1/2} \tag{6}$$

As for OH radical, a similar partial equilibrium approach can be made, according to next reaction

$$O + H_2O \overset{K_2}{\leftrightarrow} OH + OH \tag{7}$$

and the approach is [7]

$$[OH] = K_2 [O]^{1/2} [H_2O]^{1/2} T^{-0,57} \tag{8}$$

Equilibrium constants K_1 and K_2 are as follows

$$K_1 = 36{,}64 \exp\left(\frac{-27123}{T}\right)$$
$$K_2 = 2{,}129 \cdot 10^2 \exp\left(\frac{-4595}{T}\right) \tag{9}$$

Fuel NO

Composition analysis show, that nitrogen-based species are more or less present in coal, usually in amounts of tenths to units of percent by weight. When the coal is heated, these species are transformed into certain intermediates and then into NO. Fuel itself is therefore a significant source of NO pollutants. When a coal particle is heated, it is presumed, that nitrogen compounds are distributed into volatiles and char. In several studies (e.g. [9]) it is unreasonably told, that half of the coal-bounded nitrogen is distributed to volatiles and half into the char. Since there is no reason for a presupposition like this, a parameter α is introduced to describe the distribution of the coal-bounded nitrogen between the volatiles and char part of the coal particle.

$$m_{vol}^N = \alpha m_{tot}^N$$
$$m_{char}^N = (1-\alpha) m_{tot}^N \tag{10}$$

where $\alpha \in [0,1]$.As already mentioned, nitrogen transforms to pollutants via intermediates, which usually are ammonia NH_3 and hydrocyanide HCN. To proceed further, we must define four parameters to describe complex partitioning of the fuel bound nitrogen.

- β is amount of volatile bounded nitrogen which converts to HCN
- δ_1 is distribution of char bounded nitrogen which converts to HCN
- δ_2 is distribution of char bounded nitrogen which converts to NH_3
- δ_3 is distribution of char bounded nitrogen which converts to NO
- $\beta \in [0,1], \delta_1 + \delta_2 + \delta_3 = 1$

Different parametric studies should be carried out to find the best values of these parameters suitable for specific type of coal. Five overall reactions of either NO formation or depletion were incorporated in the combustion part of the numerical code.

<u>*NO, HCN, NH_3 reactions.*</u> According to [10], formation of Fuel NO is given by reactions

$$HCN + O_2 \overset{k_4}{\rightarrow} NO + Z$$
$$NH_3 + O_2 \overset{k_5}{\rightarrow} NO + Z$$
$$HCN + NO \overset{k_6}{\rightarrow} N_2 + Z \tag{11}$$
$$NH_3 + NO \overset{k_7}{\rightarrow} N_2 + Z$$

where k_* are reaction rates taken from [10] and Z are the other products we simply neglect.

Table 1
Air distribution among the burners.

Air setup	Burner 1	Burner 2	Burner 3	Burner 4	OFA
Normal	25%	25%	25%	25%	0%
Air staging 1	50%	20%	20%	10%	0%
Air staging 2	10%	20%	20%	50%	0%
Over-fire air	20%	20%	20%	20%	20%

Heterogeneous reduction of NO. Present char allows following adsorption process to occur (12)

$$Char + NO \xrightarrow{k_8} N_2 + Z$$

Levy [11] uses surface area of pore (BET) to define NO source term (13)

$$R_{NO} = k_8 c_s A_{BET} \overline{M}_{NO} p_{NO}$$

$$k_8 = 2{,}27 \cdot 10^3 \exp\left(\frac{-17168{,}33}{T}\right)$$

In order to evaluate overall NO source term, single source terms have to be summarized. This overall source term can be further used in transport equations. As for HCN and NH_3 source terms, it is possible to determine them from coal burnout rate. It is assumed, that nitrogen from both char and volatiles transforms to intermediate species quickly and totally.

NUMERICAL ALGORITHM

For numerical solution of the equations, finite volume method (FVM) is used. For left and right hand sides the advection upstream splitting method [1] is used to approximate fluxes in the FVM formulation, and edge dual-volume approximation is used to approximate the second order derivatives respectively. For detailed description of the solution procedure, see [3].

RESULTS

Here we will present computed profiles of the interesting parameters of the boiler. Properties of the coal and boiler setup used in simulations are given in the Table 2. Those parameters are consistent with lignite, with medium volume of volatile matter. Operating parameters for studied cases are given in Table 1. We investigated numerically four cases. The first case is the normal operation with air distributed equally among burners, see Figure 3. In the second case the part of total air is fetched to the over-fire-air (OFA) slot. In third and fourth case, air-staging method is used and air is distributed among burners as indicated in Table 2. Comparison of the studied cases is depicted at Figure 4. The comparison of measured data, [13], with numerically obtained is at Figure 5.

Inlet coal mass flux	16,4	kg/s

CONCLUSION

We have developed a mathematical model, which approximates the combustion process in an industrial furnace, while being affordable from the computational complexity standpoint. We show the effects of air-staging and OFA on the most important parameters of the boiler as heat production, heat transfer to the walls and NO concentration at the outlet of the boiler. It can be seen at the figures that the NO concentrations are severely affected by the air-staging techniques. Such results are in good agreement with an experimentally observed reduction of the concentration of NO by air-staging [12]. At the Figure 4, one can see that maximum heat is transferred to the walls for the Normal operation mode and for Air-staging 2 mode (which is consistent with creating fuel-rich and fuel-lean zones in order to decrease NO concentration and make the char burnout complete). In every case the char burnout was complete. We can conclude that OFA technique is the best possible for reduction of the NO concentration even if some heat transfer to the water-wall is lost (due to lower temperature of the region above the OFA slots), but the overall heat escaping with flue gases can be utilised in other parts of the flue-gas duct which are not modelled here.

OPERATING CHARACTERISTIC OF STEAM EJECTOR BASED ON THE HARTLEY'S EXPERIMENTAL SCHEME DETERMINED BY NUMERICAL MODELING OF FLOW

J. Kasperski, S.Pietrowicz*
Wroclaw University of Technology, Institute of Power Engineering and Fluid Dynamics,
Wrocław, Poland

ABSTRACT. The phenomena occurring in an ejector are complicated, especially if they concern non typical geometry and configuration of the nozzles. Nowadays numerical techniques permit modeling of thermal-flow processes occurring in steam refrigeration ejectors. The obtained numerical results show good conformity with experimental data. The numerical calculations were carried out for the fixed steam parameters on the inlets of the ejector nozzles according to the correct turbulence model. Determining of a more complete operating characteristic requires to consider changes of the steam parameters on ejector inlets. The characteristic was based on scheme`s arrangements called Hartley`s scheme, which allows to limit the number of calculation experiments. Conduction of the numerical calculations using the Hartley's scheme permits to determine polynomial coefficients of searched characteristic, especially concerning square relations and linear interaction of two or three parameters simultaneously.

Keywords: *planned experiment, steam ejector, FEM*

INTRODUCTION

The analytical relations for ejector are known for the long time, but they do not consider all phenomena occurring in a device. The phenomena are complicated, especially if they concern non typical geometry and configuration of the nozzles. Recently, in literature on ejectors one can find many theoretical models in respect of the selected flow processes. These models are based on analytical relations taking into consideration the shock wave and non isentropic processes, mixing of the streams, flow losses etc. These types of models are usually one dimensional calculated on the assumption of axisymetrical construction and stationary position of ejector.
One of the modern research methods is using the numerical techniques based on the finite element method (FEM), which allows to analyze the multidimensional phenomena considering the specific construction of nozzles, rotation and processes occurring in wet steam region. In the earlier researches the authors successfully used the numerical modeling techniques joined with ANSYS CFX in order to calculate the thermal flow processes in ejector with saturated steam as a cooling medium.
In previous work [1,2] the numerical results were compared with the experimental data achieving very satisfying correlations of the effects for suction pressure in function of entrainment ratio $p_e = f(U)$.

NUMERICAL MODELING

The physical processes occurring in ejector can be described using the continuity, momentum and energy equations [3,4]. The system of these three equations was solved by the authors using the finite element method technique in ANSYS CFX 11.0 software. The device which was subjected to the numerical analysis is shown in Figure 1a. Assuming that the flows occurring in the ejector are axisymmetric the numerical calculations were simplified to the ejector`s sector shown in Figure 1b.

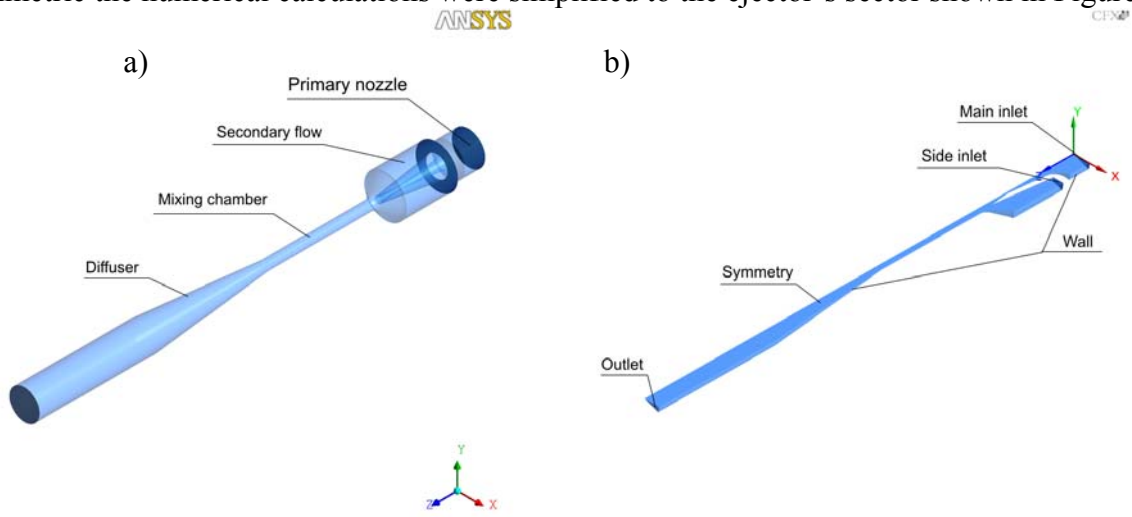

Figure 1. The main elements of the analyzed ejector; a) the physical model, b) the simplified numerical model with the applied boundary conditions

The analyzed domain of calculations was meshed using the 4986 elements: 245 elements of wedge type and 4741 elements of hexahedra type. The mesh was generated in ANSYS ICEM 11.0 software. Additionally, in the places where the high pressure and temperature gradients were expected - very near the walls and in the outlet surrounding of the primary nozzle - the mesh was thickened. The details of the structured mesh are shown in Figure 2.

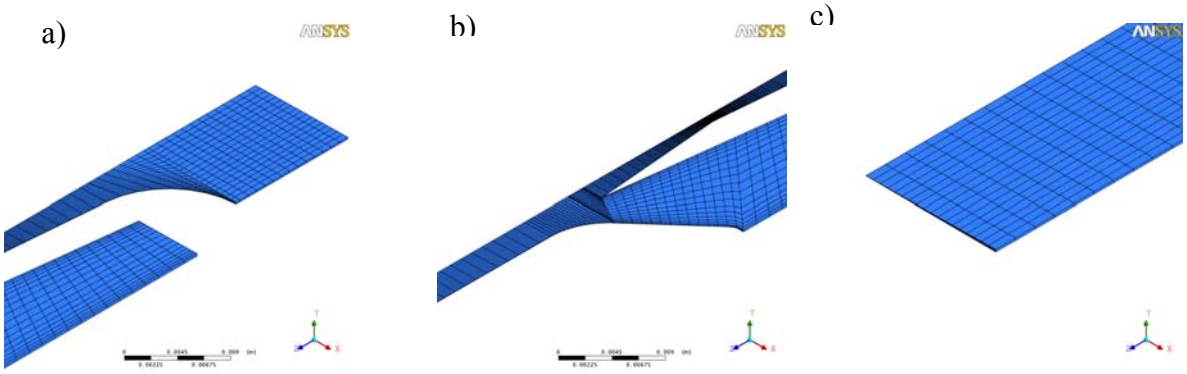

Figure 2. The details of the mesh applied in numerical calculations; a) the motive nozzle with part of the induced nozzle, b) the middle part of the ejector – the mixing region of the two streams, c) the outlet of the ejector

In the numerical domain the following boundary conditions were assumed (Fig. 1b):

- the main inlet is the *inlet* type condition at given saturated temperature of steam and the value of mass flow rate;

- the side inlet is the *inlet* type condition at given saturated temperature of steam and the value of mass flow rate;
- the outlet is the *outlet* type condition at given average absolute pressure;
- at the walls of ejector - the *adiabatic wall without slip* type condition;
- at the side-surfaces in respect of axisymmetric form of the fluid flow the *symmetry* type of conditions were applied.

The working medium was the steam (R718), whose properties were calculated on the basis of the model of steam called IAPWS-IF97 [5] proposed in ANSYS CFX 11.0 software. It was assumed that the steam supplied to primary and secondary nozzle was saturated and the quality of steam equaled x = 1.

Very important for the flow processes is using the correct turbulence model. Comparing the numerical results with the experimental data proved that one of the best models of turbulence is model called *SST - the shear stress transport*.

The examples of numerical calculations of temperature, pressure, Mach number, quality and Mach number of steam at the same entrainment ratio equaled 0.3 are shown in Figure 3.

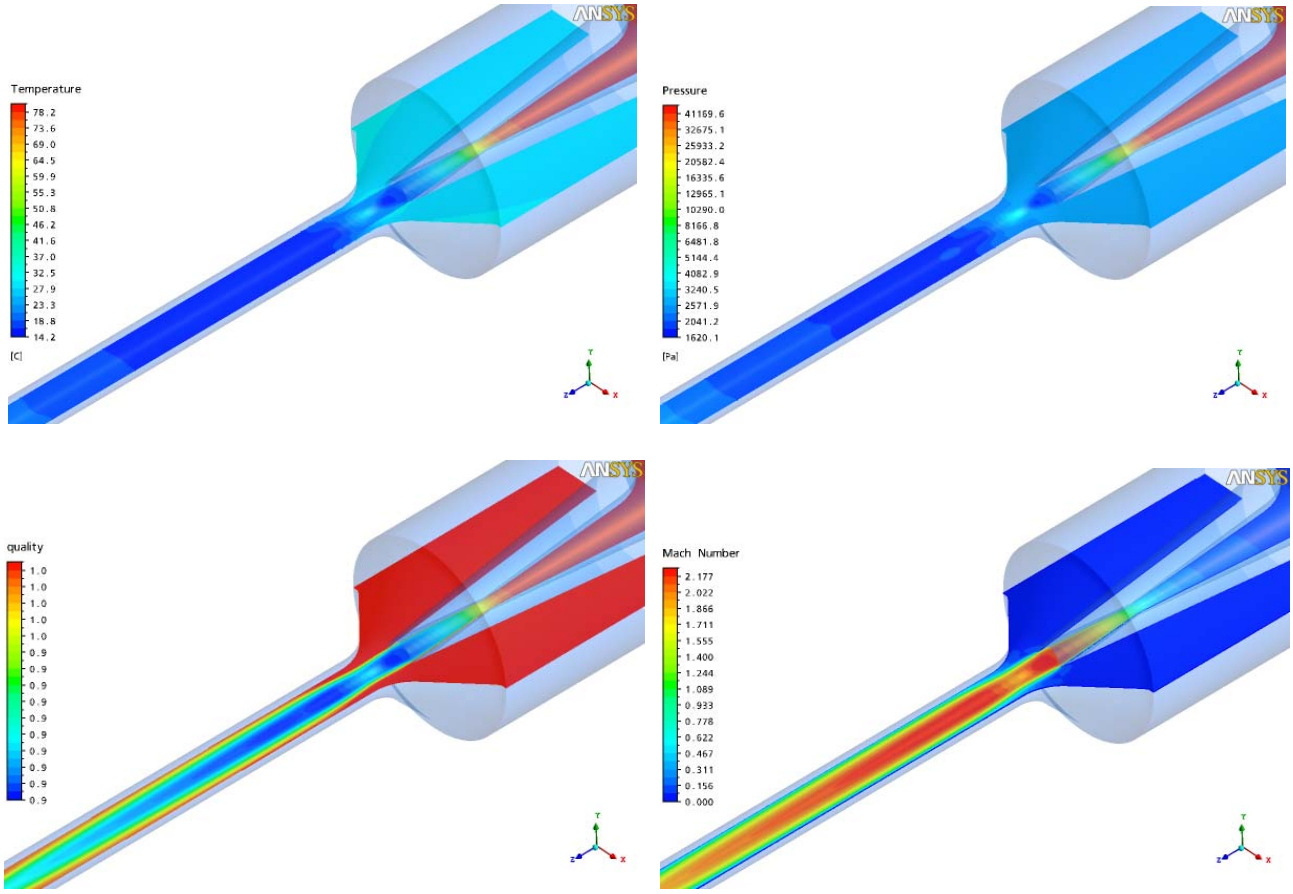

Figure 3. Example o the numerical results: a) temperature, b) pressure (in logarithm scale), c) quality, d) Mach number

OPERATIONAL CHARACTERISTIC OF THE EJECTOR

Application of the ejector in refrigeration cycle demands the knowledge about the operating characteristic taking into account the limited changes of the parameters (pressure/temperature) of motive steam from generator, induced steam from evaporator and steam flowing into condenser. The numerical procedures of thermal flow processes require an appropriate definition of operating

characteristic. One of its form is a relation of induced pressure as a function of entrainment ratio and motive pressure

$$p_e = f(U, p_g) \tag{1}$$

partly shown in the previous research. While determining the operating characteristic of the ejector for the independent variables it is important to respect non-linear relations and interaction of the input parameters. Consideration of logarithmic relation between saturated temperature and pressure permits to reduce the influence of approximation errors. In the proposed variant that relation is described by formula

$$t_e = f(U, t_g) \tag{2}$$

which improves the operating usefulness of characteristic. Determination of non-linear relation (2) demands an experiment scheme and matching the input values for all scheme`s arrangements.

NUMERICAL EXPERIMENT PLAN

In case of using the Hartley`s [6] scheme while performing the experimental tests for the two input variables (Fig. 4), the scheme can be limited to 6 from among 9 experiments of the full scheme keeping nonlinear description.

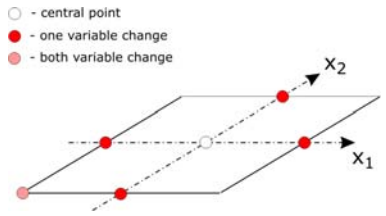

Figure 4. The value of main variables on the Hartley's scheme for two variables.

This scheme allows to calculate 6 polynomial coefficients of the relation (2) including square relations and interaction of the input parameters. According to the Hartley's plan value relation (2) can be described as follows:

$$y = a_1 + a_2 \cdot x_1 + a_3 \cdot x_1^{\,2} + a_4 \cdot x_2 + a_5 \cdot x_2^{\,2} + a_6 \cdot x_1 \cdot x_2 \tag{3}$$

For the variables t_e, U, t_g :

$$t_e = a_1 + a_2 \cdot U + a_3 \cdot U^2 + a_4 \cdot t_g + a_5 \cdot t_g^2 + a_6 \cdot U \cdot t_g \tag{4}$$

Generating of input data set for all six scheme configurations requires establishing of three levels for each input variable. After consideration of technically realistic values of variables the authors assumed the following values of variables: minimum (-1), central (0) and maximum (1) (Table 1).

Table 1
The range of input variables

variable	value		
	-1	0	+1
U (-)	0.0	0.15	0.3
t_n (^{o}C)	70	80	90

The whole scheme of calculations of the experiments were shown in the table 2, 3 and the results of time-consuming calculations were presented graphically on the figure 5.

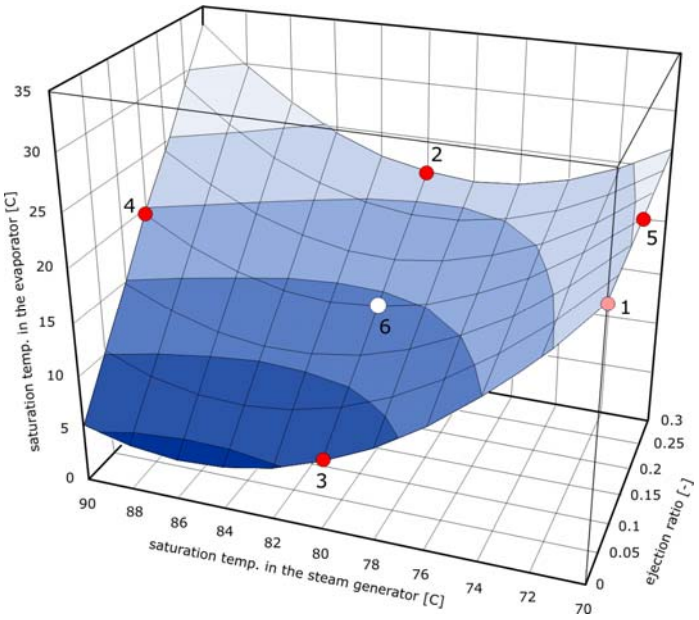

Figure 5. The relations between main parameters of analyzed ejector. The points from 1 to 6 are accordance with the position on the Hartley's scheme.

On the basis of the obtained values of induced pressure and applying standard matrix calculations the values of polynomial coefficients of equations (4) were determined. The received characteristic (4) can be transformed to more useful formula by employing numerical procedures.

$$U = f(t_g, t_e) \tag{5}$$

The graphic form of characteristic (5) is presented in Fig. 5.

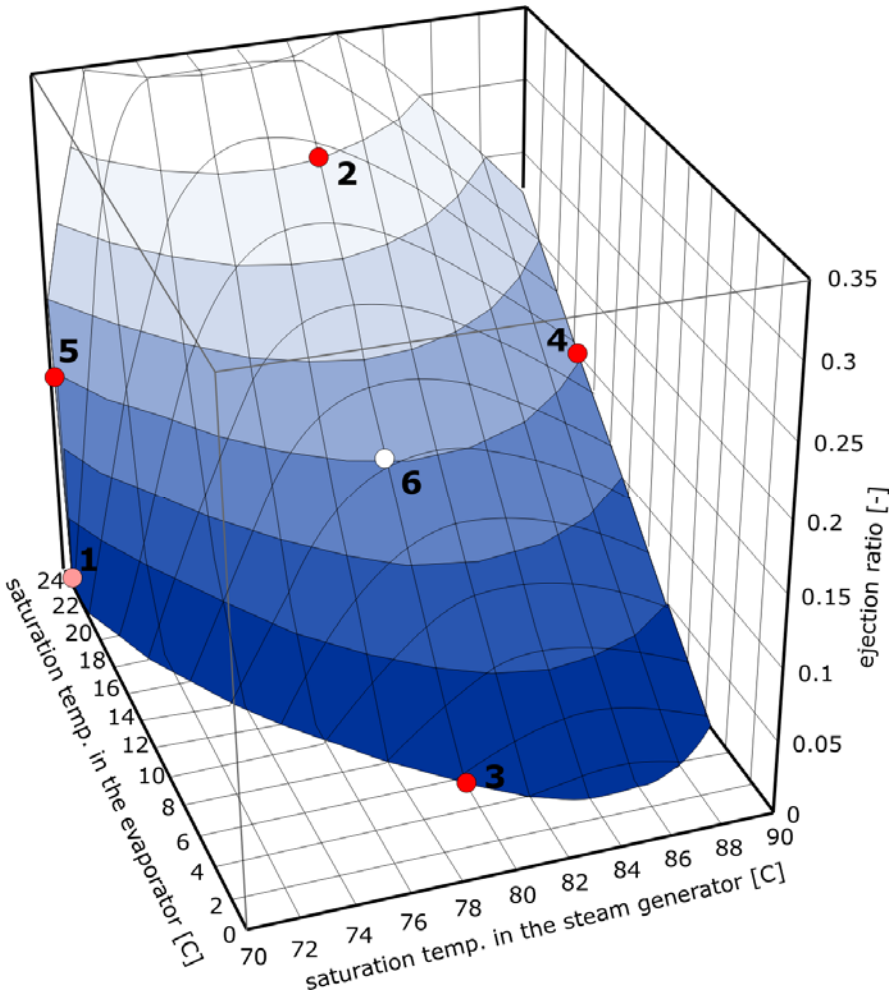

Figure 6. The inverted relations between main parameters of analyzed ejector.

CONCLUSIONS

Nowadays numerical techniques permit modeling of thermal-flow processes occurring in steam refrigeration ejectors. The obtained numerical results show good conformity with experimental data. The numerical calculations were carried out for the fixed steam parameters on the inlets of the ejector nozzles. Determining of a more complete operating characteristic requires to consider changes of the steam parameters on ejector inlets. The characteristic was based on scheme`s arrangements called Hartley`s scheme, which allows to limit the number of calculation experiments. Conduction of the numerical calculations using the Hartley's scheme permits to determine

polynomial coefficients of searched characteristic, especially concerning square relations and linear interaction of two or three parameters simultaneously.

NUMERICAL-EXPERIMENTAL METHODOLOGY TO DETERMINE FIN EFFECTIVENESS AND HEAT FLUX DISTIBUTION

A. Willockx*, C. T'Joen, H. Canière, H. Huisseune, M. De Paepe
University of Ghent - UGENT, Gent, Belgium

ABSTRACT. The goal of this study is to determine the fin effectiveness and local convection coefficients of longitudinal fins with a coupled experimental-numerical method. Therefore the conductive heat fluxes through the cooling fin need to be known. Fin temperatures are measured experimentally with infrared thermography and these measurement data are used as boundary conditions for a 3D numerical fin model. In order to determine the heat fluxes through the cooling fin from surface temperatures, a 3D inverse heat conduction problem (IHCP) has to be solved. Results from a numerical and experimental test case give accurate fin effectiveness, but still show significant fluctuations on the heat fluxes.

Keywords: *inverse conduction, fin effectiveness, infrared measurement, conjugate gradient*

INTRODUCTION

Fins are widely used in heat exchangers, for cooling of electronics,… A good fin performance indicator is important for the design. Two potential indicators are fin efficiency and fin effectiveness. Fin efficiency is the commonly used parameter, but has the big disadvantage that the real performance of the fin is compared to the performance of an ideal non-existing fin of the same shape but with infinitely high thermal conductance. This makes it difficult to compare the thermal performance of different fin forms. Fin efficiency is an idealization and has physically no meaning. On the other hand, fin effectiveness measures the heat transfer gain obtained by placement of the fin and gives an idea of its real performance. It gives the ratio of the heat transferred by the fin to the heat transferred from the surface covered by the fin's base under the same thermal conditions, in the absence of the fin. Fin effectiveness makes it possible to compare the performance of different types of fins and thus is a better performance indicator [1]. This can be used to develop a decision system to choose a fin type in order to remove a certain amount of heat from a surface for a given free surface area.
Geometrical variations of longitudinal fins for heat transfer enhancement have previously been researched [2-4]. Matrices of flat plate fins [2], perforated fins [3] and dimpled channels [4] have been considered. However the effectiveness of these fin types is not determined. The local convective heat transfer coefficients were determined but only for specific arrangements. The matrix of the flat plate fins had a significant influence on the convective heat transfer. Unlike the test cases in this paper, the fins investigated in the mentioned papers [2-4] were exposed to a perpendicular air stream. In this paper, the air flow is parallel to the longitudinal fins.
The objective of this paper is to identify the fin effectiveness as well as the variation of the local convective heat transfer coefficient on the fin surface. Therefore the heat fluxes through the fin model and the primary surface need to be known. It is very difficult to do accurate heat flux measurements or measure a heat flux distribution on a surface, especially for large surfaces. Therefore preference is given to temperature measurements, which are more accurate and easier to perform. Complete surface

temperature profiles can be measured with an infrared camera. The use of infrared thermography to measure surface temperatures from which heat flux distributions are determined is not uncommon [5,6]. Heat flux distributions [6] or convection coefficient profiles [5] can be calculated from surface temperatures by solving an inverse heat conduction problem (IHCP), which is a mathematically ill-posed problem and cannot be solved directly with CFD. There exist various solution methods for inverse heat conduction problems. The description and solution of IHCP's is highly mathematical and falls out of the scope of this paper.
In this study, a procedure is developed in which experimental measurements are coupled with an inverse numerical algorithm in order to determine fin effectiveness and local convection coefficient distribution for different fin forms. The experimental setup and measurements are described thoroughly, with special attention to the use of infrared thermography. The solution methodology of the IHCP is described, but for the detailed numerical solution method of the IHCP is referred to [7]. An example case is illustrated.

EXPERIMENTAL SETUP

Test rig

A test rig is designed in which both fin effectiveness and local heat transfer coefficients for different fin forms can be determined. In order to experimentally determine fin effectiveness, heat fluxes through the primary surface and the fin need to be measured. However, heat flux measurements are very delicate, have relatively large measurement errors and the heat flux distribution is disturbed by the measurement. Moreover, it is not possible with the current techniques to measure the heat flux distribution on a surface at one moment. This would require many sensors on the surface, which should influence the heat flux distribution and the air flow on the surface. Therefore it was chosen to measure temperatures and calculate heat fluxes from these measurements, which means that an IHCP needs to be solved. Thus the experimental measurements are processed by a numerical procedure to obtain the heat fluxes, so actually this is a coupled experimental-numerical study. This procedure has the advantage that the measurements are more accurate, easier and faster. The surface temperatures are measured with an infrared camera, which has two big advantages: it gives a temperature distribution on a surface with one measurement. and it is a non-intrusive measurement technique. Air flow, temperature and heat flux distribution are not disturbed by the temperature measurement, which increases the accuracy. The biggest error in the heat flux determination depends on the accuracy of the IHCP solution, not the experimental measurements.
The definition of fin effectiveness is the ratio of heat exchange by the fin (=Q_f) to that of the primary surface that is covered by the fin's base in absence of the fin (=Q_b), thus:

$$\eta = \frac{Q_f}{Q_b} \tag{1}$$

So in order to experimentally determine fin effectiveness, a primary surface has to be heated and the heat flux through this surface has to be known. In a second phase, a fin is placed on a part of this heated primary surface and the heat flux through the fin is determined. The setup is built as follows. A rectangular aluminum reference block is heated at the bottom. The upper surface of the block is the primary surface. A second aluminum block of the same dimensions is made, but with an aluminum cooling fin on top. Aluminum is used because of its high thermal conductivity (k = 200 W/mK). A flexible isoflux heat foil is placed at the bottom of the reference block in order to induce a heat flux through the primary surface. The heat losses sideways and especially downwards need to be minimized in order to force all heat flux upwards through the aluminum block and fin. Therefore a guard heater assembly is constructed around the primary surface. The guard heater is set at the same temperature as the bottom and side walls of the aluminum block, which are measured with thermocouples. So there are almost no conduction heat losses at the bottom of the upper heat foil and from the side walls of the block due to a lack of temperature difference. The aluminum block with cooling fin and the guard heater assembly are set in a slab of polyurethane and placed in a wind tunnel with a rectangular test

section (figure 1). The wind tunnel is used to examine the influence of Re-number on the local convective heat transfer coefficient and fin effectiveness. The Reynolds number (based on fin length as reference length) can be varied from 12750 to 63750. The base of the fin is at the same height as the bottom of the wind tunnel (figure 1) to avoid disturbance of the air flow at the test section. The temperature profiles on the fin surface and top of the reference block (primary surface) are measured by infrared thermography. Some adjustments were made to the test rig in order to use this measurement technique.

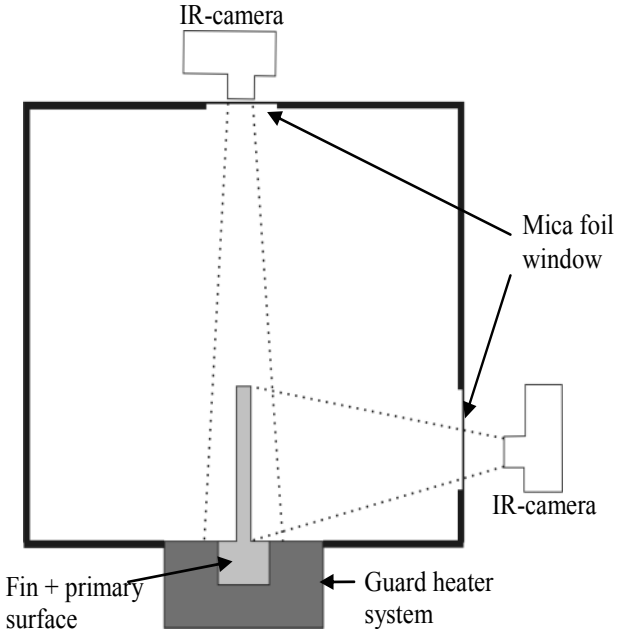

Figure 1. Experimental setup in wind tunnel

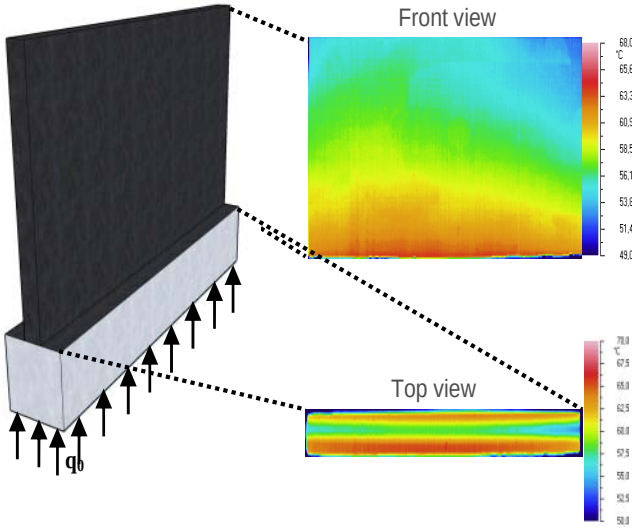

Figure 2. Infrared temperature measurements

Infrared thermography as measurement technique

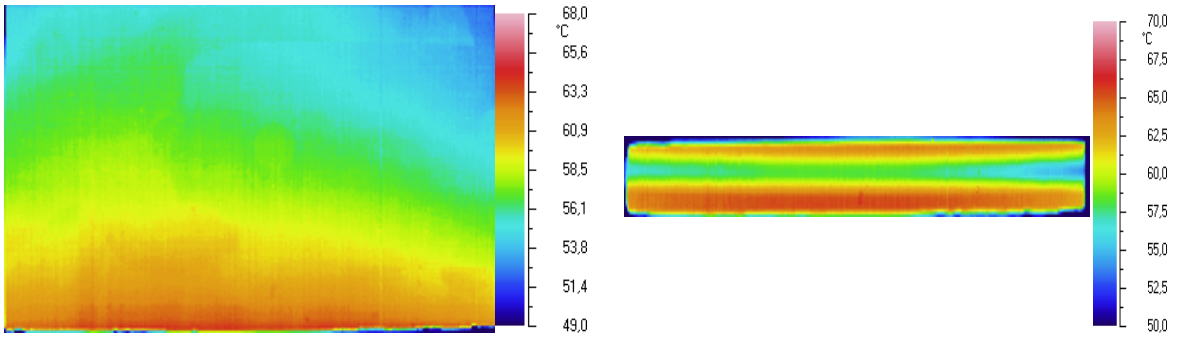
The goal of this research is to study longitudinal fins of heat sinks to cool electronics; which have dimensions of the order of magnitude of 60mm long, 40mm high and 1 mm thick. It was chosen to upscale the fin dimensions 4 times. This improves the temperature resolution, especially at the sides of the fin where there is interference with the surrounding temperatures of the colder wind tunnel wall. This influence is bigger for temperature measurements of small objects, so scaling improves the accuracy of the temperature measurement and thus on the determination of the local convection coefficient. The scaling of the fin dimensions also eases the general design of the test rig.

Thermography has the big advantage that it is a non-intrusive measurement technique and a complete temperature distribution is obtained with one measurement. However, the front and back of the wind tunnel are made out of Plexiglas. As most common solid materials, Plexiglas is not transparent for infrared radiation, which would make it impossible to measure the fin temperature with the infrared camera placed outside the wind tunnel. Therefore infrared transparent windows are necessary. The temperature image of the front side is the same as the rear side due to the symmetry and the isoflux heat flux at the bottom of the block, so only one side of the fin needs to be measured. The temperatures at the upper side of the fin and the primary surface are also measured (figure 2). Thus two windows need to be placed: one at the top and one at the side of the wind tunnel test section (figure 1). A Midas long wave (LW) infrared camera, which has a spectral response from 8 µm to 14 µm, is used. HDPE foil is very thin and has a relatively high transmittance (91%) for IR-radiation in the LW spectrum. Compared to most materials used for infrared transparent windows, HDPE is a very cheap material.

However, it can not withstand high pressure differences, both it is strong enough for the pressure differences in the low speed wind tunnel. Therefore both windows were made of HDPE foil.
An object with a high emissivity has a low reflectivity, so there is less influence of the surroundings on the temperature measurement. The fin and primary surface are made out of aluminum, which has a relatively low emissivity. Therefore they are painted with a matt white paint, which has a high emissivity and will increase the accuracy of the measurements.

MEASUREMENT DATA

First the camera was calibrated in order to do accurate measurements. The calibration techniques used are not discussed in this paper, only the results are given. The two most important parameters that need to be calibrated are the emissivity ε of the matt white paint and the transmittance of the HDPE foil window. Emissivity of the paint was determined at 94% in a temperature range of 50°C to 80°C (which is the temperature range the test fins attain in during the experiment). The transmittance of the HDPE foil is determined at 91%.
An example of the obtained temperature measurement data is shown in figure 3 for a longitudinal plate fin. In these infrared images, each pixel represents a temperature measurement.



a. Front view of fin b. Top view of fin

Figure 3. Infrared temperature measurement of a longitudinal plate fin

INVERSE CONDUCTION PROBLEM

These temperature measurement data are used as boundary conditions for a 3D numerical model of the fin and the primary surface (figure 4). In a direct heat conduction problem, the internal and surface temperatures of a body are determined for given boundary conditions. On the other hand, if temperature measurements are done on its boundary and the boundary conditions [6] have to be derived from these measurements, one has to solve an inverse heat conduction problem (IHCP). An IHCP is mathematically ill-posed, because the uniqueness, existence and stability of the solution cannot be assured [8]. This makes it difficult to solve an IHCP. There exist various solution methods for inverse heat conduction problems. Most methods are implemented for one or two-dimensional inverse problems [8]. The IHCP in this study is three dimensional and there is only limited literature on 3-D inverse problems, especially for determining local convection coefficients. A 3-D IHCP is difficult to solve due to the complexity and high computational cost [9].
The scaled numerical model of the fin and primary surface is shown in figure 4. The boundary conditions imposed on the fin model are inherent with those of the experiment, which gives the following three-dimensional IHCP (figure 4). The temperatures are measured on all fin surface (S1-S5) and on top of the primary surface (S6-S7). A constant heat flux q_0 is induced at the bottom of the primary surface (S8) and the side walls are set adiabatic (S9-S12), which was experimentally imposed by using a guard heater. There is a thermal resistance between the primary surface and the fin, as

shown in figure 4. This thermal resistance is also considered into the inverse heat conduction problem because it causes a temperature drop between the primary surface and the fin, and thus between surfaces S6-S7 and S4-S5, which could otherwise cause problems in the accuracy of the IHCP solution. The primary surface and fin are both made out of aluminium with thermal conductivity k=200W/mK.

The local convection coefficients $h(S_i)$ on S_1-S_7 have to be determined, from which the heat flux distribution can also be determined. The experimental temperature measurements on these surfaces are denoted as $Y_m(S_i)$ (m=1-M) where M is the total amount of measurement points, thus the number of pixels on the infrared image of the fin and primary surface as in figure 4. The convection coefficients $h(S_i)$ can be estimated based on these temperature measurements $Y_m(S_i)$, by minimizing the functional:

$$J[h(S_i)] = \sum_{m=1}^{M} [T_m(S_i) - Y_m(S_i)]^2 \text{ for i=1-7} \quad (2)$$

in which $T_m(S_i)$ are the computed temperatures at the measurement locations from the direct problem solution with the estimated convection coefficients $h(S_i)$. A conjugate gradient method (CGM) is used to minimize the functional J in equation (2). The CGM is coupled with the finite volume code FLUENT [10]. However, the heat fluxes on the fin surface obtained with this numerical algorithm still show significant fluctuations which are not physical but inherent to ill-posed problems. In order to dampen these fluctuations, a first order Tikhonov regularization is added to the numerical algorithm. A detailed description of the numerical algorithm is given in [7].

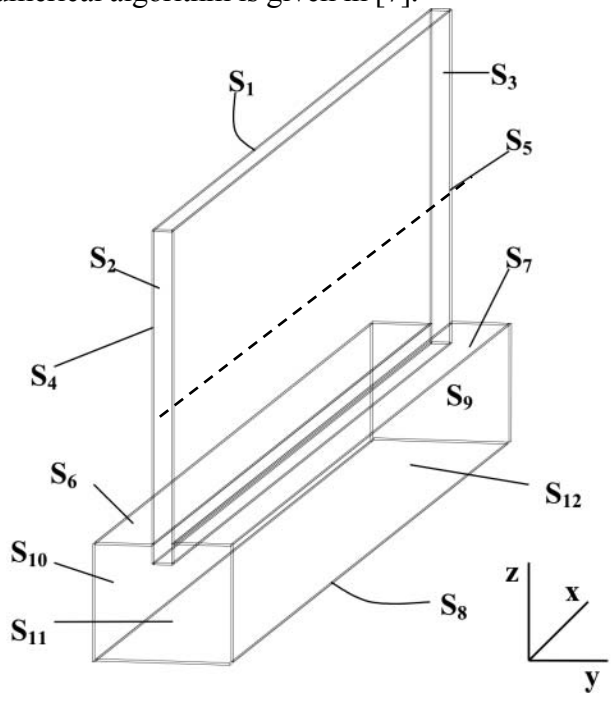


Figure 4. Fin model for inverse conduction problem

RESULTS

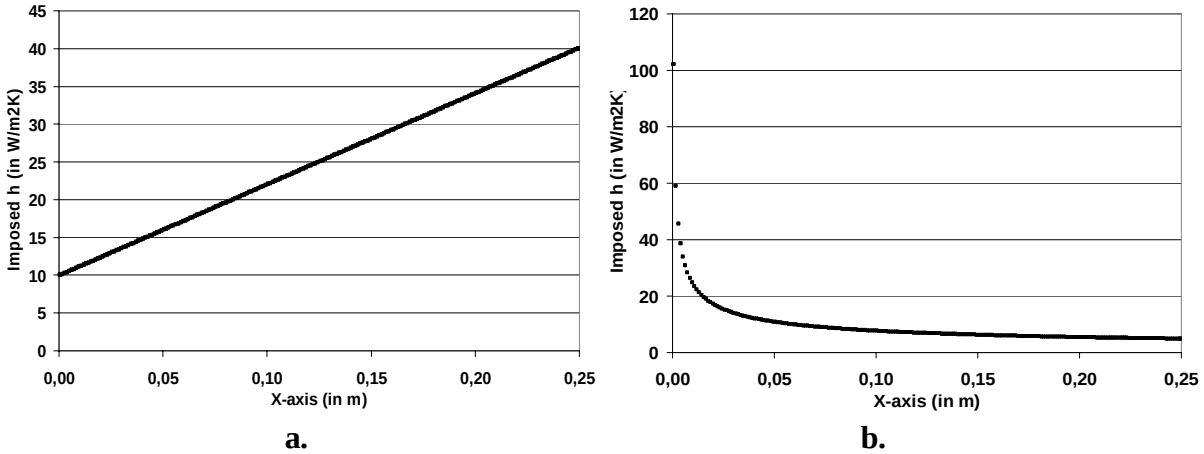
Numerical test cases

The accuracy of the numerical algorithm to solve the IHCP first has to be checked for the described model of a longitudinal fin (figure 4). Therefore some numerical test cases are developed: the temperature profiles on boundaries S_1-S_7 are numerically simulated by solving a direct heat conduction problem with imposed convection coefficient profiles on surfaces S_1-S_7. It is assumed that there are no measurement errors on these simulated temperatures. These simulated temperatures on S_1-S_7 are

denoted $Y_m(S_i)$. The grid of the fin model consists of 303057 cells. The number of cells on the fin side is equal to the number of pixels (thus measurement points) of the thermographic measurement. This means that each cell corresponds with a pixel or measurement point. On the seven surfaces S_1-S_7 there are 63477 measurement points (=M in equation (2)). This large amount of measurement points can cause long calculation times before convergence is obtained. Several test cases were simulated, two of which will be discussed

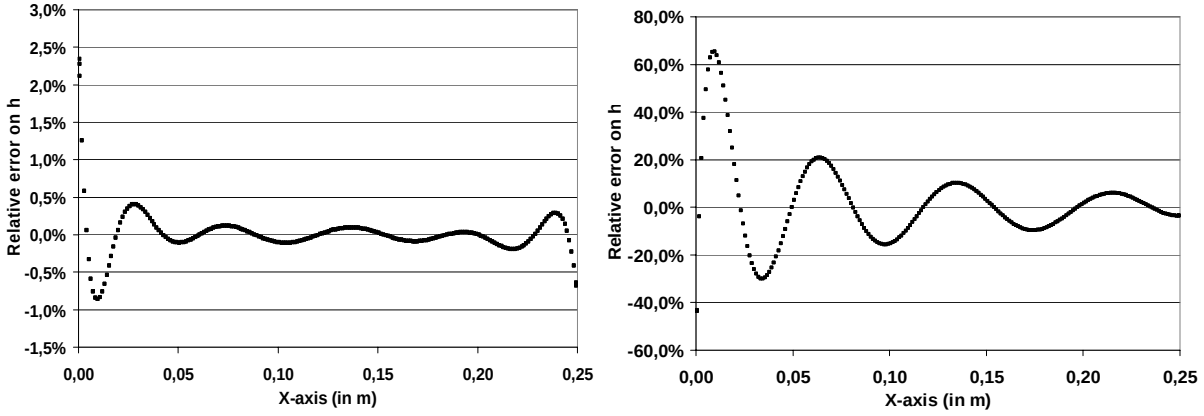
First case: Linear convection coefficient profile. In the first case a linear convection coefficient profile is imposed on S_1,S_4,S_5,S_6,S_7 over the length of the fin (x-direction in figure 4) from h=10W/m^{2}K at S_2 till 40W/m^{2}K at S_3. There is no change of the profile over the height of the fin. The convection coefficient profile is shown in figure 5a for the front side of the fin (S_5) over the length of the fin (thus along x-axis) at the middle of the fin height. (dashed line in figure 4). The simulated temperatures on S_1-S_7 are the measured temperatures $Y_m(S_i)$ of equation (2) and have to be reconstructed by solving the IHCP. The solution of the IHCP with the numerical algorithm gives the estimated convection coefficient profiles on these surfaces and is compared with the imposed convection coefficient profile. In figure 6a, the relative error between the calculated and imposed convection coefficients over the fin length of the fin at the middle of the fin height is set out. The largest error is 2.5%., so the measured and estimated temperature profiles are almost identical.

Second case:Exponential convection coefficient profile. In this case, the convection coefficient profiles on surfaces S_1-S_7 are based on the boundary layer thickness for a given wind speed along the fin. Such a convection coefficient profile has an exponential form. The convection coefficient profile is shown in figure 5b for the front side of the fin (S_5) over the length of the fin at the middle of the fin height. In figure 6b, the relative error on the estimated $h(S_i)$ is set out.



a. **b.**

Figure 5. Imposed h-profile on the fin surface halfway the fin height: a. Linear; b. Exponential



a. **b.**

Figure 6. Relative error on IHCP solution halfway the fin height. a. linear h-profile; b. exponential h-profile

Fin effectiveness. From the solution of the IHCP it is possible to determine fin effectiveness. In Table 1, the fin effectiveness is determined with the IHCP solution and with a direct conduction calculation. The results show that the solution of the IHCP with the numerical algorithm gives accurate results for the fin effectiveness. So the IHCP algorithm can be used to determine the fin effectiveness from experimental temperature measurements.

Table 1: Accuracy of numerical algorithm for fin effectiveness

	Effectiveness direct conduction	Effectiveness IHCP	Error
Case a	4.580	4.580	0.0024%
Case b	4.663	4.662	0.01%

Discussion. In the first case, the J-functional of equation (2) drops below $8*10^{-5}$ after 300 iterations of the IHCP algorithm, which means a maximum error of $3*10^{-5}$K on each temperature measurement. In the second case, the J-functional drops below 1.6 after 340 iterations, which corresponds with a maximum error of 0.003K on each temperature measurement. Although the obtained temperature profiles on S_1-S_7 are correct, there is an error on the estimated $h(S_i)$. There is a wiggle in the estimated convection coefficient profile with alternating areas of positive and relative errors (Figs.5a and 5b). In the first case, these errors are small (<1%). In the second case, they become much bigger: up to 60% on the left side of the fin (figure 6b) where the imposed exponential profile has the biggest value i.e. 100W/m^{2}K.
The big error in the second case is induced by the large $h(S_i)$ values in these first cells at the left side of S_5 and on S_2. After the first few cells, $h(S_i)$ drops quickly to values below 20 W/m^{2}K and remains between 15 and 10 W/m^{2}K for the largest part of the fin. It is seen on figure 6b that $h(S_i)$ is largely overestimated (>60%) in the first cells, followed by a larger region of underestimation (>30%), then again a zone of overestimated $h(S_i)$ (±20%), and finally a region of small over- and underestimation. So the relative errors decrease over the length of the fin, and the area of positive and negative relative error zones is inverse proportional with the absolute value of the error. The results of case a show that the algorithm gives better results if there is no large peak in the imposed h-profiles.
Thus it seems that the algorithm still has difficulties to capture peaks in convection coefficient profiles and still needs to be adjusted to improve the accuracy. These numerical test cases show that it is not possible yet to use the algorithm to determine the local convection coefficient profile from experimental temperature measurements. However, the calculated profiles fluctuate around the correct solution and the global flux distribution over the different temperature surfaces seems to be correct. The results in Table 1 confirm this: although the local convection coefficient profiles cannot be determined accurately, the fin effectiveness is calculated precisely (only 0.01% error). Therefore it is already possible to use the numerical IHCP algorithm to determine the fin effectiveness from the experimental temperature measurements.

Experimental results
Results are already obtained for the simplest longitudinal fin form: a straight rectangular longitudinal fin. It can be seen in figure 7 that there is a small drop in the fin effectiveness with increasing Re-number (2.7% drop for Re from 12500 to 62500). This drop is mainly due to measurement errors and thus the error on the fin effectiveness. So fin effectiveness remains nearly constant for varying Re in the obtained range of Re-numbers

CONCLUSION

A coupled experimental-numerical method is developed to determine fin effectiveness and local convection coefficients for longitudinal fins. Therefore a 3-D IHCP has to be solved. With the developed algorithm the 3D IHCP can be solved but still lacks accuracy for the real, more complex h-profiles. This still needs to be improved. Fin effectiveness can already be determined accurately, and results are shown for a straight rectangular fin.

ABSTRACT. Optimization of cooling system configuration within a gas turbine airfoil requires specification of thermal boundary conditions in each passage. For this purpose either empirical formulae for fluid temperature distribution along a passage or one dimensional fluid flow coupled with thermal calculations in the solid have been usually used. Imperfection of such a simplified approach is based on the fact that some effects are lost, i.e. the circumferential distribution of temperature and turbulence level. Significant improvement can be achieved with of Conjugate Heat Transfer (CHT) application for the interior of the airfoil (solid and cooling channels). A disadvantage of such an approach in connection with evolutionary search results in high computational costs. To overcome the drawbacks some computational strategy has to be worked out. This paper presents an automatic optimization process, which uses CHT analysis solved with Ansys CFX software. Numerical grid for both the solid and cooling passages is generated with ICEM CFD. The task is solved for fixed, once calculated, boundary conditions at the external wall. In this paper authors give some outlook for such a computations. Features of application of CHT for cooling optimization is assessed. The optimization results are compared to those obtained for the simplified method with empirical boundary condition evaluation.

Keywords: optimization, *evolutionary algorithm, Conjugate Heat Transfer (CHT), airfoil cooling*

INTRODUCTION

The main goal of gas turbine development is to increase its thermodynamic efficiency which depends on several factors, where the most significant are the turbine inlet temperature. Hot gas temperature raise affects the level of both the specific power and thermal efficiency of the cycle. In consequence, it improves weight/power ratio of the engine, which is one of the major goals of aerospace propulsion design (Lakshminarayana, 1996). The development in this area is possible due to the progress in material engineering as well as the prevention of high temperature effects within the materials. Modern materials additionally covered with Thermal Barrier Coatings (TBC) should meet the requirements concerning the operation regime of hot gas path components. The temperatures however are nowadays so high, that the material engineering activity is not sufficient and the application of cooling for the hot components is necessary.

Taking into account different aspects of airfoil manufacturing and the turbine performance, the most convenient way of component temperature reduction is internal convective cooling. It is based on the coolant flow, mainly air, extracted from the compressor bleed, via internal cooling passages. In the most simple form a passage is cylindrical and is supplied with air at the blade root. Coolant flows out into the hot gas at the blade tip. To enhance the heat transfer in the internal passages some turbulators in a form of ribs and pin-fins are applied, which also enlarge the heat transfer area. This paper deals with internal convective cooling realized with smooth, circular passages.

An accurate computational analysis of the processes that take place during the convective cooling is very challenging. The main difficulty emerges from the determination of boundary conditions in the passages, especially the assessment of convective heat transfer coefficient and the coolant bulk temperature. This problem can be resolved with coupled field analyses. Some attempts especially in the field of Conjugate Heat Transfer (CHT) solution for cooled geometries, were recently presented by Facchini et al. (2004), Montomoli et al. (2004) and a similar task but for the case of rib-roughened cooling channels, is discussed by Fedruzzi and Arts (2004) or Kusterer et al. (2004) for the film cooled blade. Recently Verstraete et al. (2008) presented a technique which implements a meta model of CHT based on Artificial Neural Network and Radial Base Functions. This meta model is a substitute for full CHT analysis for the optimization problem. It is however iteratively fed and improved with CHT solution data.

An internal cooling system, due to its discrete nature (local cooling with a number of passages), is a source of enhanced thermal gradients within the component, which in consequence produce higher thermal stresses and decrease the component's lifetime. So, a great care should be taken to keep the temperature variations as low as possible.

The problem of cooling system optimization seems to be quite new and has been the point of interest only in the last several years. This is due to the high computational costs of such problems, especially if accurate models need to be involved. Scientific research undertaken so far which has aimed to find the optimal cooling system has dealt with the internal passage convective cooling only. It seems to be the only cooling technique that can be, at the moment, analysed as a whole. Dulikravich with his team (Martin and Dulikravich, 2001, Jeong et al., 2003, Dennis et al., 2003a, b) for several years have studied different problems concerning blade optimization from the point of view of flow, thermal and structural criteria. They dealt mainly with optimization of internal cooling passages (Dennis et al., 2003, Martin and Dulikravich, 2001) and possible coolant outflow at the trailing edge of the blade (Dulikravich et al., 1999). The works mentioned reveal that although they operate on many design variables, the search process was significantly restrained in terms of the geometry changes (i.e. optimization undergone passage fillets or passage distance from the wall etc.). In 2003 Dennis et al. (2003a) showed a work dealing with optimization of a large number of cylindrical cooling passages. All the passages were located close to the external wall and they could move only within a narrow strap along the wall. The aim of the research was to find such a passage distribution that would, by keeping the blade temperature at an allowable limit, minimize the heat flux and also the coolant usage. Very interesting seems to be another work of Dennis et al. (2003b), where the optimization of serpentine-like cooling passage was presented. This task was realized in 3D with the thermo-mechanical criteria involved. The results showed large potential hidden in a cooling system; appropriate size and location of channels had a great influence on the coolant usage, thermal stress level and in consequence lifetime of the component. Nowak and Wroblewski (2007) presented the optimization of location and side of internal cooling passages whose shape was circular and their number was fixed. In this research the passages could freely move within the domain by satisfying the thermo-mechanical criteria for a 3D configuration.

All of the papers dealing with optimization problem used fixed thermal boundary conditions for the external surface of the blade. In the case of internal passages the heat transfer conditions were assessed on the basis of experimental relationships (usually Dittus-Bolter equation). Such estimation of thermal boundary conditions seemed to be very approximate but good enough to demonstrate the optimization techniques themselves. However, accuracy of heat transfer determination has a critical influence on the heat amount transmitted from the working medium to the coolant, which in turn determines temperature distribution within the cooled airfoil. If so, more precise estimation of thermal boundary conditions, both on the external surface of the blade and the cooling passages will influence the optimization as well. This paper demonstrates a possibility to implement the CHT analysis for the cooling system optimization, which is a step forward comparing to the approach used so far.

The optimization problems dealing with turbine blade cooling systems usually involved quite a high number of design variables as well as a complex, implicit and susceptible to slight

parameter changes, response (function) of the system in question. This response in a form of temperature, stress or other parameters was not monotonic but usually included a large number of local extremes, which was a significant problem for many gradient-based optimization methods (Mueller, 2002). In such cases, the stochastic methods were preferred, which was observed in almost all works mentioned before.

The most common was the evolutionary approach which apart from some disadvantages, was suitable to solve complex technical problems.

EVOLUTIONARY OPTIMIZATION

The optimization based on the evolutionary algorithm imitates real life with its evolution process of living organism. This method, which is based on a probabilistic search and an imitation of biological evolution, is able to overcome the settlement in local extremes, where many traditional optimization methods would finish their running.

The evolution process in a population comprised of abstract individuals, prepared for the optimization problem needs, takes place to produce better individuals in the successive populations till the optimal solution (best fitted individual) is reached. So the first step in the evolutionary search is the adequate preparation of the individual, which should include all the design parameters. In the optimization of a cooling structure the design parameters define all the variables which describe a specific configuration. The design variables in the evolutionary algorithm are usually binary or real coded to compose the chromosome of a single individual. In the case of binary coding the chromosome is structured as a string of bits, whereas while using floating point numbers it has a form of a vector built of the design parameters:

$$I = \left[a_1, a_2, a_3, \ldots a_n\right] \quad \left(a_i \rightarrow \Re\right) \tag{1}$$

Similar to biology, each individual reacts somehow to the external (surroundings) conditions. This reaction is quantified and represents the level of adoption to the conditions. This value is called fitness. In other words it shows to what extent the particular individuals fulfill the optimization criteria.

The population composed of a number of individuals, where the size of the population depends on the problem in question, is then subject to the evolutionary operations. Such operations change the genotype (some of the design parameters) of the members, which in consequence changes their fitness.

For the purpose of this research, the Single Objective Evolutionary Algorithm (SOEA) is used for the optimization search. This process is automatically coupled with the ICEM CFD and Ansys CFX software utilized for the computation of each cooling configuration.

CALCULATION PROCEDURE

The aim of the present optimization process is to find optimal size and location of circular cooling passages. The optimization is to be approached with objectives formulated on the basis of an airfoil's thermal field. This requires specification of boundary conditions both on the external profile and the cooling passages. Since the optimization changes the cooling structure and in consequence the cooling conditions it would be necessary to adjust the boundary conditions to current cooling configuration. To take the changes into consideration a CHT problem should be involved. However full CHT is computationally expensive from the point of view of the optimization where usually many cooling candidates need to be analyzed. This paper tries to implement the CHT problem into the optimization task.

Model for CHT problem

The problem is solved for a 3D model of the well known C3X profile taken from literature (Hylton et al., 1983) , which was extensively investigated by NASA. The vane profile is assumed to be aerodynamically optimal and fixed during the computation process. The report of the NASA

research has been the source of basic information for the purpose of this work. The vane in question is originally a convectively cooled one with ten internal passages as presented in Fig. 1. The airfoil was investigated within a linear 3-vane cascade supplied with exhaust gases from a burner. Cooling of the 76.2 mm high vane was provided with air. The air is flowing radially through ten circular channels.

The whole computational domain is 3D and consists of a periodic domain with one vane. It is divided into three sub domains: hot gas domain, solid domain of the vane and cooling air domain. The hot gas domain was extended in the axial direction upstream of the blade leading edge and downstream of the trailing edge to specify the uniform boundary conditions.

The vane material is stainless steel, which has a low, constant thermal conductivity of *k=16* W/m/K, a constant density of ρ=7900 kg/m^3, a molar mass of 55.85 kg/kmol and a specific heat capacity of *c=585.2* J/kg/K.

The flow conditions were assumed from the run 158, following the Hylton et al., (1983) nomenclature. The total pressure and total temperature were specified at the inlet, with the static pressure derived using p_{t1}=0.2435MPa and M_2 =0.91 specified at the exit. For the hot gas flow at the inlet, the turbulence intensity T_{u1} = 8.3% was specified to be the experimental value.
The inlet turbulence length scale L_{t1} was specified to be 0.4 mm (0.5% of the vane axial chord) as proposed by Luo and Razinsky (2007). Both the molecular viscosity and conductivity were specified as a function of static temperature using Sutherland's law. The specific heat is assumed as a constant value.

The flow conditions for the coolant flow in the passages were not taken from the experiment exactly. It was necessary to specify boundary conditions independently on the hole position and diameter. For all cooling channels the equal boundary conditions were assumed. At the inlet the total pressure p_{tc}=0.3 MPa and total temperature T_{tc}=375 K were taken. The flow at the inlet had a high turbulence level Tu_{1c}=10%. At the outlet the static pressure was p_{2c}=0.28 MPa. The coolant flow conditions ensured that the level of the blade temperature was similar to the experiment.
The end walls at hub and shroud were assumed as symmetry. Simplification of the model enabled to avoid a boundary layer modelling in those regions.

Numerical solution and turbulence model

The flow solver was the commercial CFD package ANSYS CFX. It solves 3D RANS equations on unstructured meshes of different cell types and a mixed structure. The solution strategy is based on the algebraic multi-grid method. For Conjugate Heat Transfer analysis, the energy equations for the fluid and solid are solved simultaneously. The energy equation for the solid is a degenerate form of the energy equation for fluids and is solved using the same numerical algorithm.

The turbulent eddy viscosity was obtained from the SST turbulence model. The Gamma-theta transition model is used to simulate boundary layer transition, which is one of the key features of blade heat transfer. In the Gamma-theta model two additional equations for the intermittency and transition onset Reynolds number are solved.

Mesh

The model geometry was created and meshed using the ICEM CFD package. Since the C3X vane had a constant cross section, a 2D mesh for all domains was generated first. For the external gas path region the quad dominated mesh was chosen with elements evenly distributed in the layers near the wall boundary. It ensures nearly orthogonality of the mesh near the vane surface. In the solid region the unstructured quad dominated mesh was also used. The holes were discretized using an O-type grids. The merged 2D mesh was then stretched up to form the 3D mesh. The 3D grid had only 10 layers to reduce the total mesh size, because the reduction in time consumption was strongly preferred in the optimization process. Totally, the mesh consisted of about 131000 cells for the entire domain, with about 80000 cells for the hot gas domain, 11000 for the solid domain and 40000 for the ten cooling passages.

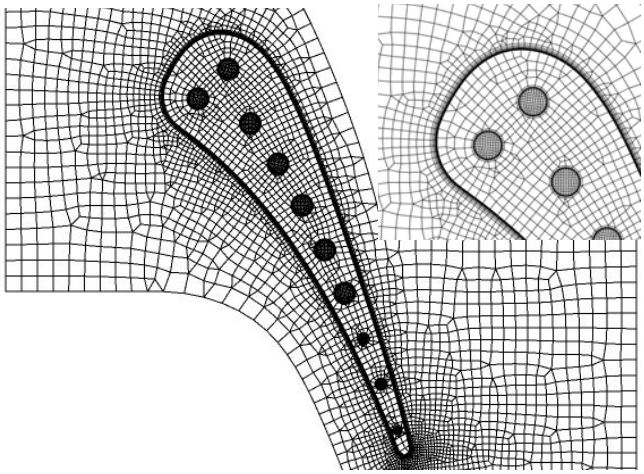

Fig 1. Computational meshes for all domains

The computational grids on the one layer are shown in Fig. 1. The near-wall spacing of the gas path mesh is about y+=1.

CHT solver protocol

The optimization procedure calls the CHT solver many times. Implementation of the full CHT problem for the optimization seems to be irrational in terms of computational cost. In order to make the problem feasible to be considered it was decided to reduce its size. There assumed that instead of full CHT solution it would do, at this stage, to take into account the CHT problem within the airfoil only (airfoil material and cooling passages), with fixed boundary conditions at the blade wall. Those boundary conditions are obtained from the full CHT prediction for the original configuration. The algorithm for the CHT solution consists of three steps. In the first step the cooling passages generated by the evolutionary algorithm are automatically meshed using a script file for ICEM CFD. Next, new meshes for the solid and the cooling channels are reloaded into the simulation file in the pre-processing of the ANSYS CFX and the solver is started. When the solver reaches the prescribed residual level (set to 1e-4 for the maximum residual) results in the third step are loaded to the postprocessor and necessary data for optimization procedure are exported. All steps are controlled by user defined procedures and proceed automatically.

Cooling structure coding

Each individual of the genetic population represented the cooling system configuration, which was equipped with ten channels and during the optimization the number was fixed. A circular passage definition requires 3 variables: 2 space coordinates and a radius. Taking into account the whole cooling system it made the optimization problem formulated in 30 dimensional design space. All the design parameters were stored within a design vector:

$$I = \left[x_1, y_1, r_1, ..., x_{10}, y_{10}, r_{10}\right] \tag{2}$$

The objective function was defined in the domain of the blade cross-section, so the constraints needed to be properly determined. The cooling passages might freely move within the blade domain, but care should be taken to prevent passages from overlapping and crossing the boundary. Even a single passage which violated the boundaries made the individual discredited for further calculations. This was because of an automatic model generation for CHT computations. To meet the modeling requirements both minimum mutual distance between neighboring passages and wall distance was restrained to 5mm and 1mm, respectively. Additionally, the minimum (1mm) and maximum (6mm) passage radius were specified.

Evolutionary search

At the beginning of the calculation process the base (initial) population was sampled with the constraint criteria being satisfied. So the whole base population was composed of a set of feasible cooling configurations. To determine the fitness function value for each cooling system candidate the chromosome was decoded (specific values were transferred from local to global system) in order to build the computational model. Then a command file for ICEM software was prepared for the flow and thermal model grid generation. In the next step the CHT computations, which involved the blade domain with cooling channels were performed giving as a result the temperature distribution within the airfoil and the flow field in the passages. On the basis of the results obtained the fitness of the specific solution was calculated. This process was repeated for each population member.

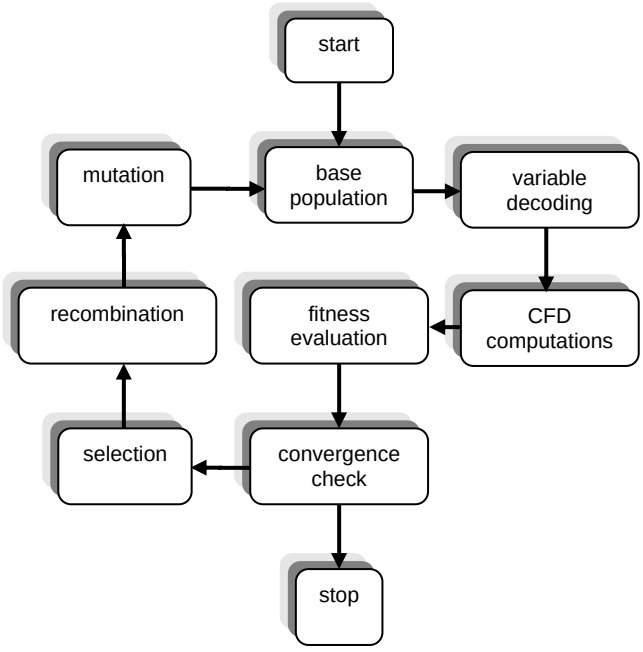

Fig. 2 Evolutionary algorithm flow chart

After that, the population was subject to the genetic operations and in consequence a new offspring population was obtained. Then the constraints for each individual of the children population were checked and the process was repeated (Fig. 2).

NUMERICAL INVESTIGATIONS

Objective Function

Turbine component cooling was provided in order to keep its temperature below the allowable limit. This was because of the safety and reliability reasons. On the other hand, the presence of cooling introduced a negative impact on airfoil thermal load and eventually durability, as well as the turbine efficiency. So, in order to meet the requirements mentioned the following objective function in a form of weighted sum of particular criteria was proposed:

$$f = w_1\left(\frac{\max_i(T_i)}{T_t}\right)^2 + w_2\left(\frac{1}{n}\sum_{i=1}^{n}\left(\frac{T_i}{T_{av}}\right)^2\right) + w_3\left(\frac{\dot{m}}{\dot{m}_t}\right)^2 \tag{3}$$

where T_i stood for temperature at node i, T_{av}, and T_t, represented the average and target temperature, respectively. Actual and target coolant mass flow was denoted with $\dot{m}$ and $\dot{m}_t$, respectively. Weight coefficients w_i are responsible for adjusting the influence of each factor on the objective function value. Function (3) tended to reduce all of its parameters to their desired values indexed with t.

Since the evolutionary algorithm searched for the best fitted (maximum fitness value) solution, the fitness function (F) was elaborated with the formula:

$$F = \frac{W}{\sqrt{f}} \tag{4}$$

where W was a constant value multiplier and f stood for the objective function (3).

Results

Before the optimization problem was approached, it was necessary to solve the full CHT problem for the entire domain and as a result the boundary conditions for the reduced CHT problem (solid and cooling passages) were obtained. As the boundary condition the HTC distribution at the blade surface was chosen assuming constant reference fluid temperature T_f=*808 K*. Fig 3 shows the distribution of the HTC at the vane midspan. On the suction side of the airfoil for the x/C_x=0.65 a sudden increase of HTC is observed, which represents the laminar-turbulent transition. From the experimental research (Hylton et al., 1983) it is known that the transition process appears earlier, and some additional work to calibrate the transition model and/or inlet boundary turbulence level could be done. At this stage of the analysis it was decided to skip the additional problem emerged and to assume that at that design level, approximation with assumed turbulence level and standard values for transition model was sufficiently accurate.

As mentioned before, the airfoil in question was originally equipped with ten cylindrical cooling passages and that number was fixed during the optimization. The original cooling configuration was the reference case for the analysis done. Since the CHT analysis for each cooling candidate required several minutes to get the solution, the computations were performed in parallel on a single PC with Quad CPU and 8 GB RAM. It was possible to run four analyses at once.

Calculations were performed for the weighted single objective function given by (3) with the following target values: T_t = 600K and m_t=0.025kg/s. The results, obtained both for air and steam cooling, showed about 40% growth of the fitness value compared to the original cooling system of the airfoil regarding to the criteria posed. It is mainly because of significantly lower coolant usage whose consumption dropped by about 60%, although the airfoil maximum temperature raised by 4% in the case of air cooling and 5% for steam cooling. There is also a growth in the mean temperature by about 11%. This however resulted in more isothermal material, which in turn would reduce thermal load and increase lifetime.

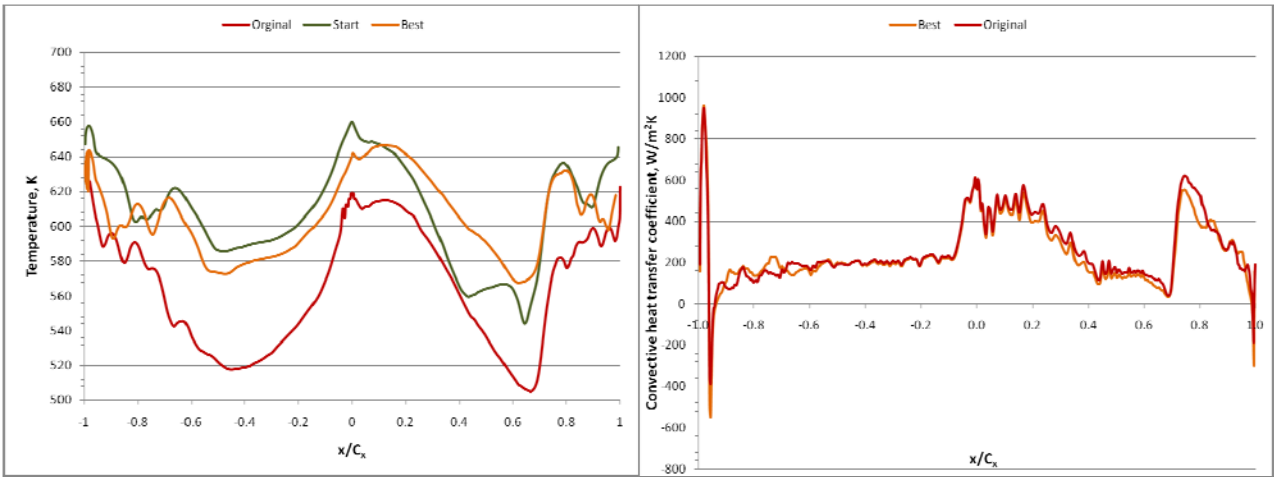

Fig. 3 Temperature distribution for the original, start and best configuration at the midspan (left) and HTC distribution for the original and best configurations (T_f=808 K) – results for the air cooling.

The results were obtained for the objective function weight coefficients: w_1=0.5, w_2=0.25 and w_3=0.25. Although the highest weight coefficient is connected with the maximum temperature factor, the most influential was the mass flow objective, which forced the design into coolant usage reduction. Of course, by weights modifications the user is able to favor specific objectives. There is also another way to keep particular objective parameters within a specified range by application of penalty for the solutions that do not meet the limitations.

Fig. 3 presents the temperature in the solid. In the original configuration the temperature level is changing strongly between the middle region of the blade and both the leading and the trailing edge region. The spanwise difference is visible especially on the rear part of the vane. The best configuration of the holes with the predicted temperature is shown in Fig.3b and 3d for air and steam cooling, respectively. The channels obtained for air cooling are visibly smaller than in the original case, whereas steam cooling required, in this particular calculations, passages of size comparable to the original ones. This was due to the cooling steam parameters, considerably lower than in the case of the air.

Comparison of the temperature distribution along the blade surface at the midsection of the vane for the original, initial and the best configuration is presented in Fig. 3. The temperature level for the original solution is lower than for the other configurations in consideration, but the difference between the minimum and maximum is greater by about 120 K. For the best solution obtained from the optimization this difference is about 80 K.

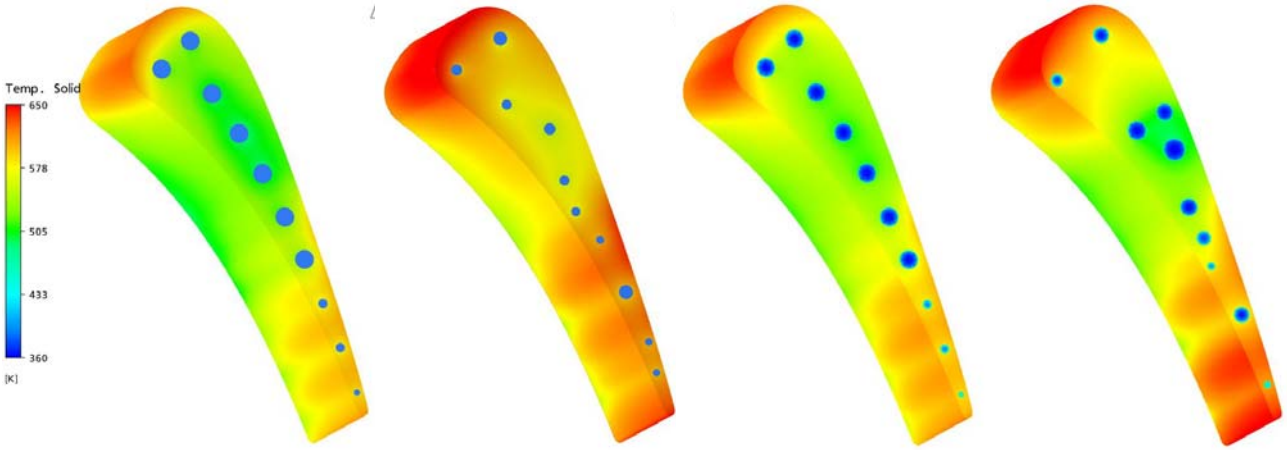

Fig. 4 Vane metal temperature a) original configuration – air cooling, b) optimized configuration – air cooling, c) original configuration – steam cooling, d) optimized configuration – steam cooling.

The best cooling candidate resulting from the optimization was analysed using the full CHT algorithm as used for the original vane. The HTC on the blade obtained for the optimized blade were compared with the original case at the midspan in Fig. 4. The position of the transition on the suction side is the same as for the original case. It enables to deduce that the change in cooling passage position does not influence the transition. The difference in the front of the blade is lower than in the rear part. The distribution is very similar. A relatively small difference in the HTC could cause the changes in the heat flux balance for the blade. From this point of view in the further research full CHT problem should be taken into account.

The optimization revealed that relocation of cooling channels could improve performance of the system both from the point of view of a cooled component's lifetime and turbine efficiency by reduction of coolant usage.

CONCLUSIONS

The paper presents the application of Conjugate Heat Transfer prediction for optimization of a cooling system configuration. The search procedure utilized the evolutionary algorithm. The evaluation of a particular solution was done on the basis of CHT analyses within a cooled airfoil. For the purpose of this research a convectively cooled airfoil was assumed and the optimization consisted in the relocation and diameter changes of the cooling passages. The search procedure was run as a Single Objective Algorithm but the fitness function entailed three different criteria: one was to minimize the blade maximum temperature, the next tended indirectly to reduce the thermal loading by providing more isothermal material and the last tried to lower down coolant usage.

Results of the optimization were juxtaposed to the original C3X airfoil. Changes in the cooling structure resulted in a significant advantage coming from more isothermal material of the blade. Also a much lower coolant usage was observed (60% reduction) with the maximum airfoil temperature only slightly higher (about 4%) than in the reference case. Applied optimization strategy is said to be one of the best tools for the global optimum search especially in the case of problems with complex geometries and a large number of design variables.
The main improvement worked out in the area of airfoil cooling optimization was the inclusion of CHT analysis for the blade interior, instead of empirical formulae for heat transfer conditions, which were widely used in such problems. This project showed the direction which should be followed to obtain more reliable designs.

One of the most painful disadvantages of the evolutionary algorithm together with the CHT analysis is their high computational cost, so a parallel computing is required while using this approach.

The next step in the development of a cooling system optimization should be the application of the full CHT prediction, which would make the whole process more reliable. Also in the future work the flow should be considered more precisely: including more layers in the spanwise direction and hub and tip boundary layer, using finer grids in the holes, analyzing the different turbulence models, calibrating a transition model. Nowadays it is a task for the single case CHT analysis and therefore extension of the optimization procedure could be done stepwise, depending on the computer power.

Experimental Methodology

EXPERIMENTAL INVESTIGATION OF EVAPORATIVE HEAT TRANSFER CHARACTERISTICS AT THE 3-PHASE CONTACT LINE

ABSTRACT. An experimental study is conducted to investigate the local heat flow at a solid-liquid-vapor contact line. A vertical channel of 600 μm width is built using two parallel flat plates; a 10 μm thick stainless steel heating foil forms a part of one of the flat plates. A liquid-vapor meniscus is formed between the plates due to capillary forces. In this study the fluid HFE7100 is evaporated inside the channel under steady state conditions. Two-dimensional microscale temperature fields at the back side of the heating foil are observed with a infrared camera with a spatial resolution of 14.8 μm ×14.8 μm. An in-situ calibration procedure is applied. The measured local wall temperature difference between the contact line area and the bulk liquid is up to 12 K. The local heat fluxes from the heater to the evaporating meniscus are calculated from the measured wall temperatures using an energy balance for each pixel element. The local heat fluxes at the contact line area are found to be about 5.4-6.5 times higher than the mean input heat fluxes at the foil.

Keywords: *3-phase contact line, meniscus, micro-region, heat transfer*

INTRODUCTION

The increasing power dissipation and miniaturization of microelectronic circuits drive extensive studies on high performance cooling systems. Such systems are often based on evaporative cooling processes in micro heat pipes, capillary pumped loops and spray cooling devices. In most of these systems the wall is only partly flooded with a macroscopic liquid layer, and the flow pattern is characterized by the presence of 3-phase contact lines. A common and important heat transfer mechanism in these cooling systems is evaporation of ultrathin liquid films in the vicinity of 3-phase contact line accompanied by extremely high heat fluxes. Understanding the phase change phenomena in the 3-phase contact line region is important for optimizing the evaporative cooling processes [1].

The thermodynamic and hydrodynamic interactions near the 3-phase contact line, or in other words the interaction between a thin film of liquid, its vapor, and a solid surface have been extensively studied. Fundamentally, most of the studies are based on a thin film evaporation concept introduced by group of Wayner [2] and first applied to macroscopic systems by Stephan and Busse [3]. Renk and Wayner [2] modelled evaporation of a tiny liquid film (later referred to as a “micro-region” [3]) between the adsorbed, non-evaporating film covering an apparently dry area and the macro-region with a high conductive heat resistance (see Fig. 1). The model has predicted that the local evaporative flux reaches a maximum value in the micro-region.

Therefore, in spite of small geometrical dimensions (typically around 1 μm), a considerable amount of the heat supplied to a macroscopic system may flow through the micro-region. Under steady conditions the liquid is constantly supplied from the macro region to the micro-region. The liquid flow is governed by the gradients of the capillary pressure and the disjoining pressure in the micro region, both of them determined by the film thickness profile. Differential equations were formulated for predicting the distribution of the film thickness and local heat flux in the micro region and shown that the film thickness profile and the apparent contact angle depend on the wall superheat.

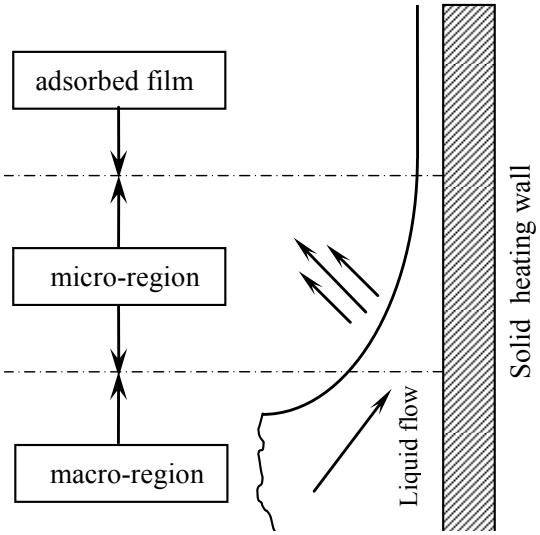

Figure 1. Micro -region model [1]

Stephan and Busse [3] have extended the micro-region evaporation theory to description of macroscopic systems and applied it to computation of temperature field and evaporation rate in a heat pipe. They have combined the solution of the equation describing the shape of the liquid-vapor interface and heat flux distribution in the micro-region with the solution of a macroscopic heat transfer problem in a heat pipe with open grooves. Stephan and Busse have found that the heat transfer in the 3-phase contact line area could have a significant influence on the overall macroscopic heat transfer.

Thin film evaporation in the micro-region has been studied experimentally [4]-[7]. The meniscus profile and the adsorbed layer thickness have been measured using interferometry technique. It has been found that the meniscus shape depends on the applied heat flux. The authors have experimentally confirmed the theoretical prediction concerning the strong influence of disjoining pressure on the flow field in the micro-region [5]. A good agreement between the experimental data and the results of theoretical models has been demonstrated.

Höhmann and Stephan [1] used a high resolution temperature measurement technique to monitor the microscale wall temperature distribution in the vicinity of evaporating liquid meniscus. This technique is based on Thermochromic Liquid Crystals (TLC), which are characterized by a temperature dependence of spectral reflective properties. The color play of TLCs has been recorded by a CCD camera in conjunction with a microscope. The pixel color values (or hue-values) have been translated into temperatures. As a result, two-dimensional temperature distribution underneath the evaporating meniscus has been determined with a spatial resolution of 1 μm. The authors have registered a local wall temperature drop in the vicinity of the 3-phase contact line which has been attributed to strong evaporative cooling in the micro-region. However, the TLC measuring technique is only applicable to relatively low input heat fluxes due to a narrow temperature range of TLCs. Therefore, the measured local temperature drop due to the micro-region evaporation was limited to 0.2 K.

The TLC technique and infrared thermography have been applied for investigation of the micro-region evaporation effect on nucleate boiling [8]-[10]. The authors have measured the non-stationary wall temperature distribution underneath a single growing bubble and a sequence of growing, departing and ascending bubbles under terrestrial and reduced gravity conditions. The measured temperature distribution has been used for computation of the wall heat flux distribution

[10]. A ring-shaped region of the wall temperature drop has been observed close to the 3-phase contact line at the bubble foot, corresponding to a ring-shaped region of high heat flux. The influence of the gravity level on the bubble frequency and the departure diameter has been evaluated with the same technique. Kandlikar *et al.* [11] and [12] have studied heat transfer from a stable evaporating meniscus formed between a needle dispensing water over a heated circular face of a rotating copper block. It has been found that the heat flux increases in direct proportion to the surface velocity and the water flow rate. The study provided an important insight into the role of the evaporating liquid-vapor interface and transient heat conduction around a nucleating bubble in pool boiling. In these experiments the wall temperature in the vicinity of evaporating 3-phase contact line has not been measured. The measurements have been performed in the air environment and not at saturation conditions.

Although numerous experimental and theoretical works on the thin film evaporation near the 3-phase contact line have been conducted, a full understanding of the relevant microscale heat and mass transport phenomena has not been yet achieved. Additional high resolution experimental investigations are needed for accurate determination of the temperature and heat and mass flux distributions in micro-region in a wide range of thermodynamic conditions and applied heat fluxes. The present investigation is focused on measurements of the wall temperature distribution near the 3-phase contact line at evaporation conditions. This temperature distribution is used to evaluate the distribution of the wall heat flux.

EXPERIMENTAL SETUP AND PROCEDURE

The schematic of the experimental setup is shown in Fig. 2. The setup contains a working fluid cell made of copper which is flooded with tempered water to guarantee isothermal conditions The temperature of the working fluid is kept near the saturation temperature at the system pressure. The control of the tempered water bath is carried out with a thermostat system. Inlet and outlet temperatures of the tempered water bath are measured and used for the temperature control. Additionally, the temperatures of the working fluid in the copper container and of the vapor entering the condenser are measured. A stainless steel vertical test channel is attached to the copper container. The 600 μm width test channel is formed by two parallel plates. A liquid column with a single liquid-vapor meniscus rises and accepts a steady position in this channel due to capillary forces. One of the two parallel plates is equipped with a 10 μm thick 22mm×14mm electrically heated stainless steel foil (see Fig. 3). The other side of the channel is formed by an unheated copper plate equipped with 5 thermocouples fixed in holes at a 0.5 mm distance from the front surface. These thermocouples are placed in front of the heating foil and used for the calibration of the infrared camera readings as well as for measurement of the average working fluid temperature in front of the heating foil. The pressure of the test cell is measured using calibrated pressure transducer. The vapor produced in the channel flows to the condenser which is located in a pressure chamber. The condenser and the pressure chamber with compensation bellow are connected with a vacuum pump controlling the pressure in the whole system. The working fluid is a methoxy-nonafluorobutane ($C_4F_9OCH_3$) fluid HFE-7100 with a normal boiling temperature of 61°C at atmospheric pressure. The back side of the foil is coated with a black paint by an airbrush.

The temperature field at the back side of the heater is observed with a high-speed infrared camera with a spatial resolution of 14.8 μm ×14.8 μm per pixel, a format of 320 × 256 pixels, and a temporal resolution of 244Hz. Thermocouples are calibrated against standard calibrated and certified temperature measurement device PT100 in the temperature range from 10°C to 90°C. The maximal error of thermocouple reading after calibration is kept within ±0.1°C.

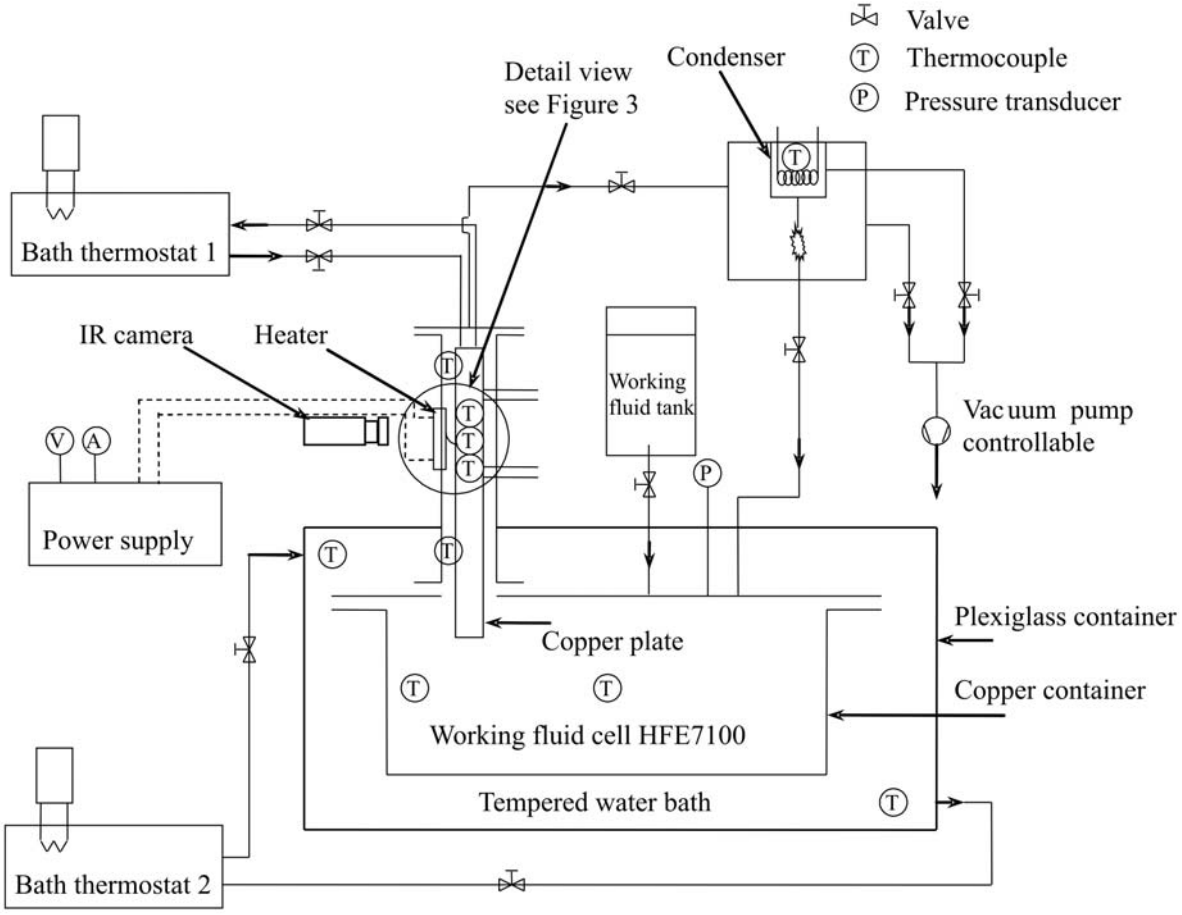

Figure 2. Flow chart of the experimental setup

The calibration of the infrared camera measurements is performed as follows. The unheated side of the channel (the copper plate of 10mm thickness) is moved toward the heating foil until a good thermal contact with the heating foil is reached. A uniform temperature of the copper plate is maintained by pumping heated water through internal heating passages manufactured within this plate. The infrared radiation from the back side of the heating foil is calibrated in the range from 10°C to 90°C.

The working fluid is carefully degassed before each experiment. The experiment is conducted at pressure of 510 mbar corresponding to saturation temperature of 41.6 °C, while the subcooling of the working fluid varies in different experiments from 3 to 6.5 K. The input heat flux to the heating foil varies from 183W/m^2 to 12.170 kW/m^2.

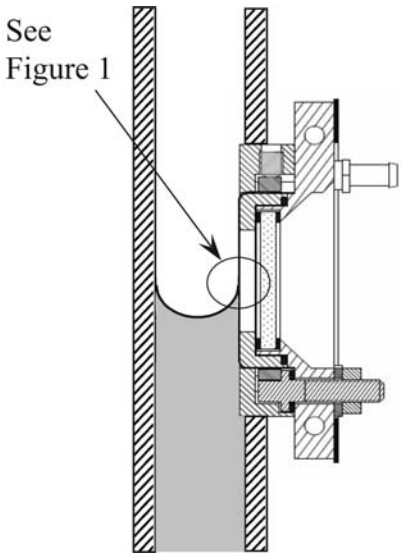

Figure 3. Channel detailed view

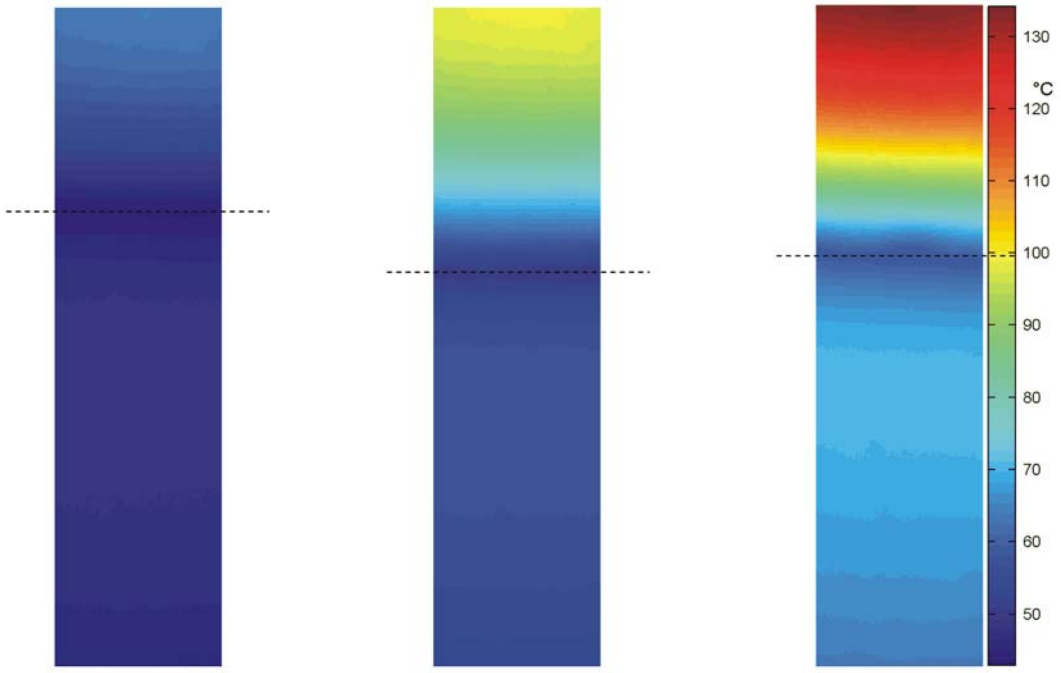
EXPERIMENTAL RESULTS

Local wall temperature and heat flux distributions underneath evaporating meniscus are presented in this section.

Figure 4 shows the two-dimensional wall temperature distributions underneath the evaporating meniscus at different input heat fluxes. It is observed that the temperature of the apparently dry region (or a region covered with adsorbed layer) is much higher than the temperature of the liquid bulk. The difference between these temperatures depends on the input heat flux. The temperature at the adsorbed layer region is high due to the very slow heat transfer in the vapor. The temperature distribution clearly shows a local minimum just underneath the 3-phase contact line separating the bulk liquid area from the apparently dry wall area. This temperature minimum is caused by strong evaporation near the contact line which is represented in Fig. 4 by horizontal dashed lines.

The difference between the minimal temperature near the 3-phase contact line and the mean bulk fluid temperature ranges from ~0.4 K to ~12 K depending on the input heat flux. The difference between the minimal temperature at the contact line and the wall temperature in the adsorbed layer region ranges from ~1.4 K to ~70 K depending on the input heat flux and on the position of the contact line which affects the percentage of wetted area of the heater. The temperature in the apparently dry adsorbed layer region increases with increasing of the dry area.



a) q= 3.425kW/m^2 b) q= 6.510kW/m^2 c) q= 10.645kW/m^2

Figure 4. Two dimensional local wall temperature distribution underneath the meniscus at different input heat fluxes (dashed line at the location of contact line area)

Figure 5 shows local wall temperature distribution along a vertical line underneath the meniscus at different input heat fluxes. The zero position on the *x*-axis coincides with the position of the contact line area defined as the location of the local temperature minimum. Negative *x*-values correspond to the liquid bulk region, and positive *x*-values correspond to the adsorbed layer region or the vapor

region where the temperature raises to high values. It has been observed that at high heat fluxes (above 9.5 kW/m^2) the liquid front is not stable, and some bubbles are formed and disturb the meniscus. At lower heat fluxes (3.4 to 9.5 kW/m^2) the liquid front seams to undergo a slow oscillatory motion which can be attributed to the instability of evaporating 3-phase contact line.

The local heat flux from the heater to the meniscus is calculated from the temperature distribution using the energy balance for each pixel element and two successive temperature images [10]. The heating foil is discretized in elements of the infrared camera pixels of 14.8µm × 14.8µm using a Matlab procedure. It is assumed that the back side of the heating foil is adiabatic thanks to the good thermal insulation provided by an air chamber at reduced pressure at the back of the heating foil. It is also assumed that there is no temperature difference between the front and the back side of the heating foil due to the small thickness of the heater.

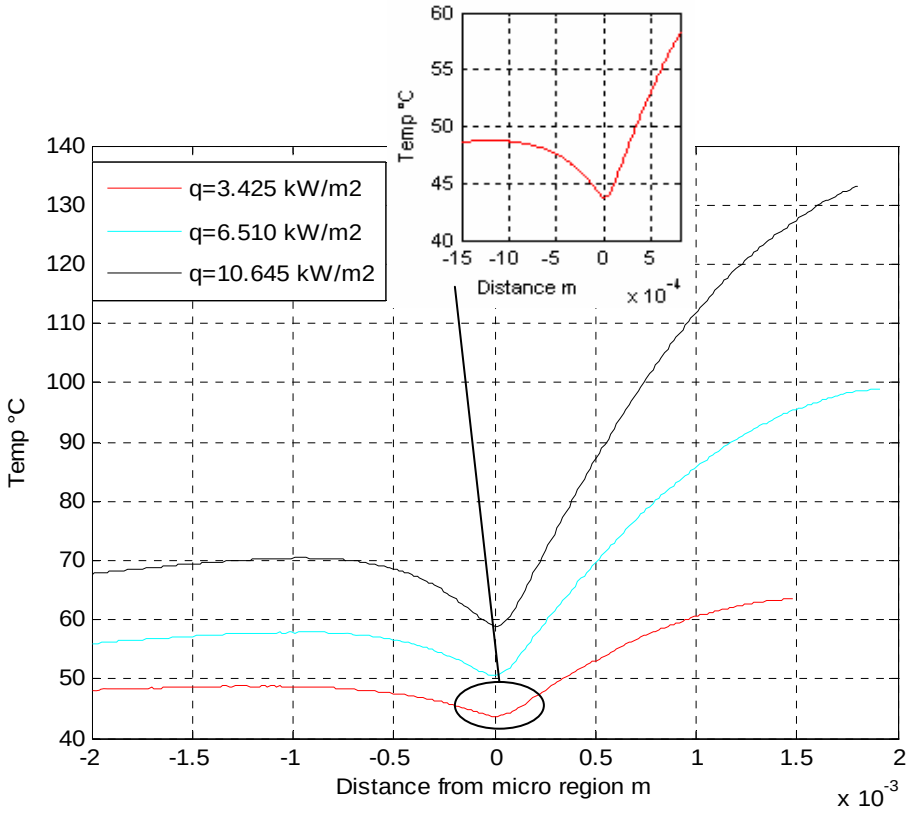


Figure 5. Linear local wall temperature distribution underneath the meniscus at different input heat fluxes

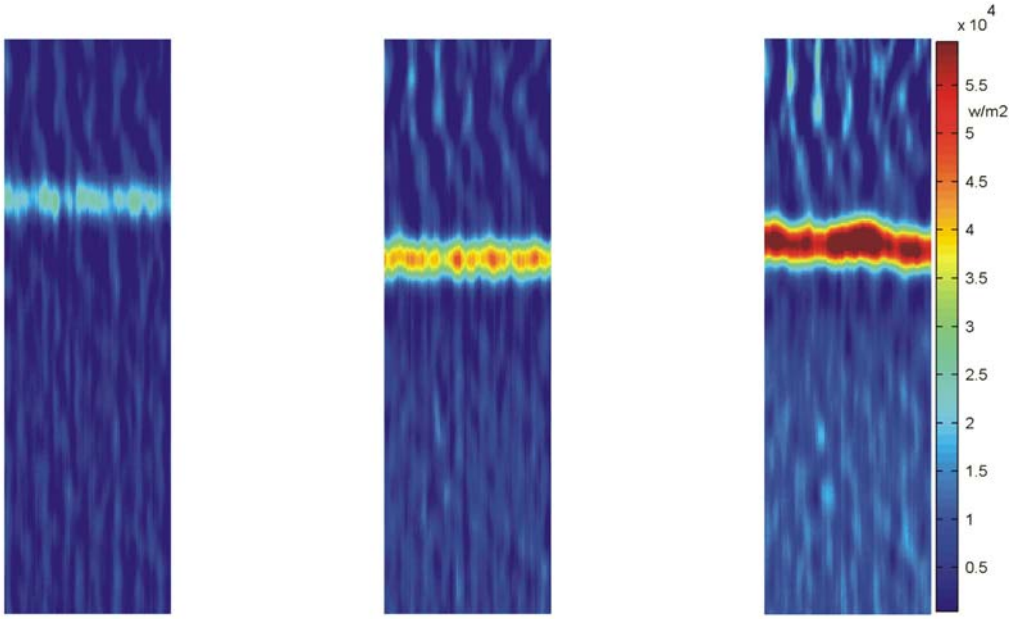
Figure 6 shows calculated two-dimensional heat flux distributions. It can be observed from this figure that the heat flux reaches a maximal value near the 3-phase contact line, even so the power input to the foil is constant and the heat generation is uniform in the heating foil. The local maximum of the heat flux is due to the high evaporation rate predicted for the contact line region, and due to conduction in the foil from neighbouring zones where the temperature is high. These phenomena are affected dramatically by the heating foil thickness, thermal conductivity, density, and heat capacity. Therefore, these properties of the heating foil are important for the modelling of the transport processes at the micro-region. Figure 7 shows the local heat flux distribution along a vertical line for different input heat fluxes. It can be observed that the heat flux in the liquid bulk decreases slightly due to heat conduction in the heating foil and due to the decreasing of the liquid

film thickness in the liquid bulk. The heat flux strongly increases at the contact line area, corresponding to the high evaporation region. The maximal heat fluxes at the contact line area exceed the mean heat fluxes by a factor of 5.4 to 6.5. The heat fluxes in the adsorbed layer region are lower than that in the bulk liquid.



a) q= 3.425kW/m^2 b) q= 6.510kW/m^2 c) q= 10.645kW/m^2

Figure 6. Two dimensional local calculated heat flux distribution to the meniscus for different input heat fluxes

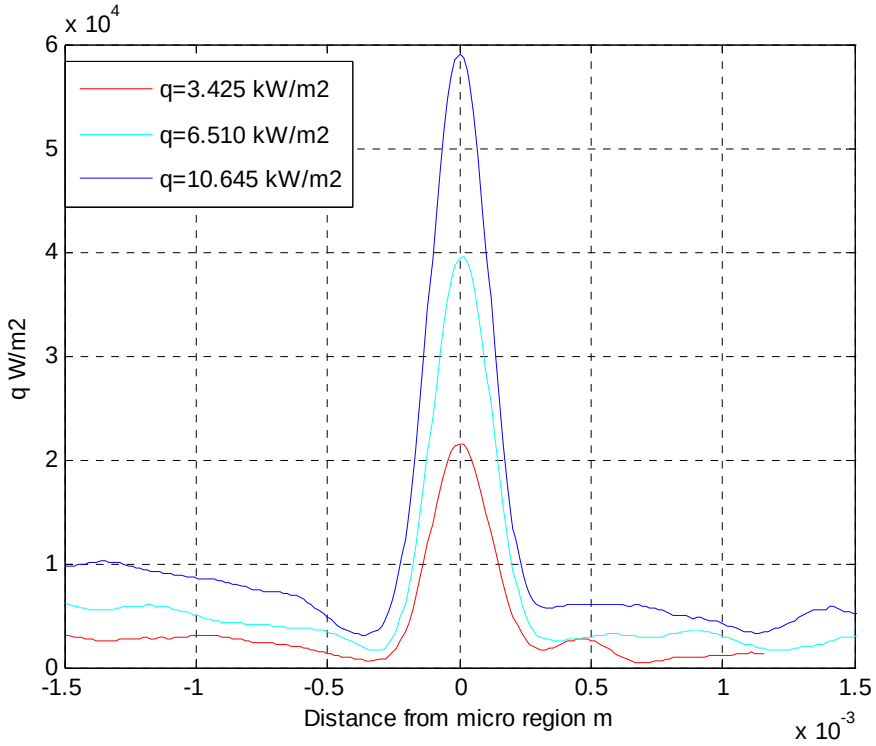


Figure 7. Linear local heat flux distribution for different input heat fluxes

CONCLUSIONS

An infrared thermography system was used to measure two-dimensional temperature distribution underneath a single evaporating meniscus in the contact line area with a high spatial resolution of 14.8 μm × 14.8 μm. Due to extremely high local evaporation rate in this area a temperature difference up to 12 K between the wall temperatures at the contact line area and the bulk liquid has been observed. The local heat flux distribution from the heater to the fluid has been calculated from the measured wall temperature distributions for constant uniform input heat fluxes.

High local heat fluxes could be observed at contact line area with values up to 5.4-6.5 times higher than the mean input heat fluxes. The experimental observations confirm the results of theoretical and numerical studies predicting strong local temperature gradients in the contact line area due to locally high evaporation rates.

EXPERIMENTAL INVESTIGATIONS ON AIR ENTRAINMENT BY MEANS OF IMPINGING JETS

D. V. Danciu*, M. J. da Silva, M. Schmidtke, D. Lucas
Institute of Safety Research, Forschungszentrum Dresden-Rossendorf e.V., Germany

ABSTRACT. The phenomenon of air entrainment as a result of an impinging water jet was experimentally studied by means of videometry and image processing methods. A series of experiments at different conditions was performed and evaluated. Each experiment consisted of a 10s recorded sequence with a frequency of 200Hz. Jet lengths varied between 0.01m and 0.2m and jet exit velocities ranged between 0.8m/s and 2.5m/s. Image processing algorithms were applied to extract information about jet penetration depth, width of the bubble plume and bubble size distribution. Therefore, images were subdued to background subtraction, binarization and averaging. Bubble sizes were estimated from single images by subsequent background subtraction, cell segmentation, bubble detection and bubble size calculation by means of a Hough-transform based algorithm. It was found that the bubble sizes were in accordance to the data present in the literature. The penetration depth of the plume was compared to an empirical formula presented by Bin in the literature. It was established that in addition to the impact velocity, the amount of entrained gas has a significant effect on the penetration depth.

Keywords: *air entrainment, impinging jet, image processing, penetration depth, bubble size*

INTRODUCTION

A water jet impinging on a free surface of a pool causes air entrainment as soon as the jet velocity is high enough (inception velocity). A swarm of bubbles appears as result of the impingement. Impinging jets may be applied in several industrial processes and also in different situations related to reactor safety analysis. The primary example for the application of impinging jets in reactor safety systems is the emergency core cooling (ECC) injection into a partially filled cold leg, which takes place in some scenarios of loss of coolant accidents. In this case, the injected cold water impinges as a jet on the surface of the hot water inside the cold leg. Depending on the velocity of the jet, steam bubbles may be entrained below the surface by the impinging jet. These bubbles contribute to heat exchange and mixing of the fluids. Heat transfer between cold and hot water and mixing in the cold leg play an important role since the mixed water enters the reactor pressure vessel and may cause high temperature gradients at the wall of the vessel (pressurized thermal shock).
The mechanism of air entrainment has been studied over the past years. Recent works in this area are those of Chirichella et al and Cummings and Chanson. The experiments described in [6] studied air entrainment produced by a translating axisymmetric laminar water jet and established three boundaries between the entrainment regimes. In [7] air entrainment was studied by means of visualization experiments. The inception conditions of air-water flows were found to depend critically upon the jet turbulence. Even though many studies have been made regarding air

entrainment caused by means of impinging jets, there is a certain lack of systematic data in the literature with regard to the penetration depth of the bubbles and the gas void fraction.
Our experimental setup was developed so that it allows studying the air entrainment phenomenon under different velocity and jet length conditions and to validate the models implemented in the CFD codes against the experimental data.

EXPERIMENTAL SETUP

Figure 1 shows a schematic of the experimental setup. The experiments were carried out in a 0.3m x 0.3m x 0.5m water tank constructed with transparent acrylic walls for visualization purposes. The water level in the tank was kept constant at 0.28 m throughout the experiments. Water was pumped out of the tank and re-injected through a smooth 6 mm diameter, 50 mm long steel pipe used as nozzle to produce a vertical falling round jet. A rotameter was used for the measurement of the flow rate. Images of the impact between the jet and the water pool were captured by a high-speed camera (DRS Technologies). For each experimental condition, a sequence of images of the region below the surface was taken. The camera was operated with a frame rate of 200 frames per second. Backlighting with high luminosity LED panels was used during the experiments in order to have a proper exposure at the required filming rate.
Experiments were realized for different nozzle heights (L_j in Figure 1) and volumetric flow rates, with both tap- and de-ionized water.
The experiments consisted in a vertical liquid jet of different lengths and velocities impinging on the calm surface of the water pool at an angle of 90°. The velocity of the jet ranged between 0.9 m/s and 2.5 m/s at the nozzle exit and the jet length was varied between 0.01 m and 0.2 m.

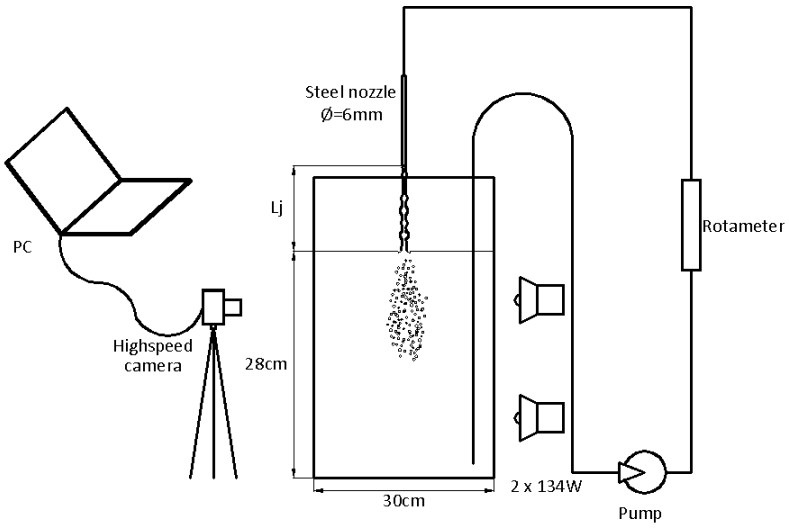

Figure 1. Schematic of the experimental setup

The velocity of the jet at the plunge point is calculated as:

$$v_j = \sqrt{v_0^2 + 2gL_j} \tag{1}$$

where v_0 is the velocity of the jet at the nozzle exit, L_j is the jet length and g the earth acceleration. In (1) free falling is assumed for the water after leaving the nozzle.

OBSERVATIONS

In some cases it is difficult to determine the conditions for the inception of air entrainment. Air entrainment can also occur for a very short period of time immediately after the impact, regardless of the nozzle height and the velocity of the jet. However, our discussion regards only cases of fully established flow.

Similar to [6], where it was stated that the incipient air entrainment takes place with the appearance of at least one bubble, in the absence of other bubbles in the water pool, which lasts longer than 2s beneath the surface of the pool, we also observed three distinct entrainment regimes during our experiments.

- The first regime is the one where during the impingement no bubbles appear; although for all our experimental conditions we had a fully turbulent flow developed in the nozzle (Re > 2300).
- The second one is the medium entrainment regime, where either only one or two bubbles appear after a period of time, remain trapped under the surface for a short time and disappear after a few seconds (incipient entrainment), or a swarm of bubbles is being entrained from time to time (intermittent entrainment).
- The last regime is that of continuous air entrainment, when large air pockets and bubble swarms are continuously being entrained.

Figure 2 illustrates the distribution of the entrainment regimes dependent on impact velocity and jet length for all experimental conditions. Both tap- and de-ionized water exhibit the same behavior.

The velocity of the jet and its diameter are affected by the gravity. According to [1], the jet diameter, d_j, can be calculated as a dependence on a reference diameter which was experimentally calculated for L_j = 3cm. However, if we consider the conservation of the mass flow rate, we can also calculate the jet diameter at the impact as a function of the jet diameter at the nozzle, d_0, and of the jet impact velocity as:

$$d_j = d_0 \sqrt{\frac{v_0}{v_j}} \tag{2}$$

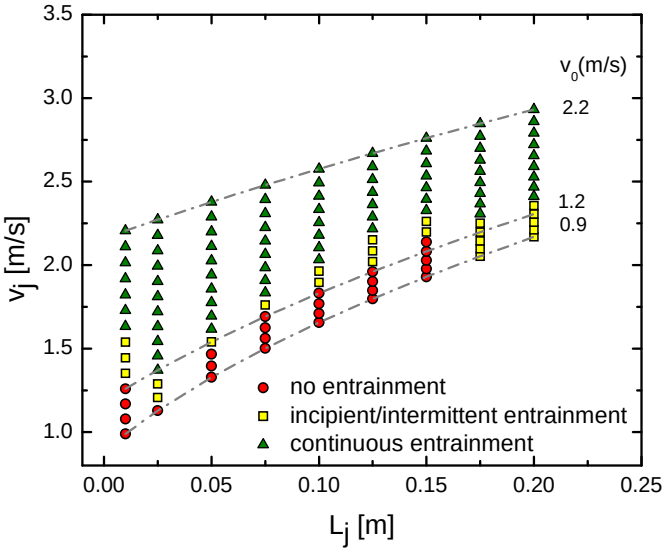

Figure 2. Entrainment regimes as a function of v_j, the jet impact velocity and the jet length, L_j.

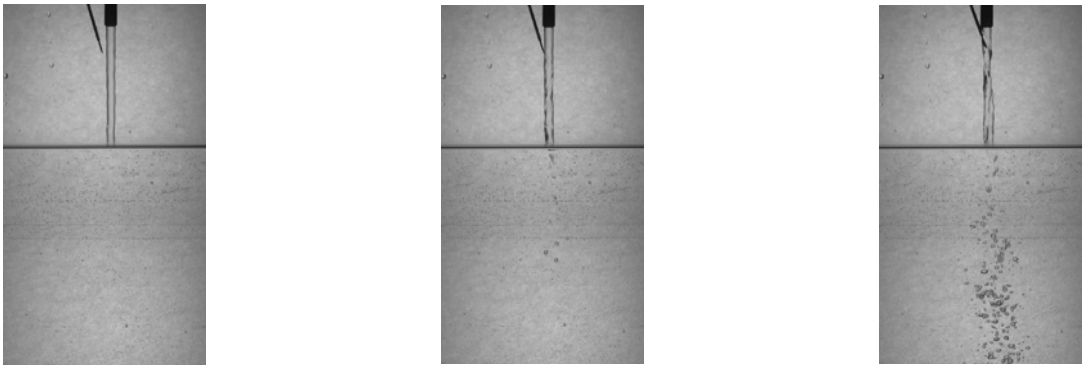
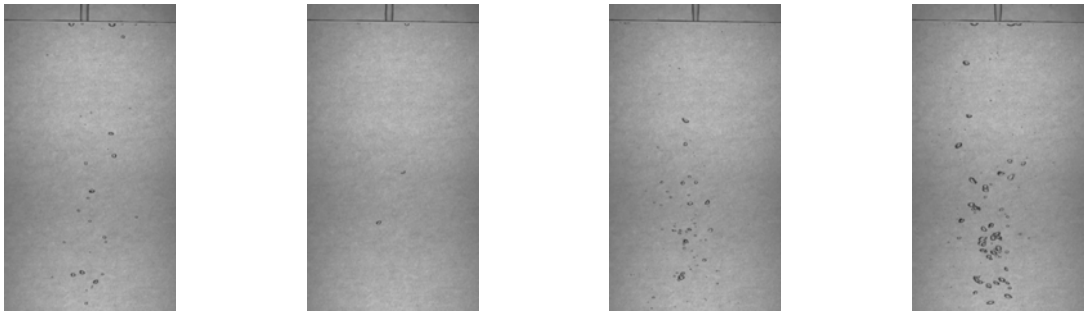
Applying equation (2) the jet diameter at the impact with the pool surface suffers a change, especially for the higher jet lengths, when the jet diameter at the impact with the pool represents only ca 75-85% of the initial jet diameter.
An important role in the occurrence of air entrainment is played by the roughness of the jet. To prove the importance of the jet surface disturbances in the entrainment process, our experiments include tests where a 7.5 cm long jet which did not entrain air was disturbed with a thin needle. Due to the appearance of waves and thus an increase of the surface roughness of the jet, air entrainment takes place. The number of the entrained bubbles is proportional to the duration of the disturbance. We also observed that if the tip of the needle barely touches the jet, only a small number of bubbles appears and the bubble sizes are smaller than in the case of a deeper disturbance, when the bubbles are larger and present in a larger number. Figure 3 presents such an example.



a. b. c.

Figure 3. Sequence presenting the influence of jet surface disturbances on air entrainment
a. no entrainment (undisturbed jet); b. superficial disturbance; c. deep disturbance

The length of the jet along with the gravitational acceleration plays an important role in the inception of air entrainment. For different flow rates, air entrainment does not occur. As soon as the length of the jet is being increased even with just a few millimeters, air entrainment occurs.
A distinctive and interesting situation takes place for v_0=1.2 m/s (for both tap- and de-ionized water), where all entrainment regimes are present. They vary with the jet length, starting with no entrainment, then jumping directly to the continuous entrainment regime, switching to incipient/intermittent entrainment followed by no entrainment for several jet lengths, returning to intermittent entrainment and continuous entrainment. Figure 4 presents the pictures corresponding to the jet lengths for which air entrainment takes place. It is important to mention that our experiments are reproducible.



L_j = 0.025 m L_j = 0.05 m L_j = 0.175 m L_j = 0.2 m

Figure 4. Air entrainment at v_0 = 1.2 m/s

METHODOLOGY AND ANALYSIS

The objective of our experiments was to gather information about the bubble size distribution, the penetration depth of the plume, the width of the plume and their variation in time.
In each experiment a sequence of 2000 frames was recorded. The flow rate and length of the jet were varied for each experiment. Image processing algorithms were applied to extract the sought information. The experiments involved two types of water: tap water and de-ionized water.

Penetration depth

During the experiments, we observed that the length of the jet plays an important role in the entrainment process. We determined the variation of the penetration depth in time for different experimental conditions. Due to the fact that the plume fluctuates, one cannot refer to the penetration depth at a distinct moment. The variation of the penetration depth is shown in Figure 5 for three different nozzle exit velocities, but equal impact velocity. The penetration depth was calculated as the deepest point toward which bubbles travel, for each single frame of the respective recorded sequences. Therefore, considering the temporal fluctuation of the penetration depth, the best way to find it for a set of experimental conditions is to average it over the entire sequence.

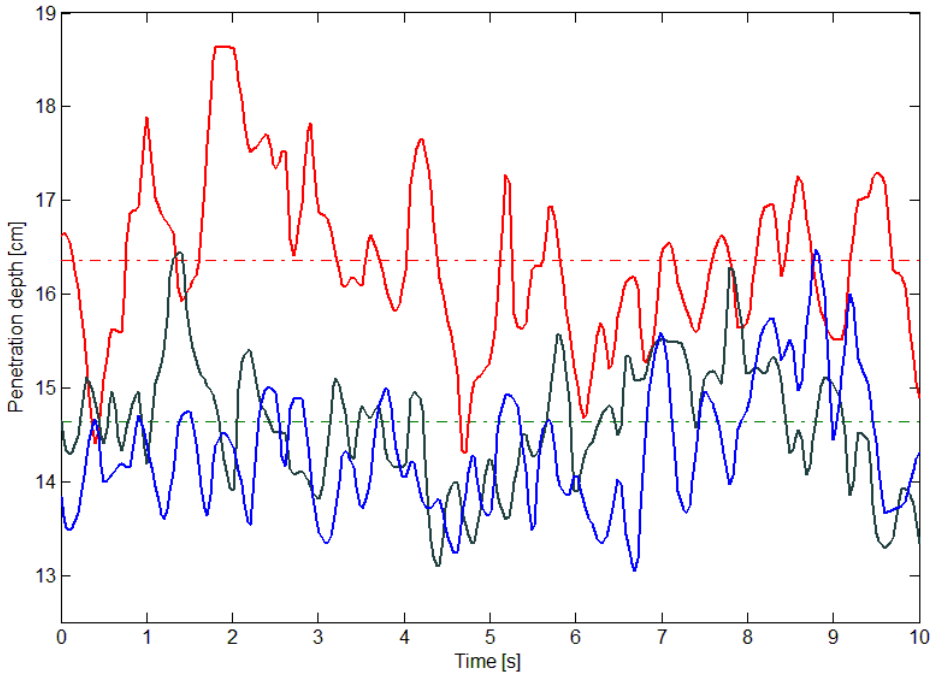


Figure 5. Penetration depth variation in time for v_0=1.8 m/s (red), v_0=2 m/s (green) and v_0=2.2 m/s (blue)

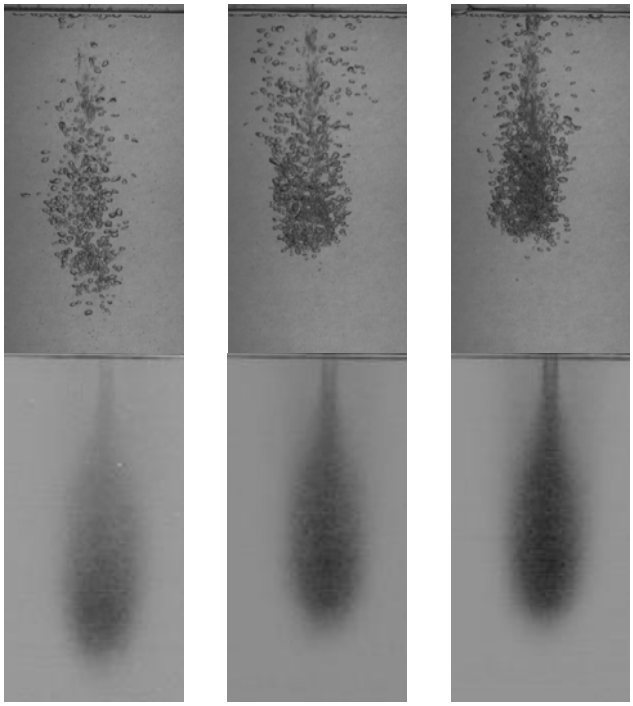
The mean penetration depth obtained with the above described method is in concordance with the values obtained by applying the averaging method described below.
Images were subdued to background subtraction, removal of the small air bubbles at the walls and averaging. Our algorithm averages over the entire 2000 frames sequence. It is noticeable in the averaged imagine (Figure 6, bottom) that, at the tip, the plume is rarefied, meaning that only a small amount of bubbles travels that deep. Therefore, we have chosen to consider as penetration depth the first grey level value from the bottom of the plume which represents only ten percent of the maximum grey level value of the averaged plume, found usually in the core of the plume.

Figure 6 shows an example of the penetration depth variation for three different nozzle exit velocities, but identical impact velocity, v_j = 2.5 m/s. The penetration depth of the air bubbles decreases with the increase of the impact velocity, most of the time. The difference between the first two cases is obvious and, although between the next two cases the penetration depth only varies with ca. 0.5 cm, one can easily note the difference in the volume of entrained air for all three examples. The plume becomes denser with the velocity and, due to the fact that the buoyancy forces surpass the viscous drag exerted by the downward moving jet, the plume retracts towards the surface of the water.



v_0=1.8 m/s L_j=15 cm | v_0=2 m/s L_j=12.5 cm | v_0=2.2 m/s L_j=7.5 cm

Figure 6. Example of the penetration depth variation for constant impact velocity v_j=2.5 m/s, for the three different nozzle exit velocities and jet lengths: snapshots (top) and processed sequences (bottom) for tap water

According to Bin [1], the penetration depth can be calculated as:

$$H_p = 2.1 v_j^{0.775} d_0^{0.67}$$

which means that for constant impact velocity, the penetration depth should be constant. The penetration depth as a result of equation 3 is found between 12 cm and 16 cm for impact velocities between 2 m/s and 3 m/s. Figure 6 shows the variation of the penetration depth for three different nozzle exit velocities and different jet lengths for tap water, as a result of our image processing algorithms. We observe that the behavior of the penetration depth is not monotonous with the impact velocity, opposite to equation 3. The values of the penetration depth for the de-ionized water experiments are found in the same range and follow the same trend as in the case of tap water. They slightly vary from the values obtained for tap water and this might be due to the difference between the surface tensions of the two fluids, induced by the bipolar molecules and unipolar ions present in the tap water which increase its surface tension. However, the values of the penetration depth are

found in the range given by Bins' formula, although we get different penetration depths for the same impact velocity and nozzle diameter (but different nozzle velocities and jet lengths). In our experiments we vary the impact velocity by modifying the length of the jet and the nozzle exit velocity. We can observe that for v_0 = 2 m/s and v_0 = 2.2 m/s, the penetration depth has a downward trend (see Figure 6). It first decreases with the jet length and then fluctuates slightly between 13 and 14 cm. By increasing the jet length for a constant nozzle exit velocity, we increase the impact velocity and the jet momentum transport into the pool. This should lead to a higher penetration depth, as predicted by equation 2. The penetration depth does not increase, though, with the impact velocity. This might be caused by the fact that for higher jet lengths the gas void fraction inside the plume increases, thus counteracting the jet momentum by buoyancy driven friction. Hence, the two opposite effects are responsible for the behavior of the penetration depth. In the case of v_0 = 1.8 m/s the penetration depth behaves non-monotonously, similar to the entrainment behavior in Figure 4. In Figure 4 (v_0 = 1.2 m/s) the amount of entrained gas varies not monotonous with the jet length. This indicates that the jet surface instabilities which trigger gas entrainment do not increase monotonous with the jet length. Maybe different kinds of surface instabilities play a role here: surface instabilities triggered by the nozzle edge and surface instabilities which grow with the jet length, such as Rayleigh instabilities.

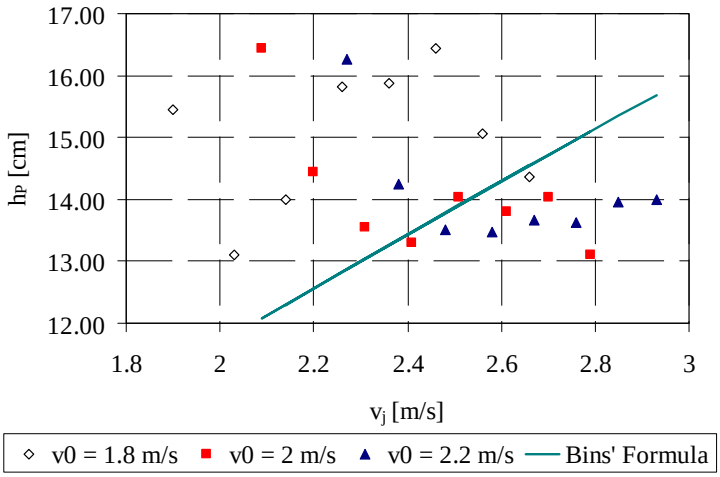


Figure 7. Processed penetration depth variation for three different nozzle exit velocities and jet length ranging between 0.025m and 0.2m (tap water)

Bubbles size distribution / estimation

Bubble sizes were estimated from single images by means of image processing through subsequent background subtraction, cell segmentation, bubble detection and bubble size calculation by means of a Hough transform based algorithm. It was found that the latter algorithm could only be used for experiments with a small number of bubbles in the plume. Otherwise, bubbles sizes could only be estimated at the edge of the plume where the bubbles do not overlap. Figure 7 shows an example of detected bubbles in a thin plume.

The Sauter mean diameter in the region of the rising bubbles was about 3 - 4mm, in agreement with previous data from the literature [1]. The smallest measurable bubbles were found to range between 0.3mm and 1.5mm. Some of the largest bubbles had diameters around the value of 7mm.

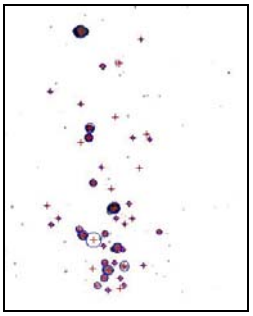

Figure 8. Image with bubbles detected (centre positions and radii marked)

CONCLUSIONS

To study the phenomenon of air entrainment by means of impinging circular jets, a video observation technique was used. Experiments have been carried out in a square tank for various jet exit velocities and jet lengths. The experimental data was processed and will be further used to validate the models implemented in CFD.

Some key parameters in air entrainment occurrence are: the velocity of the jet, the physical properties of the liquid, the length of the jet (falling height) and the turbulence of the jet. The penetration depth of the plume was measured and compared with an empirical formula by Bin. It has been found that in addition to the impact velocity, the amount of entrained gas has a significant effect on the penetration depth.

Further experiments are planned at FZD for a better observation of the liquid field velocities by means of PIV methods and quantitative void fraction measurements with x-ray radiography.

THE EFFECT OF CROSS FLOW ON MULTIPLE JET IMPINGEMENT HEAT TRANSFER ON A CONCAVE WALL

N. Yoshida[1], K. Takeishi[1,*], Y. Oda[1], H. Maeda[1]
[1]Department of Mechanical Engineering, Osaka University, Osaka, Japan

ABSTRACT. Multiple jet impingement heat transfer on a concave surface was investigated by naphthalene sublimation techniques for one-row jets and three-row jets with cross flows. The experiments were conducted for Re = 5000 at cross-flow/jet velocity ratios of 0.15, 0.2, 0.25, 0.3, and 0.4, at the nozzle to plate distance of 3.75d. The location of the maximum local Nusselt number was found to move downstream as the cross-flow rate increases. When the cross-flow/jet velocity ratio increases from 0.25 to 0.35 in one-row jets (and 0.3 to 0.4 in three-row jets), the maximum Nusselt number decreases dramatically. In addition, locally high Nusselt number regions were observed between the neighbouring jets and show streaky distributions due to the collisions of wall jets, while they gradually disappear as the cross flow rate increases.

INTRODUCTION

The demand for higher efficiency in combined cycle power plants is to be met by raising the turbine inlet temperature of gas turbines. High temperature heavy-duty gas turbines have been actively developed and the turbine inlet temperature of the latest one reaches a level of 1770 K. As the turbine inlet temperature increases further, the turbine first vane and blade will be exposed to a higher temperature gas stream and will be subjected to severer thermal conditions. Thus, sophisticated cooling schemes such as impingement cooling, film cooling and pin fin cooling have been adopted to maintain the turbine vane and blade under the allowable metallurgical temperature limit. Especially, the effective removal of locally concentrated heat by impingement jets has been utilized to cool the inner surface of the vane's leading edge, which is exposed to high temperature and subjected to high heat flux. Since the high heat transfer rate at the stagnation region decays rapidly in the wall jet region, multiple jet impingement cooling has been employed in real gas turbines to eliminate the excessive thermal load on the leading edge of gas turbine vanes.

Since the leading edge of the turbine vanes has concave surfaces, it is important to investigate the effect of the curvature on the multiple jet impingement heat transfer. Chupp et al. [1] and Metzger et al. [2] investigated the effects of jet-to-jet spacing and the nozzle to plate distance for impingement cooling with a row of circular jets on a semi-circular surface. Bunker and Metzger [3], Metzger and Bunker [4] suggested that the major influencing parameters are Reynolds number, leading edge shape, jet spacing and size, jet arrangement, the number of jet holes and the distance between jet exit and inner surface of leading edge. Gau and Chung [5] visualized the jet flow impinging on both convex and concave semi-circular surfaces and showed the distinctive characteristics of flow and heat transfer on these surfaces. They also showed that Nusselt number increased as the curvature increased due to the vigorous vortex motion in the jet mixing region.

Hrycak [6] studied heat transfer from a row of impinging jets to concave cylindrical surfaces. Choi et al. [7] studied the impinging jet flow and heat transfer on a semi-circular concave surface. However, earlier studies [8] on multiple impinging jet on concave walls employed thermocouples embedded in heated target plates. Thus, the resolution of Nusselt number profiles has been limited and heat conduction loss along the target walls was inevitable. In addition, there are few studies on multiple impinging jet heat transfer including cross flow effect, which is important in real gas turbines.

Therefore, in this study, local Nusselt number distributions of multiple impinging jets on a concave target wall were measured in high resolution using the naphthalene sublimation technique, which is enhanced by a high-precision laser displacement gauge and a *x*-*y* automatic traverse with a stepping motor to control the angle of the laser gauge. The effect of curvature and cross flow on heat transfer was investigated. In addition, corresponding numerical simulations were conducted to investigate the capability to predict local Nusselt number distributions and the complex flow structures induced by the multiple jets on a concave wall with and without cross flow.

EXPERIMENTAL METHOD

Figures 1 and 2 show a schematic layout of experimental apparatus and the test section, respectively, for the naphthalene sublimation technique based on the analogy between heat/mass transfer. Dry air for generating multiple jets and cross flow was separately supplied to the test section by two air compressors with controlled flow rates. The test section consists of a half-cylindrical nozzle plate, a jet-supply chamber, a concave target plate, and sidewalls. The nozzle plate is 1 mm in thickness and has one row ($\theta = 0°$) or three rows ($\theta = -40.5°$, 0°, 40.5°) of in-line jet holes. Each row of jet holes on the nozzle plate has seven round holes of 2 mm in diameter with a pitch of 14 mm in *x* direction. Thus, the nozzle plate generates multiple impinging jets on the concave target surface covered with a naphthalene layer. Upstream of the nozzle plate, there was a flow-settling section equipped with mesh screens, in order to reduce the turbulence intensity and to form a uniform air flow at the exit. The air velocities at the exit of each hole on the nozzle plate were measured with a total pressure tube, and the non-uniformity of the velocity distribution was confirmed to be within 3%. The volume flow rate of air was carefully measured with a rotameter to maintain the nozzle exit velocity. Cross flow was supplied from an end of the flow channel, which is in between the nozzle plate and the concave wall, through a mesh screen located upstream.

The concave target surface was covered with a naphthalene molding, which has a half-cylindrical shape of 40 mm in diameter and 110 mm in width. To make the concave surface of solidified naphthalene smooth, following manufacturing steps has been conducted. Firstly, reagent grade

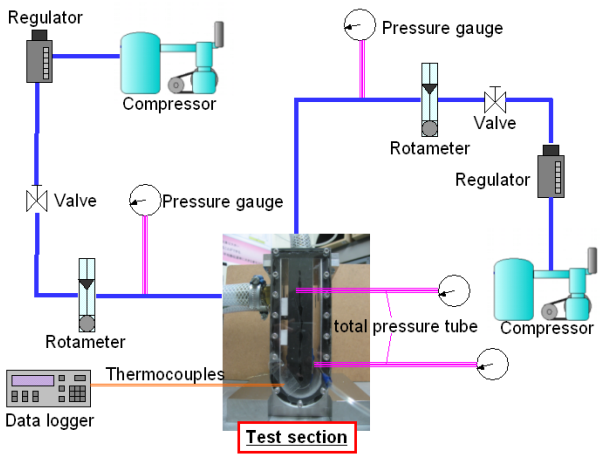

Figure. 1 Experimental apparatus

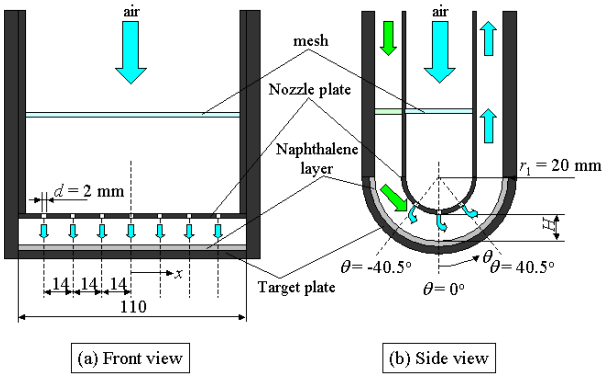

Figure. 2 Cross sectional view of test section

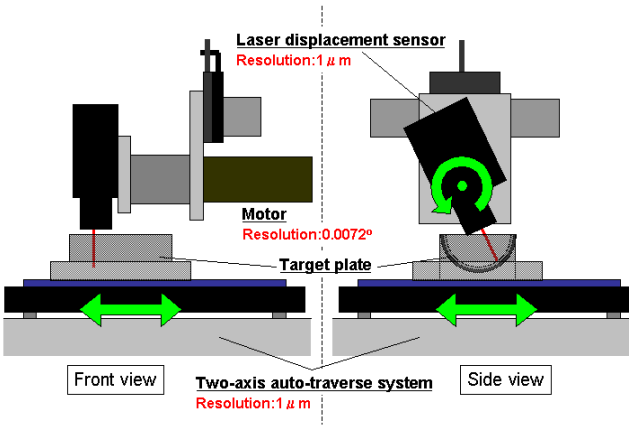

Figure. 3 Laser displacement sensing system

(98% pure) naphthalene crystals were melted on an induction heater until they boiled. After the naphthalene temperature became about 380 K, secondly, they were poured into the mold, which was preheated at about 330 K. After the mold was cooled to room temperature and naphthalene was solidified, thirdly, a cover plate of the mold was struck to be removed.

The naphthalene sublimation depth was measured with the apparatus shown schematically in Figure 3. It consists of a two-axis precision auto-traverse system, a laser displacement sensor, a stepping motor to control the angle of the laser gauge, a micrometer, a data logger, and a personal computer. Displacement was measured by the laser displacement sensor, which has the range of ±1 mm, with resolution of 0.1 μm and linearity error of 0.3%. The two-axis auto-traverse system has a resolution of 1 μm in each direction, and the stepping motor has a resolution of 0.0072°. Before air impinges on the naphthalene plates, the laser displacement sensor scanned the initial surface profile. The measurement range in the x direction was 50 mm and the scanning interval was 0.2 mm, whereas that in the θ direction was ±60° and the interval was 1°. The total scanning time was about 120 minutes. After the air impingement lasting for 20 minutes, the surface profile was scanned again. Then, the local naphthalene sublimation depth δ was calculated as the local change of surface position from the initial values. The local mass transfer coefficient at each location is calculated from the following relation:

$$h_D = \frac{RT_W}{P_W} \cdot \frac{\rho_S \delta}{t_e} \tag{1}$$

where R is the gas constant, T_w is the naphthalene surface temperature, p_w is the saturated vapor pressure of naphthalene in air, ρ_s is the density of solid naphthalene, δ is the depth of naphthalene sublimation, and t_e is the impinging time. The thermophysical properties of naphthalene were obtained from Goldstein and Cho [9]. The local mass transfer coefficient can be converted to the local heat transfer coefficient by using the analogy between heat and mass transfer:

$$h = h_D \rho C_p \left(S_c / P_r\right)^{1-n} \tag{2}$$

where ρ is the density of air, C_p is the specific heat at constant pressure, Sc is the Schmidt number, Pr is the Prandtl number, and n is the empirical constant being 0.4 in this experiment. Nusselt number is defined as $Nu = hd/\lambda$. The experiments were conducted at the nozzle to plate distance of $3.75d$ and Re = 5000, 10000, and 15000 without cross flow using one-row jets, and for Re = 5000 with cross flows at cross-flow/jet velocity ratios of V_c/V_i = 0.15, 0.2, 0.25, 0.3, and 0.4, using one-row jets and three-row jets.

NUMERICAL METHOD

In this study, numerical simulations using FLUENT 6.3 were also conducted to compare the predicted results with measured data obtained by naphthalene sublimation technique, for the case of three row jets at Re = 5000 and V_c/V_i = 0, 0.15, 0.2, 0.3, and 0.4. Figure 4 (a) shows an overall view of the computational domain, which includes a jet-supply chamber before nozzle exits to ensure appropriate profiles of velocity and turbulent quantities at the nozzle exit. Assuming periodic flows

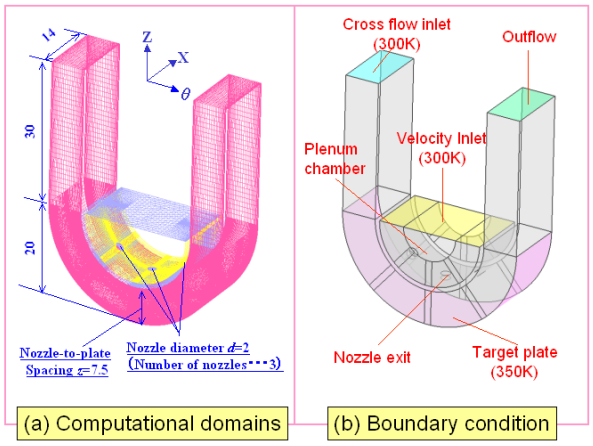

Figure. 4 Computational domains

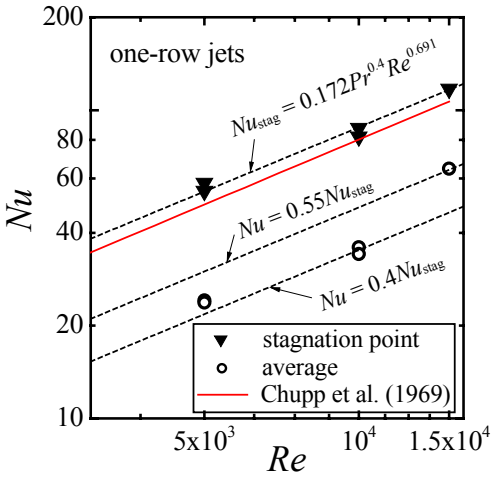

Figure. 5 Nusselt number at stagnation point

in x direction, only a single array of nozzles in the mid-plane (x = 0) was included in the domain. The number of total cells was 1,400,000. The grid spacing in the wall normal direction on the target surfaces satisfies $y^+ < 2$.

For a turbulence model, a realizable k-ε model was used with an option of the enhanced wall treatment, which is a near-wall modeling method that combines a two-layer model with enhanced wall functions and can consider the pressure gradient effect near the wall [10]. For the prediction of turbulent heat fluxes, a constant turbulent Prandtl number, Pr_t = 0.85, was used assuming the direct analogy between the turbulent heat transport and momentum transport. For stable computations, a first-order upwind differential scheme was employed to discretize the convection terms of momentum, turbulent kinetic energy and its dissipation rate. For the convective term of energy equations, a 2nd-order upwind scheme was employed.

Figure 4 (b) shows boundary conditions applied to each boundary. An appropriate magnitude of uniform velocities and temperature were applied to the top surfaces of the jet-supply chamber to achieve Re = 5000 at 300 K in the nozzles. Turbulent intensity of 0.5% was assumed at the inlet based on measurements by a hotwire anemometer. A uniform temperature of 350 K was applied to the target surfaces for a concave case to simulate the condition of naphthalene wall in the experiment.

RESULTS AND DISCUSSION

Figure 5 shows experimentally obtained relations between Reynolds number and the local Nusselt number at the stagnation point in the case of one-row jets for Re = 5000, 10000, and 15000 without cross flow, together with the averaged Nusselt number over $-20.25° \le \theta \le 20.25°$. By fitting these data using the least square method, the following empirical correlation was obtained.

$$Nu_{stag} = 0.172 Pr^{0.4} Re^{0.691} \quad (3)$$

$$0.4 \le Nu_{ave} / Nu_{stag} \le 0.55 \quad (4)$$

As shown in the figure, the present experimental data show a good agreement with the empirical relation by Chupp et al. [1].

Figures 6 and 7 show the experimentally obtained local Nusselt number distributions in one-row jets and three-row jets, respectively, for the cross-flow/jet velocity ratios of V_c/V_i = 0, 0.2, and 0.4. It is to be noted that the figures show normally-projected views of contours on concave target surfaces having a curvature, and thus the contour maps are scaled non-linearly in θ direction as indicated by

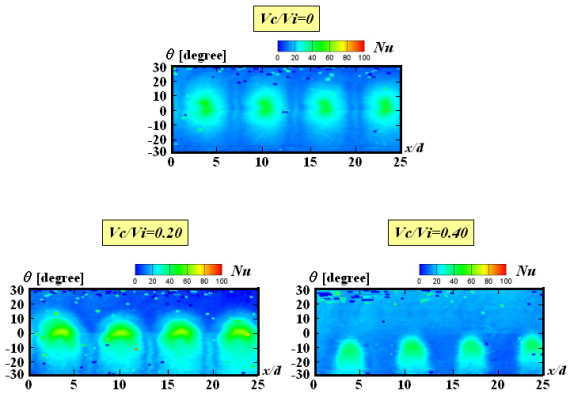

Figure. 6 Local *Nu* for one-row jets cases

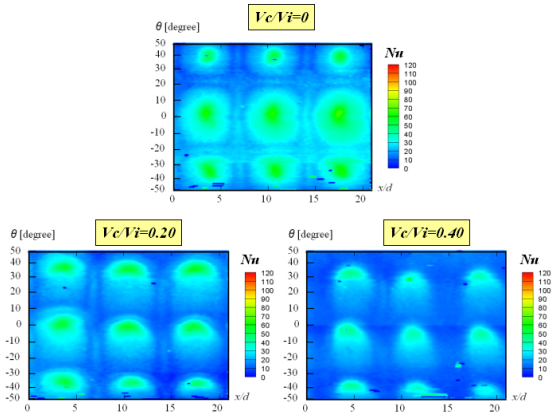

Figure. 7 Local *Nu* for three-row jets cases.

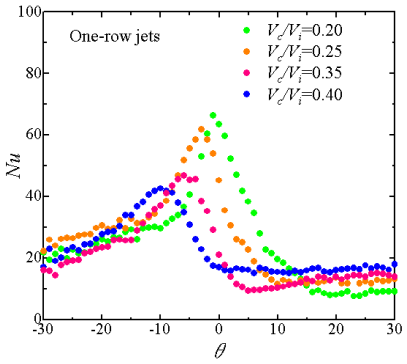

Figure. 8 *Nu* at x = const. on stagnation points for one-row jets cases

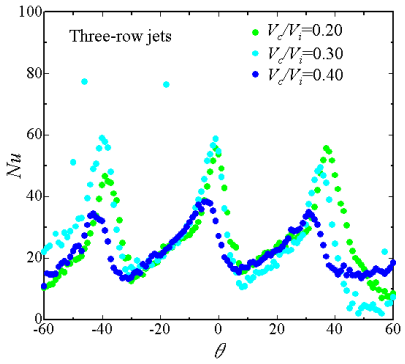

Figure. 9 *Nu* at x = const. on stagnation points for three-row jets cases

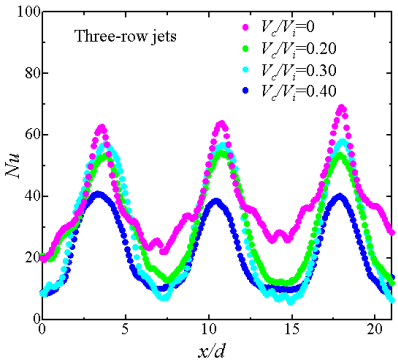

Figure. 11 *Nu* at θ = const. on stagnation points for three-row jets cases

non-uniform intervals of the ticks. Figures 6 and 7 clearly indicate that the location of the maximum local Nusselt number moves downstream from the geometrical center of each jet as the velocity ratio V_c/V_i increases. Therefore, heat transfer coefficient is lowered upstream the stagnation region of each jet and enhanced in the downstream region. The drift distance of local maximum Nusselt number in three-row jets is shorter than that in one-row jets, because the blocking of cross flow by the upstream jets occurs in the three-row jets case. In addition, locally high Nusselt number regions were observed between the neighboring jets and show streaky distributions in the θ direction at $V_c/V_i = 0$ in the one-row jets case. This indicates that collisions of wall jets occur there and affect the local heat transfer. In the three-row jets case, the locally high *Nu* region was found to surround each jet at $V_c/V_i = 0$. As the cross flow rate increases, the jet interacting regions begin to be drifted

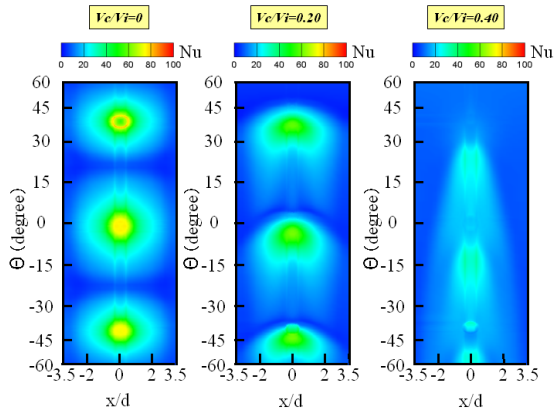

Figure. 12 Local Nusselt number on concave surface by numerical simulation

downstream and finally vanish away. This indicates that the strong cross flow weakens the impingement of jet on the target wall, which leads to weaker wall jets and their interactions, and finally results in the washout of wall jets.

Figures 8 and 9 shows the local Nusselt number distribution in a constant x line, which passes through the stagnation point, for the cases of one-row jets and three-row jets, respectively. It can be quantitatively confirmed that the cross flow rate has a strong effect on the local Nu distribution. As can be seen in Figures 6 and 7, an increase of cross flow rate decreases the maximum Nusselt number and washes out the peak position downstream. Especially, when V_c/V_i increases from 0.25 to 0.35 in one-row jets (and 0.3 to 0.4 in three-row jets), the maximum Nusselt number decreases dramatically. On the other hand, in case of one-row jets, Nusselt number increases at $15° < \theta < 30°$ when V_c/V_i changes from 0.2 to 0.4. This indicates that heat transfer augmentation by cross flows becomes larger than that by impinging jets at the region when V_c/V_i is large.

Figures 10 and 11 show the experimental results of local Nusselt number distributions in constant θ lines, where the maximum Nu were observed, for the cases of one-row jets and three-row jets, respectively. For all cross flow rates, Nu distributions of the one-row jets and three-row jets show similar values. Without cross flows, locally high heat transfer region, i.e. wall-jet interaction regions, can be clearly observed in between the impinging jets both for one-row and three-row jets cases. As the cross flow rate increases from $V_c/V_i = 0$ to 0.2, the wall-jet interaction region disappears, while the maximum Nu at the stagnation point is not affected much by cross flows. This indicates that the cross flow circumvents the impinging jets and flows through between the impinging jets, washing out the wall-jets downstream. As the cross flow rate further increases from $V_c/V_i = 0.2$ to 0.4, the maximum Nu decreases dramatically, as seen in Figures 8 and 9. This is because the strong cross flow bends the impinging jets in the cross flow direction and the potential core region of the jet cannot reach the target plate, as seen later in the numerical simulations.

Figure 12 shows the local Nusselt number distributions by numerical simulations corresponding to the experiments for three-row jets cases at $V_c/V_i = 0$, 0.2, and 0.4. Figure 13 also shows the comparison of the predicted Nu distributions at $x/d = 0$ with those in the experiments for the three-

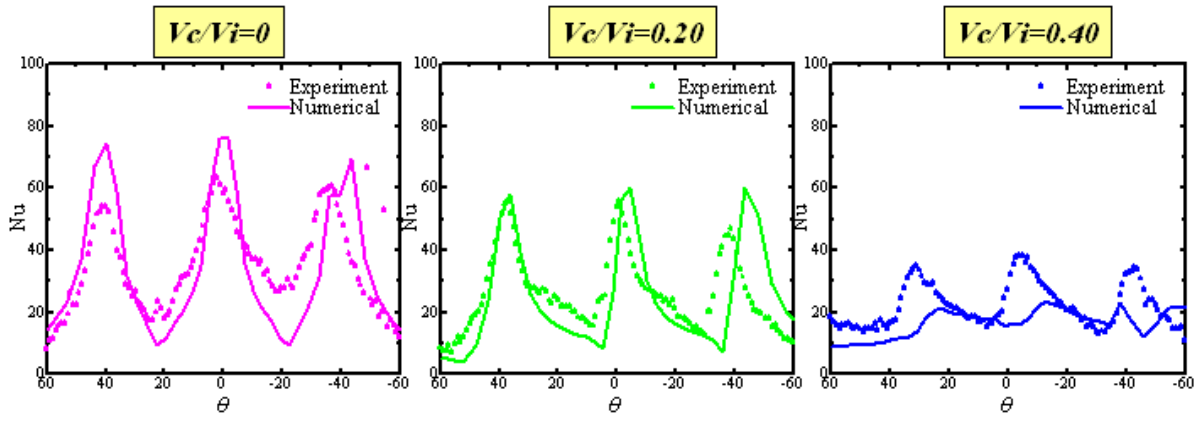

Figure. 13 Comparison of Nu at x = const. on stagnation points

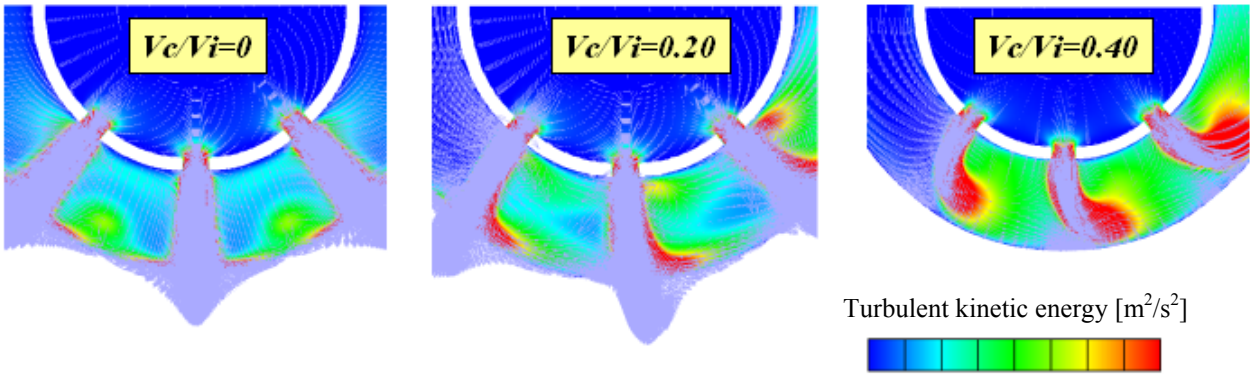

Figure. 14 Velocity vector fields with a contour of turbulent kinetic energy at $x/d = 0$

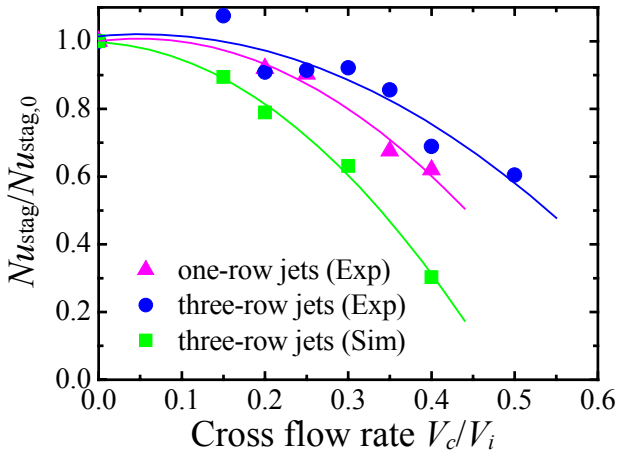

Figure. 15 Cross flow effect on stagnation Nusselt number

row jets case. The values of Nusselt number at V_c/V_i = 0 and 0.2 show similar profiles in acceptable agreement with experiments, while at $V_c/V_i = 0.40$ the present numerical simulation using a realizable k-ε model cannot predict the Nu distribution both qualitatively and quantitatively. In addition, it was found that the present simulation could not reproduce the wall jet interaction regions between the impinging jets. This indicates the limited capability of linear eddy viscosity models to predict such complex three-dimensional turbulent flows. Thus, other sophisticated turbulence models, such as non-linear eddy viscosity models, second moment closure models, hybrid RANS/LES, or LES, is required to capture the physical mechanism underlying this characteristic phenomena. In this sense, the present experimental observation gives interesting data to evaluate the prediction capability of turbulence models.

Figure 14 shows numerically predicted velocity vector fields of y and z components with contours of turbulent kinetic energy fields at $x/d = 0$ plane for the case of $Re = 5000$ at $V_c/V_i = 0$, 0.2, and 0.4. This figure clearly shows that the impinging jet from a nozzle plate is curved when a cross flow exists. Especially, at $V_c/V_i = 0.4$, impinging jet cannot reach the target plate, and a wall jet region seems to disappear at the upstream side of a cross flow. For V_c/V_i = 0 and 0.2, there are high turbulent kinetic energy regions above the stagnation regions, while no such region exists for V_c/V_i = 0.4. The high turbulent kinetic energy regions correspond well to the high Nusselt number regions around the stagnation points shown in Figure 13. In addition, low turbulent kinetic energy regions also correspond well to low Nusselt number regions. Thus, it can be concluded that turbulent kinetic energy plays an important role in heat transfer enhancement by impinging jets with cross flows.

Figure 15 shows the experimental and numerical relations between the cross flow rate and the stagnation point Nusselt number, Nu_{stag}, which is defined as the locally maximum Nu. Note that Nu_{stag} is normalized by Nu_{stag} in no cross flow. It is clear that the cross flow effect becomes remarkable when the cross flow rates exceed 0.35, where Nu_{stag}/Nu_{stag0} becomes less than 0.9 in the three-row jets case. The heat transfer coefficient of the three row jets is more weakly affected by the cross flow than that of one row jets, because the blocking of cross flow by upstream jets occurs in three-row jets cases. The present numerical simulations using k-ε realizable model can predict the tendency of cross flow effects but tend to overestimate the cross flow effects on Nu_{stag}.

CONCLUSIONS

Local Nusselt number distributions were measured by the naphthalene sublimation technique for one-row impinging jets and three row impinging jets on a concave surface with cross flow. In addition, numerical simulations using a realizable k-ε model were conducted to further investigate the heat transfer characteristics of the three-row jets impinging on a concave surface, and to clarify the detail of the complex flow structure. Consequently, the following conclusions were obtained.

1. The location of the maximum local Nusselt number moves downstream as the cross-flow/jet-velocity ratio increases. The drift distance in three-row jets is shorter than that in one-row jets, because the blocking of cross flow by the upstream jets occurs in the three-row jets case.
